### ABSTRACT

The datasets of the five Land-offline Model Intercomparison Project (LMIP) experiments using the Chinese Academy of Sciences Land Surface Model (CAS-LSM) of CAS Flexible Global-Ocean-Atmosphere-Land System Model Grid-point version 3 (CAS FGOALS-g3) are presented in this study. These experiments were forced by five global meteorological forcing datasets, which contributed to the framework of the Land Surface Snow and Soil Moisture Model Intercomparison Project (LS3MIP) of CMIP6. These datasets have been released on the Earth System Grid Federation node. In this paper, the basic descriptions of the CAS-LSM and the five LMIP experiments are shown. The performance of the soil moisture, snow, and land-atmosphere energy fluxes was preliminarily validated using satellite-based observations. Results show that their mean states, spatial patterns, and seasonal variations can be reproduced well by the five LMIP simulations. It suggests that these datasets can be used to investigate the evolutionary mechanisms of the global water and energy cycles during the past century.

**Key words:** LS3MIP, CMIP6, CAS FGOALS-g3, CAS-LSM, soil moisture, snow

## 1. Introduction

Land surface processes, including soil moisture, snow,

vegetation, runoff, and sensible and latent heat fluxes, continue to play an important role in the state-of-the-art Global Climate Models (GCMs) and Earth System Models (ESMs) (van den Hurk et al., 2016). As the land component of GCM and ESM, land surface models (LSMs) have seen considerable development during recent decades (van den Hurk et al., 2011). Moreover, there have been several LSM intercomparison projects on an international level (Boone et al., 2009; van den Hurk et al., 2011). The Land Surface, Snow and Soil moisture Model Intercomparison Project (LS3MIP; van den Hurk et al., 2016) is designed to allow the climate modeling community to address the challenges regarding the representation of land surface processes in the GCMs and ESMs and to enhance the understanding of related climate feedbacks (van den Hurk et al., 2016). It is also part of the sixth phase of the Coupled Model Intercomparison Project (CMIP6; Eyring et al., 2016). LS3MIP consists of a series of land-offline experiments driven by different land surface forcing datasets, referred to as LMIP (Land-offline MIP), and a variety of coupled model simulations, known as LFMIP (Land Feedback MIP). The goal of the LMIP experiments is to provide for a widespread evaluation of land surface, snow, and soil moisture, and to diagnose systematic biases in the land components of current GCMs and ESMs (van den Hurk et al., 2016). There are 16 Earth system modeling groups participating in LS3MIP (van den Hurk et al., 2016). Several studies have examined the preliminary performances of LMIP experiments within the framework of LS3MIP (Decharme et al., 2019; Lawrence et al., 2019; Li et al., 2019).

The Land Surface Model for the Chinese Academy of Sciences (CAS-LSM) was developed at the Institute of Atmospheric Physics (IAP), CAS (Xie et al., 2018a; Wang et al., 2019; Wang et al., 2020b). It is the land component of the climate system models of CMIP6: the CAS Flexible Global-Ocean-Atmosphere-Land System Model Grid-point version 3 (CAS FGOALS-g3), which was developed at the State Key Laboratory of Numerical Modeling for Atmospheric Sciences and Geophysical Fluid Dynamics (LASG) of the Institute of Atmospheric Physics (IAP), CAS (Li et al., 2020). Based on the experiment design for CMIP6 (Eyring et al., 2016), many CMIP6 experiments based on CAS FGOALS-g3 have been conducted, including the Diagnostic, Evaluation, and Characterization of Klima (Li et al., 2020), historical simulations, Scenario Model Intercomparison Project (Pu et al., 2020), Flux-Anomaly-Forced Model Intercomparison Project (Wang et al., 2020a), Ocean Model Intercomparison Project (OMIP; Lin et al., 2020), Paleoclimate Modeling Intercomparison Project (Zheng et al., 2020), and so on. These data sets have been published online in the Earth System Grid Federation (ESGF).

The LMIP simulations based on the CAS-LSM of CAS FGOALS-g3 were completed in 2019 and these datasets were submitted to the ESGF (<https://esgf-node.llnl.gov/projects/cmip6/>) in April 2020. We will provide a comprehensive introduction of the LMIP datasets from CAS-LSM

for a variety of users in this study. The model descriptions and experimental designs are explained in Section 2. Section 3 presents a preliminary evaluation of the LMIP experiments for CAS-LSM. Section 4 provides the data records and usage notes.

## 2. Model and experimental designs

### 2.1. Model descriptions

CAS-LSM was developed based on the LSM, Community Land Model version 4.5 (CLM4.5; Oleson et al., 2013), by simultaneously incorporating human water regulation (HWR), and changes in the depth of frost and thaw fronts (FTFs) (Xie et al., 2018a). As the land model for the Community Earth System Model 1.2, CLM4.5 was developed by the National Center for Atmospheric Research. It can represent several aspects of the land surface, including land biogeophysics, hydrological cycle, biogeochemistry, and ecosystem dynamics. For a detailed description of the biogeophysical and biogeochemical parameterizations and numerical implementation of CLM4.5, please see Oleson et al. (2013). The main changes of CAS-LSM compared with CLM4.5, including the descriptions of HWR and the changes in FTFs, are provided in the present study.

An HWR scheme was incorporated into CLM4.5 as a sub-model (Zou et al., 2015; Zeng et al., 2016, 2017), which included a human water exploitation module and water consumption from agriculture, industry, and domestic use (Xie et al., 2018a). Water withdrawal includes groundwater pumping and surface water intake. Groundwater pumping indicates extracting water from an aquifer while surface water withdrawal is the extraction of water from rivers. Groundwater pumping is expressed as

$$W' = W - q_g \Delta t, \quad (1)$$

where  $W'$  and  $W$  are the water storage in an aquifer before and after groundwater withdrawal,  $\Delta t$  is the time step,  $q_g$  is the groundwater pumping rate. The change in the groundwater table can be described as

$$h' = h - \frac{q_g \Delta t}{s}, \quad (2)$$

where  $h'$  and  $h$  are the groundwater table before and after groundwater pumping,  $s$  is the aquifer-specific yield. Surface water intake is expressed as

$$S' = S - q_s \Delta t, \quad (3)$$

where  $S'$  and  $S$  are surface water storage in an aquifer before and after surface water intake. Based on the actual water consumption data, the irrigation water was assumed to be the net water input into surface soil (Zeng et al., 2016, 2017).

The soil temperature of CLM4.5 was calculated using the second law of heat conduction. However, it could not

ization 2 (LUH2; Hurtt et al., 2011) dataset (<https://luh.umd.edu>). The irrigation dataset (Zeng et al., 2016, 2017) was generated by combining the Food and Agriculture Organization of the United Nations (FAO) global water information and the Global Map of Irrigation Areas version 5.0 data (Siebert et al., 2005). Human water use data were calculated using the methods provided in our previous studies (Zou et al., 2015; Zeng et al., 2017; Wang et al., 2019).

The LMIP experiments of CAS-LSM followed the protocol of LS3MIP (van den Hurk et al., 2016), which are land-offline simulations forced by the different atmospheric forcing datasets. The spin-up was conducted by recycling the climate mean and variability of the meteorological forcing over 20 years (1901–20) to reach equilibrium. All the five simulations had the same horizontal spacing of  $0.9^\circ$  (latitude)  $\times$   $1.25^\circ$  (longitude). The time period of atmospheric forcing was 114 years (1901–2014) except for PRINCETON (1901–2012). All atmospheric forcing datasets were bilinearly interpolated to the same spatial resolution as the model simulations.

### 2.3. Observations

To validate the performance of the five LMIP simulations from CAS-LSM, satellite-based soil moisture, snow, sensible and latent heat fluxes, and terrestrial water storage (TWS) observations or merged products were used in this study. A merged multi-decadal satellite-based soil moisture product derived from the European Space Agency Water Cycle Multi-mission Observation Strategy and Climate Change Initiative project (ESA CCI, [www.esa-soilmoisture-cci.org](http://www.esa-soilmoisture-cci.org)) was used for comparison with the model-based surface soil moisture. It was generated by blending seven passive-based and four active-based soil moisture products (Dorigo et al., 2017; Gruber et al., 2017, 2019). We used the ESA CCI version 4.7 combined product with a  $0.25^\circ$  resolution from 1979 to 2014 at a daily temporal resolution.

The monthly mean snow cover product derived from the Moderate Resolution Imaging Spectroradiometer (MODIS) was used to validate the model-based snow cover fraction (SCF) simulations. We used the MODIS Climate Modeling Grid Version 6 (Hall and Riggs, 2015) product with a  $0.05^\circ$  resolution from 2001 to 2014 (<https://nsidc.org/data/MOD10CM/versions/6>).

This study also used the data-driven global gridded land-atmosphere energy flux product (hereinafter FLUXCOM; Jung et al., 2019) to validate the latent and sensible heat fluxes. The FLUXCOM product was generated by merging energy flux measurements from FLUXNET eddy covariance towers with remote sensing data based on a machine learning method. In all, there were 27 FLUXCOM datasets which used nine machine learning methods and three energy balance corrections. The median values of the 27 monthly mean products with a spatial resolution of  $0.5^\circ \times 0.5^\circ$  for the period 2001–14 were used in this study.

The TWS derived from the Gravity Recovery and Climate Experiment (GRACE) satellite observations (Tapley et al., 2004) were used to evaluate the model simulations. We

chose the GRACE RL06 mascon product ([http://www2.csr.utexas.edu/grace/RL06\\_mascons.html](http://www2.csr.utexas.edu/grace/RL06_mascons.html)) (Save et al., 2016; Save, 2019), which is the latest version of GRACE. This study also used the monthly TWS anomaly (TWSA) data which is computed relative to the mean of 2004–2009. The TWSA data covered the period 2003–2014 and had a spatial resolution of  $0.25^\circ$ .

To be consistent with the CAS-LSM simulations, all of these observations, including ESA CCI, MODIS, FLUXCOM, and GRACE data, were re-gridded to the same resolution as the model-based simulations ( $0.9^\circ \times 1.25^\circ$ ) before validation using conservative remapping.

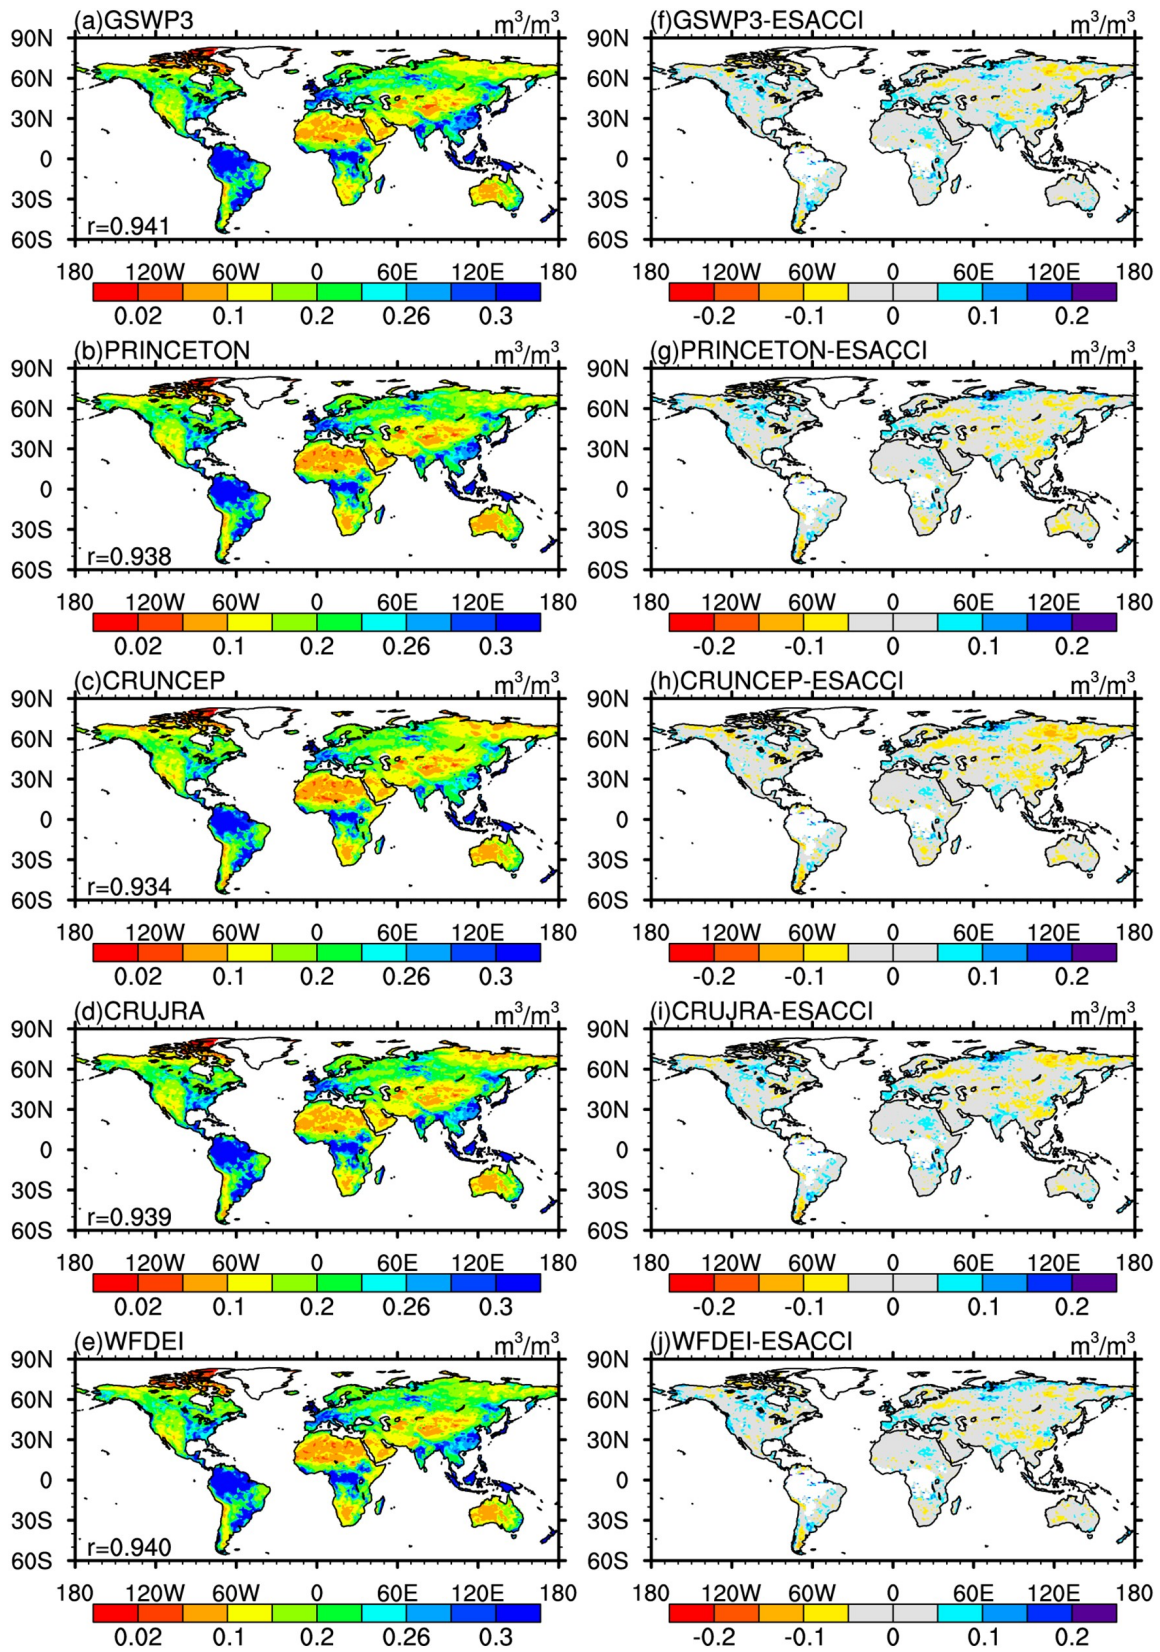

## 3. Preliminary validation

### 3.1. Soil moisture

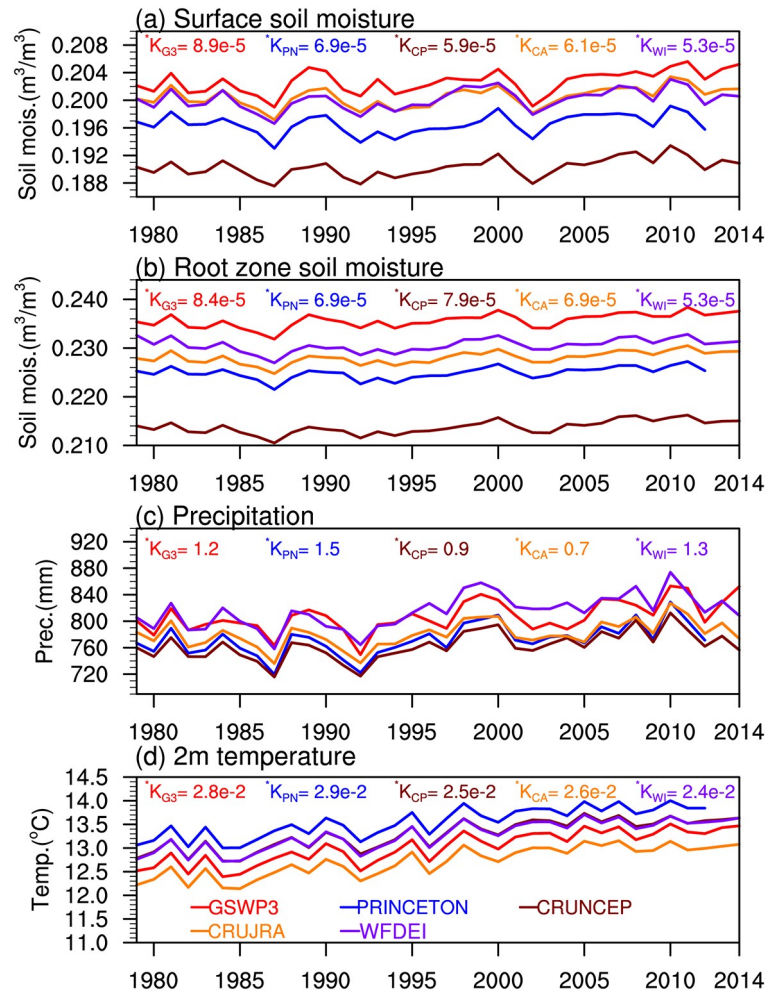

The basic results of the five LMIP experiments underwent preliminary validation before the submission of all the datasets. Figure 1 shows the annual means of surface soil moisture (0–10 cm) at the global scale derived from five LMIP simulations and their differences with the ESA CCI product. The comparisons were made from 1979 to 2014 and all the model simulations in Fig. 1 have been masked while the ESA CCI soil moisture data were available. Compared with ESA CCI, all five LMIP simulations show similar broad patterns of surface soil moisture, with high spatial correlation coefficients ranging between 0.934 and 0.941. However, the model-based simulations show drier soil in northeastern Asia and wetter soil in northwestern Asia than ESA CCI. CRUNCEP has lower soil moisture over northeastern Asia than the other four simulations or the ESA CCI product. In addition, the spatial distributions of the Pearson correlation coefficient and root mean square deviation (RMSD) between five LMIP simulations and the ESA CCI product were presented in Figs. S1 and S2 [in the electronic supplementary material (ESM)], respectively. It is found that these simulations show high temporal correlations and low RMSD in most areas except for northern high latitudes, which may be related to the poor data quality of satellite-retrieved soil moisture products under frozen conditions (Dorigo et al., 2017).

As shown in Figs. 2a and 2b, the five LMIP simulations show significantly increasing trends in surface and root zone soil moisture during the past 36 years (1979–2014) due to significantly increased precipitation (Fig. 2c). Compared with the other four simulations, GSWP3 has the wettest surface and root zone soil moisture due to higher precipitation. In contrast, CRUNCEP shows the lowest soil moisture, which may be related to the lower precipitation (Fig. 2c) and higher temperature (Fig. 2d). Clear differences in soil moisture can be observed among the five LMIP simulations; however, they are mainly systematic biases and the temporal correlation coefficients for the five datasets are high (over 0.9), indicating that the five LMIP simulations have consistent temporal variations in soil moisture. Additionally, all five forcing data sets show

**Fig. 1.** The spatial patterns of surface soil moisture (top 10 cm) derived from five LMIP simulations (GSWP3, PRINCETON, CRUNCEP, CRUJRA, and WFDEI) and their differences with the ESA CCI soil moisture product between 1979 and 2010.  $r$  in the left column indicates the spatial correlation coefficient of the model-based simulations with ESA CCI.

**Fig. 2.** Interannual variations of (a) surface soil moisture (top 10 cm), (b) root zone soil moisture (0–200 cm), (c) precipitation, and (d) 2 m temperature for the five LMIP simulations (GSWP3, PRINCETON, CRUNCEP, CRUJRA, and WFDEI) averaged globally (excluding Greenland) between 1979 and 2014.  $K$  is the trend for soil moisture ( $\text{m}^3 \text{m}^{-3} \text{yr}^{-1}$ ), precipitation ( $\text{mm yr}^{-1}$ ), and temperature ( $^{\circ}\text{C yr}^{-1}$ ) calculated using the Mann-Kendall test method; the subscript of  $K$ : G3 (GSWP3), PN (PRINCETON), CP (CRUNCEP), CA (CRUJRA), and WI (WFDEI). The asterisk represents the statistically significant trends ( $p < 0.05$ ).

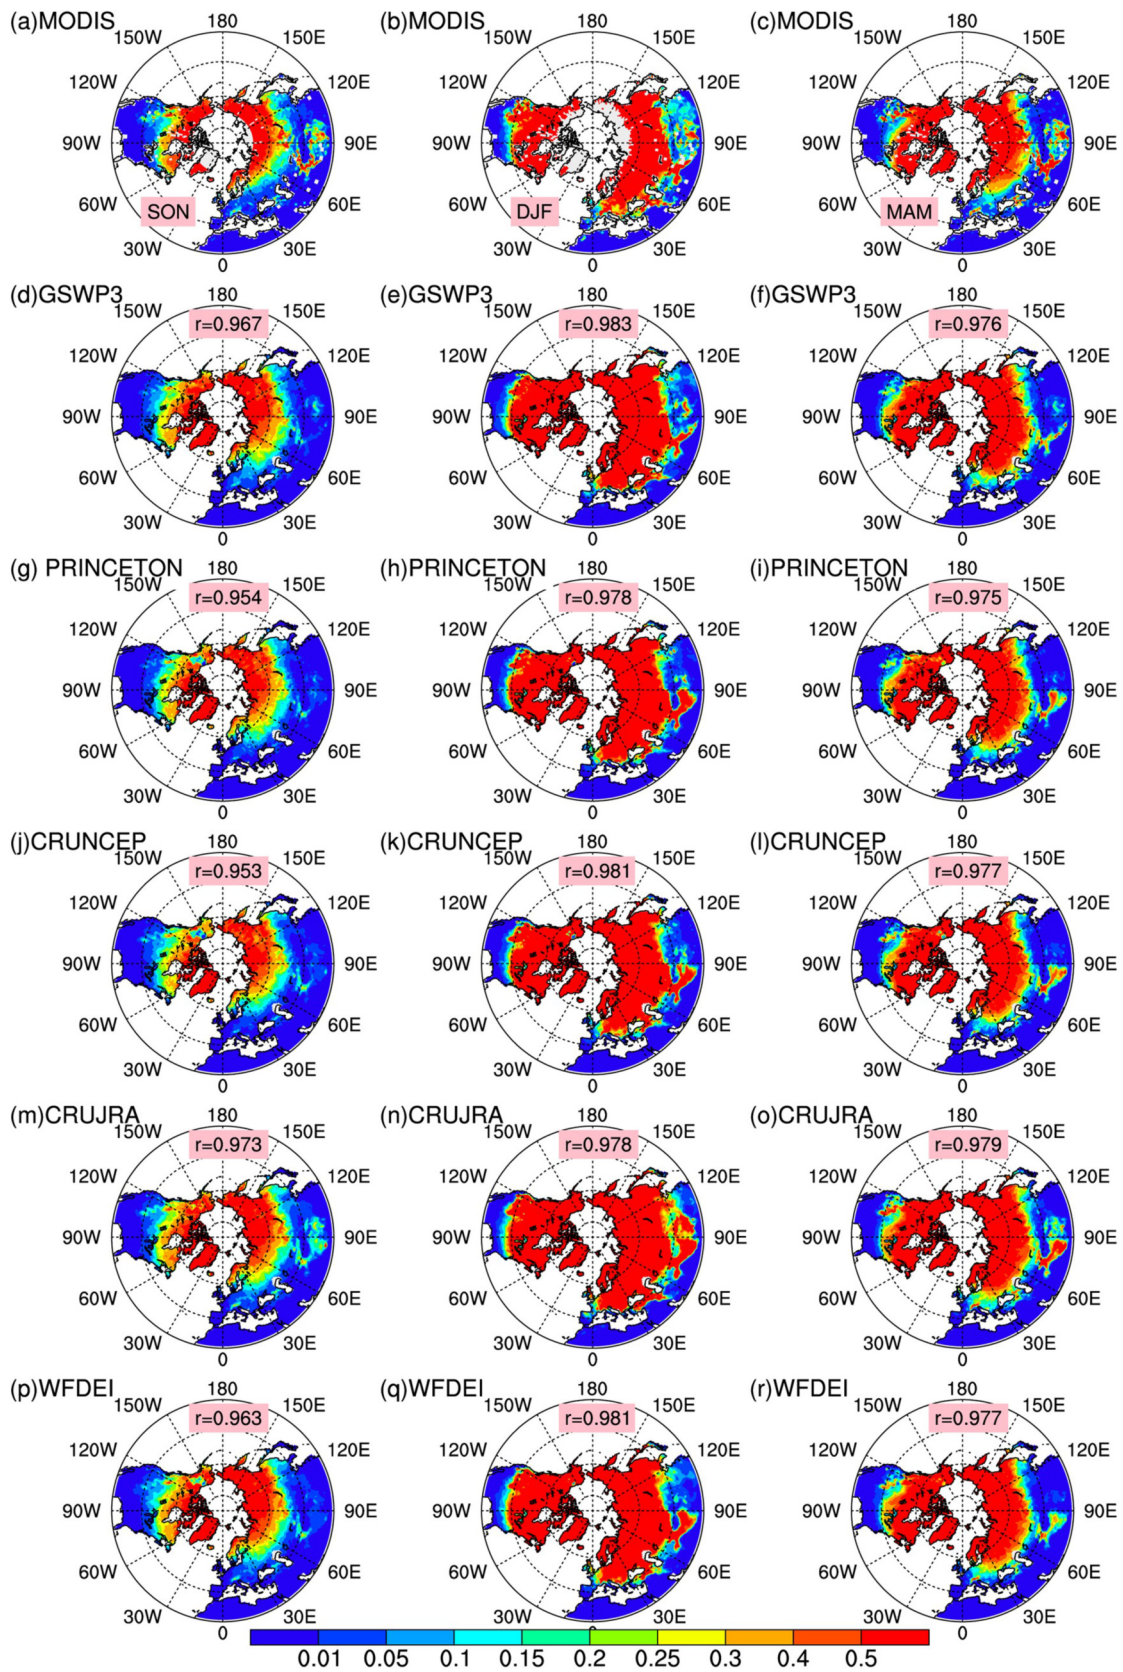

similar spatial distributions of the air temperature (not shown), since they were all bias corrected to different versions of CRU products. In contrast, the annual precipitation shows some differences. WFDEI shows slightly larger precipitation than GSWP3 over most land areas, while CRUNCEP and PRINCETON shows lower values globally (Wang et al., 2020b). This is because the precipitation of GSWP3 and WFDEI was bias corrected to different versions of GPCC products with different approaches to under-catch correction while CRUNCEP, CRUJRA, and PRINCETON were bias-corrected to different versions of CRU products. Interannual variations in precipitation and the 2 m temperature are presented in Figs. 2c and 2d, respectively. The global mean land precipitation shows a consistent increasing trend ( $0.7\text{--}1.5 \text{ mm yr}^{-1}$ ,  $p < 0.05$ ) concurrent with a rapid warming trend ( $0.024^{\circ}\text{C yr}^{-1}\text{--}0.029^{\circ}\text{C yr}^{-1}$ ,  $p < 0.05$ ) in the five

datasets.

### 3.2. Snow

The changes in snow over the Northern Hemisphere (NH, poleward of  $25^{\circ}\text{N}$ ) were examined using the satellite-based SCF. The climatological seasonal cycles in Fig. 3 were computed for 2001–2014, but only autumn (SON), winter (DJF), and spring (MAM) seasons were presented. In general, the SCF estimates from the five LMIP simulations capture the spatial patterns of the MODIS-derived SCF product well, with spatial correlation coefficients of over 0.957 for the three seasons. However, differences could be observed in the areas with complex terrain, for example, in the western United States, and on the Tibetan Plateau. This may be due to sub-grid scale snow variations, in complex terrain, not being accurately represented in the CAS-LSM,

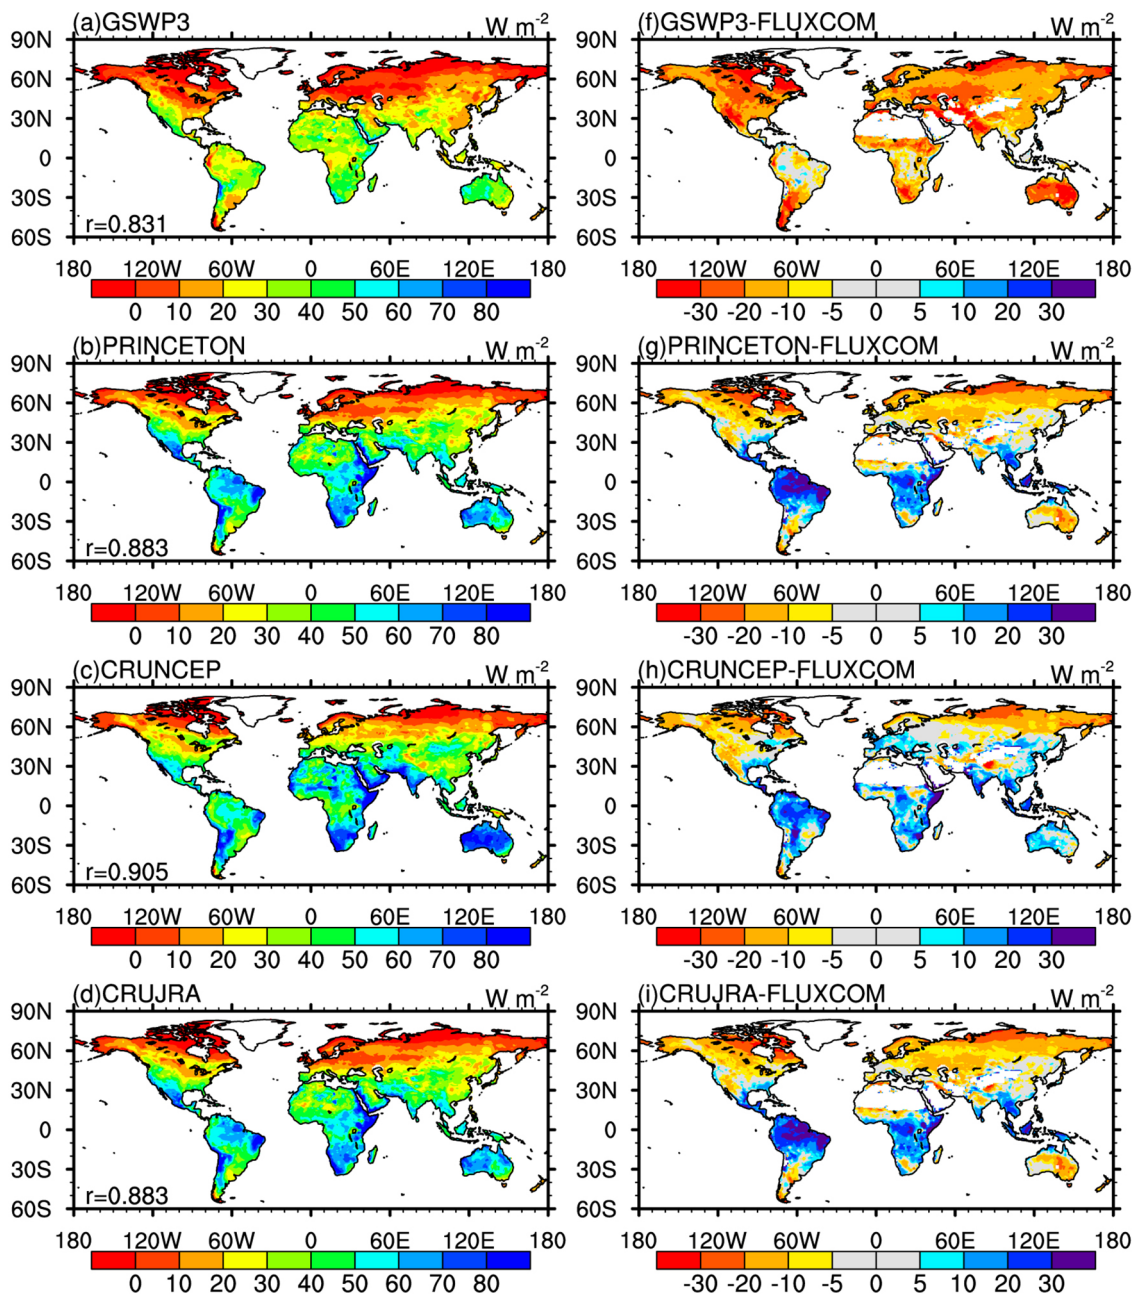

**Fig. 3.** Northern Hemispheric distributions of the mean seasonal snow cover fractions from (a–c) MODIS and (d–r) the five LMIP simulations during autumn (SON, left column), winter (DJF, middle column), and spring (MAM, right column) between 2001 and 2014. The  $r$  is the spatial correlation coefficient of the model-based simulations with MODIS.

including blowing snow and the effect of aspect and slope on snow accumulation and melting (Xie et al., 2018b). The SCF is positively biased over the Tibetan Plateau, Alaska, and parts of western Siberia. In contrast, all five LMIP simulations tend to overestimate the SCF over most of the middle latitudes of Asia, Europe, and North America. In addition, there are larger positive biases over the high latitudes across the central and eastern United States and northern Europe during winter and spring. Detailed comparison results with ground measurements and satellite-based observations including SCF, snow depth, and snow water equivalent can be found in Wang et al. (2020b).

### 3.3. Latent and sensible heat fluxes

We validated the spatial patterns of latent and sensible heat fluxes from the five LMIP simulations using the FLUXCOM product. All model simulations show acceptable agreement with the spatial variation of sensible heat flux from FLUXCOM (Fig. 4), with correlation coefficients ranging between 0.831 and 0.905. However, a systematic overestimation is observed over parts of the northern low latitudes and most of the Southern Hemisphere for PRINCETON (Fig. 4g), CRUNCEP (Fig. 4h), CRUJRA (Fig. 4i), and WFDEI (Fig. 4j). All five simulations exhibit lower sensible heat fluxes over the northern high latitudes than FLUXCOM. Sim-

**Fig. 4.** Spatial patterns of sensible heat flux from the five LMIP simulations (GSWP3, PRINCETON, CRUNCEP, CRUJRA, and WFDEI) and their differences with FLUXCOM between 2001 and 2014. The *r* in the left column indicates the spatial correlation coefficient of the model-based simulations with FLUXCOM.

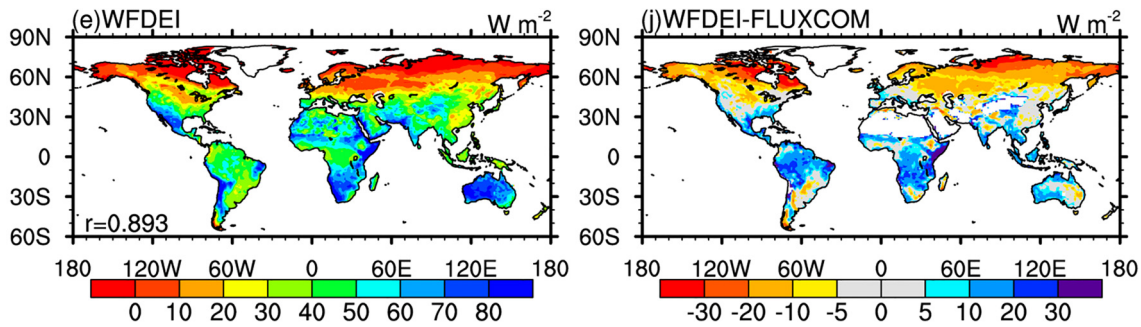

Fig. 4. (Continued).

ulations with GSWP3 appear to have sensible and latent heat fluxes that are generally higher across the globe than the other four simulations and FLUXCOM. As shown in Fig. 5, all LMIP simulations capture the spatial pattern of the latent heat flux very well, with spatial correlation coefficients around 0.96. Model simulations show slight underestimations over most of the globe. This is particularly visible over the northern parts of South America and southern Africa. In addition, some systematic overestimations are

found over Australia and the Tibetan Plateau.

### 3.4. Terrestrial water storage

TWS is the sum of water stored above and underneath the surface of the earth (Syed et al., 2008; Zeng et al., 2008) and plays an important role in Earth's climate system (Zeng et al., 2008; Jia et al., 2020). The seasonal variations of TWSA from GRACE and five LMIP simulations for the period 2003–2014 are presented in Fig. 6. In general, the sim-

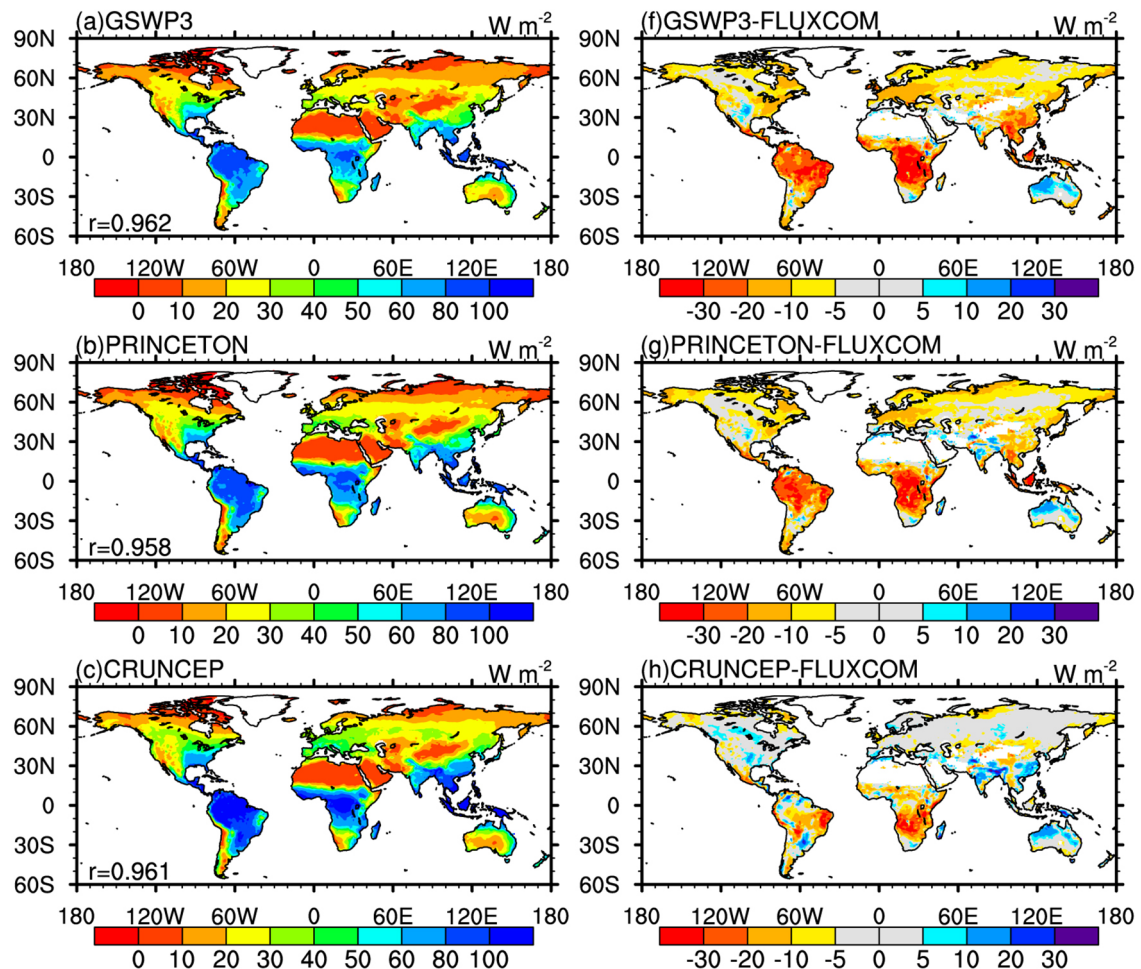

Fig. 5. Spatial patterns of latent heat flux from the five LMIP simulations (GSWP3, PRINCETON, CRUNCEP, CRUJRA, and WFDEI) and their differences with the FLUXCOM product between 2001 and 2014. The  $r$  in the left column indicates the spatial correlation coefficient of the model-based simulations with FLUXCOM.

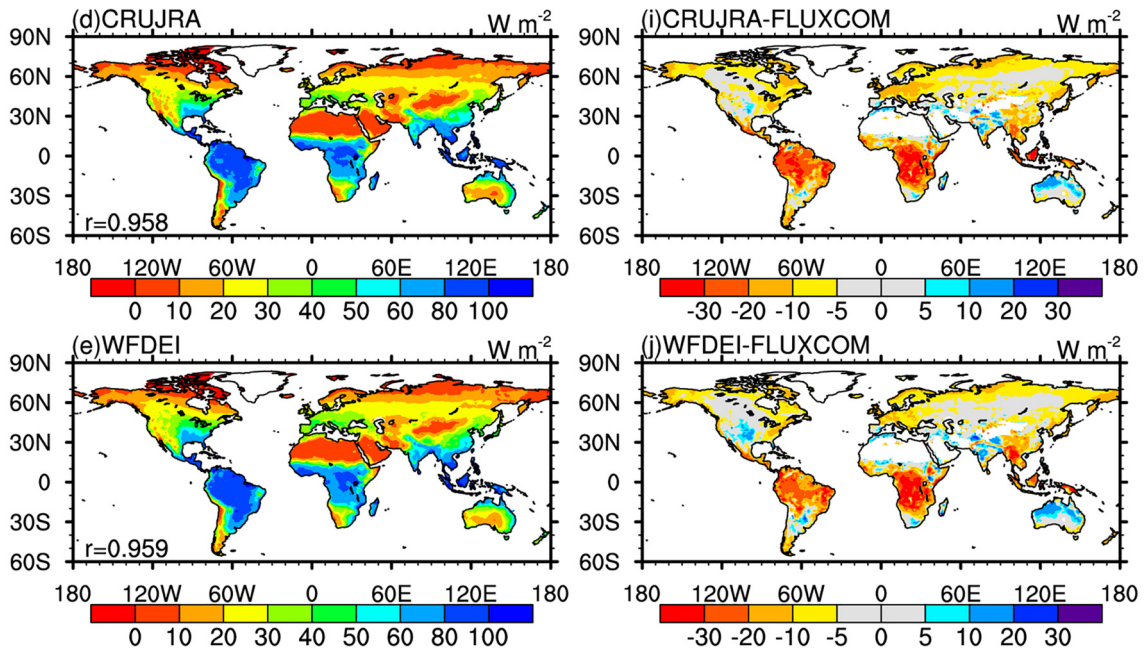

Fig. 5. (Continued).

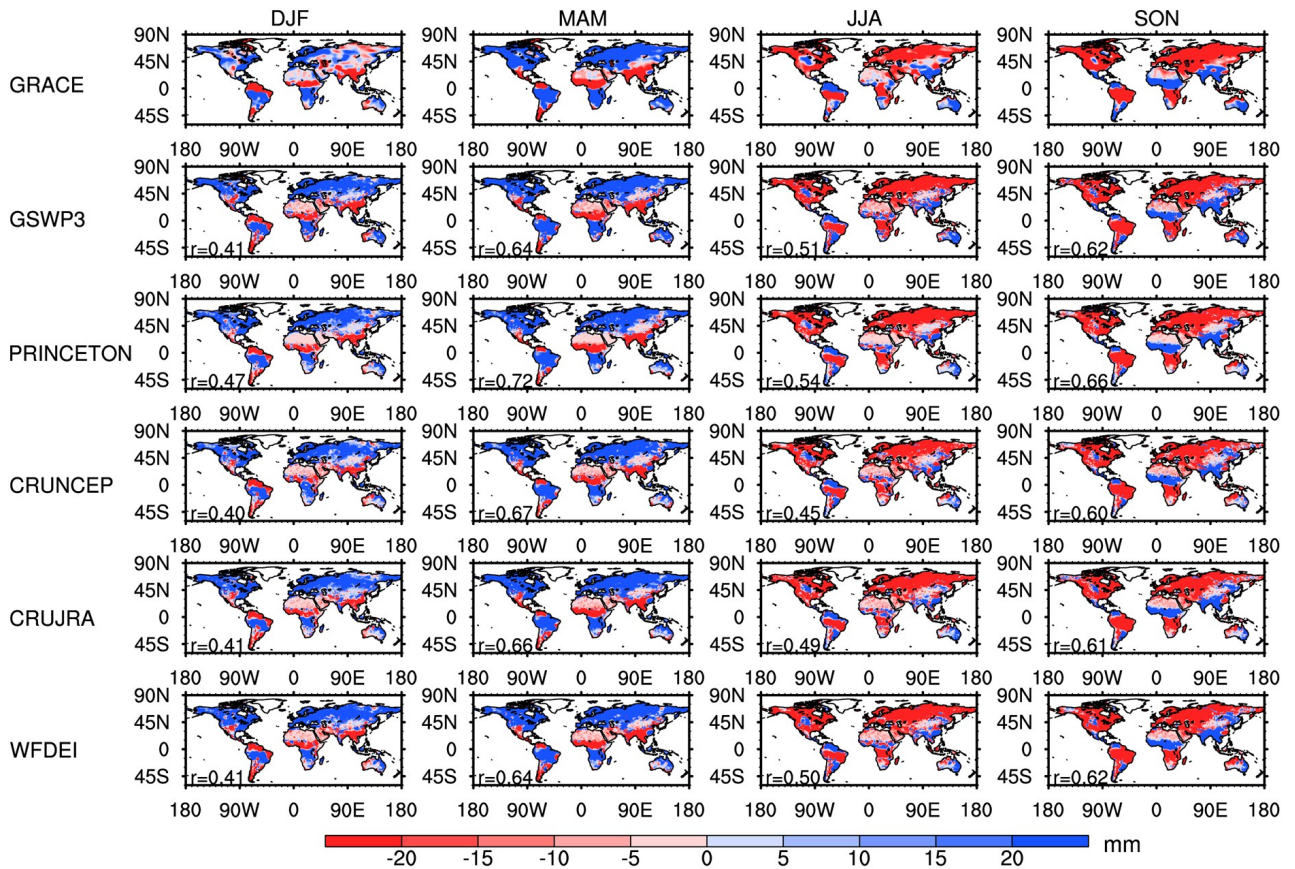

Fig. 6. Seasonal terrestrial water storage anomaly (TWSA) estimated using GRACE and simulated from the five LMIP simulations (GSWP3, PRINCETON, CRUNCEP, CRUJRA, and WFDEI) between 2003 and 2014. The  $r$  indicates the spatial correlation coefficient of the model-based simulations with GRACE.

ulated seasonal patterns from CAS-LSM appear to be in good agreement with those from GRACE, with spatial correla-

tion coefficients ranging between 0.40 and 0.72. In addition, “hot spots” with significantly negative TWSA values were

present due to groundwater overexploitation (Rodell et al., 2009; Feng et al., 2013; Sinha et al., 2017; Wang et al., 2019), such as in northern India, the North China Plain, and the central United States. These negative anomalies were detected in both the GRACE observations and the model simulations for boreal winter, spring, and summer (Fig. 6).

#### 4. Data records and usage notes

Based on the meetings and seminars of participating modeling groups, the core team members of LS3MIP decided to use the CRUJRA instead of CRUNCEP (initial plan) (<https://wiki.c2sm.ethz.ch/LS3MIP/LandHistWithAlternat->

[iveForcingDatasets](https://wiki.c2sm.ethz.ch/LS3MIP/LandHistWithAlternat-iveForcingDatasets)). Therefore, the four datasets for the LMIP simulations of CAS FGOALS-g3 (GSWP3, PRIN-CETON, CRUJRA, WFDEI) were uploaded onto the ESGF node (<https://esgf-node.llnl.gov/projects/cmip6/>). Note that the experiment ID of CRUJRA was still “land-hist-cruNcep”. The model outputs have been post-processed using CMOR software and saved as the format of the Network Common Data Form (NetCDF) version 4.

The standard output of variables requested by LS3MIP (see <https://wiki.c2sm.ethz.ch/LS3MIP> for details) have been generated. There were 16 Priority 1 variables available on the ESGF node. Detailed information on these variables can be found in Table 2.

**Table 2.** Summary of the output data tables for the LMIP of LS3MIP derived from CAS-LSM of CAS FGOALS-g3.

Name	Long Name	Unit	Direction <sup>a</sup>	Dim <sup>b</sup>	Frequency

<sup>c</sup>"TZYX", T: time, Y: latitude, X: longitude, and Z: soil layers (15 layers).

#### 5. Summary

This paper introduced the model datasets of five LMIP experiments using CAS-LSM of CAS FGOALS-g3 within the framework of LS3MIP. Preliminary evaluation against satellite-based observations shows that CAS-LSM can reasonably capture the mean states, spatial patterns, and seasonal variations of the soil moisture, snow, and land-atmosphere energy fluxes. As one of the participating models in LS3MIP, CAS-LSM considered both the effects of HWR and the changes in the FTFs, which could enhance the performances of modeling water and energy fluxes. It improves the coupled climate system model in such a way so that it becomes a more comprehensive platform for water resource management. However, there are still some limitations in this study. Groundwater-surface water interactions have not been fully considered in the current CAS-LSM and CAS FGOALS-g3. Lastly, more in-depth evaluation against ground-based observations and comparison with other LSMs are needed in future studies.
