The associations listed in Table 1 and Fig. 1 are the results of infections of various insect lineages with different prokaryotes. These associations became stable, resulting in the emergence of a new composite (of host and endosymbiont) organism. The endosymbiont became heritable through the acquisition of mechanisms ensuring vertical, maternal transmission to progeny. The association also became obligate, or beneficial, for host growth. Because the host depended on the association, and because horizontal or infectious transmission between hosts did not occur, the phylogeny of the endosymbionts is congruent with the phylogeny of the hosts. With some exceptions, heritable associations tend to become mutualistic (Lipsitch et al., 1995; Werren and O'Neill, 1997). In most cases, the host cannot survive without the endosymbiont, or the elimination of the endosymbiont has a deleterious effect. Although the advantage for the host is in most cases apparent, the advantage for the endosymbiont is not always clear. Perhaps it is more correct to think that the host domesticates the endosymbiont for its own welfare, utilizing functions that are present in the prokaryote but lacking in the host (Douglas and Smith, 1989; Maynard Smith and Szathmáry, 1995). In this chapter, the organism which is present in all the species of an insect group and which appears to be of essential value to the host is designated by either its scientific name or, if one is lacking, by the term primary (P-) endosymbiont.

Superimposed on this fundamental association may be associations with additional endosymbionts. Although these are heritable, they appear to be the result of multiple independent infections, horizontal transmission, or both. Since these endosymbionts may be absent in some hosts, their contribution to the welfare of the organism may not be major or essential. These organisms are designated as secondary (S-) endosymbionts. In this connection it is relevant that some bacterial strains may exist within the body cavity of insects for long periods without obvious deleterious effects, thus serving as

Table 1. General properties of the considered endosymbiotic associations.[a]

potential endosymbiont precursors of endosymbiotic associations (Boman and Hultmark, 1987; Faye, 1978).

These conclusions are tentative and, with the possible exception of the *Sitophilus*-endosymbiont association, are probably applicable to most of the endosymbiotic associations considered in this chapter. One well-studied, contrasting association is between many arthropods and the intracellular prokaryote, *Wolbachia* (O'Neill et al., 1997). Although this organism is typically heritable, being transmitted maternally, results of phylogenetic studies imply some incidence of horizontal exchange between very different lineages. *Wolbachia* causes a number of different reproductive alterations favoring the spread of infected host lineages and has properties characteristic of a parasite (O'Neill et al., 1997). Recent work may necessitate a modification of this conclusion because newly discovered *Wolbachia* in filarial worms appear to be essential for host survival and may show phylogenetic congruence with their hosts, indicating vertical evolution (Bandi et al., 1998, 1999).

Symbionts of Insects Which Utilize Plant Sap as Food

Aphids, psyllids, whiteflies and mealybugs share a number of common structural and nutritional

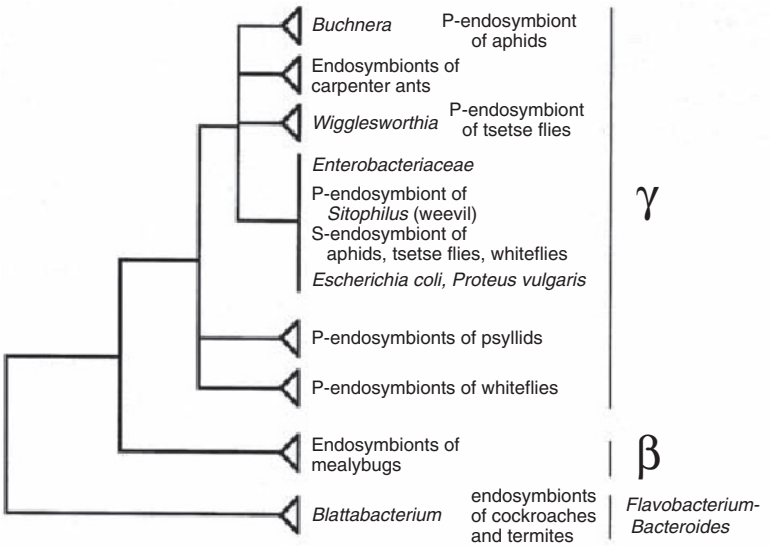

Fig. 1. Phylogenetic tree resulting from parsimony analysis of insect endosymbionts based on 16S rDNA sequence analysis. P-, primary endosymbiont; S, secondary endosymbiont; Greek letters, subdivisions of the Proteobacteria. References given in text.

properties (Borror et al., 1989) and constitute four separate lineages within the suborder Sternorrhyncha (order Homoptera; Campbell et al., 1994; von Dohlen and Moran, 1995). All of these groups feed predominantly or exclusively on plant phloem sap. This mode of life necessitates the penetration of plant tissue by flexible tubular mouthparts (stylets) and the ingestion of plant phloem sap. This diet is unbalanced, as it is rich in carbohydrates but deficient in amino acids and other nitrogenous compounds (Dadd, 1985; Sandström and Pettersson, 1994). Because of the low concentrations of nitrogenous compounds, phloem-feeding insects ingest a large amount of plant sap and then excrete the excess sugar as honeydew. This mode of feeding is conducive to the transmission of plant viruses, and members of the Homoptera are important vectors of viral plant pathogens (Blackman and Eastop, 1984; Gray and Banerjee, 1999; Sylvester, 1985). In addition, these insect populations may reach enormous numbers on plants, causing nutrient deprivation, leaf curling, and gall formation (Borror et al., 1989).

In spite of these common properties, aphids, whiteflies, psyllids, and mealybugs have different prokaryotic P-endosymbionts (Table 1, Fig. 1). These insects, like other animals, require ten essential amino acids, and endosymbionts are thought to upgrade the diet by synthesizing these essential amino acids and providing them to the host (Baumann et al., 1995, 1997a, b; Douglas, 1989; Moran and Telang, 1998). Of these four symbiotic associations, the most extensively studied is that between *Buchnera* (the P-endosymbiont) and aphids. This association will be considered in some detail and followed by a brief discussion of three other associations.

Aphid Endosymbionts

Buchnera—the Primary Endosymbiont of Aphids

Phylogeny

The initial characterization of the 16S-rDNA gene of *Buchnera* involved the use of an *Escherichia coli* 16S rDNA hybridization probe to perform a restriction enzyme and Southern blot analysis on total *Acyrthosiphon pisum* DNA, which established that this gene was present as a single copy (Unterman et al., 1989). Subsequently three overlapping DNA fragments were cloned and the 16S-rDNA gene was sequenced. In addition, bacteriomes were dissected from the aphid and the DNA purified. Restriction enzyme and Southern blot analysis gave the same results with whole aphid DNA and DNA obtained from dissected bacteriomes, indicating that the bacteriomes were the source of endosymbiont DNA. In all subsequent studies, the 16S rDNA was obtained by PCR amplification using whole aphid DNA preparations cloned into plasmid vectors and then sequenced (Munson et al., 1991b).

Based on 16S rDNA analysis, *Buchnera* is a distinct lineage within the γ-3 subgroup of the Proteobacteria (Fig. 1; Moran et al., 1993; Munson et al., 1991b; Unterman et al., 1989; van Ham et al., 1997). The closest known organisms are the endosymbionts of carpenter ants, endosymbionts of tsetse flies (*Wigglesworthia*), and members of the Enterobacteriaceae as defined by Brenner (Brenner, 1984; Aksoy, 1995a, b; Schröder et al., 1996). Phylogenetic analyses based on 16S rDNA indicate that these organisms are four separate lineages but do not permit

firm conclusions regarding their relationships to one another. *Buchnera* contains a single copy of rRNA genes which are arranged as two transcription units, 16S rRNA and tRNAGlu-23S rRNA-5S rRNA (Munson et al., 1993; Rouhbakhsh and Baumann, 1995). This organization of the rRNA genes into two transcription units is somewhat rare but also has been found in *Wolbachia* (Bensaadi-Merchermerk et al., 1995) and *Rickettsia* (Andersson et al., 1998), organisms which are in the α-subdivision of the Proteobacteria and also associated with insects. In the endosymbionts of carpenter ants, the rRNA genes are also split into two transcription units (C. Sauer and R. Gross, personal communication) whereas in *Wigglesworthia* (Aksoy, 1995b) and the Enterobacteriaceae the order is 16S–23S (Berlyn, 1998). The organization of the rRNA genes into two transcription units suggests a possible relationship between *Buchnera* and the endosymbionts of carpenter ants.

The results of phylogenetic analyses involving all of the currently available *Buchnera* sequence information are presented in Fig. 2. Most of the characterized endosymbionts are from the family Aphididae. Based on 16S rDNA, *Buchnera* forms one clade within which two well-supported subclades are apparent. These are the aphids of the Aphididae and the Sc and Mr from the tribe Fordini in the family Pemphigidae. Additional studies using a portion of *trpB* (Fig. 2b) confirmed some of these relationships and provided further resolution within the genus *Uroleucon*. These relationships are in broad agreement with the results of evolutionary studies of plasmid-associated *trpE*, *leuBCD*, and *repA1* (Fig. 2c, d, e; Baumann et al., 1997b, 1999b; Bracho et al., 1995; Rouhbakhsh et al., 1996, 1997; Silva et al., 1998; van Ham et al., 1997, 1999). Within the genus *Uroleucon*, the phylogeny based on *trpB* is in good agreement with the more extensive analysis of host phylogeny based on mitochondrial and nuclear genes (Clark et al., 2000; Moran et al., 1999).

The congruence of phylogenies derived from *Buchnera* chromosomal and plasmid genes, as well as host mitochondrial and nuclear genes, is strong evidence for a vertical mode of evolution with no exchange of either bacteria or plasmids among host lineages (Moran and Baumann,

1994). An implication of the congruence between the phylogenies of *Buchnera* and corresponding aphid hosts is that dates for branch points inferred from fossil aphids can be extended to ancestral *Buchnera* (Moran et al., 1993). A further implication is that modern *Buchnera* descend from an infection of a common ancestor of all modern aphids. From the aphid fossil record, we can infer that this infection by a free-living bacterium must have occurred at least 150–250 million years ago. The divergence in 16S rDNA of modern *Buchnera* is consistent with this hypothesis of an ancient infection followed by cospeciation of *Buchnera* and hosts.

Buchnera shows a rate of base substitution in its 16S rDNA that is about twice as great as that in related free-living bacteria based both on relative rate comparisons with free-living taxa and on comparisons of rates calibrated with respect to absolute time (Clark et al., 1999b; Moran, 1996). The elevated substitution rate of *Buchnera* relative to that of related free-living bacteria extends to genes encoding proteins (Brynnel et al., 1998; Clark et al., 1999b; Moran, 1996; Wernegreen and Moran, 1999). Based on calibrated rates for protein-coding genes, synonymous sites evolve about twice as fast and nonsynonymous sites about six times as fast in *Buchnera* as in *E. coli*/*Salmonella typhimurium*, based on an absolute time scale (Table 3). The rate differences are considerably greater on a scale based on generations, since *Buchnera* appears to have fewer generations per year than do natural populations of enteric bacteria (Clark et al., 1999b).

The most plausible explanation for the faster rate of substitution in *Buchnera* is that the population structure of *Buchnera*, involving strictly vertical transmission of a small inoculum between hosts, results in greater levels of genetic drift, which can increase the fixation rate of mildly deleterious mutations. Several observations support this explanation. First, the rate increase is found at all genes and is concentrated at sites, such as nonsynonymous sites, that are

Table 3. Substitution rates in *Buchnera* and enteric bacteria.[a]

Species pair	Estimated time of divergence	Synonymous rate		Nonsynonymous rate	
		Absolute[b]	Generation[c]	Absolute[b]	Generation[c]
Buchnera (Sg/Dn)	50–70MY	6.8–9.5	0.14–0.19	1.0–1.4	0.02–0.03
Buchnera (Sc/Mr)	50–70MY	5.1–7.2	0.17–0.24	1.1–1.6	0.04–0.05
E. coli/S. typhimurium	100–150MY	2.9–4.4	0.03–0.04	0.1–0.2	0.001–0.002

[c]Substitutions/site/10° generations.

expected to be under selective constraint (Moran, 1996; Wernegreen and Moran, 1999). Second, polypeptide compositions are consistently biased towards amino acids that allow more adenine and thymine in the DNA sequence, indicating that mutational bias has affected protein evolution. Third, faster substitution rates in 16S rDNA are observed in other insect endosymbionts that share a similar transmission mode, suggesting that the endosymbiotic lifestyle has repeatedly produced the same changes in patterns of molecular evolution. Finally, the 16S rRNA secondary structure of *Buchnera* and other endosymbionts has lower thermal stability than that of related free-living bacteria, as expected if the DNA base substitutions are mildly deleterious (Lambert and Moran, 1998).

The 16S rDNA substitution rate of *Buchnera* is about 35 times greater than that of homologous regions of 18S rDNA of hosts, based on comparisons of pairwise divergences of corresponding aphid and *Buchnera* taxa (Moran et al., 1995). Thus, the hypothesis of a universal rate of substitution in rDNA is not even approximately true.

Taxonomy

The genus *Buchnera* contains one species, *Buchnera aphidicola*, and the type strain is the endosymbiont of the aphid *Schizaphis graminum* (Munson et al., 1991a). Currently this species name designates the lineage consisting of the P-endosymbionts of aphids. There are over 4,000 species of aphids (Blackman and Eastop, 1984; Remaudière and Remaudière, 1997) of which only 35 have been characterized by molecular methods. Consequently our conclusions are based on a very small sample of aphid species. Although 16S rDNA has been useful for showing the monophyletic origin of aphid endosymbiosis and the establishment of major aphid subgroups, it is far too conserved to be useful for defining relationships among endosymbionts of closely related aphids. Some success has been obtained by the use of other, less conserved, molecules (Fig. 2). The 16S rDNA sequence difference of *Buchnera* in Sg and Sc (the most distantly related aphids) is about the same as that between *E. coli* and *Proteus vulgaris*. Thus, subsequent studies using less conserved molecules will probably indicate that *Buchnera* should be subdivided into new species. So far, no studies have addressed the range of variation within endosymbionts of a single aphid species.

Habitat

Location and Ultrastructure During their reproductive phase, aphids contain within their body cavity a bilobed structure called a bacteriome consisting of 60–90 uninucleate, polyploid cells called bacteriocytes (Douglas and Dixon, 1987). These cells are filled with host-derived vesicles containing *Buchnera* (Fig. 3a). This organism is spherical or oval in shape, 2–4 m in diameter, with a cell wall consisting of two-unit membranes, as is characteristic of Gram-negative bacteria (Fig. 3b; Akhtar and van Emden, 1994; Griffiths and Beck, 1973; Hinde, 1971b; McLean and Houk, 1973). A thin layer corresponding to peptidoglycan has been detected (Houk et al., 1977). The presence of peptidoglycan also is indicated by penicillin-induced alterations of the cell wall as well as by chemical analysis (Griffiths and Beck, 1974; Houk et al., 1977).

Number of Endosymbionts *Buchnera* contains one copy of the 16S rRNA gene (Munson et al., 1991b, 1993; Unterman et al., 1989) and one copy of *groEL* (Ohtaka et al., 1992; Hassan et al., 1996). The number of copies of *Buchnera* 16S rRNA genes in the aphid Sg was studied by quantitative PCR (Baumann and Baumann, 1994) and was found to be $0.5–1.2 \times 10^7$ mg^{-1} aphid wet weight. Using quantitative hybridization of a *Buchnera groEL* probe, the number of genome copies in Ap was estimated at $1–2 \times 10^7$ mg^{-1} aphid wet weight (Humphreys and Douglas, 1997). In both of these studies the number of *Buchnera* cells was assumed to be identical to the number of genome copies. However a recent study has demonstrated that *Buchnera* (Ap) is polyploid, containing an average of about 120 genomes per cell (Komaki and Ishikawa, 1999). If the average number of genomes per

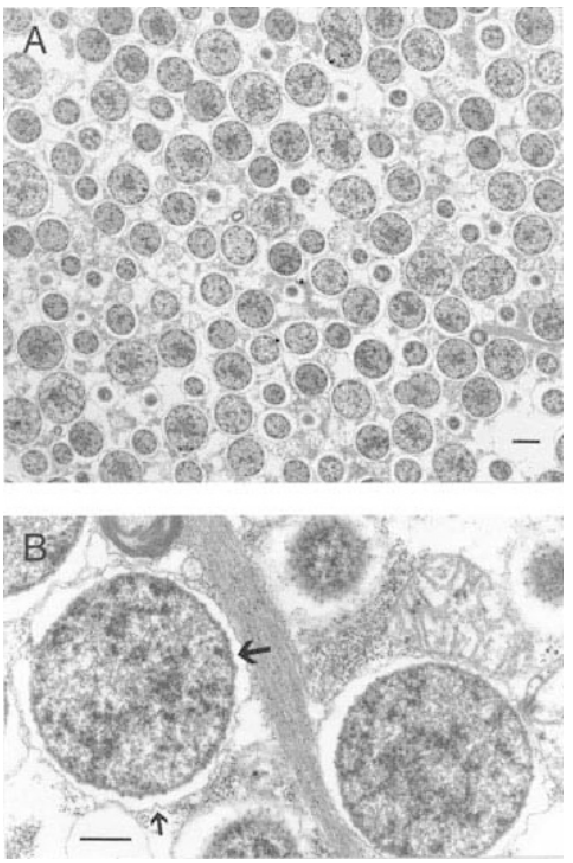

Fig. 3. Electron micrographs of *Buchnera*, the P-endosymbiont of aphids. (a) Endosymbionts within a bacteriocyte, bar = 1 m. (b) Higher magnification showing the Gram-negative cell-wall (large arrow) and the vesicle membrane (small arrow), bar = 0.5 m. Photos courtesy of Marv Kinsey and Don McLean.

endosymbiont is relatively constant, then the number of endosymbionts is about 100-fold less than estimated previously, or about 105 mg^{-1} aphid wet weight. This value is considerably lower than the estimates for Ap of $1.6–1.8 \times 10^6$ endosymbionts mg^{-1} aphid wet weight, based on microscopic enumeration of the endosymbionts (Harrison et al., 1989).

Growth and Reproduction In their most active stage, aphids are wingless females, which reproduce by parthenogenesis, giving birth to live young. There is telescoping of generations in that the mother aphid contains embryos that, in turn, may contain other embryos (Dixon, 1973, 1992). Studies on the growth of Sg (Baumann and Baumann, 1994) have indicated that newly born aphids weigh 24 μg and contain 2×10^5 copies of the *Buchnera* genome. The increase in the number of endosymbiont genomes parallels the increase in the weight of the aphid. The maximum weight is reached in 9–10 days at which time the aphid weighs 540 μg and contains 5.6×10^6 *Buchnera* genomes. The endosymbionts are partitioned between maternal and embryonic bacteriocytes. In a mature aphid, most of the *Buchnera* genomes are found in the embryos (Humphreys and Douglas, 1997). The first young are born in 8–9 days; each aphid can produce 60 to 80 live young during its lifetime. Douglas and Dixon (1987) showed that, during the period of growth, there is a concomitant increase in the maternal bacteriocyte volume as well as a small drop in bacteriocyte number. In the adult aphid the number of maternal bacteriocytes in the bacteriome undergoes a sharp decrease probably due, in part, to their dispersion within the abdomen, their degradation, as well as the degradation of *Buchnera* (Brough and Dixon, 1990; Douglas and Dixon, 1987; Griffiths and Beck, 1973; Hinde, 1971a).

Aphids may also produce sexual forms with the females depositing eggs that overwinter and hatch in the spring. *Buchnera* is maternally transmitted (transovarial transmission) to both developing embryos and eggs. Maternal bacteriocytes adjacent to an embryo near the blastoderm stage form a small opening through which the endosymbionts pass. *Buchnera* then moves through the intervening hemolymph and enters a nearby opening on the oocyte surface. During early embryonic development, the presumptive bacteriocytes form, and the endosymbionts migrate into these cells (Buchner, 1965; Blackman, 1987; Hinde, 1971a). Symbiont invasion of eggs also occurs from the dispersed bacteriocytes and they can be observed as an aggregate at the posterior pole of the mature egg (Buchner, 1965; Brough and Dixon, 1990). *Buchnera* and bacteriomes appear to be nearly universal in aphids (Buchner, 1965). However, some species of the tribe Cerataphidini lack both and instead contain yeast-like extracellular symbionts within their body cavity (Buchner, 1965; Fukatsu and Ishikawa 1992a, 1996). Some species of aphids may produce dwarf males and/or sterile female soldiers that may also lack endosymbionts (Buchner, 1965; Fukatsu and Ishikawa, 1992b; Fukatsu et al., 1994).

Physiology

Nutrition and Metabolism Plant sap, the diet of aphids, has an excess of carbohydrate relative to amino acids and other nitrogenous compounds (Dadd, 1985; Douglas, 1998; Sandström and Pettersson, 1994; Sandström and Moran, 1999). Aphids, like other insects, are thought to require 10 preformed amino acids and these essential amino acids are present in low amounts in plant sap. Some species of aphids can grow on synthetic diets even in the absence of essential amino acids. Adding antibiotics to such diets

results in the elimination of endosymbionts and the failure of the aphids to reproduce. There is some sparing effect when the essential amino acids are included in the antibiotic-containing diet. These experiments have generally been interpreted as indicating that one of the functions of *Buchnera* is the synthesis of essential amino acids for the aphid host (reviewed by Baumann et al., 1995; Douglas, 1998). A major problem is that compared with growth on plants, growth on artificial diets is poor and generally limited to a few generations. In addition, aphid growth on complete synthetic diets in the presence of antibiotics is even worse, indicating that *Buchnera* provides nutrients or functions that cannot be provided by the artificial diets. The effects of antibiotics on a number of aphid properties have been recently reviewed (Wilkinson, 1998). There is a further complication with some of the nutritional studies, in which physiological effects have been attributed to the removal of *Buchnera*. The aphid strain used may also contain S-endosymbionts, as is true of the strain of the aphid Ap used in the studies of A. E. Douglas and her collaborators (Douglas and Prosser, 1992; Wilkinson 1998). The S-endosymbiont probably does not perform any essential functions for the host (see section on S-endosymbionts of aphids in this Chapter); nevertheless, the use of antibiotics eliminates both endosymbionts, and consequently the observed effects of this loss may not be attributable solely to the loss of *Buchnera*.

Currently one of the more complete studies involves the essential amino acid tryptophan. Using a strain of Ap containing an S-endosymbiont, Douglas and Prosser (1992) have shown a sparing effect of tryptophan in chlortetracycline-containing synthetic diets on aphid growth. In addition they detected low levels of tryptophan synthase in *Buchnera* and found that activity was absent in chlortetracycline-treated and thus endosymbiont-free aphids. The assays used (Smith and Yanofsky, 1962) crude extracts of whole aphids as well as preparations enriched in endosymbionts and measured the disappearance of the substrate indole and not the appearance of the product tryptophan. Indole or indole derivatives may be substrates for a variety of reactions catalyzed by enzymes found in crude extracts of insects. No information was provided about the linearity of increasing enzyme activity with increasing crude extract concentration. In spite of possible difficulties with this assay, the dependence of the reaction on "the substrate [sic] pyridoxal phosphate" (Douglas and Prosser, 1992) is consistent with it being a measure of tryptophan synthase activity.

Using synthetic diets containing radiolabelled sulfate, it was shown that *Buchnera* can reduce this compound to the level of hydrogen sulfide and incorporate it into methionine and cysteine and that these amino acids are found in aphid tissue (Douglas, 1988). Using ^{14}C-radiolabelled amino acids, it was found that the synthesis of the essential amino acids arginine, threonine, isoleucine and lysine was reduced or eliminated by the inclusion of rifampicin in the diet (Liadouze et al., 1996). Sasaki and Ishikawa (1995) also showed that treatment of aphids with rifampicin eliminated the incorporation of dietary ^{15}N-glutamine into the essential amino acids arginine, histidine, isoleucine and/or leucine, phenylalanine, threonine, and valine.

Glutamine is the predominant amino acid in phloem and also in aphid hemolymph (Sandström and Pettersson, 1994; Sasaki et al., 1990). Isolated bacteriocytes were found to take up glutamine and convert it to glutamate, which subsequently was taken up by *Buchnera* (Sasaki and Ishikawa, 1995). Isolated endosymbionts incorporated the nitrogen of glutamine into the essential amino acids isoleucine, leucine, valine, and phenylalanine as well as a number of other amino acids, and these amino acids were excreted into the suspending medium. Whitehead and Douglas, however, could not find any evidence for excretion of amino acids by *Buchnera* (cited in Douglas, 1997).

Using synthetic diets, Nakabachi and Ishikawa (1999) demonstrated a requirement for riboflavin by rifampicin-treated aphids. These results indicate that *Buchnera* is required for the synthesis of at least one vitamin for the aphid host.

Whitehead and Douglas (1993) isolated vesicles containing *Buchnera* and showed that they readily took up acetic, glutamic and aspartic acid as well as tricarboxylic acid cycle intermediates and oxidized them to CO_2. Oxygen consumption was also detected and was greatly reduced by KCN. These results suggest the presence of a tricarboxylic acid cycle in the endosymbionts and indicate a respiratory metabolism. The latter conclusion is consistent with the presence of a gene for a subunit of NADH dehydrogenase I, an enzyme involved in the generation of a proton motive force during respiration, and of all the genes for ATP synthase, a membrane-associated enzyme which utilizes the proton motive force for the synthesis of ATP (Table 4).

Gene Expression *Buchnera* messenger RNA (mRNA) has been detected for a variety of genes encoding proteins involved in amino acid biosynthesis (Table 4). This includes genes for amino acids of the glutamate (*argA*) and aspartate (*thrB*) families (Nakabachi and Ishikawa, 1997), the shikimate pathway (*aroH*), as well as the biosynthetic pathway for tryptophan (*trpE*, *trpD*,

Table 4. Genes of *Buchnera* from the aphid *S. graminum*.[a]

Gene symbol	Gene product description	Linkage group[b]
I. SMALL-MOLECULE METABOLISM		
B. Energy metabolism		
1. Glycolysis		
gap A	Glyceraldehyde-3-phosphate dehydrogenase	13
tpiA	Triosephosphate isomerase	3
5. Pentose phosphate pathway		
a. Oxidative branch		
gnd	Gluconate-6-phosphate dehydrogenase	2
7. Respiration		
a. Aerobic		
nuoC(D)[c]	NADH dehydrogenase I, subunits cd	
c. Electron transport		
fdx	Ferredoxin	1
fpr	Ferredoxin-NADP reductase	12
9. ATP proton motive force		
atp A	ATP synthase, α-subunit	1
atp B	ATP synthase, subunit a	1
atp C	ATP synthase, ε-subunit	1
atp D	ATP synthase, β-subunit	1
atp E	ATP synthase, subunit c	1
atp F	ATP synthase, subunit b	1
atp G	ATP synthase, γ-subunit	1
atp H	ATP synthase, -subunit	1
D. Amino acid biosynthesis		
1. Glutamate family		
argA[d]	N-acetylglutamate synthase	
argH	Argininosuccinate lyase	7
2. Aspartate family		
dapD	Succinyl-diaminopimelate aminotransferase	4
thrA	Aspartokinase I	
thrB[d]	Homoserine kinase	
3. Serine family		
cysE	Serine acetyltransferase	7
serC	Phosphoserine amino transferase	3
4. Aromatic amino acid family		
aroA	5-Enolpyruvylshikimate-3-phosphate synthase	3
aroC	Chorismate synthase	2
aroE	Dehydroshikimate reductase	8
aroH	3-deoxy-*D-arabino*-heptulosonate-7-phosphate synthetase (DAHP synthetase)	10
trpA	Tryptophan synthase, A protein	5
trpB	Tryptophan synthase, B protein	5
trpC(F)	Indole-3-glycerolphosphate synthetase and *N*-(5-phosphoribosyl) anthranilate isomerase	5
trpD	Phosphoribosylanthranilate transferase	5
trpE (p)[e]	Anthranilate synthase, A subunit	16
trpG (p)[e]	Anthranilate synthase, B subunit (glutamine amidotransferase)	16
5. Histidine		
hisA	*N*-(5′-phospho-L-ribosyl-formimino)-5-amino-1-(5′-phosphoribosyl)-4-imidazolecarboxamide isomerase	2
hisB	Imidazoleglycerolphosphate dehydratase and histidinol phosphate phosphatase	2
hisC	Histidinol-phosphate aminotransferase	2
hisD	Histidinol dehydrogenase	2
hisF	Imidazoleglycerol phosphate synthase subunit (with HisH)	2
hisG	ATP phosphoribosyl transferase	2
hisH	Glutamine amidotransferase subunit (with HisF)	2
hisI	Phosphoribosyl-AMP cyclohydrolase and phosphoribosyl-ATP pyrophosphatase	2
7. Branched-chain family		
ilvC	Acetohydroxy acid isomeroreductase	1
ilvD	Dihydroxyacid dehydratase	1
ilvH	Acetohydroxyacid synthase, small subunit	4
ilvI	Acetohydroxyacid synthase, large subunit	4
leuA (p)[e]	2-Isopropylmalate synthase	15
leuB (p)[e]	3-Isopropylmalate dehydrogenase	15
leuC (p)[e]	Isopropylmalate isomerase subunit	15
leuD (p)[e]	Isopropylmalate isomerase subunit	15

(Continued)

Table 4. *Continued*

Gene symbol	Gene product description	Linkage group[b]
F. Purines, pyrimidines, nucleosides, and nucleotides		
3.2′-Deoxyribonucleotide metabolism		
dcd	2′-Deoxycytidine 5′-triosephosphate deaminase	2
trxB	Thioredoxin reductase	3
G. Biosynthesis of cofactors, prosthetic groups, and carriers		
9. Riboflavin		
ribE[d]	Riboflavin synthase, β-chain	
10. Thioredoxin, glutaredoxin, and glutathione		
trxA	Thioredoxin	1
II. BROAD REGULATORY FUNCTIONS		
rpoD	RNA polymerase, σ^{70} subunit	7
rpoH[d]	RNA polymerase, σ^{32} subunit, regulation of proteins induced at high temperature	
III. MACROMOLECULE METABOLISM		
A. Synthesis and modification of macromolecules		
1. rRNA and "stable" RNAs		
rrf	5S rRNA	8
rrl	23S rRNA	8
rrs	16S rRNA	11
2. Ribosomal protein synthesis and modification		
rplL	50S ribosomal protein L7/L 12	9
rplT	50S ribosomal protein L20	10
rpmH	50S ribosomal protein L34	1
rpmI	50S ribosomal protein L35	10
rpsA	30S ribosomal protein S1	3
rpsD	30S ribosomal protein S4	14
rpsK	30S ribosomal protein S11	14
4. tRNAs		
tRNA^{Glu}	Glutamate-tRNA	8
tRNA^{Phe}	Phenylalanine-tRNA	1
tRNA^{Trp}	Tryptophan-tRNA	1
5. Aminoacyl tRNA synthetases and their modification		
argS	Arginine tRNA synthetase	11
aspS	Aspartic tRNA synthetase	3
cysS	Cysteine tRNA synthetase	8
metG	Methionine tRNA synthetase	2
serS	Serine tRNA synthetase	3
thrS	Threonine tRNA synthetase	10
trmE	tRNA methyltransferase	1
7. DNA replication, restriction/modification, and recombination		
dnaA	DNA biosynthesis, initiation of chromosome replication, global transcription regulator	1
dnaG	DNA biosynthesis, DNA primase	7
dnaN	DNA polymerase III holoenzyme, β-subunit	1
dnaQ	DNA polymerase III holoenzyme, ε-subunit	11
gidA	Chromosome replication?	1
gyrB	DNA gyrase subunit B	1
himD	Integration host factor, β-subunit	3
rep	Rep helicase, ssDNA-dependent ATPase	1
8. Protein translation and modification		
efp[f]	Elongation factor EF-P	
infC	Initiation factor IF-3	10
tuf[g]	Elongation factor EF-Tu	
9. RNA synthesis, RNA modification, and DNA transcription		
rho	Transcription termination factor Rho	1
rpoA	RNA polymerase, α-subunit	14
rpoB	RNA polymerase, β-subunit	9
rpoC	RNA polymerase, β′-subunit	9
11. Phospholipids		
clh[h]	Cardiolipin synthase	
B. Degradation of macromolecules		
1. RNA		
rnh	RNase H	11
rnpA	RNase P	1
3. Proteins, peptides, and glycopeptides		
hslU	Heat shock protein, protease?	12
htrA	Periplasmic serine protease and heat shock protein	4
soh[i]	Periplasmic protease	

Table 4. *Continued*

Gene symbol	Gene product description	Linkage group[b]
C. Cell envelope		
2. Surface polysaccharides, lipopolysaccharides, and antigens		
kdtB	Putative enzyme of lipopolysaccharide synthesis	12
4. Murein sacculus and peptidoglycan		
ddlB	D-alanine-D-alanine ligase	6
murC	L-alanine-adding enzyme, UDP-*N*-acetyl-muramate-alanine ligase	6
murE	*meso*-Diaminopimelate-adding enzyme	4
IV. CELL PROCESSES		
B. Chaperones		
dnaJ[d]	Heat shock protein	
dnaK[d]	Heat shock protein (Hsp 70), DNA biosynthesis	
groEL	Heat shock protein (Hsp 60)	1
groES	Heat shock protein (Hsp 10)	1
hscA	Cold shock protein (Hsp 70)	1
hscB	Cold shock protein	1
C. Cell division		
ftsA	Cell division protein, complexes with FtsZ	6
ftsI	Septum formation; penicillin binding protein 3; peptidoglycan synthase	4
ftsL	Cell division protein; ingrowth of wall at septum	4
ftsZ	Cell division, forms circumferential ring	6
E. Protein and peptide secretion		
secB	Protein export, molecular chaperone	7
V. OTHER		
F. Adaptations and atypical conditions

[a]Gene list arranged according to the classification of gene products of Riley and Labedan (1996). Genes from *Buchnera* from other species of aphids are indicated.
[b]See Table 5.
[c]From *Buchnera* (Usn).
[d]From *Buchnera* (Ap) (Nakabachi and Ishikawa, 1997, 1999; Sato and Ishikawa, 1997a, b).
[e]p, plasmid associated gene.
[f]From *Buchnera* (Mp) (Hogenhout et al., 1998).
[g]From Brynnel et al. (1998).
[h]From *Buchnera* (Dn, Usn).
[i]From *Buchnera* (Sc) (Lai et al., 1995).

trpA), branched-chain amino acids (*ilvI*, *ilvD*, *leuA*), and histidine (*hisG*; Baumann et al., 1999a). *Buchnera* mRNA has been detected also for a gene involved in the biosynthesis of riboflavin (*ribE*; Nakabachi and Ishikawa, 1999) as well as for genes involved in the heat shock response (*groEL*, *groES*, *dnaK*, *dnaJ*; Table 4; Sato and Ishikawa, 1997a, b). Numerous *Buchnera* proteins have also been detected by immunological methods. These include *GroEL*, *GroES*, and *DnaK* (Kakeda and Ishikawa, 1991; Sato and Ishikawa, 1997b) as well as ribosomal protein S1 (the product of *rpsA*; Clark et al., 1996) and the protein involved in septum formation during cell division (the product of *ftsZ*; Table 4; Baumann and Baumann, 1998).

In bacteria, rRNA genes are transcribed from strong promoters. Comparisons of the regions upstream of rRNA genes from six species of *Buchnera* indicated conservation of sequences resembling the –35 and –10 regions of σ^{70} promoters as well as boxA and boxC (Munson et al., 1993; Rouhbakhsh, 1995). Similar putative –35 and –10 regions were found in *Buchnera* plasmids containing genes for tryptophan and leucine biosynthesis (Baumann et al., 1999b; Rouhbakhsh et al., 1996; Silva et al., 1998).

GroEL Overproduction and Its Significance In *Buchnera* the chaperonin, GroEL, constitutes a major fraction of the total protein (Sato and Ishikawa, 1997a). In addition, GroEL is present in aphid hemolymph (van den Heuvel et al., 1994). Overproduction of GroEL is a characteristic of some endosymbionts and pathogens in the intracellular environment (Hogenhout et al., 1998). This protein mediates the folding of peptides into their functional forms as well as the repair of damaged proteins (Gross, 1996). *Buchnera* GroEL is able to complement *E. coli* mutants (Ohtaka et al., 1992). GroEL has been localized in maternal and embryonic *Buchnera* by immunohistochemistry (Fukatsu and Ishikawa, 1992c). Electron micrographs indicate that the purified *Buchnera* GroEL has the characteristic double-ring appearance observed with the *E. coli* protein (Filichkin et al., 1997; Hara and Ishikawa, 1990). The endosymbiont protein has ATPase activity and in the presence of *E. coli*, GroES could reconstitute denatured *Rhodospirillum rubrum* ribulose-1,5-biphosphate carboxylase (Kakeda and Ishikawa, 1991).

The *Buchnera groESL* operon organization resembles that of *E. coli* (Hassan et al., 1996; Hogenhout et al., 1998; Ohtaka et al., 1992). Upstream of *groES* are nucleotide sequences characteristic of the –35 and –10 regions of σ^{32} promoters. A message of 2.1 kb (containing both *groES* and *groEL*) is made by the endosymbiont using only this promoter (Sato and Ishikawa, 1997a). It is not understood why GroES is low in the endosymbiont, in contrast to the high quantities of GroEL (Kakeda and Ishikawa, 1991). The genes for σ^{32} (*rpoH*) as well as *dnaKJ* have been cloned and sequenced (Sato and Ishikawa, 1997a, b). The latter also are transcribed solely from a σ^{32} promoter. In *E. coli* as well as other organisms, transcription of the *groESL* operon and the *dnaKJ* operon is part of the σ^{32} regulon, and their synthesis is increased by heat shock (Gross, 1996). It would appear that this mode of regulation is modified in *Buchnera* (Sato and Ishikawa, 1997a, b). Synthesis of *groESL* and *dnaKJ* mRNA is constitutive and is not increased by heat shock. This conclusion is supported by the observation that there is no increase in the level of total GroEL in aphids shifted from 23 to 33°C for one day (Baumann et al., 1996).

Baumann et al. (1996) arrived at an estimate of the amount of GroEL per *Buchnera* cell, based on the premise that the endosymbiont contained only one genome copy. Recently it has been shown that *Buchnera* is polyploid, containing an average of 120 genome copies per cell (Komaki and Ishikawa, 1999). If this result is incorporated into the calculation, an impossible excess of GroEL would be present in each endosymbiont cell. Since protein extracts of whole aphids were used in the estimation of GroEL content, this result could be explained by the finding that GroEL is also present in the hemolymph (van den Heuvel et al., 1994).

Perhaps the major economic effect of aphids on agriculture is their ability to transmit plant viruses (Blackman and Eastop, 1984; Gray and Banerjee, 1999; Sylvester, 1985). *Buchnera*-derived GroEL has been implicated in the survival of luteoviruses in the hemolymph (Filichkin et al., 1997; van den Heuvel et al., 1994; Hogenhout et al., 1998). These viruses replicate in the plant and are ingested by aphids when they feed on phloem sap. Subsequently they are transported from the digestive tract into the hemolymph and from there, into the salivary gland for transmission to plants via salivary secretions. The viruses are retained in an infective form (without replication) in the hemolymph throughout the life span of the aphid. There is evidence that the GroEL that is found in the hemolymph coats the virus particles and protects them from host defenses. A region in *Buchnera* GroEL has been identified which is essential for binding to the virus (Hogenhout et al., 1998), and similarly a portion of a viral capsid protein has been identified as the region to which the endosymbiont GroEL binds (van den Heuvel et al., 1997). Transmission of plant viruses may be advantageous to the aphid because infected plants have higher levels of nutrients in their sap (Blua et al., 1994).

An additional reason for the constitutive synthesis of high amounts of GroEL by *Buchnera* may be to compensate for the accumulated amino acid substitutions which have occurred at a high rate in this endosymbiont (Moran, 1996; Table 3). These slightly deleterious changes may result in proteins of decreased stability, and the high levels of GroEL may compensate for these changes, allowing proper folding and retention of function. A similar role for chaperones in masking deleterious mutations has been recently suggested on the basis of work on *Drosophila* heat shock protein (Pennisi, 1998; Rutherford and Lindquist, 1998).

Genetics

Genome Analysis The guanine + cytosine (G+C) content of *Buchnera* is about 28 mol% (Clark et al., 1998a; Ishikawa, 1987). The genome size of the endosymbiont from the aphid Ap has been found to be 0.657 Mb (Charles and Ishikawa, 1999). This is considerably below such free-living organisms as *E. coli* (4.6 Mb; Blattner et al., 1997) and *Haemophilus influenzae* (1.8 Mb; Fleischmann et al., 1995) and the intracellular pathogens, *Chlamydia trachomatis* (1.0 Mb; Stephens et al., 1998) and *Rickettsia prowazekii* (1.1 Mb; Andersson et al., 1998). The *Buchnera* genome is somewhat larger than that of the pathogen *Mycoplasma genitalium* (0.58 Mb; Fraser et al., 1995). An unusual property of the *Buchnera* genome is that it appears to be present as about 120 copies per cell (Komaki and Ishikawa, 1999).

Approximately 130 kb of DNA have been sequenced from *Buchnera* (from Sg) (Baumann and Baumann, 1998; Baumann et al., 1995; Clark et al., 1998a, b; Thao and Baumann, 1998). The choice of this aphid was predicated on the fact that it contains only one endosymbiont as indicated by morphological examinations as well as extensive restriction enzyme and Southern blot analysis of whole aphid DNA, using probes for many different genes. The latter results indicated that, with the exception of plasmid amplified DNA, only one copy of the targeted genes was present in the endosymbiont genome. In many cases, the DNA that was used for cloning was also endosymbiont-enriched. There were many independently cloned DNA fragments with identical overlapping sequences, indicating that the aphids did not contain several closely related endosymbionts. At least 20 kb of DNA also have been sequenced from *Buchnera* of each of the aphids Dn, Sc and Mr (Baumann et al., 1998a; Clark et al., 1999b; Lai et al., 1995, 1996). Table 4 lists, under different functional categories, the genes found in *Buchnera*, primarily in (Sg). The order of these genes in the DNA fragments is presented in Table 5. A total of 126 open reading frames were detected, of which 101 corresponded to *E. coli* genes with known function. The remaining 25 open reading frames all had homologs of no known function in the *E. coli* chromosome (Blattner et al., 1997). Table 6 presents the codon usage of the *Buchnera* structural genes. As expected from the G+C content, there is a strong bias for A and T, especially in the third codon position. This bias also affects the composition of proteins, favoring amino acids for which

[a]Based on 19037 codons (Clark et al., 1998a).

codons contain more A and T (Moran, 1996; Clark et al., 1999b).

Buchnera was found to contain *dnaA*, encoding a protein which initiates bidirectional chromosome replication, and *ftsZ*, encoding a protein involved in septum formation during cell division (Baumann and Baumann, 1998; Lai et al., 1992a). Among other genes that were found are those encoding proteins for: peptidoglycan synthesis, cell division, DNA replication, DNA transcription, ribosomal proteins, amino acid tRNA synthases, ATP synthase, electron transport, protein secretion and glycolysis. In addition, genes for three tRNAs were detected. Genes encoding homologs of proteins involved in the *E. coli* heat shock response (*groEL*, *groES*, *htrA*, *dnaK*, *dnaJ*) and the cold shock response (*hscA*, *hscB*) were also detected (Clark et al., 1998a; Hassan et al., 1996; Ohtaka et al., 1992; Sato and Ishikawa, 1997b). Nakabachi and Ishikawa (1999) detected a gene (*ribE*) encoding a protein involved in riboflavin biosynthesis. In addition some of the genes encoding enzymes for the biosynthesis of aromatic amino acids (shikimate pathway, tryptophan branch), branched-chain amino acids (isoleucine, valine, leucine), lysine, cysteine and serine as well as genes for the complete pathway of histidine biosynthesis were found (Clark et al., 1998a, b; Thao and Baumann, 1998). The presence of genes for enzymes of amino acid biosynthesis is in marked contrast to the obligate intracellular pathogens *Rickettsia prowazekii* and *Chlamydia trachomatis*, as well as such fastidious organisms as *Mycoplasma genitalium* and *Borrelia burgdorferi*, all of which lack genes encoding enzymes of amino acid biosynthesis (Andersson et al., 1998; Fraser et al., 1995, 1997; Stephens et al., 1998). Retention of amino acid biosynthetic genes by *Buchnera* probably reflects the role of these pathways in the mutualistic association with the host aphids. Overall, these results on gene content indicate that *Buchnera* has many of the properties of free-living bacteria and would appear to be, in many respects, a self-contained, physiologically autonomous unit enclosed within bacteriocyte-derived vesicles.

Currently the most interesting comparison of the *Buchnera* genome is with the recently sequenced obligate intracellular pathogen *R. prowazekii*, an organism which is a member of the α-subdivision of the Proteobacteria (Andersson et al., 1998). Compared to the sequenced bacterial genomes, this organism is unusual in that 24% of its DNA is noncoding. In addition it has a number of pseudogenes. These findings are interpreted as a stage in the adaptation of *R. prowazekii* to an intracellular lifestyle, involving the loss of genes encoding metabolic pathways for products that are provided by the host. Currently about 20% of the *Buchnera* genome has been sequenced, and the organization of the genes in these genome fragments is highly compact and similar to that of other bacteria (Clark et al., 1998a). These findings indicate that if, as seems probable, *Buchnera* originated from an organism with a larger genome (Charles and Ishikawa, 1999), then the reduction in the genome size has already been accomplished and what has been retained is the essential gene complement required for the endosymbiotic association.

Plasmid-Associated Amplification of Biosynthetic Genes Some species of aphids have *Buchnera* in which genes for enzymes of amino acid biosynthesis are amplified on plasmids (Bracho et al., 1995; Lai et al., 1994; van Ham et al., 1999). This plasmid-associated gene amplification has been interpreted as an adaptation of *Buchnera* to an endosymbiotic association in which one of its functions is the overproduction of amino acids. This interpretation is based on analogies with other prokaryotic systems in which gene amplification is viewed as an attribute of prokaryotic

genome plasticity allowing the organism to adapt to new environments (for recent reviews see Romero and Palacios, 1997; Roth et al., 1996). Currently *Buchnera* has been found to contain three different types of plasmids. The properties of these plasmids are summarized in Table 7. The plasmid-amplified genes encode the first enzyme of the tryptophan biosynthetic pathway (TrpEG) and four enzymes (LeuA, LeuB, LeuC, LeuD) of the leucine portion of the branched-chain amino acid biosynthetic pathway. For purposes of grouping of plasmid types and ease of presentation, we have used the plasmid designations given in Table 7 followed by the abbreviation corresponding to the aphid species (Table 2).

Table 7. Designations and characteristics of *Buchnera* plasmids.[a]

1) **pTrpEG.** Two or more DnaA boxes in a putative origin of replication (Fig. 5a–h). Arrangement of DnaA boxes varies, one conserved pattern is recognized and designated at *ori*-3.6. (Fig. 5a–c). The plasmids usually consist of tandem repeats of identical or similar units containing gene(s) for a putative anthranilate synthase (TrpEG), the first enzyme of the tryptophan biosynthetic pathway.
2) **pTrpEG-R.** Plasmid contains genes for putative replication initiation proteins (*repAC1, repAC2*) which are related to replication initiation proteins of broad host range plasmids of the IncA/C group (Fig. 5i, 7c). Within the DNA encoding the C-terminal end of the replication initiation proteins and/or downstream of this gene are 19 nt-long repeats which correspond to putative interons (Fig. 5i). Plasmid consists of tandem repeats of similar units and contains genes for a putative anthranilate synthase (TrpEG), the first enzyme of the tryptophan biosynthetic pathway.
3) **pLeu.** Plasmid contains genes for putative replication initiation proteins (*repA1, repA2*) which are related to replication initiation proteins of plasmids of the IncFII group (Fig. 9a-c). Putative origin of replication downstream of *repA1*. Plasmids contain one copy of genes encoding for enzymes of leucine biosynthesis (*leuA, leuB, leuC, leuD*).

[a]For references see text.

When first used, the designation is followed by the original plasmid name given in parentheses (if applicable). There are a number of other examples of plasmid amplification of biosynthetic genes. Amplification has been interpreted as a means of increasing the rate of synthesis of endproducts. These include genes of purine biosynthesis in *Borrelia* (Margolis et al., 1994), cysteine biosynthesis in *Synechococcus* (Nicholson et al., 1995), and histamine biosynthesis in *Vibrio* (Barancin et al., 1998).

The trpEG-Containing Plasmids and Gene Silencing Figure 4 is an outline of the aromatic amino acid biosynthetic pathway. It consists of a common portion leading to chorismate (shikimate pathway) and branches to 1) phenylalanine and tyrosine as well as 2) tryptophan. In the shikimate pathway, arrows that have designations correspond to genes detected in *Buchnera* (Sg). The activity of the tryptophan biosynthetic pathway is regulated by anthranilate synthase (TrpEG) which is feedback inhibited by tryptophan (Crawford, 1989). In *Buchnera* from 11 species of aphids, *trpEG* has been found to be plasmid-associated (Fig. 5; Baumann et al., 1997b; Lai et al., 1994, 1996; Rouhbakhsh et al., 1996, 1997; van Ham et al., 1999). The remaining genes of the pathway [*trpDC(F)BA*] have been found to have a chromosomal location in all cases examined [*Buchnera* (Sg, Dn, Sc, Mr)] (Baumann et al., 1998a; Clark et al., 1999b; Lai et al., 1995). In contrast to the situation in Aphididae, in *Buchnera* (Sc, Mr), *trpEG* is not plasmid-associated but is present as one copy on the endosymbiont chromosome (Fig. 4; Clark et al., 1999b; Lai et al., 1995).

The structure of plasmids of the pTrpEG-type usually consists of tandem repeats of a nearly identical unit (Fig. 5a–h). In *Buchnera* (Sg, Rp) the plasmids contain four tandem repeats of a 3.6 kb unit, in *Buchnera* (Rm) the plasmid consists of one 3.6 kb unit, while in *Buchnera* (Ap) plasmids containing 5, 6, or 10 tandem repeats

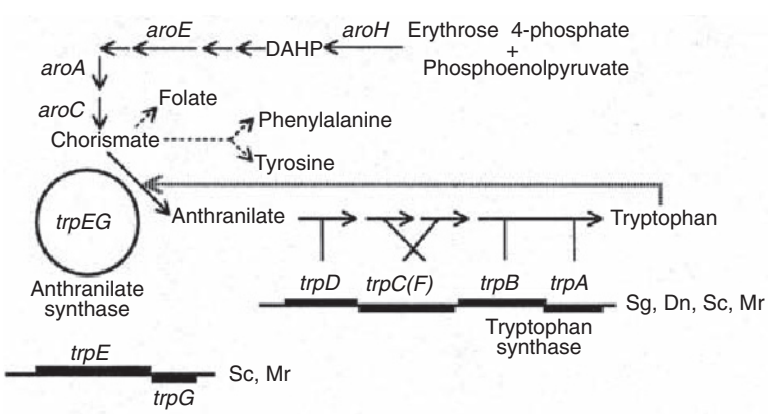

Fig. 4. Outline of the pathway for the biosynthesis of aromatic amino acids. Arrows, single enzymatic reactions; dashed arrows, several enzymatic reactions; striped arrow, feedback inhibition; genetic designations above striped line, genes detected in *Buchnera* (Sg); other genes, detected in *Buchnera* from the designated host aphids; circle, plasmid containing one or multiple copies of trpEG; DAHP, 3-deoxy-D-arabinoheptulosonate 7-phosphate. For a description of genes see Table 4; for references see text.

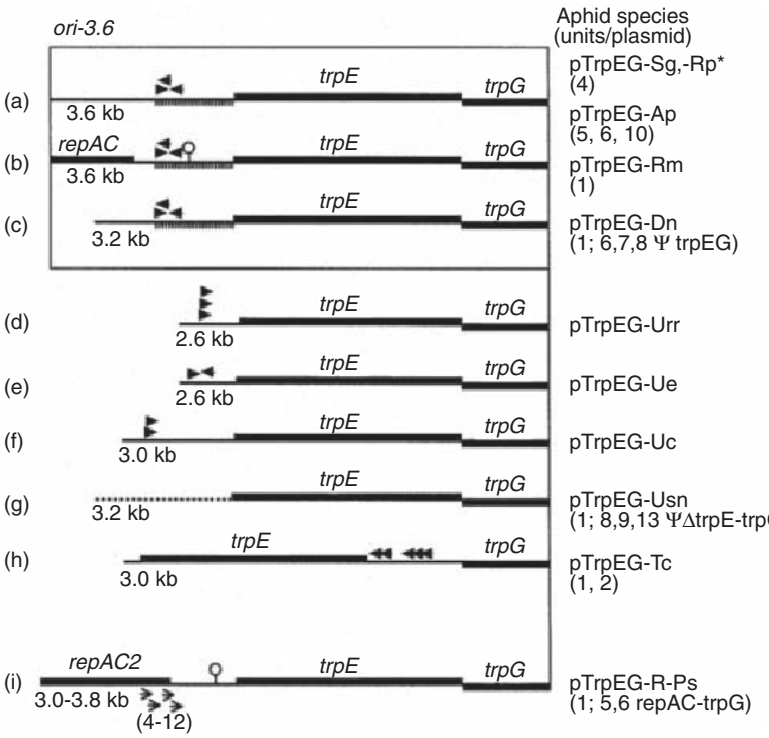

Fig. 5. Genetic maps of the repeated units which constitute trpEG-containing plasmids. Filled arrowheads, position and direction of DnaA boxes which are components of a putative origin of replication; circle on stem in (b) and (i), position of a 19 nt sequence similar to the interon of the broad host range plasmid RA1; ori-3.6, putative origin of replication found primarily in plasmids consisting of 3.6 kb repeat units (boxed); striped line, conserved sequence; dashed line, DNA that has not been sequenced; arrow in (i), 19 nt repeated sequence corresponding to a putative interon; Rp*, TrpEG-Rp also contains a remnant of repAC. For references see text.

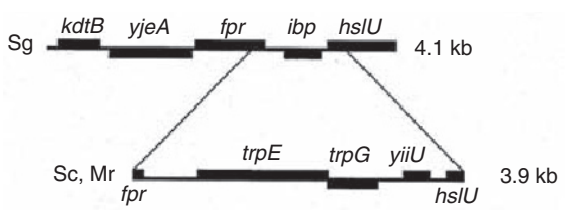

Fig. 6. Genetic map of similar chromosomal DNA fragments from Buchnera (Sg) as well as (Sc, Mr). Buchnera (Sg) lacks trpEG due to its presence on a plasmid while in Buchnera (Sc, Mr) trpEG is chromosomal. For a description of genes see Table 4; for references see text.

are found. *Buchnera* (Sg) contains about 4 plasmids per endosymbiont chromosome resulting in a 16-fold *trpEG* amplification. In *Buchnera* (Sc, Mr), in which *trpEG* is chromosomal, these two genes are found between *fpr* and *hslU* (Fig. 6). In *Buchnera* (Sg), in which *trpEG* is plasmid-associated, *trpEG* is absent from this chromosomal location, consistent with its transfer to the plasmid (Fig. 6). Instead *ibp* is present at this position, suggesting a concomitant or a subsequent acquisition of this gene (Clark et al., 1999a).

The plasmids in Fig. 5a–h all share in common the presence of 2–5 DnaA boxes which are 9 nt-long sequences to which the DnaA protein binds, thereby initiating chromosomal replication (Messer and Weigl, 1996). There is also considerable variation in the length of the repeated units (2.6 to 3.6 kb). Within this plasmid group, a readily recognized subset contains a unique arrangement of three DnaA boxes and a conserved region upstream of *trpEG* which has been designated as *ori-3.6* (Fig. 5a–c; Lai et al., 1996; Rouhbakhsh et al., 1996). *Buchnera* in aphids of the genus *Uroleucon* (which is derived from *Buchnera* within the cluster that has *ori-3.6*-containing plasmids, Fig. 2b, c) have *trpEG* units which show a considerable size range and substantial differences in the arrangement of the DnaA boxes (Fig. 5d–g; Baumann et al., 1997b; Rouhbakhsh et al., 1997). All of these *Buchnera* are from aphid species of the family Aphididae (Fig. 2a). Plasmid pTrpEG-Tc (pBTc2; Fig. 5h) is from an aphid within the family Pemphigidae (van Ham et al., 1999). The predominant form of this plasmid consists of one 3.0 kb unit; a minor form consists of two units. A distinctive feature is the presence of DnaA boxes between *trpE* and *trpG* (Fig. 5h) and not upstream of *trpEG* as is the case of the other plasmids (Fig. 5a–g). However, since there is considerable rearrangement of the DnaA boxes within plasmids in *Buchnera* of *Uroleucon* (Fig. 5d–g), it is plausible that the arrangement of DnaA boxes within pTrpEG-Tc is not a fundamental difference but a variation on the arrangement observed in the other *trpEG*-containing plasmids (Fig. 5a–g).

A totally different *trpEG*-containing plasmid is pTrpEG-R-Ps (pBPs2; Fig. 5i), which does not contain DnaA boxes but instead has putative

replication initiation proteins (RepAC) which are related to those of plasmids of the broad host-range group IncA/C (van Ham et al., 1999). Within the DNA encoding the C-terminal portion of *repAC* and/or downstream of it are 4–12 repeats of a 19 nt-long sequence corresponding to a putative interon. In addition, there is a single copy of a 19 nt-long sequence similar to the interon sequence of IncAC plasmid RA1 (Llanes et al., 1996). Curiously pTrpEG-Rm (Fig. 5b) contains in its DNA a gene for a putative RepAC protein and the 19 nt-long sequence similar to that found in plasmid RA1, while pTrpEG-Rp from a closely related aphid has a remnant of *repAC* (van Ham et al., 1999).

In several pTrpEG plasmids, the expression of most of the *trpEG* copies appears to be silenced (Baumann et al., 1997b; Lai et al., 1996; van Ham et al., 1999). In *Buchnera* (Dn) there are about two copies of pTrpEG-Dn for each endosymbiont genome (Lai et al., 1996). Plasmid pTrpEG-Dn consists of a single 3.2 kb unit containing an open reading frame corresponding to the putative protein TrpEG (Fig. 7a). This is followed by a 2.6 kb unit containing *trpEG* pseudogenes and 5–7 repeats of a 3.2 kb unit also containing *trpEG* pseudogenes. (By pseudogenes, we mean segments of DNA which are clearly recognizable as *trpEG* but which contain numerous frameshifts and stop codons preventing the synthesis of an intact protein.) A comparison of the sequences between the 3.2 kb fragments with and without pseudogenes indicated 244 differences of which 93% were localized in an approximately 900-bp DNA segment which included the putative promoter and the N-terminus of *trpE* (Fig. 7a). These changes should result in the reduction or elimination of mRNA synthesis; if messenger is made, it would be translated into short peptides because of the numerous frame shifts and stop codons in the region of the N-terminus of *trpE*.

Another instance of *trpEG* silencing is illustrated by pTrpEG-Usn (Fig. 7b). This plasmid consists of a 3.2 kb unit of *trpEG* followed by 10–14 2.1 kb units consisting of DNA with a deletion of about 56% of the N-terminal region of *trpE* and an intact trpG. A more remarkable example of gene silencing is found in pTrpEG-R-Ps (Fig. 7c), which consists of a 3.6–3.8 kb unit containing *repAC2-trpEG* followed by 1.8 kb units consisting of *repAC1*, a deletion of *trpE*, and an intact *trpG* (van Ham et al., 1999). Preceding the latter is a short DNA segment which appears to be a remnant of DNA encoding the C-terminus of *trpE*. The structure of this plasmid suggests that, in *Buchnera* (Ps) of the family Pemphigidae, *trpEG* amplification had an origin independent of that of the remaining plasmids shown in Fig. 5. The initial plasmid probably contained tandem repeats of *repAC-trpEG*. Subsequently there was selection pressure for gene silencing resulting in a plasmid with one intact copy of *repAC-trpEG* and tandem repeats of *repAC-trpG* which contain a deletion of the putative promoter region and most of *trpE*.

Speculation Concerning trpEG Amplification

The following is a summary of the results obtained from studies of *trpEG* in *Buchnera*. 1) *trpEG* amplification is widespread in *Buchnera* within the family Aphididae and is also present in at least two members of the family Pemphigidae. In *Buchnera* from two aphid species of the latter family, *trpEG* is chromosomal and is found in the same location. In most cases *trpEG* amplification is affected by plasmids consisting of tandem repeats of the same or similar unit.

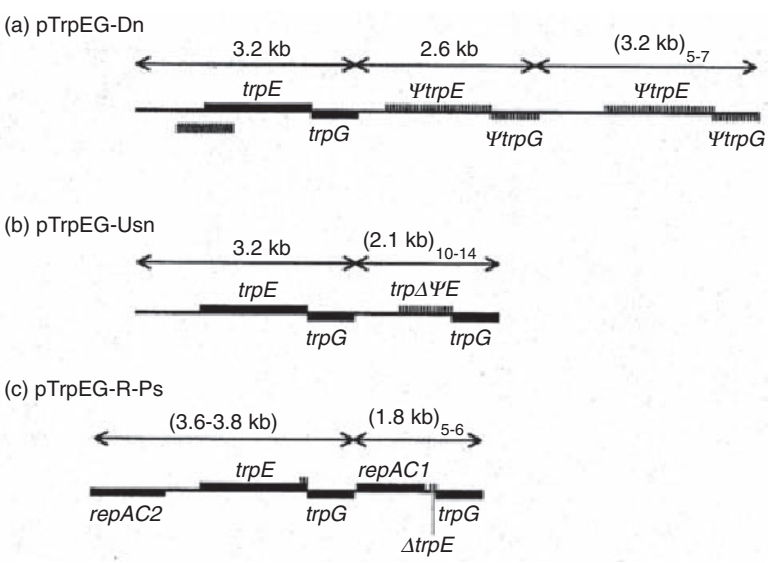

Fig. 7. Genetic map of plasmids which contain silenced trpEG. Stippled line in (a), region which in the pseudogene containing fragments has most of the changes; striped line in (a) and (b), pseudogenes (Ψ); Δ in (b), deletion of the N-terminal portion of trpE; striped line in (c), sequence homologous to the end of trpE. For references see text.

2) Evolution of plasmid-associated *trpEG* is vertical, that is, *Buchnera* from different aphid species do not exchange plasmids. 3) The *trpEG*-containing plasmids constitute at least two replicon types, one of which is based on the presence of DnaA boxes, while the other is based on the presence of interons and replication-initiation proteins related to plasmids of the IncA/C group. *Buchnera* from the related aphids Rm and Rp which belong to the first replicon type also have a gene and/or the remnant of a gene for a replication-initiation protein related to plasmids of the IncA/C group. 4) In *trpEG* plasmids of both replicon types, gene silencing of some of the *trpEG* tandem repeats is observed. 5) In *Buchnera* (Sg) the sequence of two of the 3.6-kb units is virtually identical, as is the sequence of the 2.6 and 3.2-kb *trpEG* pseudogene-containing units of *Buchnera* (Dn). While results above are derived from genetic analyses, the interpretations that follow are speculative and based in large part on analogies with other prokaryotic systems.

Gene amplification is currently viewed as a reversible aspect of genome plasticity which occurs at a frequency considerably higher than that of mutation in structural genes (Romero and Palacios, 1997; Roth et al., 1996). Gene amplification is frequently used by an organism as a means of increasing the amount of a growth-limiting enzyme to levels beyond that achieved by gene regulation of expression. One of the functions of *Buchnera* is the synthesis of essential amino acids (including tryptophan) for the aphid host. In almost all prokaryotes, the limiting enzyme TrpEG (which is feedback inhibited by tryptophan) regulates the activity of the tryptophan biosynthetic pathway. The *Buchnera* enzyme is probably also feedback inhibited by tryptophan since *trpE* has the conserved amino acid residues that are involved in feedback inhibition (Lai et al., 1994). To overproduce tryptophan, the activity of TrpEG must be increased, the potential effect of tryptophan accumulation on activity must be overcome, or both. Since even in high concentrations of tryptophan the activity of TrpEG is not fully inhibited, an increase in enzyme protein will result in increased tryptophan production. This has been the case in experiments on overproduction of tryptophan for industrial purposes; an increase in allosterically inhibitable TrpEG is the primary means of achieving excretion of high amounts of tryptophan into the medium (Katsumata and Ikeda, 1993).

In free-living bacteria, gene amplification is frequently transient. Its persistence depends on a constant selective pressure, the absence of which leads to a rapid decrease in number of repeats primarily by means of RecA-mediated homologous recombination (Roth et al., 1996). There may be differences or fluctuations in the levels of tryptophan in aphid diets; furthermore, the high level of TrpEG protein may impose an energy burden on the endosymbiont. Both of these conditions could provide short-term selective pressure for the elimination of plasmids from *Buchnera* (Baumann et al., 1997a). Consequently some mechanism of stabilization may be necessary for the maintenance of *trpEG*-containing plasmids. The gene *recA* has been cloned and sequenced from many bacterial taxa, and adequate oligonucleotide primers are available for its amplification by PCR (Eisen, 1995). We have made extensive unsuccessful attempts to detect this gene by PCR, suggesting that it may be absent from *Buchnera* or is greatly modified. Once plasmid stabilization occurs, the aphid may encounter conditions in which *trpEG* amplification is no longer necessary due to availability of tryptophan in the diet. If the usual mechanisms (homologous recombination?) which effect a decrease in *trpEG* amplification are absent, then one way of reducing the potentially wasteful synthesis of TrpEG is gene silencing.

In the past we have speculated that *trpEG* amplification is a property of rapidly growing aphids and that gene silencing may occur when following plasmid stabilization, the diet of aphids is nutritionally enriched (Baumann et al., 1997a; Lai et al., 1994, 1995, 1996). Recent studies have indicated that these speculations are overly simplistic. It has been suggested that the lack of *trpEG* amplification in *Buchnera* (Sc, Mr) which are in the Pemphigidae is due to the slow growth rate of these aphids compared to that of aphids within the Aphididae (Lai et al., 1995). There are, however, few studies on the growth rate of aphids, and the finding of amplification in *Buchnera* (Ps, Tc) which are in the family Pemphigidae and presumably also have a slow growth rate makes this explanation questionable. Dn causes major tissue histolysis of plants and it has been suggested that the presence of higher amounts of tryptophan in the diet may be the explanation for gene silencing (Lai et al., 1996). Recent studies on amino acid composition of ingested phloem sap are not strongly supportive of this hypothesis as a sole explanation for the presence of pseudogenes (Sandström and Moran, 1999; Sandström et al., 2000; Telang et al., 1999). *Buchnera* (Rp) and *Buchnera* (Sg) are similar in that both have pTrpEG consisting of four tandem repeats of a 3.6-kb unit (Fig. 5a). In spite of this similarity, Rp causes essentially no modification of the amino acid composition of plant phloem while Sg causes substantial increases (Sandström et al., 2000). Dn contains a plasmid with *trpEG* pseudogenes (Fig. 7a). The ingested diet of Dn has approximately doubled

concentrations of tryptophan, yet the changes it causes in the amino acid composition of phloem are less than those caused by Sg. This suggests that pseudogene formation is not solely the result of increased dietary tryptophan (Sandström et al., 2000; Telang et al., 1999). However, in the case of Usn, the presence of *trpEG* pseudogenes is consistent with the finding of unusually high levels of essential amino acids in the phloem diet (Sandström and Moran, 2000). Thus the availability of nutrients in plant sap may be a partial explanation for *trpEG* amplification and pseudogene formation, but other factors must also be involved.

In this connection it should be mentioned that the past speculations attempt to correlate adaptations of *Buchnera* with properties of the aphid host (growth rate, modification of nutrient content of plant sap). The environment of the endosymbiont is the bacteriocyte vesicle, which harbors the endosymbiont. This environment is a reflection of the activities of the aphid host and is a function of its ability to obtain nutrients from the plant as well as its demands on the biosynthetic attributes of the endosymbiont. Therefore, host properties, such as the efficiency of nutrient uptake from the plant and their transformation and delivery, may determine the nutritional parameters within the bacteriocyte vesicles and impose the selective pressure resulting in *Buchnera* adaptation to the endosymbiotic association.

Some of the phenomena encountered in pTrpEG from *Buchnera* also have been found in other systems. Promoter inactivation by multiple sequence changes is the mechanism used for silencing the expression of the *Bordetella pertussis* toxin gene (Gross and Rappuoli, 1988) and the expression of the *Bordetella* urease gene cluster (McMillan et al., 1998). The changes resemble those observed in gene silencing of *trpEG* in *Buchnera* (Dn; Fig. 7a). Multiple copies of nearly identical chromosomal enzyme-encoding genes have been found in *Thiobacillus ferroxidans* (Kusano et al., 1991) and *Nitrosospira* sp. (Norton et al., 1996). This situation is similar to that found with the repeats of *trpEG* and *trpEG* pseudogenes and has led to the postulation of mechanisms for the preservation of sequence identity of the repeated units (Klotz and Norton, 1998).

The phylogenetic trees constructed on the basis of plasmid-associated genes are congruent with the phylogenetic trees based on *Buchnera* chromosomal genes (Fig. 2a–c). One exception, the basal position of *Buchnera* (Tc; Fig. 2c), is probably an artifact arising from the more rapid change of *trpE* in this lineage (van Ham et al., 1999). These results strongly suggest that there is no exchange of *trpEG*-containing plasmids between endosymbionts of different aphids. Plasmids of the pTrpEG type (Fig. 5a–h) could have an endogenous origin. DnaA boxes are found in other locations of the *Buchnera* genome (Clark et al., 1998c), and their assembly with *trpEG* could generate a separate replicon. In contrast to these plasmids, the *repAC* genes of pTrpEG-R are related to replication initiation proteins of IncA/C plasmids. Thus, this plasmid may be the result of an invasion of *Buchnera* by an exogenous plasmid that recombined with endosymbiont genes, resulting in their amplification. It has been established that some bacteria may persist for a long time in insects; conceivably, such organisms transferred their plasmids to *Buchnera* during the infection of embryos or eggs at a stage at which the endosymbionts are not sequestered within bacteriocytes. It is, however, difficult to explain the presence of *repAC* and its remnant in *Buchnera* (Rm, Rp). One possibility is that it is the result of another invasion by a similar plasmid. However, organization of *ori-3.6* in *Buchnera* (Rm, Rp) closely resembles that of *Buchnera* of related aphids, suggesting a common plasmid origin for this group (Fig. 5a–c). Alternatively, van Ham et al. (1999) suggested that a plasmid of the pTrpEG-R type is the ancestor of all *trpEG* amplification plasmids. This hypothesis requires the subsequent occurrence of multiple losses of *repAC* and the interons in pTrpEG-R type plasmids and the acquisition of DnaA boxes in *Buchnera* of Aphididae.

pLeu Plasmids Figure 8 is an outline of the pathway of branched-chain amino acid biosynthesis. The gene for aspartokinase (*thrA*) has been found in *Buchnera* (Sg). The genes *ilvIH*, *ilvC*, and *ilvD* have been found in *Buchnera* (Sg, Dn, Sc, Mr) and encode three enzymes which func-

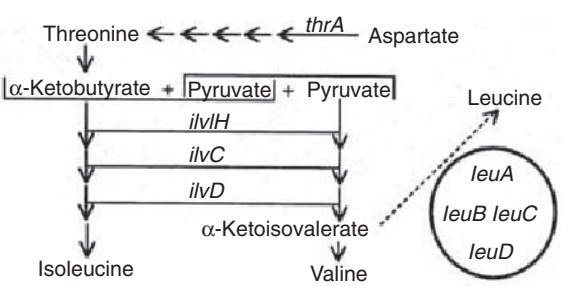

Fig. 8. Outline of the pathway for branched chain amino acid biosynthesis. Arrows, single enzymatic reactions; horizontal lines, enzymatic activities functional in both isoleucine and valine biosynthesis; dashed arrow, four enzymatic reactions; circle, plasmid containing genes for leucine biosynthesis. thrA was detected in *Buchnera* (Sg); ilvIH, ilvC, ilvD were detected in *Buchnera* (Sg, Dn, Sc, Rm); leuACBD were detected in *Buchnera* (Sg, Dn, Rm). For a description of genes see Table 4; for references see text.

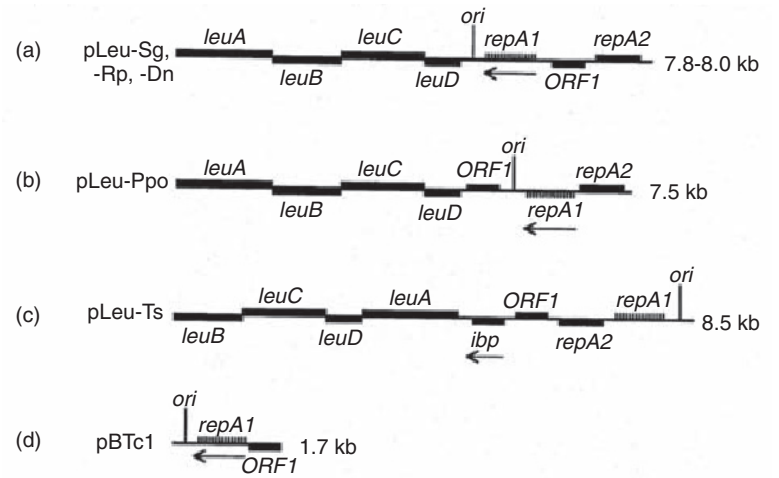

Fig. 9. Genetic maps of pLeu plasmids. Unless indicated by an arrow, transcription is left to right. ori, putative origin of replication; striped line, repA1 downstream of which is ori. For a description of genes see Table 4; for references see text.

tion in both the isoleucine and valine biosynthetic pathways (Clark et al., 1998c, 1999b; Thao and Baumann, 1998). The pathway of leucine biosynthesis is a branch off the valine pathway (Fig. 8). Bracho et al. (1995) found that in *Buchnera* (Rp), the genes for leucine biosynthesis (*leuABCD*) were present on a plasmid (Fig. 9a). This plasmid represents a third type (Table 7), designated pLeu, which is characterized by the presence of genes (*repA1*, *repA2*) encoding putative replication initiation proteins related to those of plasmids of the IncFII incompatibility group. Besides these genes, pLeu also contains *ORF1* encoding a putative membrane-associated protein. The closely related *Buchnera* (Sg, Rp, Dn) all contain very similar plasmids of 7.8 to 8.0 kb in which the genes are arranged in the same order (Fig. 9a; Baumann et al., 1999a; Bracho et al., 1995). In *Buchnera* from the more distantly related pLeu-Ppo (Fig. 2e), there are rearrangements of the *repA* genes and *ORF1* (Fig. 9b; Silva et al., 1998). All of these aphids are within the family Aphididae. In pLeu-Ts (pBTs1; Fig. 9c), which is from an aphid of the family Thelaxidae, there is also a rearrangement of the *leu* genes as well as an acquisition of *ibp* which encodes a heat shock protein (van Ham et al., 1997). All of these plasmids have a conserved region, downstream of *repA1*, which is probably an origin of replication (*ori*) (Baumann et al., 1999; Bracho et al., 1995; van Ham et al., 1997). Remarkably pBTc1 (Fig. 9d), a 1.7 kb plasmid from *Buchnera* (Tc), which is found in an aphid belonging to the family Pemphigidae, contains only *ori*, *repA1*, and *ORF1* and probably constitutes a minimal replicon.

In *Buchnera* (Sg), there are about 24 copies of pLeu per endosymbiont genome while in *Buchnera* (Dn) there are only 2 copies (Thao et al., 1998). This difference in functional gene copy number parallels that observed with pTrpEG in the endosymbionts of these two aphid species. In the case of pLeu, in which only one copy of the genes is present, the reduction in amplification in *Buchnera* (Dn) is achieved by means of a reduction of copy number. In pTrpEG, which contains tandem repeats of the same unit, the reduction in amplification is accomplished by means of pseudogene formation (Fig. 7a).

The similarities of pLeu plasmids suggest a single origin with pBTc1 (Fig. 9d) being the ancestral state (Baumann et al., 1999). In the lineage common to the Aphididae and the Thelaxidae, there was probably a duplication of *repA1* and the acquisition of *leu* genes. This was followed by a rearrangement of the genes and in one lineage the acquisition of *ibp* [for another interpretation, see van Ham et al. (1997)]. Silva et al. (1998) sequenced *repA2* from *Buchnera* of six additional aphids. A phylogeny based on this gene (Fig. 2e) as well as a more limited analysis based on *leu* genes (Fig. 2d) is congruent with trees established on the basis of other *Buchnera* chromosomal and plasmid genes. These results indicate that the pLeu plasmids are not exchanged among endosymbionts from different aphid species and that their evolution is vertical, as is the case with the *trpEG*-containing plasmids.

Unanswered Questions; Other Possible Adaptations One unanswered question is, why are only the *trp* and *leu* genes amplified? The endosymbiont produces other essential amino acids for the aphid host and their overproduction would in principle also be enhanced by plasmid amplification. It has been speculated that aphids make indole acetic acid which is involved in gall formation (Forrest, 1987). In many plant pathogens that cause gall formation, tryptophan is the

precursor of indole acetic acid (Patten and Glick, 1996). Amplification of *trpEG* is, however, found in aphids that do not produce galls (Sg, Dn, Rp, Usn) and is absent in some that do (Sc, Mr). Consequently this does not appear to be a probable explanation for *trpEG* amplification. Leucine, lysine, valine, arginine and threonine are the most common amino acid in aphids (Sandström and Moran, 1999), yet only genes for leucine biosynthesis have been detected on plasmids. It is possible that, in other cases where amino acids are overproduced for the host, an increase in enzyme activity is obtained by increasing the expression of the gene(s) by promoter modification. Alternatively changes of the allosteric properties of regulated enzymes may allow retention of activity in the presence of endproducts.

A possible example of the latter is *cysE* of *Buchnera* (Sg; Lai and Baumann, 1992b). This gene encodes an enzyme of the biosynthetic pathway of cysteine, and its activity is regulated by cysteine feedback inhibition (Kreditch, 1996). It has been established that the amino acids at the C-terminus of the *E. coli* enzyme are involved in cysteine feedback inhibition (Denk and Böck, 1987). The *Buchnera* (Sg) enzyme lacks these C-terminal amino acids and consequently is probably not subject to feedback inhibition by the endproduct; this change would result in cysteine overproduction (Lai et al., 1992b).

Secondary Endosymbionts of Aphids

Besides *Buchnera*, many aphids have additional endosymbionts usually called secondary (S-) endosymbionts (Buchner, 1965; Houk and Griffiths, 1980; Moran and Baumann, 1994). In many cases these endosymbionts are spheres or rod-shaped with different width and length; they were initially recognized by differences in size and shape from the round or oval *Buchnera*. The S-endosymbionts are also maternally inherited. They have not been extensively studied, and most of the available information is for the S-endosymbionts of the aphid Ap. Electron microcopic studies have shown that the rod-shaped S-endosymbionts are located within vesicles found in the flattened, syncytial, sheath cells which surround the bacteriome (Griffiths and Beck, 1973). Using a probe derived from *E. coli* 16S rDNA and restriction enzyme and Southern blot analysis of total aphid DNA, it was found that the S-endosymbiont from Ap contained a single copy of the 16S rDNA-gene (Unterman et al., 1989). DNA obtained from dissected bacteriocytes gave the same restriction pattern, indicating that the S-endosymbiont was located in the bacteriome. Two DNA fragments of 2.3 kb each were cloned and the 16S rDNA sequence determined. A phylogenetic analysis indicated that the S-endosymbiont was a member of the Enterobacteriaceae (Fig. 1). As in other members of this family, the 16S-rDNA gene of the S-endosymbiont was directly upstream of 23S rDNA (Unterman and Baumann, 1990).

Chen and Purcell (1997) found that 88% of the strains of Ap had the S-endosymbiont. In addition, the S-endosymbionts of Ap and *Macrosiphum rosae* were identical, suggesting recent infection or horizontal transmission. Interestingly, it was also found that the hemolymph of 48% of Ap strains contained a rod-shaped organism which had a 16S rDNA sequence nearly identical to that of *Rickettsia bellii*, an organism found in ticks (Chen et al., 1996). As a result of these studies strains of Ap became available which had 1) only the S-endosymbiont, 2) only the *Rickettsia* sp., as well as 3) neither of these two organisms. Chen (1996) injected one or both of these organisms into Ap, which originally lacked both, and observed their effect on fecundity, longevity and the length of the reproductive period. The results were complex in that they were affected by the plant on which the aphids grew and by the temperature of growth. At 20°C both the S-endosymbiont and the *Rickettsia* sp. reduced the fecundity, longevity and reproductive period of Ap on clover but had no significant effects on Ap grown on alfalfa or sweet pea (Chen, 1996). In some cases, both of these organisms appeared to cause an increase in the fitness of Ap when grown at 25°C. These results suggest that both the S-endosymbiont and the *Rickettsia* sp. can have either a deleterious or a beneficial effect on the host, depending on the environmental conditions (Chen, 1996). The S-endosymbiont, upon injection into the closely related species, *Acyrthosiphon kondoi*, was found to be pathogenic. Although the rate of maternal transmission of both the S-endosymbiont and the *Rickettsia* sp. was high, one instance of S-endosymbiont loss was observed (Chen and Purcell, 1997).

Studies based on light and electron microscopy have suggested that some S-endosymbionts in some aphid species may inhabit syncytial cells or, possibly, bacteriocytes that appear similar to those containing *Buchnera* (Buchner, 1965; Hinde, 1971b; Iaccarino and Tremblay, 1973). Fukatsu and Ishikawa (1993) surveyed 61 aphids for the presence of S-endosymbionts. Previously it was found that *Buchnera* (Ap) overproduced GroEL (Kakeda and Ishikawa, 1991). Using anti-*E. coli*-GroES for immunoprecipitation of

Buchnera (Ap) GroES, it was concluded that *Buchnera* produced low levels of this protein (Kakeda and Ishikawa, 1991). This antiserum as well as anti-*E. coli*-GroEL was used to detect GroEL and GroES in immunoblots of whole aphid extracts as well as for histochemical detection in thin sections of aphids. From these experiments it was concluded that the synthesis of substantial amounts of GroES by S-endosymbionts distinguishes them from *Buchnera*, and that this property can be used for the identification of S-endosymbionts (Fukatsu and Ishikawa, 1993). These studies have a number of problems that limit their general applicability to the survey of S-endosymbionts. The principal one is the use of antisera against *E. coli* GroES for the detection of cross reactivity of GroES from organisms that have an unknown relationship to *E. coli*. Since it is probable that many of the S-endosymbionts are members of the Enterobacteriaceae, a stronger cross-reaction would be expected with their proteins than with the proteins from *Buchnera*; consequently, an increased reactivity need not indicate a major difference in the amount of the protein. Conversely, in those cases where the S-endosymbiont is not a member of the Enterobacteriaceae, the distant relationship may preclude a strong cross-reaction (Eremeeva et al., 1998). The cross-reactivity of the *Buchnera* and S-endosymbiont proteins with the anti-*E. coli* protein antisera has not been compared. Finally, the relative production of GroES may vary among S-endosymbionts of different types.

The studies of Fukatsu and Ishikawa (1993, 1998), in which thin sections of aphids were stained by immunohistochemistry and examined by light microscopy, do suggest that in many aphids the S-endosymbionts occupy bacteriocytes distinct from those containing *Buchnera*. The authors also state that the S-endosymbionts have a variety of different shapes. The methods used and the photographs presented do not, however, allow adequate visualization of cell shape and the resolution of bacteriocyte structure. In addition the designation of some of the endosymbionts as *Buchnera* or S-endosymbionts appears to be arbitrary.

Fukatsu et al. (1998) used group-specific oligonucleotide probes for *in situ* detection of aphid P- and S-endosymbionts. A universal eubacterial 16S rRNA probe was used as well as probes specific for the 23S rRNA γ- and β-subdivision Proteobacteria. The sequences of the latter two probes differ by only one nucleotide. *Buchnera* and S-endosymbionts all hybridized with the 16S eubacterial probe, although the intensities of the signal differed considerably. Curiously the putative P-endosymbionts of two out of seven aphids did not hybridize with the 23S γ-subdivision probe. Using the total DNA preparation from these aphids, the 16S rDNA was amplified, cloned and sequenced. Two sequences were detected in each aphid DNA preparation, and one of these was related to *Buchnera* 16S rDNA. Based on this result, it was concluded that these aphids contained *Buchnera* but that their 23S-rDNA gene was changed to such an extent that hybridization with the γ-subdivision probe no longer occurred. This conclusion is questionable since the 23S rDNA of *Buchnera* (Sg, Dn, Sc, Mr), which span the diversity of aphid hosts (Fig. 2), contains the exact sequence complementary to the probe used (Clark et al., 1999b; Rouhbakhsh and Baumann, 1995). The S-endosymbiont of *Tetraneura radicicola* hybridized with the probe to the β-subdivision but not to the γ-subdivision, suggesting that this endosymbiont is a member of the former group. Since there is only a single nucleotide difference between these two probes, a confirmation of this conclusion by sequencing the rDNA from this organism seems desirable. The S-endosymbiont from two other aphid species did not hybridize with either the γ- or β-subdivision probe. In view of the technical difficulties encountered with some of the specimens, these conclusions cannot be interpreted as indicating that the S-endosymbionts of these aphids belong to different bacterial groups.

Absence of a Stable Bacterial Flora in Aphid Guts

Aphids maintained under clean conditions do not appear to have a bacterial gut flora (Douglas, 1990; Grenier et al., 1994; Harada and Ishikawa, 1993). Older aphids as well as aphids reared under crowded conditions may acquire a gut flora which appears to consist of members of the Enterobacteriaceae (*Serratia*, *Erwinia*), *Pseudomonas*, *Staphylococcus*, and *Bacillus* (Grenier et al., 1994; Harada and Ishikawa, 1993). These organisms are frequently associated with plant surfaces. None of these organisms has a close relationship to *Buchnera*, precluding a recent common ancestor from which they and *Buchnera* are descended. The presence of this bacterial flora has a deleterious effect on aphid performance (Grenier et al., 1994). The actual bacterial numbers have not been established. Harada et al. (1996) have isolated 38 bacterial strains from the guts of 20 aphids. This hardly suggests the presence of an indigenous bacterial flora and the numbers are insignificant compared to the numbers of *Buchnera* or the S-endosymbionts. These studies indicate that the guts of aphids are generally sterile but under certain conditions a transient bacterial gut flora may be present.

Endosymbionts of Other Plant Sap-Utilizing Insects

Psyllids, whiteflies and mealybugs are three separate lineages of the suborder Sternorrhyncha and contain P-endosymbionts from three distinct bacterial groups (Table 1, Fig. 1). These insects have obligatory sexual reproduction with the young hatching from eggs (Borror et al., 1989). The endosymbionts are housed within bacteriocytes, and at least during some stage of the insect's life cycle, the bacteriocytes are associated with the ovarioles resulting in the transmission of endosymbionts to the eggs (Buchner, 1965).

Psyllid Endosymbionts

Fukatsu and Nikoh (1998) sequenced the 16S rDNA of endosymbionts from *Anomoneura mori*, while Spaulding and von Dohlen (1998) performed a similar study of the endosymbionts of *Blastopsylla occidentalis*, *Pachypsylla venusta*, and *Trioza magnoliae*. These authors came to the same conclusion, namely that the P-endosymbionts of psyllids constitute a distinct lineage within the γ-subdivision of the Proteobacteria (Fig. 1). These endosymbionts have an unusual property, namely, the lowest known G+C content of any 16S rDNA (36.4 mol%). In addition, this lineage appeared to have a substantial acceleration of the rate of evolutionary change within the 16S sequence. *A. mori*, *B. occidentalis*, and *T. magnoliae* all had different S-endosymbionts, which belong in the γ-subdivision. Only the P-endosymbiont was found in *P. venusta* (Spaulding and von Dohlen, 1998). The studies were limited to few taxa but were consistent with cospeciation of the P-endosymbiont and the psyllid host and multiple acquisitions of S-endosymbionts (Fukatsu and Nikoh, 1998; Spaulding and von Dohlen, 1998).

Psyllids contain bilobed bacteriomes made up of round uninucleate bacteriocytes and a multinucleate syncytial region (Buchner, 1965). Many psyllids have endosymbionts in both the bacteriocytes and the syncytium; some have endosymbionts only within the bacteriocytes (Buchner, 1965). Using electron microscopy, Chang and Musgrave (1969) and Waku and Endo (1987) found that two psyllid species have endosymbionts in the bacteriocytes which are distinguishable from those found in the syncytium and that both endosymbiont types have a Gram-negative cell wall. In general, the bacteriocyte-associated endosymbionts are more numerous than the syncytium-associated endosymbionts (Buchner, 1965). Fukatsu and Nikoh (1998), using an oligonucleotide probe specific for the P- or S-endosymbiont, showed by means of *in situ* hybridization that the former was localized in the bacteriocytes while the latter was in the syncytium (Fig. 10). There is currently no information on the requirement of the endosymbiont(s) by the psyllid host or on their function. The similarity in diet between psyllids and aphids raises the possibility that psyllid endosymbionts may provide nutrients as do *Buchnera*.

Whitefly Endosymbionts

16S rDNA sequences have been obtained for endosymbionts of *Bemisia tabaci*, *B. argentifolii* (previously *B. tabaci* B biotype), *Siphonius phillyreae*, and *Trialeurodes vaporariorum* (Clark et al., 1992). The P-endosymbionts of these insects are a lineage within the γ-subdivision of the Proteobacteria (Fig. 1). *B. tabaci* and *B. argentifolii* have an S-endosymbiont which is

a member of the Enterobacteriaceae. The P-endosymbionts and the S-endosymbionts from these two species have identical 16S rDNA sequences, consistent with their close relationship (Brown et al., 1995; Clark et al., 1992).

The ultrastructure of the endosymbionts of *B. tabaci*, *B. argentifolii*, and *T. vaporariorum* has been studied by electron microcopy (Costa et al., 1993b, 1995). There is evidence for at least two morphological types. Whiteflies are unusual in that they transmit an entire bacteriocyte containing endosymbionts to the egg (Buchner, 1965; Costa et al., 1996). Some prokaryote-specific antibiotics affect the growth and development of whiteflies, indicating a requirement for the endosymbiont(s) by the host (Costa et al., 1993a, 1997).

Mealybug Endosymbionts

16S rDNA sequences have been obtained for endosymbionts of *Pseudococcus longispinus*, *P. maritimus*, and *Dysmicoccus neobrevipes* (Munson et al., 1992), and these organisms were found to be a distinct lineage within the β-subdivision of the Proteobacteria (Fig. 1). The morphology of endosymbionts from several mealybug species has been studied by means of electron microscopy (Tremblay, 1989). Within the bacteriocytes the endosymbionts appear to be embedded in mucous spherules of unknown composition. There is no information on the function or the requirement for the endosymbionts by the host.

Tsetse Fly Endosymbionts

Tsetse flies (genus *Glossina*) are important vectors of trypanosomes, which are causative agents of African sleeping sickness and various diseases of animals (Harwood and James, 1979). They have a somewhat unusual reproductive cycle in that the female gives birth to fully grown larvae. Only one larva is carried at a time within the uterus. During this stage the larva is fed nutritive fluids from special glands, commonly known as "milk glands." The female requires several blood meals to complete the development period of each larva, and it is these blood meals which result in the transmission of trypanosomes (Harwood and James, 1979).

Tsetse may be associated with three prokaryotes: 1) *Wigglesworthia* (P-endosymbionts), 2) *Sodalis* (S-endosymbionts), and 3) *Wolbachia*. The last are parasites found in reproductive tissue and causing reproductive disorders (O'Neill et al., 1997) and will not be considered here.

Wigglesworthia—the Primary Endosymbiont of Tsetse Flies

PHYLOGENY Based on 16S rDNA, *Wigglesworthia* was found to constitute a distinct lineage within the γ-3 subgroup of the Proteobacteria (Fig. 1; Aksoy et al., 1995; Chen et al., 1999). These organisms are related to but distinct from *Buchnera* of aphids and the P-endosymbionts of carpenter ants (Fig. 1). Using the host rDNA transcribed spacer-2, it was found that the phylogeny of the host was the same as that of *Wigglesworthia*, indicating cospeciation of the host and the endosymbiont (Chen et al., 1999). These results suggest a single infection of a tsetse ancestor with a bacterium followed by long-term vertical transmission of the endosymbiont, that is, a lack of exchange of *Wigglesworthia* between different tsetse fly species. The age of this association has been estimated to be at least 50 million years (Aksoy et al., 1997). A list of the species of tsetse flies for which the 16S rDNA of *Wigglesworthia* has been sequenced is presented in Table 8.

TAXONOMY The genus *Wigglesworthia* contains one species, *W. glossinidia*, which designates the lineage consisting of the P-endosymbionts of tsetse flies (Aksoy, 1995b). The type strain of this species is the P-endosymbiont of *G. morsitans morsitans*.

HABITAT Tsetse flies contain a U-shaped bacteriome located in the anterior region of the gut, which is made up of bacteriocytes containing *Wigglesworthia* (Aksoy, 1995b; Aksoy et al., 1995). These endosymbionts have a Gram-negative cell wall and are somewhat pleomorphic, occurring mostly as 4–5 m long rods. They are found free (not enclosed within host-derived vesicles) in the bacteriocyte cytoplasm. *Wigglesworthia* is maternally transmitted. Since neither the milk gland nor the developing eggs contain *Wigglesworthia*, the mechanism of their transmission is not known (Aksoy et al., 1997).

PHYSIOLOGY The feeding of tsetse flies on animals immunized with *Wigglesworthia* results in

elimination of the P-endosymbiont and sterility of the flies (Nogge, 1976). A similar effect is observed upon treatment of tsetse with prokaryote-specific antibiotics (Aksoy et al., 1995; Nogge, 1976, 1982). These results indicate that the P-endosymbiont is essential for reproduction. There is evidence that one of the functions of the *Wigglesworthia* is the production of B-complex vitamins (Nogge, 1982). *Wigglesworthia* produces a high level of GroEL (Aksoy, 1995a). In this respect it is similar to a number of other endosymbionts as well as other intracellular organisms (Hogenhout et al., 1998).

GENETICS The *Wigglesworthia* genome has one copy of the 16S rRNA gene (Aksoy, 1995a). In this organism 16S-rRNA gene is directly upstream of 23S-rRNA gene, suggesting that, as in the case of many other bacteria, these genes are a part of a single transcription unit. The presence of one copy of the rRNA operon is characteristic of slow-growing bacteria and also is found in several other endosymbionts (Baumann et al., 1995).

Sodalis—The Secondary Endosymbiont of Tsetse Flies

Tsetse flies may also contain S-endosymbionts. These are primarily found within midgut cells but also have been detected in hemolymph and in a variety of other tissues excluding ovaries (Aksoy et al., 1997; Beard et al., 1993b; Cheng and Aksoy, 1999). Their numbers are age-dependent, being higher in older insects (Cheng and Aksoy, 1999). The 16S rDNA has been sequenced from the S-endosymbionts of five different tsetse fly species, and it was found that they are members of the Enterobacteriaceae (Aksoy et al., 1997; Beard et al., 1993b). The sequences were found to be virtually identical, indicating either multiple recent infections with the same organism or horizontal transmission of the S-endosymbiont. The S-endosymbiont is maternally transmitted via the "milk gland" secretions to developing larvae (Aksoy et al., 1997).

The S-endosymbionts have been cultivated in cell-free liquid media (Beard et al., 1993b) and recently on solid media (Dale and Maudlin, 1999). The latter allowed a phenotypic characterization of this organism and led to its assignment into a new genus and species, *Sodalis glossinidius* (Dale and Maudlin, 1999). This species consists of Gram-negative rods 1–1.5 m in diameter and 2–12 m in length. It is microaerophilic, lacking catalase, and has a relatively limited capacity for carbohydrate utilization.

The S-endosymbiont has seven copies of 16S rDNA, a number which is similar to that found in rapidly growing free-living organisms (Aksoy, 1995a). Plasmids of 80 kb and about 130 kb have been detected in these organisms (Beard et al., 1993b). The S-endosymbiont has been transformed with pSUP204, and plasmid-encoded resistance to ampicillin, tetracycline and chloramphenicol was expressed (Beard et al., 1993b). Similarly the S-endosymbiont has been transformed with a pSUP204 derivative, which expressed the green fluorescent protein, allowing ready visualization of this organism in insect tissues (Cheng and Aksoy, 1999).

In one case, the S-endosymbiont from one tsetse fly species when microinjected into another species became pathogenic, killing the flies within 48 h (Cheng and Aksoy, 1999). This result is similar to the observations made with the S-endosymbiont of aphids (Chen and Purcell, 1997). The variation in the number of S-endosymbionts and their possible absence from some insects suggest that they do not perform a function essential for the survival of tsetse flies.

Sitophilus (Weevils) Endosymbionts

Weevils of the genus *Sitophilus* are major pests of stored grain (Borror et al., 1989). The female bores a hole in kernels and deposits an egg. The larva develops inside the grain from which the young adults emerge. Three related species have been studied with respect to their endosymbionts, *S. oryzae*, *S. granarius*, and *S. zeamais* (Dasch et al., 1984). Of these three species, the most extensive studies deal with *S. oryzae* (Nardon and Grenier, 1988). In addition, weevils may harbor the pathogen *Wolbachia* (O'Neill et al., 1997).

PHYLOGENY Early studies of *Sitophilus* endosymbiont morphology and the G+C content of its DNA suggested that weevils have different endosymbionts (Dasch, 1975; Dasch et al., 1984; Grinyer and Musgrave, 1966; Musgrave and Grinyer, 1968). *S. oryzae* has one endosymbiont with a G+C content of about 54 mol%, *S. granarius* has one with a G+C content of 50 mol%, while *S. zeamays* appears to have both endosymbionts (Dasch, 1984; Heddi et al., 1998). One type of endosymbiont 16S-rDNA sequence was detected in *S. oryzae*, and two types were detected in *S. zeamais* (Campbell et al., 1992; Heddi et al., 1998). Phylogenetic analysis indicated that all of these endosymbionts

are members of the family Enterobacteriaceae (Fig. 1).

Habitat

In larvae, endosymbionts are present in bacteriocytes which make up a bacteriome located at the junction of the foregut and the midgut as well as in the rudimentary ovaries (Charles et al., 1995; Nardon and Grenier, 1988). The endosymbionts are transmitted via the eggs. *S. oryzae* endosymbionts are rod-shaped, 5–15 m long, and free (not within host-derived vesicles) in the cytoplasm (Dasch et al., 1984; Nardon and Grenier, 1988).

Physiology

S. oryzae may be cured of endosymbionts by treatment with heat or antibiotics (Baker and Lum, 1973; Nardon and Grenier, 1988). Such aposymbiotic weevils are softer and paler, have an increased development time, and the fertility of their eggs is reduced (Nardon and Gernier, 1988). On some nutrient-rich grains, they can grow indefinitely. Aposymbiotic weevils lack bacteriomes, indicating that the endosymbiont triggers their development. Naturally occurring aposymbiotic weevils also may be found. There is evidence that one of the functions of the endosymbiont is the synthesis of vitamins as well as possibly phenylalanine or tyrosine (Baker, 1975, 1979; Wicker and Nardon, 1982). An additional function is the conversion of excess methionine in the diet to methionine sulfoxide (Gasnier-Fauchet and Nardon, 1986, 1986). Aposymbiotic weevils also have mitochondria with reduced levels of enzymes involved in respiration (Heddi et al., 1991). Isolated endosymbionts of *S. oryzae* do not consume oxygen and lack a number of enzymes of respiratory metabolism (Heddi et al., 1991, 1993). These results suggest that they have an anaerobic metabolism. As in the case of *Buchnera* and *Wigglesworthia*, the endosymbionts of *S. oryzae* overproduce GroEL (Charles et al., 1997b). Unlike *Buchnera*, the endosymbionts of *S. oryzae* have a heat shock response, as is indicated by an increase of *groEL* mRNA (Charles et al., 1997b).

Genetics

The genome of the endosymbiont of *S. oryzae* is 3.0 Mb and has two copies of the rRNA operon (Charles et al., 1997a). In addition, the endosymbiont contains a plasmid of about 138 kb. This genome size puts the endosymbiont within the range of many free-living bacteria (Heddi et al., 1998).

Comparisons with Other Associations

Although the information is somewhat limited, comparison of the *Sitophilus*-endosymbiont association with other insect-endosymbiont associations suggests that the former has some unique features. In several insect endosymbiotic associations, the S-endosymbionts are members of the Enterobacteriaceae, suggesting that organisms within this lineage have an enhanced capacity to enter into such associations. An interesting feature of the *Sitophilus* association is that these organisms are the sole endosymbionts. The morphological diversity of the endosymbionts, the large endosymbiont genome size, and the fact that aposymbiotic weevils are viable suggest that the associations arose through multiple recent infections and that major adaptations resulting in obligatory mutual interdependence of both partners have not evolved as yet. This association may consequently be an example of an endosymbiosis at an early stage of its development.

Carpenter Ant Endosymbionts

Ants feed on complex diets, and the presence of endosymbionts has been reported in only two groups. These two groups are the genus *Formica* and the genus *Camponotus*, commonly known as the carpenter ants (Borror et al., 1989; Buchner, 1965; Dasch et al., 1984). Both groups can use a broad range of food types but typically utilize plant nectar and honeydew (the liquid feces of sap-feeding Homoptera) as major components of their diet. Only in the carpenter ants have symbionts been studied using modern methods, and we focus on these. The contribution of ant endosymbionts to host nutrition is not clear (Dasch et al., 1984).

Phylogeny

The G+C content of the DNA of carpenter ants is 30–32 mol% (Dasch, 1975; Dasch et al., 1984). The sequence of the 16S rDNA has been determined for endosymbionts of the species *Camponotus floridanus*, *C. rufipes*, *C. ligniperdus* and *C. herculeanus* (Schröder et al., 1996). A phylogenetic analysis indicated that the endosymbionts constitute a distinct, monophyletic group related to, but different from, the endosymbionts of aphids, tsetse flies, and the members of the Enterobacteriaceae (Fig. 1). The order of branching reflects the relationships between the carpenter ant species and is consistent with a single infection and subsequent vertical evolution of the endosymbionts. The age of the association is estimated at over 100 million years

(Schröder et al., 1996). In endosymbionts of carpenter ants, the 16S-rRNA gene is not directly upstream of the 23S-rRNA gene, suggesting that these genes are organized in two transcription units, as is the case in *Buchnera* (C. Sauer and R. Gross, personal communication).

Habitat

In both workers and queens of *Camponotus*, the endosymbionts are located in bacteriocytes, which are intercalated between epithelial cells of the midgut (Fig. 11a) (Buchner, 1965; Schröder et al., 1996). The endosymbionts are rods of 1 µm in width to 5–15 µm in length (Fig. 11b). They have a Gram-negative type cell wall and are free (not enclosed in host-derived vesicles) in the cytoplasm (Schröder et al., 1996). Transmission is via infection of the ovaries and incorporation into the eggs.

Blattabacterium-Endosymbionts of Cockroaches and Termites

Cockroaches (order Blattaria) utilize a complex diet and harbor prokaryotic endosymbionts (Dasch et al., 1984). It has been hypothesized that cockroaches and termites (order Isoptera) are phylogenetically related (Kambhampati, 1995). Common ancestry is suggested from the fact that the wood-eating cockroach, *Cryptocercus punctulatus*, has a cellulose-digesting protozoal gut flora which is similar to that of termites (reviewed in Bandi and Sacchi, 1999). In addition, *Mastotermes darwiniensis*, a primitive termite, lays eggs in rows resembling those made by cockroaches (Borror et al., 1989; Sacchi et al., 1998b).

Phylogeny

The G+C content of the DNA of *Blattabacterium* is 26–28 mol% (Dasch, 1975; Dasch et al., 1984). Phylogenetic analysis of the 16S rDNA from *Blattabacterium* of cockroaches and the termite *M. darwiniensis* indicates that the endosymbionts form a distinct lineage within the *Flavobacter-Bacteroides* group of bacteria (Bandi et al., 1994, 1995; Fig. 1). The phylogenetic tree obtained on the basis of endosymbiont 16S rDNA is the same as that derived from host taxonomy. This result is consistent with a single infection in an ancestor of cockroaches and termites and vertical evolution of the endosymbionts, that is, a lack of endosymbiont exchange among different species. *M. darwiniensis* is the only termite known to harbor *Blattabacterium*, suggesting that, with the exception of this termite, the endosymbionts were eliminated in the lineage leading to the present termite species (Bandi and Sacchi, 1999; Bandi et al., 1997). The 16S-rDNA sequence has been determined for endosymbionts of the cockroach species *Periplaneta australasiae*, *P. americana*, *Blatella germanica*, *Pynoscelus surinamensis*, *Nauphoeta cinerea* and *C. punctulatus*, as well as the termite species *M. darwiniensis* (Bandi et al., 1994, 1995). The association between *Blattabacterium* and termites is estimated to be 135–300 million years old (Bandi et al., 1995).

Taxonomy

The genus *Blattabacterium* contains one species, *B. cuenoti*, and currently designates the lineage consisting of the bacteriocyte-associated endosymbionts of cockroaches and one termite (Bandi et al., 1995; Dasch et al., 1984). The type strain is the endosymbiont of *Blatta orientalis* (Dasch et al., 1984).

Habitat

Blattabacterium is found in bacteriocytes, polyploid cells which are found within the abdominal fat bodies of cockroaches and the termite *M. darwiniensis* (Fig. 12a) (Bigliardi et al., 1995; Sacchi et al., 1996, 1998a, b). The endosymbionts are rods of 1 μm in width and 1.6–9 μm in length (Fig. 12b; Dasch et al., 1984). They have a Gram-negative cell wall and are located within vesicles derived from the host cell. The bacteriocytes originate from plasmatocytes, which are phagocytic cells present in the hemolymph. There are extensive electron microscopic studies that document the infection and differentiation of plasmatocytes into bacteriocytes and the transmission of the endosymbionts to oocytes and eggs (Bigliardi et al., 1995; Sacchi et al., 1996, 1998a, b).

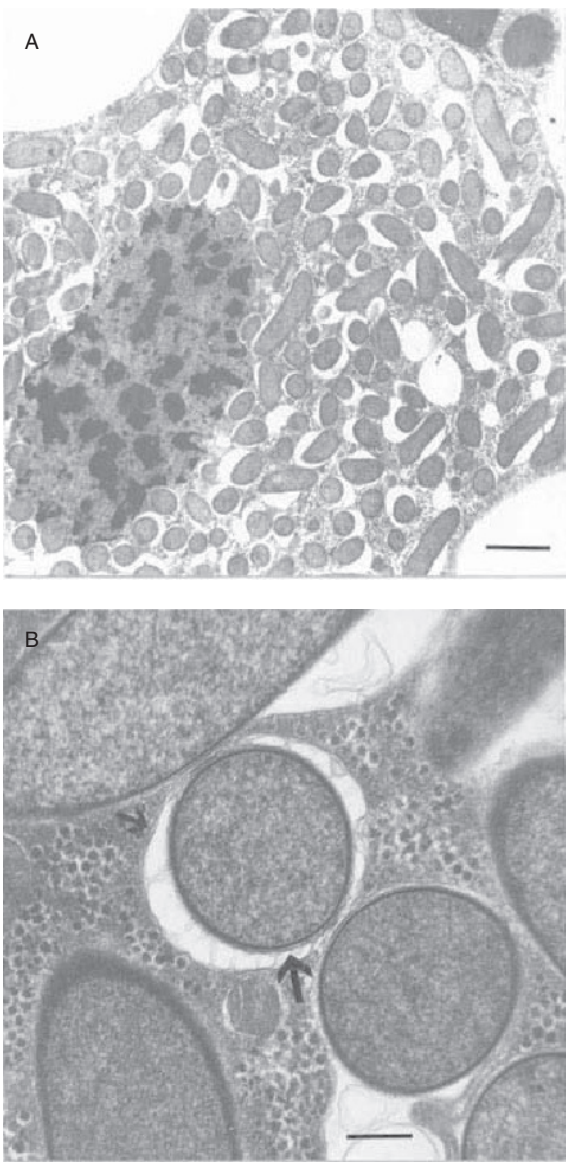

Fig. 12. Electron micrographs of *Blattabacterium cuenoti*, the endosymbiont of cockroaches and termites. (a) Endosymbiont within bacteriocytes of the cockroach *Periplaneta americana*, bar= 3.0 μm (photo courtesy of L. Sacchi); (b) ultrastructure of the endosymbiont of *Cryptocercus punctulatus* showing the Gram-negative cell wall (large arrow) and the vesicular membrane (small arrow), bar= 0.3 μm. From Sacchi et al. (1998) with permission of the authors and Balaban Publishers.

Physiology

Aposymbiotic cockroaches can be obtained by rearing the insects on antibiotic-containing foods (Bandi and Sacchi, 1999; Dasch et al., 1984). The resulting insects can be propagated on enriched diets. The aposymbiotic insects are smaller in size, light in color, and have a reduced fecundity and an increased development time. They also have an increased level of uric acid in fat bodies, suggesting that one function of *Blattabacterium* is nitrogen recycling (Cochoran, 1985). The proximity of bacteriocytes and urate cells (which store uric acid) in the fat body and the presence of adhesion sites between their plasma membranes suggest direct metabolic interactions between these cells (Sacchi et al., 1998a). There is also evidence that the bacteria provide essential amino acids for the host (Henry, 1962).

Isolation

P-endosymbionts have been isolated from aphids and also from *Sitophilus*. In the case of aphids, the starting material is usually whole insects; in the case of *Sitophilus*, the starting material is dissected bacteriomes. Since the two methods are similar, only the method for the isolation of *Buchnera* from aphids will be considered. Details of the isolation of the endosymbionts from *Sitophilus* are described by Heddi et al. (1991).

The methods for the isolation of *Buchnera* have been developed by Ishikawa (1982), Sasaki and Ishikawa (1995), and Charles and Ishikawa (1999). The resulting preparations are suitable for isolation of high molecular weight DNA for genome analysis as well as for physiological studies. The best criteria of purity have involved examination of the preparations by electron microscopy, which also allows determination of whether the endosymbionts are still within host-derived vesicles. Both the aphids and the endosymbionts have a similar mol% G+C in their DNA (Ishikawa, 1987; Unterman and Baumann, 1990). Consequently, endosymbiont DNA

cannot be separated from host DNA by CsCl density gradient centrifugation.

As starting material, it is best to use an aphid strain that has only *Buchnera* and lacks S-endosymbionts. All of the reagents and equipment are kept on ice, and the procedures are performed as rapidly as possible. Approximately 2 to 3 g (wet weight) aphids are transferred to a 1.5 cm diameter tissue grinder. Ten ml of buffer A of Ishikawa (1982) is added, and the aphids are ground with a lose fitting plunger for 5 min. [Buffer A contains 0.25 M sucrose, 35 mM Tris-HCl (pH 7.6), 25 mM KCl, 10 mM $MgCl_2$, and 1 mM dithiothreitol.] The preparation is then passed through a double layer of a nylon mesh to remove large particulate material. The filtrate is brought to a volume of about 100 ml with buffer A and then quickly passed through a 100-µm nylon filter followed by filtration through 20-µm and 10-µm nylon filters (in some cases filtration through 5- and 3-µm filters is also performed). Only slight vacuum pressure is applied during the last two filtration steps. The suspension is centrifuged in a swinging bucket rotor for 6–10 min at 1,500 g. The pellets are gently resuspended in 1–2 ml buffer A and centrifuged through a Percoll gradient (12,000 g, 15 min). The gradient consists of 27–70% Percoll in buffer A, 5% PEG 6000, 1% Ficoll, and 1% bovine serum albumin (Pharmacia Biotech, Uppsala, Sweden; Charles and Ishikawa, 1999). Mitochondria are in the upper phase, host nuclei are in the pellet, and *Buchnera* appears as a green band.

Identification

Currently none of the P-endosymbionts has been cultured and consequently identification is based primarily on sequence analysis of their 16S rDNAs. Since these studies are just beginning, we will briefly discuss the methods used for both their characterization and identification. The success of the approach used in most of the studies has been dependent on the use of fresh or frozen insect samples which meet the following criteria: 1) the predominant bacterial flora of the insect consists of one or a few endosymbiont types, 2) there is no significant gut flora, and 3) the samples are relatively clean.

An ideal study would utilize the full-cycle rRNA analysis formulated by Amann et al. (1995). In this approach the 16S rDNA is amplified by PCR and sequenced. Based on comparisons with 16S rDNA(s) in databases, the organism(s) are identified. Specific oligonucleotide probes are designed and used in *in situ* hybridization to identify the endosymbiont associated with the sequence. This approach is extremely useful when more than one endosymbiont is present and, in the case of insects, has been applied to the identification of two types of psyllid endosymbionts (Fukatsu and Nikoh, 1998).

In studies in which the primary goal was a phylogenetic characterization of the P-endosymbiont, one approach used is an initial thorough study of one or more representative insects that can be cultivated or are readily available. Then characterization is extended to taxa obtained as field collections and preserved in dry ice or absolute ethanol. For example, in the initial study of aphid endosymbionts, the insect specimen chosen (Ap) was known from electron microscopy to harbor two morphologically distinct endosymbionts (Unterman et al., 1989). Using total aphid DNA, a probe to *E. coli* 16S rDNA, and restriction enzyme and Southern blot analysis, only two restriction maps could be constructed corresponding to the two endosymbionts. There were differences in the intensities of the bands, indicating that one of the endosymbionts was present in larger numbers than the other. In addition, the results were consistent with the presence of only one copy of the 16S-rRNA gene per endosymbiont genome. Based on the restriction maps, DNA fragments containing 16S-rRNA genes of both endosymbionts were cloned and sequenced. In addition, DNA was isolated from dissected bacteriomes, and restriction enzyme and Southern blot analysis indicated the association of both endosymbionts with the bacteriome. Subsequently, restriction enzyme and Southern blot analysis using DNA from other aphid species indicated the presence of only one copy of the 16S-rRNA gene, a finding consistent with only one or a single predominant endosymbiont (Munson et al., 1991b). Upon amplification of the 16S rDNA by PCR, the sequences detected were all related to *Buchnera*. This approach is suitable for the study of insects in which there is one predominant P-endosymbiont and does not exclude the possibility of not detecting S-endosymbionts that are present in lower numbers.

Instead of initial studies involving restriction enzyme and Southern blot analysis, it is much more convenient to use oligonucleotides complementary to the front and back of 16S rDNA and PCR to amplify DNA fragments for cloning, sequencing, or both. Localization of the endosymbiont may be performed by dissection of different tissues, purification of the DNA, and amplification of the 16S rDNA by PCR (Aksoy et al., 1995; Bandi et al., 1994, 1995; Schröder et al., 1996). Differences in the types of rDNA amplified may be established by restriction fragment polymorphism (Clark et al., 1992; Fukatsu and Nikoh, 1998). Once a pattern of relationship is established this method may be applied using

whole insect DNA. It should be noted that there are potential problems associated with PCR such as selective amplification of some sequences and hybrid formation, which are reviewed by Wintzingerode et al. (1997).

One additional approach to the detection of different kinds of organisms in the DNA samples is to use oligonucleotide primers that are complementary to the front of the 16S-rDNA and the middle of the 23S-rDNA. In bacteria in which the order of genes is 16S-23S (most species), there is a spacer region between the genes the length of which is labile and usually differs among species. If, after PCR, several bands are observed, they probably correspond to different bacteria. This approach has been applied to the cloning of P-endosymbionts of psyllids and to the putative S-endosymbionts which differ in the size of their 16S-23S spacer (Thao, M. L. and Baumann, P., unpublished observations).

Specific oligonucleotide primers also can be made complementary to unique sequences of the endosymbiont 16S and 23S rDNA. This has been done for *Buchnera* 16S rDNA (Rouhbakhsh et al., 1994). Another approach is to take advantage of unique linkage relationships. *Buchnera*-specific probes have been made which span the region *argS-16SrDNA* and *aroE-23SrDNA* (Munson et al., 1993; Rouhbakhsh and Baumann, 1995; Rouhbakhsh et al., 1994). The latter is especially useful, since most bacteria have 16S rDNA directly upstream of 23S rDNA.

Application

Aphids, psyllids, whiteflies, and mealybugs, which utilize plant sap as food, are of major economic importance in that they may cause plant debilitation and the transmission of a variety of plant pathogens (Gray and Banerjee, 1999; Sylvester, 1985). Tsetse flies, which suck blood, are important in the transmission of human and animal disease, especially in tropical regions of Africa (Harwood and James, 1979). Since these organisms are dependent on their P-endosymbionts for survival, an understanding of the genetics and physiology of the endosymbionts may be of use in devising strategies, which are based on interference with their endosymbionts, for the control of these insect pests. An additional approach, which is currently being developed, is the potential use of endosymbionts to produce compounds that would result in modification of the vector competence of an insect. Such an insect would be unable to harbor and/or transmit the disease agent. This approach has been discussed by Beard et al. (1993a) and Durvasula et al. (1997).

CHAPTER 2.4

Symbiotic Associations Between Termites and Prokaryotes

ANDREAS BRUNE

Introduction

The symbiotic associations of termites with microorganisms comprise different levels of interaction, ranging from the extracorporal cultivation of fungus gardens to the most intimate associations, where bacteria reside intracellularly in dedicated bacteriocytes. However, the majority of prokaryotic symbionts of termites are located in the intestinal tract, where they are free-swimming, attached to the gut epithelium, or associated with the intestinal protozoa (Fig. 1). Although it is suggestive that the gut microbiota of termites is directly or indirectly involved in the digestion of lignocellulose or has other nutritional implications, the exact nature of the associations and possible benefits for the partners of each particular symbiosis are often far from clear. Therefore, this chapter will use the term "symbiosis" in its broader sense, as originally defined by Anton de Bary (de Bary, 1878). A definitive classification of the associations into the different categories of symbiosis, such as mutualism, parasitism, or commensalism, would require a level of understanding that is yet to be reached.

In view of the enormous body of literature on the intestinal microbiota of termites and its role in lignocellulose digestion, the subject cannot be covered exhaustively. This chapter will attempt to summarize the current state of knowledge on the prokaryotic communities within the intestinal tracts of termites, the major populations and their metabolic activities, and their interactions. In addition, it will focus on the gut as a microbial habitat. The chapter will touch only briefly on the intestinal flagellates, which are most important in the phylogenetically lower termites, the exosymbiotic fungi in fungus-cultivating Macrotermitinae, and the intracellular bacteria in termite tissues. For details on these subjects and for many other aspects of the termite gut symbiosis, the reader will be referred to the pertinent review articles.

Symbiotic Digestion

Termites, like other insects thriving on a lignocellulosic diet, possess a pronounced gut microbiota housed in specially adapted regions of the alimentary tract (Fig. 2). The symbionts convert a substantial portion of the dietary components to microbial fermentation products, which are then eventually resorbed by the intestinal epithelia. It is generally assumed that the intestinal symbioses provide metabolic capacities that are otherwise not available to the host. For reviews, see Breznak and Brune (1994b), Kane (1997), Brune (1998), Brune (2003), Bignell (2000), Breznak (2000), Brune and Friedrich (2000a), and Ohkuma (2003).

The symbiotic digestion of lignocellulose by termites is a complex series of events involving both the host and its gut microbiota (Fig. 3). While the events in the foregut and midgut seem to be mainly due to host activities, the digestive processes in the hindgut are largely controlled by the symbionts. Many aspects of lignocellulose digestion are common to all termites, but there are also several noteworthy differences between the phylogenetically lower and higher taxa.

Fiber Degradation

The degradation of plant cell walls requires the synergistic action of many different enzymes and, in the case of lignified substrates, also a mechanism to break up the lignocellulose complex (Breznak and Brune, 1994b). Microorganisms, i.e., bacteria, protozoa, and fungi, are the most efficient cellulose and hemicellulose degraders in nature, and fungi and certain actinomycetes are also the only organisms that have developed a strategy for the chemical breakdown of lignin (Béguin and Aubert, 1994; Jeffries, 1994). Not surprisingly, termites and other animals have made use of these capacities by employing microbial symbionts in the digestion of lignocellulosic food (Martin, 1983).

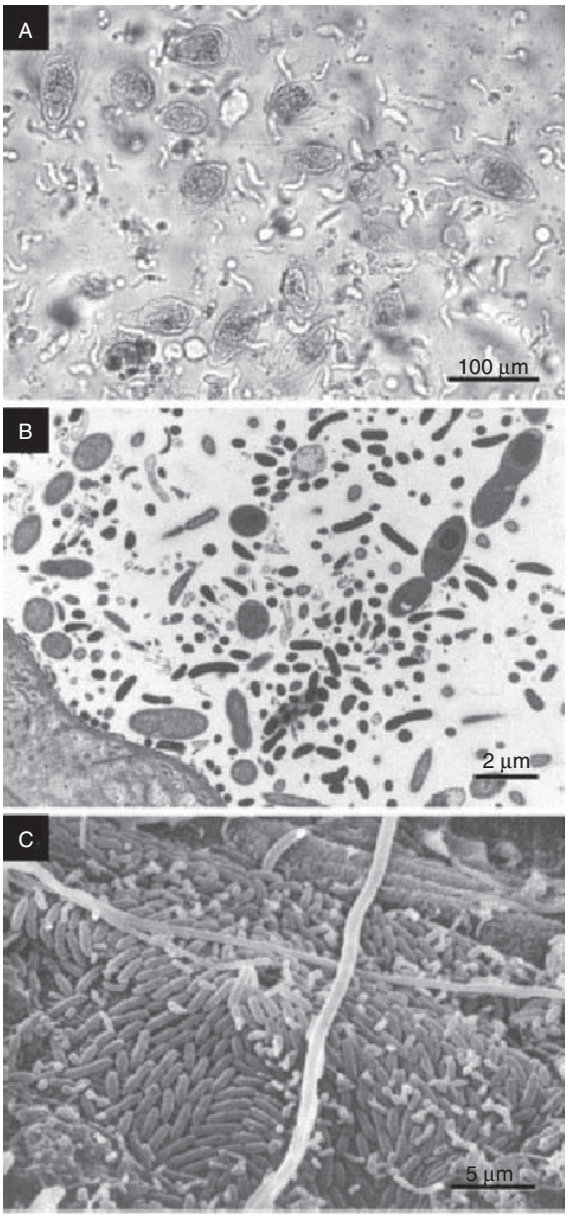

Fig. 1. Examples of microbial symbionts in the hindgut of *Reticulitermes flavipes* (Isoptera: Rhinotermitidae), a wood-feeding lower termite. A) Preparation of anaerobic protozoa from the hindgut of a worker larva, showing the large hypermastigote flagellate *Trichonympha agilis*, filled with wood particles, and numerous smaller flagellates (mainly oxymonads, *Dinenympha* spp.). Differential interference contrast photomicrograph taken by U. Stingl. B) Transverse section through the peripheral hindgut, showing the diverse bacterial microbiota associated with the thin cuticle of the hindgut wall (bottom left). Transmission electron micrograph provided by J. A. Breznak. C) Preparation of the hindgut wall, showing the dense colonization of the cuticle by numerous rod-shaped and filamentous bacterial morphotypes. Scanning electron micrograph provided by J. A. Breznak. Reproduced from Brune (2003).

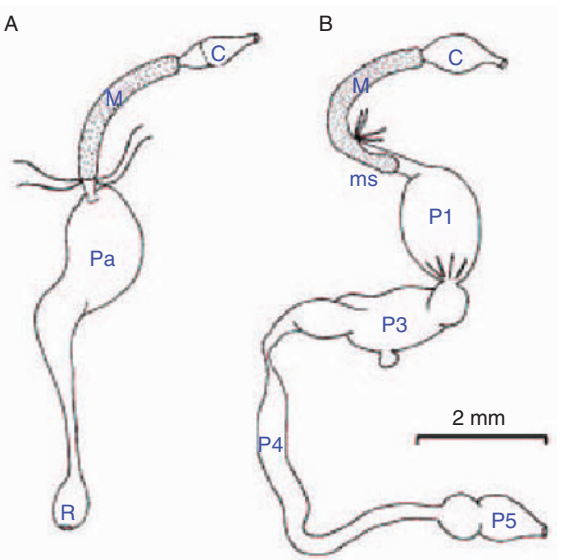

Fig. 2. Structure of the intestinal tract of *Reticulitermes* species (A) and *Cubitermes* species (B). All lower termites harbor the gut microbiota in a single, strongly dilated hindgut paunch (Pa) that tapers out via the colon into the rectum (R). In most higher termites, especially the soil-feeding species, the hindgut is more elongated and has additional dilatations. Abbreviations: crop (C), midgut (M), mixed segment (ms), and proctodeal segments (P1–P5).

Role of Intestinal Protozoa The presence of protozoa in termite guts was recognized very early, although they were initially considered to be parasites (e.g., Leidy, 1881; Koidzumi, 1921). The American protozoologist L. R. Cleveland recognized that the wood-feeding lifestyle in the evolutionarily "lower" termites is based on a mutualistic association with their intestinal protozoa (Cleveland, 1925a; Cleveland, 1926). In a series of elegant experiments, he established that the ability of lower termites to live on a diet of wood or cellulose depends on the digestive capacities of their intestinal flagellates. His pioneering work, published in 1923–1928, paved the way for many later studies (see reviews by Honigberg [1970], Inoue et al. [2000], and Brune and Stingl [2005]).

About 15 years later, Hungate elucidated the biochemical basis for this symbiosis (Hungate, 1939; Hungate, 1943). He showed that the gut flagellates depolymerize and ferment lignocellulose to short-chain fatty acids, which are resorbed and oxidized by the host (reviewed by Hungate [1955] and Breznak and Brune [1994b]). The importance of protozoa for the metabolic processes in the hindgut of lower termites is most impressively evidenced by their enormous numbers, which may constitute more than one-third of the body mass in *Zootermopsis* species (Katzin and Kirby, 1939).

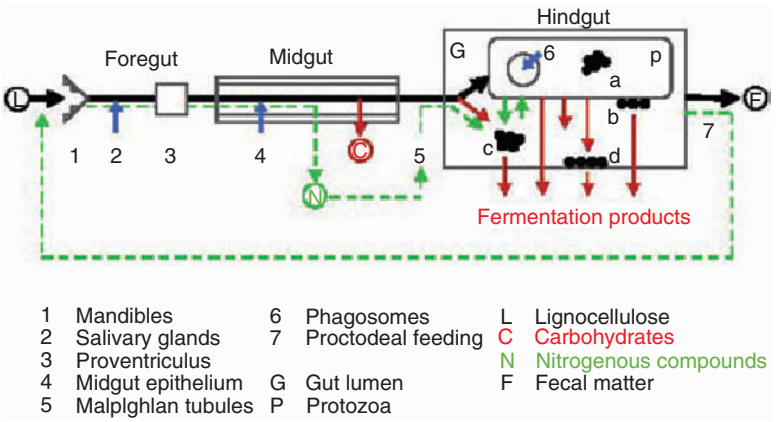

Fig. 3. Major events in the symbiotic digestion of lignocellulose by wood-feeding lower termites. The black lines show the path of the insoluble material whose lignin-rich residues are released as feces, whereas the red lines represent soluble degradation products, which are eventually resorbed by the host. The green lines indicate the cycling of nitrogenous compounds. Blue arrows mark the sites where cellulolytic enzymes are secreted. Lower-case letters refer to the different groups of bacteria, which are either endobionts (a) or epibionts (b) of the protozoa, suspended in the gut lumen (c) or attached to the gut wall (d). The scheme has been simplified for the sake of clarity; not all possible interactions are shown. Adapted from Brune (2003).

There is a large body of literature on the decomposition of wood and cellulose by termite gut flagellates (for references, see O'Brien and Slaytor [1982], Breznak and Brune [1994b], and Inoue et al. [2000]). Apparently, the different flagellate species are nutritionally specialized, and each species might fill a specific niche in lignocellulose digestion (Yoshimura et al., 1996; Inoue et al., 2000). Most of the endoxylanase and β-xylosidase activity in the lower termite *Reticulitermes speratus* is located in the anterior hindgut and is lost upon defaunation (removal of protozoa by ultraviolet irradiation; Inoue et al., 1997), and the effects of artificial diets on the composition of the protozoan community corroborate that different gut flagellates are involved in xylan and cellulose degradation (Inoue et al., 1997; Cook and Gold, 2000).

The protozoa possess their own cellulase genes, which fall into different glycosyl hydrolase families (Ohtoko et al., 2000; Nakashima et al., 2002a; Watanabe et al., 2002; Li et al., 2003; Inoue et al., 2005) and may even exploit host cellulases that are secreted in the anterior gut regions (Li et al., 2003). There is no evidence that the prokaryotic symbionts of the gut flagellates (see the section Interactions Between Prokaryotes and Protozoa in this Chapter) confer cellulolytic activity to their hosts.

The Role of Fungi The role of fungi in the digestion of lignocellulose by termites is less clear. There are termites that can thrive on sound wood, but many species show a strong preference for decaying wood colonized by saprophytic fungi, which may either precondition the wood for digestion or provide metabolic products important for termite nutrition (Sands, 1969; Rouland, 2000; Cornelius et al., 2002). Schäfer et al. suggested that the yeasts and other fungi present in the guts of the lower termites *Zootermopsis angusticollis* and *Neotermes castaneus* are involved in hemicellulolytic degradation (Schäfer et al., 1996).

Higher termites of the subfamily Macrotermitinae have established a unique exosymbiosis with basidiomycetes of the genus *Termitomyces*, which are maintained on predigested plant litter in so-called "fungus gardens" within the nests. The symbiosis has rendered fungus-cultivating termites independent of the intestinal protozoa, which probably allowed for the obvious diversification in their diet (Sands, 1969; Rouland, 2000). The specificity of this symbiosis, whose enormous evolutionary success is impressively evidenced by the huge nests of fungus-cultivating termites populating the grasslands of Africa, is documented by several instances of coevolution between the termites and their fungal partners, indicating both horizontal and vertical transmission of the fungal symbionts (Aanen et al., 2002; Katoh, 2002; Rouland-Lefevre et al., 2002; Taprab et al., 2002).

The association with the lignin-degrading fungus enables the fungus-cultivating termites to utilize lignocellulose nearly completely, as reflected in the small volume of their final feces (Darlington, 1994). The key activities attributed to the fungal partner in this mutualistic symbiosis are extensive delignification of the substrate (Hyodo et al., 1999, 2000; Johjima et al., 2003) and the conversion of plant fiber to fungal biom-

ass, as proposed earlier in the *lignin degradation hypothesis* of Grassé and Noirot (1958). Evidence for an activity within the gut of fungal cellulases ingested by the termites together with the fungus comb material (Abo-Khatwa, 1978; Martin and Martin, 1978; Martin and Martin, 1979) gave rise to the *acquired enzyme hypothesis* of Martin (1983). However, claims that the fungal cellulases are essential for cellulose digestion in the termite gut remain controversial (Slaytor, 1992; Bignell et al., 1994b; Crosland et al., 1996), especially in view of the recently discovered ability of termites to produce their own cellulases (see the section The Role of Host Enzymes in this Chapter).

The Role of Host Enzymes Since phylogenetically higher termites (family: Termitidae) lost their gut flagellates in the course of termite evolution, it was initially assumed that either ingested fungal enzymes (see the section The Role of Fungi in this Chapter) or prokaryotic symbionts took over the function of the cellulolytic protozoa. However, there is still no clear evidence that bacteria play a major role in cellulose degradation in any of the termites investigated (see the section Cellulolytic Bacteria in this Chapter), which may find its explanation in the recently discovered ability of termites to produce their own cellulases.

In all insects, the digesta are exposed to a variety of digestive enzymes secreted by the salivary glands and the midgut epithelium (Terra, 1990). Cook (1943) had already demonstrated that termites are able to absorb sugars directly, and evidence is accumulating that termites secrete a full complement of enzymes necessary for the digestion of plant structural polysaccharides, including cellulose, into the midgut (e.g., Rouland et al., 1989; Slaytor, 1992; Rouland, 2000). The presence of protease and lysozyme activities has been documented for several termites, which indicates that also microbial cells can be digested (Rohrmann and Rossman, 1980; Fujita et al., 2001; Fujita and Abe, 2002a; Fujita et al., 2002b). Although experimental evidence is scarce, one can safely assume that—as in other insects—most of the easily digestible material has been mobilized and resorbed by the time the digesta reach the end of the midgut (Fig. 3).

The persisting dogma that higher animals do not possess their own cellulases has been unequivocally refuted by the demonstration of endoglucanase genes in the termite genome and their expression in the cells of the midgut epithelium and in the salivary glands (reviewed by Watanabe and Tokuda, 2001). Even in lower termites, host cellulases secreted by the salivary glands and complement (and surpass) the cellulolytic activities of the intestinal protozoa in the hindgut (Nakashima et al., 2002b; Tokuda et al. 2004); There is evidence that glycosyl hydrolase family 9 (GHF9) cellulases present in the genomes of termites are ancient and widespread in Metazoa (Lo et al., 2003b; Davison and Blaxter, 2005).

Soil-Feeding Termites The majority of termite species are humivorous, yet little is known about the exact nature of the dietary components exploited by these ecologically important soil macroinvertebrates (Brauman et al., 2000). Besides fragments of plant tissue, fungal hyphae, and numerous microorganisms, their diet consists largely of undefined humic material intimately associated with the mineral soil matrix (Donovan et al., 2001). While the aromatic component of humus was initially assumed to be the principal substrate of soil-feeding termites (Noirot, 1992; Bignell, 1994a), feeding trials with soil-feeding *Cubitermes* spp. have shown that peptidic soil components—free or polymerized into humic model compounds—are preferentially digested and mineralized (Ji et al., 2000; Ji and Brune, 2001; Ji and Brune, 2005).

The anterior hindgut of soil-feeding termites is extremely alkaline (Bignell and Eggleton, 1995; Brune and Kühl, 1996), which favors the extraction of organic matter from the soil (Brune, 1998; Kappler and Brune, 1999). Microbial biomass and its structural components are assimilated more efficiently than cellulose, which supports the hypothesis that soil microorganisms and the nitrogenous components of humus are an important dietary resource for humivorous soil macroinvertebrates (Ji et al., 2000; Ji and Brune, 2001).

Host Nutrition

Irrespective of their contribution to polymer degradation, the majority of prokaryotes in termite guts are probably involved in the fermentation of the soluble products released into the gut (see the section Microbial Fermentations in this Chapter), which are derived either directly from the food by the digestive enzymes (see the section The Role of Host Enzymes in this Chapter) or by the fermentative activity of the intestinal protozoa (see the section Role of Intestinal Protozoa in this Chapter). The major products of the hindgut metabolism are acetate and, to a smaller extent, other short-chain fatty acids (mainly propionate and butyrate), which accumulate in the hindgut fluid and are eventually resorbed by the hindgut epithelium (Fig. 3). Termites—like other insects—cannot use acetate as a substrate for gluconeogenesis, but as long as the digestive processes in the midgut release sufficient amounts of soluble sugars and amino acids, this is not a problem. Breznak calculated

that acetate produced by the hindgut microbiota of *Reticulitermes flavipes* would suffice to support the respiratory activity of the host (Breznak, 2000).

Besides being difficult to degrade, lignocellulose is also an extremely nutrient-poor substrate. While non-lignified plant cells are usually rich in protein and other nitrogenous compounds, the C-to-N ratio of sound wood is up to 100-fold higher than that of the insect body (La Fage and Nutting, 1978). Moreover, a lignocellulosic diet lacks most of the essential nutrients required by animals, such as amino acids, vitamins, and sterols. Many microorganisms are capable of fixing dinitrogen, assimilating nitrate and ammonia, or synthesizing those amino acids and vitamins essential for the host. Animals, including termites, have developed means of exploiting these biosynthetic capacities, which include—in the simplest case—the digestion of the intestinal symbionts.

Wood-feeding termites, especially those feeding on sound wood, have an extreme shortage of nutrients in their diet, and the digestion of microbial biomass acquired in the course of anal trophallaxis supplies them with high-quality nutrients (Machida et al., 2001). The gut microbiota supplies essential precursors for the biosynthesis, e.g., of methyl-branched hydrocarbons (Guo et al., 1991), and might play a role in nestmate recognition (Matsuura, 2001). To date, the lack of knowledge on the individual components of the prokaryotic microbiota and their metabolic capacities and activities in situ still makes it difficult to define the essential functions and understand the complex interactions.

The Gut Microenvironment

The intestinal tract of insects is organized into three major gut regions: a short foregut, a midgut (which is the main site of digestion), and a usually short hindgut (proctodeum). The hindguts of all termites, however, have immensely increased in length and volume over the course of evolution (Fig. 2). In the more primitive, lower termites, the hindgut is still relatively simple, consisting of a dilated "hindgut paunch" that tapers out into the colon and ends in the rectal compartment (Noirot, 1995). While this organization has been retained in the fungus-cultivating termites (Termitidae: Macrotermitinae), all other lineages of higher termites show a trend towards a further elongation and additional compartmentalization of the hindgut (Noirot, 2001), which is most pronounced in the soil-feeding representatives. The gut morphologies of lower and higher termites and the significance of the adaptations for the digestive process have been reviewed exhaustively (Noirot, 1995; Noirot, 2001).

The proctodeal dilatations increase the residence time of the digesta, thereby prolonging the exposure to the activities of the intestinal microbiota. Moreover, host factors and microbial activities give rise to physicochemical gradients that create distinct microenvironmental conditions in each gut compartment. This has been shown for oxygen, hydrogen, redox potential, and intestinal pH and has to be expected also for any other metabolite when source and sink are spatially separated (Brune and Friedrich, 2000a), especially since the microbiota are not randomly distributed within the gut (see the section Spatial Organization in this Chapter).

Physicochemical Gradients

Redox Conditions and Oxygen Status The general concept of termite guts as anoxic habitats had been based on several pieces of circumstantial evidence (outlined by Veivers et al., 1980): 1) the oxygen sensitivity of the intestinal protozoa, already recognized by Cleveland (Cleveland, 1925a; Cleveland, 1925b); 2) the demonstration of a fermentative metabolism of cellulose by these flagellates (Hungate, 1939; Hungate, 1943) and the high concentrations of microbial fermentation products in the hindgut of all termites investigated; and 3) the presence of oxygen-sensitive or strictly anaerobic processes, such as nitrogen fixation and methanogenesis (Breznak et al., 1973; Breznak, 1975). Also, the subsequent isolation of anaerobic bacteria from termite guts (see the section Isolates and Major Metabolic Activities in this Chapter) supported the general assumption that the principle of symbiotic digestion in termite guts was analogous to that in the rumen.

Slaytor and coworkers were the first to question the anoxic status of termite guts. Following the color reaction in the hindgut of redox indicator dyes fed to *Nasutitermes exitiosus* and *Coptotermes lacteus*, they initially claimed that the hindgut paunch was "aerobic," since methylene blue remained oxidized (Eutick et al., 1976). In a later study, however, using a more refined technique, they obtained E_h values between –230 mV and –270 mV in the hindgut paunch of these and seven other termite species (Veivers et al., 1980). The initial error had been caused by the color of the reduced dye within the gut being obscured by that of the oxidized dye, which had also impregnated the oxic gut epithelium.

Moreover, Slaytor and coworkers demonstrated that the vitality of *Nasutitermes exitiosus* and *Coptotermes lacteus* depended on the presence of their prokaryotic gut microbiota (Eutick et al., 1978b) and that bacteria play an important

role in maintaining the low redox potential of the hindgut paunch (Veivers et al., 1982), which led to the postulation that they maintain anoxic conditions by removing oxygen from the hindgut.

Bignell (1984) pointed out that arthropods are relatively small animals with surface-to-volume ratios higher than those in practically all vertebrates, and that they are likely to reach equilibrium with their environment unless efficient permeability barriers for oxygen are established or oxygen is sequestered by the animal or by intestinal microorganisms. In a series of studies employing oxygen microsensors, Brune and coworkers clarified the situation (Brune et al., 1995a; Ebert and Brune, 1997; Schmitt-Wagner and Brune, 1999) by demonstrating that the steep gradient in oxygen partial pressure between the oxic gut epithelium and the anoxic gut contents drives a continuous influx of oxygen into the hindgut (Fig. 4). In all termites investigated, oxygen penetrated 50–200 µm into the periphery of the hindgut lumen, leaving only the central portion of the dilated compartments anoxic (Ebert and Brune, 1997; Brune, 1998; Kappler and Brune, 1999; Schmitt-Wagner and Brune, 1999).

The maintenance of anoxia in the termite hindgut is not a trivial issue. Since the removal of oxygen in the gut periphery is fueled by the fermentative processes in the hindgut lumen, there must be a lower size limit for arthropods with a symbiotic digestion. However, even the smallest of all termites investigated to date (*Anoplotermes pacificus*, Termitidae: Apicotermitinae) seems to possess a symbiotic gut microbiota, although the spectrum of fermentation products in the hindgut differs from that of other termites (Bauer et al., 2000).

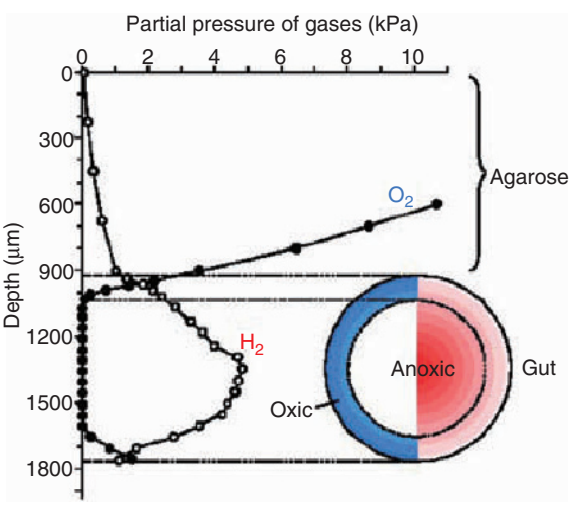

Fig. 4. Radial gradients of oxygen (●) and hydrogen (○) in an agarose-embedded hindgut (paunch region) of *Reticulitermes flavipes* worker larva. A schematic cross-section through the paunch illustrates the relative sizes of the oxic and anoxic zones. Modified after Brune (1998).

Fine-scaled redox measurements with platinum microelectrodes in wood- and soil-feeding termites (Ebert and Brune, 1997; Kappler and Brune, 2002) have shown that the redox potential in the gut mirrors the oxygen gradients (Fig. 5), and also the absolute values are in good agreement with the previously published data based on feeding experiments with redox dyes (Veivers et al., 1980). The most negative redox potentials are found in the regions of high hydrogen partial pressure, although in soil-feeding termites of the genus *Cubitermes*, parameters other than oxygen or hydrogen partial pressure seem to control the redox status of the intestinal contents (Kappler and Brune, 2002). There is evidence for ferric iron reduction in the gut of soil-feeding and wood-feeding species, which may be a microbial process, possibly mediated by the presence of humic acids or other phenolic polymers (Kappler and Brune, 2002; Vu et al., 2004).

Hydrogen Partial Pressure Despite the massive hydrogen production by the intestinal protozoa (Odelson and Breznak, 1985b), the hydrogen emission rates of termites are relatively low (Odelson and Breznak, 1983; Ebert and Brune, 1997; Sugimoto et al., 1998; Schmitt-Wagner and Brune, 1999). Originally, it had been assumed that the situation in the intestinal tract of termites was similar to that in other methanogenic habitats, where low hydrogen partial pressures result from a tight coupling between hydrogen-producing and hydrogen-consuming processes (Breznak, 1994a; Breznak and Brune, 1994b). However, hydrogen microsensor measurements revealed that the situation in termites is quite different, giving rise to steep radial gradients of hydrogen towards the gut epithelium and enormous differences in hydrogen partial pressure along the gut axis (Ebert and Brune, 1997; Schmitt-Wagner and Brune, 1999; Kappler and Brune, 2002), which gave rise to the hypothesis that the spatial organization of the hydrogen-producing and hydrogen-consuming populations controls the hydrogen partial pressure in different gut regions.

Intestinal pH The intestinal pH in the hindgut of most phylogenetically lower termites seems to be around neutral (Eutick et al., 1976; Bignell and Anderson, 1980a; Veivers et al., 1980; Brune et al., 1995a). Kovoor (1967) was the first to report the alkaline region in the anterior hindgut of wood-feeding termites; this observation was later extended also to soil-feeding species (Bignell and Anderson, 1980a). Since then, a large body of data has accumulated (Bignell, 1994a;

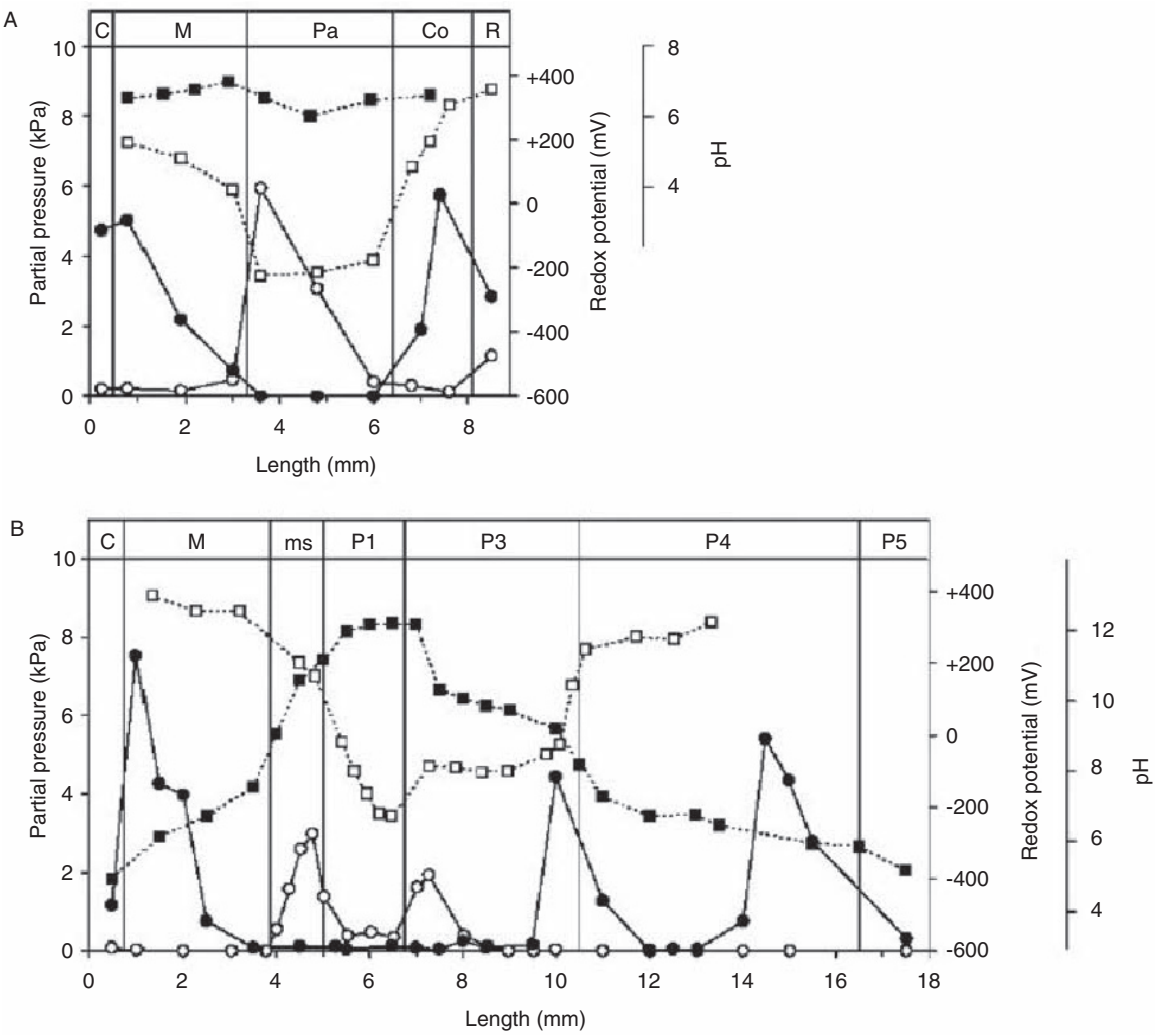

Fig. 5. Profiles of physicochemical conditions along the gut axis of *Reticulitermes flavipes* (A) and *Cubitermes orthognathus* (B). Oxygen (●) and hydrogen (○) partial pressures, intestinal pH (■), and apparent redox potential (□) (against a standard hydrogen reference electrode [SHE]) were measured with the respective microsensors. Guts were embedded in agarose-solidified Ringer's solution. The borders between the different gut regions (see legend to Fig. 2) are indicated by the vertical lines. Data from Brune et al. (1995a), Brune and Kühl (1996), Ebert and Brune (1997), Schmitt-Wagner and Brune (1999), and Kappler and Brune (2002).

Bignell and Eggleton, 1995), documenting a tendency towards strong alkalinity in the anterior hindgut of all higher termites except the Macrotermitinae (Anklin-Mühlemann et al., 1995).

While the initial measurements (performed mostly by spotting pooled, disrupted samples of individual gut regions on pH indicator paper) still lacked accuracy and resolution, studies with pH microsensors allowed alkaline regions to be precisely located (Brune et al., 1995a; Brune and Kühl, 1996). The latter measurements are not biased by homogenization and documented that guts of soil-feeding termites are even more alkaline than reported previously. The most alkaline values (pH 11–12.5) were found among soil-feeding Termitinae and represent the highest values ever encountered in biological systems (Brune and Kühl, 1996). In all species tested, the pH of the gut contents increases sharply from circumneutral in the midgut to highly alkaline between the midgut–hindgut junction and the first proctodeal dilation (P1), which coincides exactly with the location of the mixed segment (Fig. 5), a morphologically unique gut region present in all higher termites except the Macrotermitinae (Noirot, 2001).

Gut Compartmentation and Microhabitats

Each gut compartment provides various microhabitats differing in many environmental parameters (see the section Physicochemical Gradients

in this Chapter). The small size of the guts results in large surface-to-volume ratios (Brune, 1998), and the epithelial surfaces provide ample attachment sites for gut microorganisms, which are thus protected from washout (Bignell, 1984). Additional compartmentalization is created by the protozoa inhabiting the hindgut lumen of lower termites.

Midgut Epithelium, Ectoperitrophic Space As in other insects, the midgut epithelium is not protected by a cuticle, but a peritrophic membrane separates the epithelial surface from the digesta (Terra, 1990). The ectoperitrophic space harbors a distinct bacterial microbiota, which can be intimately associated with the microvilli of the brush border (Breznak and Pankratz, 1977). In addition, the so-called "mixed segment" in many Termitidae, a region where midgut and hindgut epithelia overlap (Noirot, 2001), is a microhabitat that harbors a specific bacterial microbiota. Kovoor (1968) described a "pure culture of spore-forming fusiform bacteria" in the mixed segment of *Microcerotermes edentatus*, located outside of the peritrophic membrane in a posterior pocket formed by the mesenteric side. Also Potts and Hewitt (1973) observed a prominent flora of "thin long filaments with terminal spores" in the mixed segment of the harvester termite, *Trinervitermes trinervoides* (Nasutitermitidae), located in the ectoperitrophic space posterior to the Malphigian tubules. Other authors described dense populations of different but also relatively uniform microorganisms in the mixed segment of *Nasutitermes exitiosus* (Czolij et al., 1985) and of soil-feeding Termitinae (*Procubitermes aburiensis* and *Cubitermes severus*; Bignell et al., 1980b; Bignell et al., 1983). Recently, Tokuda et al. (2000) demonstrated that the bacteria populating the mixed segment of *Nasutitermes takasagoensis* are phylogenetically within the radiation of the Clostridiales (see the section Clostridiales in this Chapter). Electron microscopy confirmed their close association with the mesenteric epithelium, suggesting that there is some kind of interaction with the gut tissue (Tokuda et al., 2001).

Hindgut Cuticle Electron-microscopy studies revealed intimate associations of microorganisms with the cuticle of the hindgut epithelium in all termites investigated (Breznak and Pankratz, 1977; To et al., 1980; Czolij et al., 1985; Yara et al., 1989; Fig. 1). Bacteria are associated with cup-like indentations on the epithelial surface of the hindgut in *Reticulitermes flavipes* (Breznak and Pankratz, 1977). Although *Mastotermes darwiniensis* and *Nasutitermes exitiosus* possess similar structures, they seem not to be associated with microorganisms (Czolij et al., 1984). In certain soil-feeding termites, cuticular spines protrude from the hindgut wall into the lumen of the P4 compartment and form additional attachment sites for the gut microbiota (*Procubitermes aburiensis*; Bignell et al., 1980c).

Hindgut Protozoa The protozoa in the hindgut of lower termites occupy the bulk of the hindgut volume (Katzin and Kirby, 1939) and represent an enormous surface area in the hindgut (Berchtold et al., 1999). Pierantoni (1936) was first to point out the association of gut flagellates with bacteria; since then, ectobiotic and endocytobiotic bacteria have been found on and in almost every flagellate investigated. For example, the hypermastigote flagellate *Joenia annectens*, a symbiont in the hindgut of *Kalotermes flavicollis*, is densely colonized by prokaryotic microorganisms (Hollande and Valentin, 1969). The body is covered with rod-shaped bacteria, and the nucleus and the cytoplasm contain various types of endocytobiotic bacteria (Radek et al., 1992; Patricolo et al., 2001). Also the oxymonadid flagellate *Streblomastix strix*, a hindgut symbiont *Zootermopsis* species, is associated with several, morphologically distinct types of bacteria that are orderly arranged end-to-end on six or seven longitudinal vanes, lending *S. strix* a stellate appearance in transverse section (Leander and Keeling, 2004). Adhesion of bacteria to the flagellate surfaces is based on different mechanisms and facilitated by special surface structures (e.g., Radek et al., 1996; Radek and Tischendorf, 1999b; Rother et al., 1999; Patricolo et al., 2001). The literature has been recently reviewed by Radek (1999). Possible significance of these associations of prokaryotes with hindgut flagellates is discussed in a different section (see the section Interactions Between Prokaryotes and Protozoa in this Chapter).

Prokaryotic Gut Symbionts

In view of the variety of microhabitats and microenvironmental conditions in the intestinal tracts of termites (see the section The Gut Microenvironment in this Chapter), it is not astonishing to find an equally large diversity among the microorganisms colonizing the gut. The amount of diversity indicated already by the morphological and ultrastructural features of the microbiota is greatly exceeded by that encountered at the phylogenetic level.

Morphological Diversity

Already the observation of gut preparations with a phase-contrast light microscope reveals a wide

variety of prokaryotic life forms. Several comprehensive studies of the bacterial gut microbiota of termites using transmission electron microscopy have provided detailed accounts of the morphological diversity of gut microorganisms for several termite species from different families. In addition to the abundant protozoan fauna in all so-called "lower termites" (Yamin, 1979), at least 20–30 different bacterial morphotypes have been distinguished among the microorganisms colonizing the intestinal tract of *Reticulitermes flavipes* and *Coptotermes formosanus* (Rhinotermitidae; Breznak and Pankratz, 1977) and *Pterotermes occidentis* (Kalotermitidae; To et al., 1980).

The so-called "higher termites" (Termitidae) lack intestinal flagellates, but the morphology of their prokaryotic microbiota appears to be equally diverse. The hindgut of the wood-feeding *Nasutitermes exitiosus* (Termitidae: Nasutitermitinae) contains almost 30 different bacterial morphotypes (Czolij et al., 1985), and also the hindgut microbiota of the fungus-growing termite *Odontotermes formosanus* (Termitidae: Macrotermitinae) comprises at least 20 different morphotypes (Yara et al., 1989). Numerous bacterial morphotypes, including many filamentous forms, colonize the intestinal epithelia and the ectoperitrophic space of the soil-feeding termite *Procubitermes aburiensis* (Termitidae: Termitinae; Bignell et al., 1980b).

Although the morphological features usually do not allow the affiliation of a bacterium to a specific taxon, members of the termite gut microbiota have conspicuous forms or other morphological features that are of (albeit limited) taxonomic value, or conspicuous forms that seem to occur in different species of termites. One example is the thin, spore-forming filaments described by Leidy (1881) as "Arthromitus" species, which occur in many invertebrates, including termites (Leidy, 1881; Margulis et al., 1990). Also, many of the spirochetal forms are so large and conspicuous that they can be morphologically distinguished (Breznak, 1984a; see also Termite Gut Spirochetes in Volume 7). On the basis of the detailed morphological features visualized by transmission electron microscopy, Margulis and coworkers (Bermudes et al., 1988; Wier et al., 2000; see also Large Symbiotic Spirochetes: *Clevelandia*, *Cristispira*, *Diplocalyx*, *Hollandina*, and *Pillotina* in Volume 7) proposed a number of new species for the larger spirochetes.

Phylogenetic Diversity and Community Structure

In the recent years, the microbiota in the intestinal tracts of termites has been investigated also with molecular tools (see Ohkuma [2002a] for a review). Most studies employed the 16S rRNA gene as a molecular marker. As in most other environments, phylogenetic diversity of the intestinal microbiota is enormous, and there is still little overlap between the phylotypes recovered with cultivation-independent techniques and the isolates obtained by cultivation (see the section Isolates and Major Metabolic Activities in this Chapter). Molecular fingerprinting has been used to compare the structure of gut communities and to follow temporal changes. The bias inherent in all polymerase chain reaction (PCR)-based approaches has been addressed by backing the results with independent methods, such as fluorescence in situ hybridization (FISH).

Bacterial Diversity

König and coworkers were among the first to use the 16S rRNA-based approach to identify the phylogenetic position of uncultivated spirochetes in the gut of *Mastotermes darwiniensis* (Berchtold et al., 1994; Berchtold and König, 1996); a parallel study of Paster et al. (1996) was aimed at characterizing the spirochetes in the gut of *Nasutitermes lujae*. At about the same time, Ohkuma and coworkers attempted to characterize the full diversity of archaea and bacteria in the intestinal tract of *Reticulitermes speratus* and *Cryptotermes domesticus* using a similar strategy (Ohkuma et al., 1995; Ohkuma and Kudo, 1996a; Ohkuma and Kudo, 1998).

Although the cultivation-independent approach documented the presence of many new, hitherto uncultivated phylotypes in the intestinal tracts of termites (for a review, see Kudo et al., 1998), these early studies lacked resolution since only small numbers of clones were investigated. Later studies documented that diversity coverage of the clone libraries was far from exhaustive, even if larger numbers of clones were used. The most comprehensive assessment of molecular diversity and bacterial community structure in termite guts to date involved the gut microbiota of *Reticulitermes* species. Hongoh et al. analyzed 14 clone libraries (96 clones each) of the bacterial 16S rRNA genes in the hindgut of the Japanese termite species *Reticulitermes speratus* to characterize phylogenetic diversity and to address the bias introduced by different primer combinations and PCR conditions (Hongoh et al., 2003a; Hongoh et al., 2003b). Yang et al. (2005) performed a similar analysis with more than 500 clones from the European termite species *Reticulitermes santonensis*, focusing on the differences between the bacterial communities in the four major intestinal habitats: the midgut, the wall of the hindgut paunch, the hindgut fluid, and the intestinal protozoa (see the section Gut

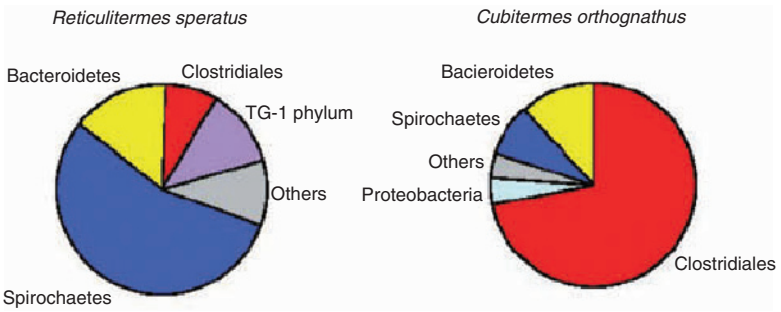

Fig. 6. Relative abundance of the major bacterial phyla in clone libraries of 16S rRNA genes from the hindgut of the wood-feeding, lower termite *Reticulitermes speratus* and the soil-feeding, higher termite *Cubitermes orthognathus*. Data from Hongoh et al. (2003a) and Schmitt-Wagner et al. (2003b).

Compartmentation and Microhabitats in this Chapter).

The intestinal community of the two *Reticulitermes* species is quite similar, comprising representatives of several bacterial phyla (Fig. 6). Both termite species harbor Gram-positive bacteria (mainly clostridia, streptococci, and Mycoplasmatales-related clones), members of the Bacteroidetes, spirochetes, and a number of Proteobacteria, albeit at slightly different ratios. A large number of clones fall into the so-called "Termite group 1" (TG-1) phylum, which were most abundant in *Reticulitermes santonensis* (Yang et al., 2005); spirochetal clones were less abundant in this termite but accounted for approximately half of the analyzed clones in *Reticulitermes speratus* (Hongoh et al., 2003b).

The situation in soil-feeding termites is quite different. In a study analyzing bacterial diversity in the highly compartmentalized intestinal tract of *Cubitermes orthognathus* (Schmitt-Wagner et al., 2003a; Schmitt-Wagner et al., 2003b), the authors combined clone analysis with FISH and a molecular fingerprinting analysis, which not only substantiated the data obtained by the individual approaches but also allowed differences in community structure between the different gut compartments to be investigated. In contrast to the situation in *Reticulitermes speratus*, the bacterial clone libraries contained no clones from the TG-1 phylum and only few spirochetal clones. In the anterior gut sections, most clones represented Firmicutes. In the posterior gut sections, clones belonging to the Bacteroidetes and different subgroups of the Proteobacteria gained some numerical significance. A study of the bacterial microbiota in the P1 compartment of several higher termites extended the presence of a compartment-specific microbiota and a predominance of Firmicutes in the highly alkaline gut regions also to representatives of other feeding guilds (Thongaram et al., 2005).

All PCR bias notwithstanding, these large datasets, together with the numerous clones obtained from other termite species (for references, see Ohkuma, 2003), allow a reasonably accurate picture of the dominant phylogenetic groups to be drawn. Most clones obtained in the different studies represent lineages of microorganisms that were exclusively recovered from the intestinal tract of termites. The termite specificity of these lineages was underscored by the finding that the closest relatives of the bacterial clones within each lineage were usually derived also from the most-closely related termites, supporting the concept of coevolution between gut microbiota and host (Yang et al., 2005).

Spirochaetes Not astonishingly, in view of the numerical predominance of this morphologically diverse and conspicuous group in most wood-feeding termites (Breznak, 2002), the majority of the clones obtained with bacteria-specific primers from the hindgut of *Reticulitermes speratus* represent spirochetes (Hongoh et al., 2003a). Already the first molecular studies had indicated that termite gut spirochetes represent a lineage phylogenetically distinct from other Spirochaetes (Berchtold and König, 1996; Ohkuma and Kudo, 1996a; Paster et al., 1996). Better diversity coverage was achieved by Lilburn et al. (1999), who targeted the intestinal spirochetes of *Reticulitermes flavipes* with spirochete-specific primers. They demonstrated that the 12–15 spirochete morphotypes in *Reticulitermes flavipes* (Breznak and Pankratz, 1977) were paralleled by 21 different spirochete phylotypes, which formed two major clusters of treponemes, one of them containing only clones of termite origin (Lilburn et al., 1999). *Treponema*-related clones have also been recovered from a variety of other termite species (Lilburn et al., 1999; Ohkuma et al., 1999a). In several cases, the ectosymbiotic association of certain phylotypes with flagellate protozoa has been documented using FISH with group-specific oligonucleotide probes (Berchtold and König, 1996; Iida et al., 2000; Noda et al., 2003).

"Endomicrobia" In their first survey of the bacterial diversity in *Reticulitermes speratus*, Ohkuma and Kudo (1996a) obtained a number

of clones whose sequences were only distantly related to other bacteria and which were subsequently recognized as a novel bacterial phylum (Hugenholtz et al., 1998). Also many clones in the comprehensive libraries subsequently obtained with *Reticulitermes speratus* (Hongoh et al., 2003a) and *Reticulitermes santonensis* (Yang et al., 2005) belong to this lineage, indicating that members of the TG-1 phylum represent a hitherto uncultivated but numerically dominant group of prokaryotes in the gut of *Reticulitermes* species.

Using a full-cycle molecular approach, combined with transmission electron microscopy, Stingl et al. (2005) showed that the TG-1 bacteria in *Reticulitermes* species are endosymbionts that colonize—exclusively and in high abundance—the cytoplasm of the larger flagellate species. The symbionts were specific for their respective host flagellate and were provisionally classified in the candidate genus "*Endomicrobium*." Members of the TG-1 phylum, for which the name "Endomicrobia" has been proposed, are phylogenetically quite diverse and seem to be present in and also restricted to the guts of those insects (lower termites and wood-feeding cockroaches of the genus *Cryptocercus*) that are in mutualistic association with such cellulose-fermenting flagellates (Stingl et al., 2005).

Firmicutes In clone libraries of lower termites, clones affiliated with the Clostridia are abundant and fall into apparently termite-specific lineages (Hongoh et al., 2003a; Yang et al., 2005). In the higher termite *Cubitermes orthognathus*, they dominated the clone library of the alkaline hindgut sections (Schmitt-Wagner et al., 2003b), which was confirmed using FISH with cluster-specific probes and supported by molecular fingerprints of the different gut compartments (Schmitt-Wagner et al., 2003a).

One of the clostridial clusters from the *Cubitermes orthognathus* clone libraries falls into the *Clostridium propionicum* group (Schmitt-Wagner et al., 2003b). Interestingly, this cluster comprises also clones from the termite *Nasutitermes takasagoensis*, which were localized in the mixed segment between the midgut epithelium and the peritrophic membrane using FISH (Tokuda et al., 2000). Other clones are affiliated with homoacetogenic isolates (see the section Homoacetogenic Bacteria in this Chapter).

Clone libraries and molecular fingerprints indicated that Clostridia dominate also the bacterial microbiota in the most alkaline hindgut compartment (P1) of *Termes comis*, *Pericapritermes lathignathus*, and a *Microcerotermes species* (all Termitinae), whereas Bacilli dominate the P1 of a *Speculitermes* species (Apicotermitinae) (Thongaram et al., 2005). Many of the clones derived from the P1 region form phylogenetic clusters that are unique to termites and are often related to clones obtained from the other insects with alkaline digestive tracts, which suggests that they represent lineages of alkaliphilic bacteria (Schmitt-Wanger et al., 2003; Thongaram et al. 2005).

Bacteroidetes Clones affiliated with the Bacteroidetes were recovered from the guts of numerous termite species (Ohkuma et al., 2002b; Schmitt-Wagner et al., 2003b). There is an enormous diversity of such phylotypes in *Reticulitermes* species (Hongoh et al., 2003a; Yang et al., 2005). Most clones are only distantly related to described taxa and often form monophyletic clusters with clones recovered from the gut of other termite species. While some of the phylotypes seem to be associated with the hindgut cuticle (Yang et al., 2005), others represent epibionts of protozoa (see the section Interactions Between Prokaryotes and Protozoa in this Chapter).

Other Groups Clone libraries of *Reticulitermes* species contained clones related to the Mycoplasmatales in a distinct and apparently termite-specific lineage (Hongoh et al., 2003a; Yang et al., 2005) that were abundant in the protozoan fraction of *Reticulitermes santonensis* (Yang et al., 2005) and comprised also a clone obtained from a symbiont of the termite gut flagellate *Koruga bonita* from *Mastotermes darwiniensis* by single-cell PCR (Fröhlich and König, 1999a). Among the Lactobacillales, most clones were affiliated with the genus *Streptococcus* and were mainly from the midgut clone library. Most clones affiliated with the Proteobacteria formed distinct, termite-specific lineages in the α-subgroup (only distantly related to other lineages of the Rickettsiales) or in the β-subgroup (most closely related to *Dechlorimonas agitatus* or to fermenting bacteria of the genus *Propionivibrio*; Brune et al., 2002). Clones belonging to the δ-subgroup were rare but virtually identical to the sequences of *Desulfovibrio desulfuricans* and of a sulfate-reducing isolate from *Reticulitermes santonensis* (Kuhnigk et al., 1996).

Only a single clone among the >100 clones retrieved from the hindgut of the soil-feeding termite *Cubitermes orthognathus* was affiliated with the Planctomycetales (Schmitt-Wagner et al., 2003b). However, a large fraction of the cells in the posterior hindgut of the closely related *Cubitermes ugandensis* hybridized with a mixture of FISH probes targeting this phylum. This severe underestimation of this phylum in the clone libraries is probably caused by the inadequacy of the commonly used Bacteria-specific

PCR primers to amplify the 16S rRNA genes of planctomycetes (Derakshani et al., 2001) and underlines the importance of backing the results of PCR-based analyses with an independent method. Although FISH analysis indicates that more than one-third of the bacteria in the second hindgut compartment (P3 segment) of *Cubitermes ugandensis* may be planctomycetes (Schmitt-Wagner et al., 2003b), their metabolic function remains obscure.

Archaeal Diversity Molecular phylogenetic profiling of the microbial communities by dot-blot hybridization with domain-specific probes has indicated that archaea represent 0.1–2.6% of small subunit (SSU) rRNA extracted from the guts of 24 nutritionally and taxonomically diverse termite species (Brauman et al., 2001). Interestingly, the relative abundance of archaea seems to be related to the host diet. The percentage of archaeal 16S rRNA among prokaryotic 16S rRNA in the gut of soil-feeding termite species (1.4–3.1%) was significantly higher than in wood-feeding and litter-feeding termite species (0.1–1.7%). This is in agreement with the methane emission rates, which are generally higher among soil-feeding termite species (Brauman et al., 1992), and it has been speculated that the majority of the archaea in termite guts are methanogens (Brauman et al., 2001).

Methanogenic Archaea Partial sequences of the genes encoding for 16S rRNA and for subunit A of the methyl coenzyme M reductase (*mcrA*) of methanogens indicated that the methanogens in *Reticulitermes speratus* belong to the order Methanobacteriales (Ohkuma et al., 1995) and are closely related but not identical to the *Methanobrevibacter* species isolated from *Reticulitermes flavipes* (Leadbetter and Breznak, 1996; Leadbetter et al., 1998; also, see the subsection Methanogenic Archaea in section "Hydrogen Metabolism"). Later studies concentrated on the 16S rRNA genes and confirmed the presence of Methanobacteriales in *Reticulitermes speratus* (Shinzato et al., 1999), *Cryptotermes domesticus* (Ohkuma and Kudo, 1998; Shinzato et al., 2001), *Hodotermopsis sjöstedti* (Ohkuma et al., 1999c), *Neotermes koshunensis*, *Reticulitermes kanmonensis*, *Coptotermes formosanus*, and *Mastotermes darwiniensis* (Shinzato et al., 2001). All sequences cluster within the radiation of the genus *Methanobrevibacter*, but the sequences from termites differ from those of known methanogens, forming unique lineages in the phylogenetic trees. A single clone related to Methanomicrobiales was recovered from *Reticulitermes speratus* (Shinzato et al., 1999).

Dot-blot hybridization indicated that Methanobacteriales constitute one-third to more than one-half of the archaea in the guts of almost all termite species studied (Brauman et al., 2001). By contrast, Methanosarcinales seem to be present only in the guts of about half of the termite species, apparently forming the dominant group of methanogens in 4 of the 24 species studied and accounting for the total archaeal signal in the fungus-growing species *Macrotermes subhyalinus* (Brauman et al., 2001). Additionally, the clones retrieved from the guts of the phylogenetically higher termites *Nasutitermes takasagoensis*, *Odontotermes formosanus* and *Pericapritermes nitobei* clustered mostly among the Methanomicrobiales and Methanosarcinales (Ohkuma et al., 1999c). In a detailed study of archaeal diversity in the gut of the soil-feeding higher termite, *Cubitermes orthognathus*, most archaeal clones were affiliated with Methanobacteriales, Methanomicrobiales and Methanosarcinales, and a few clones had their closest relatives among the Methanococcales (Friedrich et al., 2001). Similar results were obtained in a study with *Cubitermes* fungifaber, which also corroborated that there is little overlap between the communities of methanoarchaea present in the gut and in the food soil (Donovan et al., 2004). In contrast, the similarities between the methanoarchaeal communities of congeneric termites are substantial, and many clones obtained from the intestinal tract of termites cluster with clones retrieved from other insects. However, a purely vertical transmission of the methanogenic gut microbiota is not supported (Donovan et al., 2004).

Methanobrevibacter spp. in *Reticulitermes* are associated with the hindgut wall (Leadbetter and Breznak, 1996; Leadbetter et al., 1998) and, in the gut of *Reticulitermes speratus* and *Hodotermopsis sjoestedti*, attached to the flagellated protist species *Dinenympha* and *Microjoenia* (Tokura et al., 2000): there are indications that the lineages attached to the flagellates are phylogenetically different from those associated with the gut epithelium. Fröhlich and König (1999a) retrieved single cells of endosymbiotic methanogens from the anaerobic flagellate *Pentatrichomonoides scroa* occurring in the hindgut of *Mastotermes darwiniensis* that were affiliated with the genus *Methanobrevibacter*.

Methanogens are among the few groups of organisms for which one can infer metabolic information from the 16S rRNA gene sequence. FISH with an archaea-specific probe revealed that archaea are largely restricted to the gut sections P3 and P4 in *Cubitermes ugandensis*, which is in agreement with the distribution of F_{420}-fluorescent cells and methane-emission rates along the gut axis of *Cubitermes* species (Schmitt-Wagner and Brune, 1999). Cells hybridizing with the archaea-specific probe presented

1.6% and 3.8% of the DAPI-stained cells in the P3 and P4 section, respectively (Schmitt-Wagner et al., 2003b), but since many of the abundant and morphologically diverse F_{420}-fluorescent microorganisms in these gut sections were filamentous forms and appeared to be fragmented or destroyed during homogenization, they were likely underestimated by the FISH analysis.

Non-methanogenic Archaea In a dot-blot analyses of many termite species, the total combined value of the subgroup-specific probes was much lower than that of the Archaea domain probe, indicating that termite guts may contain (possibly non-methanogenic) archaeal populations whose 16S-like rRNAs do not hybridize with probes for methanoarchaeal subgroups employed in this study (Brauman et al., 2001).

Shinzato et al. (1999) provided the first evidence for the presence of Thermoplasmales in the intestinal tract of *Reticulitermes speratus*. Friedrich et al. (2001) obtained numerous clones of Thermoplasmales and a few clones related to the Thermococcales from the gut of the soil-feeding termite *Cubitermes orthognathus* and also documented for the first time the presence of crenarchaeota in an intestinal tract. Donovan et al. (2004) retrieved several clones related to the haloalkaliphile genus *Natronococcus* from *Cubitermes fungifaber*, which is quite intriguing in view of the extreme alkalinity of the anterior hindgut of *Cubitermes* species (Brune and Kühl, 1996).

Spatial Organization As mentioned above, termite guts are axially and radially structured, providing numerous microhabitats with different physicochemical microenvironments (see the section The Gut Microenvironment in this Chapter). Not astonishingly, therefore, the distribution of gut microbiota is not random but seems to be spatially organized. Detailed descriptions of the spatial arrangement of the intestinal prokaryotes in situ (Breznak and Pankratz, 1977; To et al., 1978; To et al., 1980; Czolij et al., 1985; Yara et al., 1989), together with numerous other observations of certain morphotypes in particular regions of the gut (see the section Gut Compartmentation and Microhabitats in this Chapter), indicate that many microhabitats harbor characteristic microbial populations.

Until recently, most of such evidence was based purely on morphological data, and the line of evidence is far from complete. With the advent of molecular tools, however, it became possible to address not only the diversity of the termite gut microbiota but also the spatial distribution of individual phylotypes or phylogenetic groups. A study employing whole-cell hybridization in homogenates of different gut regions and in situ hybridization of gut cryosections with group-specific oligonucleotide probes provided the first results documenting differences in microbial community structure between different regions of the hindgut of *Mastotermes darwiniensis* at the level of phylogenetically defined microbial groups (Berchtold et al., 1999). Other studies used FISH to document the association of gut protozoa with certain phylotypes of hitherto uncultivated spirochetes (Berchtold and König, 1996; Iida et al., 2000; Noda et al., 2003), Bacteroidetes (Wenzel et al., 2003; Stingl et al., 2004), members of the TG-1 phylum (Stingl et al., 2005), or methanogenic archaea (Tokura et al., 2000).

Also, PCR-based approaches allow one to resolve differences in the community structure of different gut regions or gut compartments (Friedrich et al., 2001; Schmitt-Wagner et al., 2003b; Yang et al., 2005). Costs and effort involved in sequencing and phylogenetic analysis limit investigations based on clone analysis, but molecular fingerprinting allows expansion of the investigation of diversity and—observing the necessary cautions inherent to all PCR-based techniques—community structure to include a larger number of samples. Terminal-restriction-fragment-length polymorphism (T-RFLP) analysis in the higher, soil-feeding termite *Cubitermes orthognathus* documented that the different archaeal and bacterial populations are not randomly distributed along the gut and that the prokaryotic communities in the individual gut segments differ considerably with respect to diversity and abundance (Friedrich et al., 2001; Schmitt-Wagner et al., 2003a). By contrast, the bacterial community structure in homologous compartments in three different species of *Cubitermes* was quite similar, indicating the existence of gut-segment-specific communities (Schmitt-Wagner et al., 2003a).

Isolates and Major Metabolic Activities

The major metabolic activities of the gut microbiota have been outlined (Breznak, 2000; Slaytor, 2000; Tholen and Brune, 2000; Fig. 7), but there are still considerable gaps in our knowledge that underline the need for a refined concept (Tholen and Brune, 2000). Numerous attempts have been made to characterize the prokaryotic gut microbiota of termites by isolating microorganisms that either were numerically abundant or possessed a metabolic potential considered important in the metabolism of the hindgut. Many of these efforts have yielded results of uncertain significance, either because the methods were not fully described or because no quantitation of bacteria was made relative to

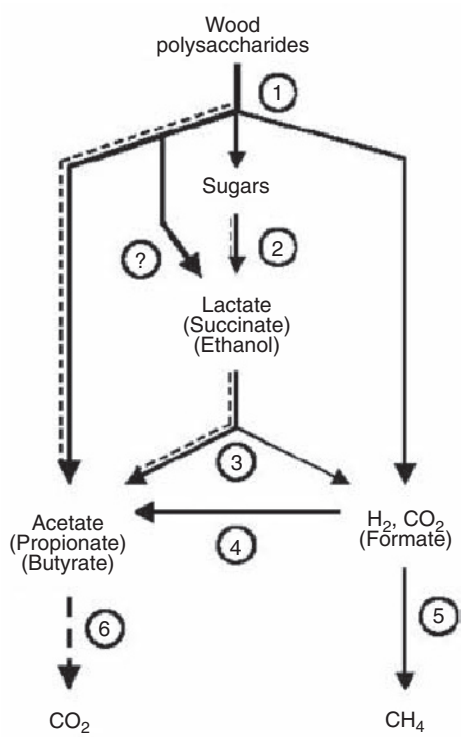

Fig. 7. Schematic presentation of the metabolic processes involved in the fermentative degradation of polysaccharides in the hindgut of *Reticulitermes flavipes*. The dashed lines indicate metabolic fluxes which seem to be strongly influenced by the continuous influx of oxygen into the gut periphery. Line thickness indicates the relative importance of the process. The major metabolic groups are gut flagellates (1), primary (2) and secondary (3) fermenting bacteria, homoacetogens (4), and methanogens (5); it remains to be clarified whether the flagellates are also a major source of lactate (?). Short-chain fatty acids are oxidized by the host (6). Adapted from Brune (2003).

the total number of microorganisms present. As there is little overlap between the existing isolates and the 16S rRNA genes obtained in the molecular studies (see the section Phylogenetic Diversity and Community Structure in this Chapter), it is apparent that many of the microorganisms responsible for the major metabolic activities remain to be cultivated.

Numerically Predominant Isolates Most cultivable heterotrophic bacteria in the hindgut of *Reticulitermes flavipes* are *Streptococcus* and *Enterococcus* species, followed by *Bacteroides* species and representatives of the Enterobacteriaceae, mostly *Citrobacter* species and *Enterobacter cloacae* (Schultz and Breznak, 1978; Tholen et al., 1997). Coccoid lactic acid bacteria also dominated among the isolates obtained from the hindguts of the lower termites *Mastotermes darwiniensis* and *Cryptotermes primus* (Eutick et al., 1978a) and the higher termites *Nasutitermes arborum*, *Thoracotermes macrothorax* and *Anoplotermes pacificus* (Bauer et al., 2000). While *Enterobacter* species were found to dominate among the isolates from the rhinotermitid species *Heterotermes ferox*, *Coptotermes acinaciformes*, *Coptotermes lacteus* and *Schedorhinotermes intermedius* (Eutick et al., 1978a), most isolates from termitid species *Nasutitermes exitiosus*, *Nasutitermes graveolus* and *Nasutitermes walkeri* were staphylococci. Isolates from these genera have been recovered also in earlier studies (e.g., Mannesmann and Piechowski, 1989).

Although some of these studies were at best semiquantitative and many employed only aerobic techniques, the pattern of bacterial species cultivated from each host species is remarkably constant. Most importantly, the majority of the isolates obtained from termite guts are either aerobes or aerotolerant anaerobes. The absence of obligate anaerobes among the isolates in those studies that did not attempt to apply a methodology appropriate for the successful cultivation of such bacteria is not astonishing. However, even in the studies that explicitly used the Hungate technique and employed reduced media for cultivation, the fraction of obligate anaerobes was always smaller than that of aerotolerant anaerobes and aerobes (Schultz and Breznak, 1978; Tholen et al., 1997). It is not clear whether this phenomenon is caused by the oxygen status of the termite gut (see the section Redox Conditions and Oxygen Status in this Chapter) or the strong cultivation bias against certain groups of bacteria (see the section Cultivation Bias in this Chapter).

Cultivation Bias A comparison of the viable counts of heterotrophic bacteria to the direct microscopic counts of the microorganisms in the hindgut of *Reticulitermes flavipes* indicates that about 90% of the microbial cells have escaped cultivation (Schultz and Breznak, 1978; Tholen et al., 1997). Viable counts obtained in a similar study attempting to characterize the major gut bacteria of nine species of termites indicate an even larger cultivation bias (Eutick et al., 1978a).

When the isolates obtained in these studies are compared to the results of the cultivation-independent characterization (see the section Phylogenetic Diversity and Community Structure in this Chapter), there are enormous discrepancies between the frequencies of the phylogenetic groups dominating the clone libraries (Fig. 6) and the species recovered by cultivation. Nevertheless, many isolates are unique to the termite gut habitat, and their characterization has provided valuable information on metabolic properties and other physiological

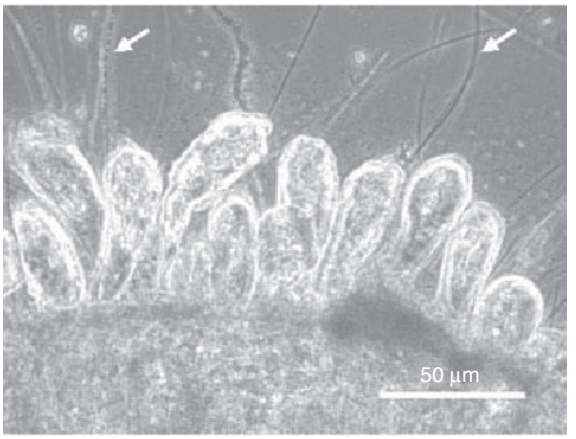

Fig. 8. Phase contrast photomicrograph of the hindgut wall of *Reticulitermes santonensis*, colonized by *Pyrsonympha flagellates* and "Arthromitus"-like filaments (arrows). Reprinted from Yang et al. (2005).

features relevant for the colonization of this particular habitat (Table 1). To increase cultivation efficiency, it will be necessary to develop new cultivation strategies that take into account the special environmental conditions within the gut, in particular the steep physicochemical gradients (see the section The Gut Microenvironment in this Chapter) and the metabolic interactions among the microbiota (see the section Microbe-Microbe Interactions in this Chapter).

Like many arthopods, termites harbor filamentous bacterial morphotypes with refractile inclusions resembling endospores. These bacteria are usually attached to the hindgut wall (Fig. 8) and were first described in 1849 as "Arthromitus" by Leidy (1849, 1881). The filaments have not been cultivated, but Margulis et al. (1998) have proposed that they represent a different life stage of aerobic, rod-shaped bacteria closely related to *Bacillus cereus*, a species group that occurs ubiquitously in soil. However, their conclusions were based merely on the isolation of such bacteria from the boiled intestines of ten species of soil arthropods containing "Arthromitus"-like filaments and on earlier reports on the isolation of *B. cereus* from arthropod guts. A phylogenetic identity of the filaments with the isolates has not been confirmed with molecular methods. In this context, it should be noted that other authors had previously identified the segmented filamentous bacteria in the gut of mice, rats, and chickens as a new lineage of Clostridiales, based on a 16S rRNA gene sequence analysis (Snel et al., 1994). The same group has proposed "Candidatus Arthromitus" as a provisional generic name for the segmented filamentous bacteria falling into this lineage (Snel et al., 1995)—unfortunately without verifying whether they are indeed related to the morphologically similar filaments in arthropods originally described by Leidy.

Lignocellulose Degradation There are numerous reports on the presence in termite guts of enzyme activities acting on different cellulose and hemicellulose preparations. The enzyme activities in foregut and midgut are most likely of host origin or are ingested fungal cellulases that remain active within the gut (see the section Fiber Degradation in this Chapter), whereas most activities in the hindgut are probably due to the microbiota. In the lower termites, it is also important to differentiate between protozoan and bacterial origin.

Cellulolytic Bacteria Cellulolytic prokaryotes have been isolated from the guts of lower and higher termites on numerous occasions (for references, see Breznak [1975], Breznak and Brune [1994b], and Wenzel et al. [2002]). However, many of these efforts either were unsuccessful or have yielded positive results of uncertain significance, either because the methods were not fully described or because the population size had not been established (Schultz and Breznak, 1978). Therefore, the contribution of bacteria to cellulose degradation in the termite gut has always been a matter of debate (see the section Fiber Degradation in this Chapter).

Interestingly, successful attempts to isolate cellulolytic bacteria usually employed oxic cultivation conditions; only a few anaerobic strains have been reported. Hungate isolated an anaerobic actinomycete, "*Micromonospora propionici*," from *Amitermes minimus* (Hungate, 1946). *Clostridium termitidis* was isolated from the gut of the wood-feeding termite *Nasutitermes lujae* (Hethener et al., 1992). All attempts to isolate anaerobic cellulolytic bacteria from the gut of *Reticulitermes flavipes* were negative (Schultz and Breznak, 1978). No cellulose-degrading bacteria were present among the numerically predominant isolates recovered from nine species of termites representing all major families, using both aerobic and anaerobic techniques (Eutick et al., 1978a). No anaerobic cellulolytic bacteria were isolated from the soil-feeding termite *Cubitermes speciosus* using serial dilutions of gut homogenates and the Hungate technique (Brauman et al., 1990b).

By contrast, numerous studies have yielded aerobic bacteria, albeit of often dubious numerical significance. Frequent isolates, found in numerous studies, were assigned to *Serratia marcescens* and *Bacillus cereus* (e.g., Thayer, 1976). Strains of both species, isolated from *Reticulitermes hesperus*, formed soluble, and in the case of *Bacillus cereus* also cell-bound, car-

Table 1. Described species of prokaryotes unique to the intestinal tract of termites.

Group species	Termite species[a]	Unusual feature	References
Firmicutes

[a]Termites belong to the families Kalotermitidae (K), Mastotermitidae (M), Rhinotermitidae (R), Termitidae (T), and Termopsidae (Z).
[b]*Candidatus* taxon: not cultivated, but well-characterized with respect to morphology, ultrastructure, phylogeny, and specific location.

boxymethylcellulases (Thayer, 1978). *Serratia marcescens* seems to be a common but minor inhabitant of the intestinal tract of insects that on occasion can become pathogenic (see the section Pathogens in this Chapter).

On the basis of the few studies where the number or density of cellulolytic bacteria in the gut had been determined (e.g., Paul et al., 1993; Wenzel et al., 2002), it appears that bacteria are not very relevant for cellulose digestion. The most abundant among 23 groups of Cellulolytic isolates from *Zootermopsis angusticollis* were closely affiliated with *Bacillus megaterium*, *Bacillus cereus* or *Paenibacillus polymyxa* (Wenzel et al., 2002). Many of the cellulolytic isolates are species known to occur also in soil and other habitats and may represent transient permanent populations of microorganisms ingested with the food, while others are apparently specific for the intestinal tracts of insects (Table 1).

Isoptericola variabilis (formerly *Cellulosimicrobium variabile*; Stackebrandt et al., 2004) and other closely related bacteria were isolated from the hindgut of *Mastotermes darwiniensis* and various other termites (Bakalidou et al., 2002) and form significant populations also in the gut of other insects (Cazemier et al., 2003).

Cellulolytic activity has been detected also among numerous actinomycetes isolated from the gut of several soil-feeding Termitidae (Pasti and Belli, 1985); some of the isolates were also lignolytic (Pasti et al., 1990). Although an unusual association of soil-feeding termites (Termitidae, Termitinae) with actinomycete-like bacteria has been documented (Bignell et al., 1979; Bignell et al., 1980b) and facultatively aerobic actinomycetes have been isolated from the gut, parent soil, and mound materials of the termites *Procubitermes aburiensis* and *Cubitermes severus* (Bignell et al., 1991), their significance in the degradation of lignocellulose remains to be established.

Hemicellulolytic Bacteria Compared to the information on cellulose degradation, our understanding of the degradation of the hemicellulose component of lignocellulose in termite guts is rather meager. Xylanase activity has been observed in midgut and hindgut of several termites, including wood-feeding, soil-feeding, and fungus-cultivating species (Breznak and Brune, 1994b; Rouland, 2000). In the fungus-cultivating *Macrotermes bellicosus*, there is evidence that the source of xylanase activity may be a symbiotic fungus (Matoub and Rouland, 1995), but analogous to the host cellulases, a host origin of the midgut xylanases remains to be scrutinized.

In lower termites, the gut flagellates also seem to play a major role in the degradation of xylan (see the section Role of Intestinal Protozoa in this Chapter). However, also bacteria and yeasts might be involved in the metabolism of hemicelluloses. Aerobic and facultatively anaerobic hemicellulose-degrading bacteria and yeasts were isolated from the guts of several wood-feeding termites, with xylan-degrading bacteria (10^6–10^7 per ml) dominating in *Mastotermes darwiniensis* and xylan-degrading yeasts (10^7–5×10^8 cells per ml) in *Zootermopsis angusticollis* and *Neotermes castaneus* (Schäfer et al., 1996). Gram-positive isolates belonged to the genera *Bacillus* and *Paenibacillus* or to the Actinobacteria, while Gram-negative strains were affiliated with the genera *Pseudomonas*, *Acinetobacter*, and *Ochrobactrum* or with the enterobacteria.

Several strains of alkaliphilic bacteria, which were isolated from the extremely alkaline P1 compartment the soil-feeding *Sinocapritermes mushae* and *Amitermes longignathus* and represent a novel lineage of *Paenibacillus*, express alkalitolerant xylanase activity with a high PH optimum (Ohkuma et al., 2003; Thongaram et al., 2003). An unusual xylanase, distantly related to xylanases of bacteria and fungi colonizing the bovine rumen (GHF11), has been discovered in a genomic library to microbial DNA extracted from the intestinal tract of an unspecified higher termite belonging to the subfamily Nasutiermitinae (Brennan et al., 2004).

Lignin-Degrading Bacteria The degradation of lignin involves the "enzymatic combustion" of the highly recalcitrant polyphenolic resin by peroxidases. Despite a few claims to the contrary, there is currently no conclusive evidence that bacteria lacking extracellular peroxidative activity solubilize or degrade polymeric core lignin significantly, and lignin degradation by the gut microbiota has been questioned (Breznak and Brune, 1994b; Kuhnigk et al., 1994). A ^{13}C-nuclear magnetic resonance (NMR) analysis of the feces of the wood-feeding termites *Microcerotermes parvus* and *Coptotermes formosanus* indicated a preferential loss of polysaccharide during gut passage, whereas lignin accumulated and was modified only in its O-aromatic-C and O-methyl-C components were modified (Hopkins et al., 1998; Hyodo et al., 1999).

However, extensive delignification occurs in the fungal gardens of fungus-cultivating termites (Hyodo et al., 2000) and has to be expected also in any wood colonized by lignolytic fungi. Many lignin-derived aromatic compounds (representing the major subunits and lignin-carbohydrate linkages found in lignins and their depolymerization products) can be degraded by aerobic bacteria, and numerous bacteria degrading lignin

monomers or certain dimeric lignin model compounds have been isolated from various wood-feeding termites (Kuhnigk et al., 1994; Kuhnigk and König, 1997; Harazono et al., 2003). They comprised a wide range of Gram-positive bacteria and Proteobacteria, with strict aerobes dominating in *Nasutitermes nigriceps* and enterobacteria in the lower termites. An aerobic isolate able to degrade hydroxybenzoic acids was described as a new species, *Bacillus oleronius* (Kuhnigk et al., 1995).

All attempts to enumerate bacteria degrading aromatic compounds indicated that termite guts contain significant numbers of aerobic bacteria capable of degrading aromatic rings, whereas anaerobic degradation of the aromatic nucleus appears to be of little significance (Brune et al., 1995b; Kuhnigk and König, 1997). Under anoxic conditions, only ring and side-chain modification seem to be of importance (Kuhnigk et al., 1994; Brune et al., 1995b). Some isolates from termite guts involved in anaerobic modification or degradation of aromatic compounds were novel taxa (Table 1).

The digestibility of lignocellulose is improved if the phenylpropanoic acid residues esterified to the hemicellulose chains and the diferulic ester linkages between the hemicellulose chains in plant cell walls are hydrolyzed, since this increases the solubility of the macromolecules and reduces steric hindrance of hydrolytic enzymes (Jeffries, 1994). A strain of *Clostridium xylanolyticum* (producing hydroxycinnamoyl esterases) that hydrolyzes and then hydrogenates ferulic and *p*-coumaric acid residues has been isolated from the gut of the grass-feeding termite *Tumulitermes pastinator* (McSweeney et al., 1999). Several termites have been shown to possess also activities cleaving non-phenolic β-O-4 type-lignin model compounds representing the major linkage within the lignin macromolecule (Hirai et al., 2000).

Lignin-solubilizing actinomycetes have been isolated from the gut of soil-feeding termites (Pasti et al., 1990), and all isolates were *Streptomyces* strains. Moreover, in lower termites, the only isolate decolorizing Remazol Brilliant Blue and Azure B was a *Streptomyces* strain (Kuhnigk and König, 1997). Since isolation and phylogenetic characterization of actinomycetes from termite guts indicated that the actinomycete flora of termites depends largely on their geographical origin (Watanabe et al., 2003), it is not clear whether such isolates simply represent spores ingested with the food.

Oxygen Reduction The bacteria and protozoa colonizing the gut periphery, especially those directly associated with the gut epithelium (Fig. 8), are exposed to the continuous influx of oxygen (Brune et al., 2000b). Oxygen microprofiles indicate that the anoxic status of the termite hindguts must be attributed to the oxygen consumption of the microbiota located in the gut periphery (see the section Redox Conditions and Oxygen Status in this Chapter), which can represent a substantial fraction of the respiratory activity of the host (Brune et al., 1995a). This conclusion is supported by the predominance of facultatively or even obligately aerobic isolates in all cultivation-based studies.

However, there are several indications that not all oxygen-consuming activities in termite guts are of a respiratory nature. In the extremely alkaline gut regions, the high rates of oxygen consumption might be partly attributable also to chemical reactions, such as the autoxidation of phenolic residues in lignin or humic substances (see Kappler and Brune, 1999). On the other hand, radiotracer analysis of the in situ metabolism in the hindgut of *Reticulitermes flavipes* demonstrated that the high oxygen fluxes also significantly influence fermentation processes in the hindgut (Tholen and Brune, 2000). This is supported by the oxygen reduction potential found in obligate anaerobes such as lactic acid bacteria (see the section Lactic Acid Bacteria in this Chapter), homoacetogenic bacteria (see the section Homoacetogenic Bacteria in this Chapter), and sulfate-reducing bacteria (see the section Sulfate-Reducing Bacteria in this Chapter).

Microbial Fermentations In lower termites, the bulk of the fermentative activity should be caused by the intestinal protozoa, which immediately phagocytize the wood particles entering the hindgut. The identity of the substrates of the prokaryotic microbiota is far from clear. Since most of the prokaryotic symbionts probably do not participate in fiber degradation, presumably they ferment either soluble products entering the hindgut from the midgut or intermediates released by the protozoa (Fig. 7). The composition of short-chain fatty acids and other fermentation products in the hindgut fluid of termites indicates that a variety of microbial fermentations occur simultaneously (Schultz and Breznak, 1979; Odelson and Breznak, 1983; Anklin-Mühlemann et al., 1995; Tholen and Brune, 2000). However, the exact nature and amount of the monomeric substrates entering the hindgut are not known, and the spectrum of fermentation products formed by the protozoa might be much larger than initially assumed (Tholen and Brune, 2000).

The apparent absence of pyruvate dehydrogenase activity in termite tissues (O'Brien and Breznak, 1984) and several other observations

prompted the suggestion that the termite releases pyruvate into the hindgut to be converted to acetate and reabsorbed by the host (Slaytor et al., 1997; Slaytor, 2000). However, recent findings documented that termite mitochondria possess a pyruvate dehydrogenase complex, although the difference in activity suggests differences in pyruvate metabolism between lower and higher termites (Itakura et al., 1999; Itakura et al., 2003).

Lactobacillales Coccoid lactic acid bacteria predominate among the carbohydrate-utilizing bacteria isolated from the hindguts of termites of the families Mastotermitidae, Kalotermitidae, and Rhinotermitidae (Eutick et al., 1978a; Schultz and Breznak, 1978; Tholen et al., 1997; Bauer et al., 2000) and have been isolated also from several representatives of the Termitidae (Eutick et al., 1978a; Bauer et al., 2000). The most abundant isolates obtained from the hindguts of *Reticulitermes flavipes* and *Thoracotermes macrothorax* belong to the genera *Enterococcus* and *Lactococcus* (Bauer et al., 2000). Howerver, the low frequency of such clones in cultivation-independent studies indicates that lactic acid bacteria might be present only in moderate numbers (Hongoh et al., 2003a; Schmitt-Wagner et al., 2003b; Yang et al., 2005).

Physiological characterization of the isolates has revealed high potential rates of O_2 reduction in the presence of fermentable substrates (Tholen et al., 1997; Bauer et al., 2000), which might represent an adaptation to variable oxygen tensions and could explain why lactococci and enterococci are regularly encountered in the intestinal tracts of termites and other insects and possibly restricted to specific compartments of the intestinal tract (Yang et al., 2005).

Clostridiales Compared to their abundance in bacterial clone libraries derived from termite guts, clostridial isolates are underrepresented in cultivation-based studies. Several isolates have been described as new species and seem to be unique to termite guts (Table 1), but their numerical significance is either low or has not been established. Bacteria distantly related to *Clostridium oroticum*, detected in an alkaline enrichment culture derived from gut homogenates of *Pericapritermes latignathus*, may prove to be first exception, since they were represented also in a clone library obtained from the P1 compartment (Thongaram et al., 2005).

Bacteroidetes Besides the coccoid lactic acid bacteria, a relatively large proportion of the isolates from the hindgut of *Reticulitermes flavipes* have been identified as *Bacteroides* species (Schultz and Breznak, 1978). The strains fall into two groups: aeroduric anaerobes fermenting lactate to propionate and acetate (Schultz and Breznak, 1979) and anaerobic strains forming butyrate and isobutyrate as characteristic products from complex media (Schultz and Breznak, 1978). The only described *Bacteroides* species isolated from termite guts, *Bacteroides termitidis* (Sebald) from *Reticulitermes lucifugus*, was phylogenetically misplaced (Paster et al., 1985) and recently reclassified among the Fusobacteria in the genus *Sebaldella* (Collins and Shah, 1986). A recent isolate, obtained from the hindgut of *Reticulitermes speratus* by dilution plating of gut suspensions, has a 16S rRNA gene sequence identical to that of a group of clones recovered exclusively from termite guts, representing a lineage of bacteria within the radiation of the Bacteroides subgroup but only distantly related to the genus *Bacteroides* (Ohkuma et al., 2002b).

The uricolytic activity of *Bacteroides* isolates from termite guts (Potrikus and Breznak, 1980) suggests a potential role in nitrogen cycling (see the section Nitrogen Recycling in this Chapter). Many of the clones from termite guts clustering among the Bacteroidetes fall into a lineage comprising epibionts of protozoa (see the section Interactions Between Prokaryotes and Protozoa in this Chapter).

Hydrogen Metabolism The enormous accumulation of hydrogen at the gut center and the steep radial hydrogen gradients in the gut periphery of several termites (Ebert and Brune, 1997; Schmitt-Wagner and Brune, 1999) indicate that molecular hydrogen is a key intermediate in the microbial food chain. Hydrogen-dependent CO_2 reduction by methanogens and homoacetogens is probably the most important hydrogen sink in termite hindguts. To understand the metabolism in termite guts, it is important to identify the hydrogen-producing and hydrogen-consuming populations and their functional interactions (see the section Microbe-Microbe Interactions in this Chapter).

Hydrogen-Producing Microorganisms On the basis of the few pure culture studies available, it is generally assumed that the polysaccharides of the wood particles taken up by the gut flagellates are oxidized to acetate and CO_2, and the reducing equivalents are released as H_2 (see Breznak and Brune [1994b] and Brune and Stingl [2005]; Fig. 7). This is in agreement with the enormous accumulation of hydrogen in the hindgut of *Reticulitermes flavipes* (Ebert and Brune, 1997; Fig. 4). In view of the wide variety of clostridial clones retrieved from *Reticulitermes* species (Hongoh et al., 2003a; Yang et al., 2005), bacterial fermentations may also contribute to the intestinal H_2 production. Such assumptions are

substantiated by the considerable amounts of H_2 produced in certain gut regions of soil-feeding *Cubitermes* species (Schmitt-Wagner and Brune, 1999), a group of termites that lack gut flagellates but contain a similar assemblage of clostridial clones (Schmitt-Wagner et al., 2003b). The cellulolytic bacterium *Clostridium termitidis* isolated from *Nasutitermes lujae* (Hethener et al., 1992) is affiliated with a number of clones from *Cubitermes orthognathus* guts (Schmitt-Wagner et al., 2003b), but nothing is known about the physiology of the bacteria represented by these 16S rRNA genes.

Homoacetogenic Bacteria Reductive acetogenesis from H_2 and CO_2 in termite gut homogenates was first demonstrated by Breznak and Switzer (1986). In the following years, the presence of homoacetogenic activities was established for a large number of termite species from all major feeding guilds, including representatives of wood-feeding, fungus-cultivating, and soil-feeding termites (Breznak and Kane, 1990; Brauman et al., 1992; Williams et al., 1994). Although reductive acetogenesis in gut homogenates of soil-feeding termites was always outcompeted as a hydrogen sink by methanogenesis (Brauman et al., 1992; Breznak, 1994a), microinjection of $H^{14}CO_3^-$ into intact hindguts of soil-feeding *Cubitermes* spp. has identified a high potential for reductive acetogenesis (Tholen and Brune, 1999), which indicates that the contribution of reductive acetogenesis to the overall electron flow in the guts of soil-feeding termites might be larger than expected. Possibly, part of the explanation lies in the ability of homoacetogens to grow mixotrophically on H_2 and other substrates (Breznak and Switzer, 1991; Breznak, 1994a).

Although reductive acetogenesis has been demonstrated to occur in a large number of termite species from all major feeding guilds (Brauman et al., 1992), only seven species of homoacetogenic bacteria from termites have been described to date (Table 1). *Sporomusa termitida* (isolated from *Nasutitermes nigriceps*; Breznak et al., 1988), *Sporomusa aerivorans* (isolated from *Thoracotermes macrothorax*; Boga et al., 2003b), and *Acetonema longum* (isolated from *Pterotermes occidentis*; Kane and Breznak, 1991a) are three spore-forming representatives in the *Sporomusa* group of Gram-positive bacteria that are characterized by a Gram-negative cell wall. All isolates are capable of H_2-dependent reduction of CO_2 to acetate and possess a large potential for hydrogen-dependent oxygen reduction (Boga and Brune, 2003a).

Clostridium mayombei has been isolated from *Cubitermes speciosus* (Kane et al., 1991b) and belongs to the *Clostridium lituseburense* group. A very unusual homoacetogen (*Sporobacter termitidis*, isolated from *Nasutitermes lujae*) clusters in the *Clostridium leptum* group together with numerous clones of 16S rRNA genes retrieved from the anterior hindgut of *Cubitermes orthognathus* (Schmitt-Wagner et al., 2003b). It grows exclusively by the disproportionation of methyl groups derived from methoxylated aromatic compounds but not on $H_2 + CO_2$ or other typical substrates of homoacetogens, and it methylates sulfide and cysteine if these compounds are present in the medium (Grech-Mora et al., 1996).

Recently, numerous spirochetal strains have been isolated from the gut of *Zootermopsis angusticollis* (Leadbetter et al., 1999). They belong to the *Treponema* branch of Spirochaetes that contains mainly sequences obtained from termite guts (Lilburn et al., 1999), and many are capable of H_2-dependent acetogenesis from CO_2 (Leadbetter et al., 1999). One of the homoacetogenic isolates, which has been described as a new species, *Treponema primitia* (Graber et al., 2004b), utilizes a wide range of substrates and is capable of mixotrophic growth, i.e., the simultaneous utilization of H_2 and organic substrates (Graber and Breznak, 2004a). These represent important clues for the unknown metabolic function of the enormous populations of spirochetes colonizing the hindgut lumen of termites and the surfaces of many intestinal protozoa (Breznak, 2002).

Generally, there seems to be a strong cultivation bias against homoacetogens from termite guts, and their numerical abundance and contribution to reductive acetogenesis in situ are not clear. Recently, sequences clustering with the formyl tetrahydrofolate synthase (FTHFS) homologues of termite-gut spirochetes were found to dominate the diversity of genes in the hindgut of *Zootermopsis angusticollis* coding for FTHFS (Salmassi and Leadbetter, 2003). FTHFS is a key enzyme in reductive acetogenesis, which makes the FTHFS gene a good functional marker for homoacetogenic bacteria (Leaphart and Lovell, 2001; Leaphart et al., 2003). Quite likely therefore homoacetogenic spirochetes are responsible for the large potential activities of H_2-dependent acetogenesis encountered in most wood-feeding termites (Breznak, 1994a; Breznak, 2002).

All investigated homoacetogens isolated from termite guts catalyzed hydrogen-dependent oxygen reduction (Boga and Brune, 2003a); the isolate *Sporomusa aerivorans* has the highest known oxygen-reducing capacity among obligately anaerobic bacteria other than sulfate-reducing bacteria of the genus *Desulfovibrio* (see the section Sulfate-Reducing Bacteria in this Chapter), which possibly indicates an adaptation to the oxygen status of the gut environment.

Although the location of homoacetogens relative to the oxygen gradient remains to be established, it is rather unlikely that the homoacetogens in *Reticulitermes flavipes* contribute substantially to the removal of oxygen diffusing into the gut: in contrast to methanogenesis, the in situ rates of reductive acetogenesis in this termite species are not affected by oxygen (Tholen and Brune, 2000).

Methanogenic Archaea Methane formation by termites, first documented by Breznak (Breznak, 1975; Odelson and Breznak, 1983), has received considerable attention owing to its implication for the global methane budget (Sanderson, 1996). Methane formation is restricted to the archaea; therefore, the methane production by all termites investigated indicates that methanogenic archaea are present in virtually all termites (Brauman et al., 1992). Furthermore, the gas bubbles around termites entrapped in amber (Fig. 9), which have been attributed to continuing methanogenesis in the fresh resin, are palaeontologic evidence for the presence of methanogenic archaea in termite guts.

The autofluorescence of coenzyme F_{420} allows easy visualization of methanogens by epifluorescence microscopy. They are either located free in the hindgut lumen, attached to the hindgut cuticle, or associated with other microorganisms (Breznak and Brune, 1994b). In *Zootermopsis*, methanogens are almost exclusively associated with the gut flagellates (Lee et al., 1987). On the basis of their F_{420}-like autofluorescence, filamentous bacteria colonizing the cuticular spines in the fourth proctodeal segment of soil-feeding termites (Bignell et al., 1980b) also appear to be methanogens (Schmitt-Wagner et al., 2003b).

Fig. 9. Termites entrapped in a block of copal (young amber) from the Andean uplift region of Boyaca Province, Colombia (Pleistocene). The photograph shows gas bubbles around the termites, presumably methane that escaped from the body after the termites had been engulfed by the resin.

Despite their relative abundance and phylogenetic diversity in termite guts (see the section Archaeal Diversity in this Chapter), to date only a few methanogens from *Reticulitermes flavipes* have been isolated in pure culture. The isolates represent new species in the genus *Methanobrevibacter* (Table 1), grow best with H_2 and CO_2, and form large populations that are attached to the luminal side of the gut epithelium or adhere to other prokaryotes colonizing the hindgut wall (Leadbetter and Breznak, 1996; Leadbetter et al., 1998). Already the location in the microoxic gut periphery and the presence of catalase activity in *Methanobrevibacter cuticularis* indicated a considerable oxygen tolerance (Leadbetter and Breznak, 1996). This was substantiated by the finding that – despite a general inability among Methanobacteriales to synthesize heme—the wetwood isolate *Methanobrevibacter arboriphilus* expresses a catalase when the medium is supplemented with hemin (Shima et al., 2001). The documentation of a $F_{420}H_2$ oxidase in *M. arboriphilus* (Seedorf et al., 2004) finally provided also a biochemical basis for the high rates of H_2-dependent O_2 reduction exhibited by *Methanobrevibacter* species colonizing the periphery of the termite hindgut (A. Tholen and A. Brune, unpublished results) and their apparent ability to cope with the continuous influx of oxygen (Leadbetter and Breznak, 1996; Ebert and Brune 1997).

Sulfate-Reducing Bacteria Sulfate-reducing bacteria have been isolated from the intestinal tracts of many different termite species (Brauman et al., 1990a; Brauman et al., 1990b; Trinkerl et al., 1990; Kuhnigk et al., 1996; Fröhlich et al., 1999b). All isolates are members of the genus *Desulfovibrio* and seem to form substantial populations in the gut of certain termites. The relevance of sulfate reduction under in situ conditions is not clear, but the sulfate-reducing bacteria in termite guts might partake also in the removal of oxygen or play a role in syntrophic fermentations (Kuhnigk et al., 1996). Like other *Desulfovibrio* species isolated from sediments (for references, see Cypionka, 2000), all strains isolated from termite guts show extremely high rates of O_2 reduction in the presence of H_2 (Kuhnigk et al., 1996; Fröhlich et al., 1999b).

Nitrogen Transformations The diet of the termites ranges from sound wood to lignocellulosic plant materials in various stages of humification, including soil and animal dung. Owing to the high C-to-N ratio of sound wood, many xylophagous termites are strongly limited by nitrogen (Collins, 1983). They conserve nitrogen by recycling—a strategy that has been termed "carbon

elimination" (Higashi et al., 1992). Another way to improve the C/N balance of the colony is through nitrogen fixation.

This section will summarize the present knowledge on these processes and the microorganisms involved. For details, the reader is referred to the comprehensive review of Breznak (2000).

Nitrogen Recycling The best way to deal with a rare resource is conservation and recycling. Termites, like other insects, secrete uric acid and urea, the waste products of nucleic acid and protein metabolism, via the Malpighian tubules into the intestinal tract (Terra, 1990; Fig. 3). Potrikus and Breznak (1981) demonstrated that termites lack uricase and that uric acid is recycled by anaerobic bacteria in the hindgut of *Reticulitermes flavipes*, including *Streptococcus* and *Citrobacter* species and *Bacteroides* (now *Sebaldella*) *termitidis* (Potrikus and Breznak, 1980).

Despite the low nitrogen content of the diet, nitrogen recycling creates high ammonia concentrations in the hindgut of wood-feeding termites, which allows the maintenance of an active gut microbiota and thus ensures high rates of carbon mineralization. The concentration of ammonia in the paunch of *Nasutitermes walkeri* is in the range of 3 mM (Slaytor and Chappell, 1994). The efficient assimilation of ammonium into microbial biomass (and possibly also resorption of ammonium in the posterior hindgut) avoids the loss of nitrogen via the feces (Breznak, 2000). The transformation to high-quality microbial protein also leads to an upgrading of any low-quality nitrogen in the diet.

The nitrogen cycle is closed by the digestion of microbial cells. Since termites cannot access the microbes in the hindgut directly, worker larvae solicit hindgut contents from their nestmates. This behavior, termed "proctodeal trophallaxis," is unique to this group of social insects and increases in frequency with the level of nitrogen limitation (Machida et al., 2001). Digestion of the hindgut contents and resorption of the nitrogenous products probably take place in the foregut and midgut (Fig. 3), as indicated by lysozyme and protease activities in these gut regions (Fujita et al., 2001; Fujita and Abe, 2002; Fujita, 2004). The efficiency of nitrogen conservation within the colony is increased further by the consumption of exuviae and dead nestmates.

Nitrogen Fixation Though nitrogen cycling is efficient in termites, termite colony growth is limited by the net nitrogen taken in with food (Breznak, 2000). Therefore, many termites show a preference for lignocellulosic substrates that are colonized by fungi and therefore have a decreased C-to-N ratio (Amburgey et al., 1980; Cornelius et al., 2002). Termites living on sound wood, however, rely on the exclusive capacity of their prokaryotic gut microbiota to fix atmospheric nitrogen.

After the first convincing demonstrations of N_2 fixation in termites using the acetylene reduction assay (Benemann, 1973; Breznak et al., 1973) and the incorporation of ^{15}N into biomass by termites incubated under an $^{15}N_2$-enriched atmosphere (Bentley, 1984), a large body of data on nitrogen fixation in termite guts has accumulated. A few aspects will be mentioned; for more details, the reader is again referred to the excellent review of this subject by Breznak (2000).

Nitrogen fixation is widespread among termites, although the rates differ considerably. Nitrogenase activity in certain *Nasutitermes* spp. would be sufficient to double the nitrogen content of a colony within a few years (Breznak, 2000), and stable isotope analysis has revealed that 30–60% of the nitrogen in *Neotermes koshunensis* workers is derived via this pathway (Tayasu et al., 1994).

However, the nitrogen content of the diet increases with humification of the organic matter, and peptides, amino sugars, and microbial biomass are potential sources of nutrition for soil-feeding *Cubitermes* spp. (Ji et al., 2000; Ji and Brune, 2001). The natural abundance of the ^{15}N isotope indicates that dietary nitrogen and not atmospheric nitrogen fixation is an important nitrogen source in humivorous termite species (Tayasu et al., 1997; Tayasu, 1998). The enormous ammonium concentrations in feces and nests (constructed from feces) of soil-feeding termites (Ndiaye et al., 2004; R. Ji and A. Brune, unpublished results) suggest that termites in this feeding guild are not nitrogen-limited.

There are also many indications that the nitrogen fixation rates cannot easily be extrapolated to the colony level or ecosystem level. Apart from methodological aspects, there are interspecific differences, intraspecific variations, seasonal patterns, and effects of laboratory maintenance (Curtis and Waller, 1995; Curtis and Waller, 1998) to consider. Additionally, the reduced oxygen partial pressure in subterraneous nests and galleries has to be taken into account (Curtis and Waller, 1996). The problems are discussed in detail by Breznak (2000).

Dinitrogen-fixing bacteria isolated from termite guts include enterobacteria (French et al., 1976; Potrikus and Breznak, 1977; Eutick et al., 1978a), sulfate-reducing bacteria (Kuhnigk et al., 1996), and spirochetes (Leadbetter et al., 1999; Graber et al., 2004b). Molecular approaches, using the *nifH* gene as a functional marker, have revealed a much wider spectrum of potentially N_2-fixing microorganisms, including clostridia, Proteobacteria, and methanogenic archaea, comprising several sequence clusters

unique to termites (Ohkuma et al., 1996b; Ohkuma et al., 1999b). However, a gene-expression study at the community level has revealed that only a few *nifH* homologs, probably representing alternative nitrogenases (*anf* genes), were actually transcribed under in situ conditions in the gut of *Neotermes koshunensis* (Noda et al., 1999). The preferential expression of *anf* genes might be related to an insufficient molybdenum (Mo) supply with the lignocellulosic diet (Ohkuma, 2002a). The number of unrelated *nifH* homologs in a single spirochete species and the variety of apparently spirochete-related *nifH* homologs in hindgut clone libraries indicate that spirochetes are potentially important nitrogen-fixing microorganisms in termite guts (Lilburn et al., 2001).

Symbiotic Interactions

The enormous complexity of this subject emerges from the large number of species present within the gut, the different organizational levels of the potential partners, their metabolic capacities and topological orientation, and the numerous possibilities for metabolic interactions especially within anaerobic communities. In addition, symbiotic interactions can be extremely specific with respect to the partners involved or may simply consist of a cross-feeding of metabolites or nutrients between populations that are not even in direct contact with each other.

Microbe–Microbe Interactions

Trophic cascades and cross-feeding of metabolites can form a network of interactions between the individual populations of any microbial community. In termite guts, the resulting uneven distribution of sources and sinks of microbial metabolites within the system gives rise to metabolic gradients (see the section Physicochemical Gradients in this Chapter), which are indicators of the location of microbial activities in situ. Additionally, the spatial organization of different populations, including intimate associations between prokaryotes and protozoa, underlines the importance of studying the nature of the respective interactions.

Interactions Among Prokaryotes At least three metabolically different groups of microorganisms are involved in the metabolism of hydrogen in the gut of lower termites: the protozoa, which produce H_2 as a product of their fermentative metabolism, and methanogens and homoacetogens, which reduce CO_2 to methane or acetate, respectively (see the section Hydrogen Metabolism in this Chapter). It is generally assumed that hydrogenotrophic methanogens outcompete homoacetogens owing to their higher affinity for the common substrate (Cord-Ruwisch et al., 1988). Nevertheless, both metabolic groups occur simultaneously in the hindgut of termites. In *Reticulitermes flavipes*, where methanogens are mostly restricted to the gut periphery (Leadbetter and Breznak, 1996), in situ rates of reductive acetogenesis surpass those of methanogenesis considerably (Tholen and Brune, 2000), whereas in *Zootermopsis angusticollis*, where methanogens are located mostly inside the gut protozoa (Lee et al., 1987), methanogenesis appears to be the major hydrogenotrophic process (Brauman et al., 1992).

The methanogens in termites seem to be hydrogen-limited in situ, as indicated by the stimulation of methane emission by externally supplied H_2 (Odelson and Breznak, 1983; Messer and Lee, 1989; Ebert and Brune, 1997; Schmitt-Wagner and Brune, 1999). Also, the per cell rates of methanogenesis determined in vitro with *Methanobrevibacter cuticularis*, multiplied by the viable counts of methanogens in *Reticulitermes flavipes*, are much higher than the methane emission rate of living termites (Leadbetter and Breznak, 1996). The relative rates of methane and hydrogen emission by different termites vary considerably (Sugimoto et al., 1998), and evidence is accumulating that the spatial organization of the hydrogen-producing and hydrogen-consuming microorganisms determines the competition and coexistence of different populations (Ebert and Brune, 1997; Tholen and Brune, 2000).

Although reductive acetogenesis is outcompeted as a hydrogen sink by methanogenesis in gut homogenates of soil-feeding termites (Brauman et al., 1992), intact guts of soil-feeding *Cubitermes* spp. show a large potential for reductive acetogenesis (Tholen and Brune, 1999). Taking into account the possibility of an intercompartmental transfer of H_2 (Schmitt-Wagner and Brune, 1999), as has been demonstrated between the midgut and hindgut compartments of cockroaches (Lemke et al., 2001), the contribution of reductive acetogenesis to the overall electron flow in the guts of soil-feeding termites might be larger than expected.

A cross-feeding of hydrogen could also be the basis for the interaction between the prokaryotic epibionts on filamentous bacteria in the gut of *Reticulitermes flavipes* (Breznak and Pankratz, 1977), some of which seem to be methanogenic archaea (Leadbetter and Breznak, 1996). Schultz and Breznak (1979) had demonstrated a cross-feeding of lactate between *Lactococcus lactis* and a propionigenic *Bacteroides* species, to consolidate the predominance of these species among the cultivable bacteria in the hindgut fluid of

Reticulitermes flavipes with the absence of lactate accumulation. Microinjection of ^{14}C-labeled lactate confirmed that lactate is an important intermediate under in vivo conditions but raised several new questions regarding the source of lactate and the role of oxygen in shifting the product spectrum from propionate to acetate (Tholen and Brune, 2000).

An example for cross-feeding of nutrients has been provided by Graber and Breznak (2005), who made a convincing case that *Treponema primitia*, a homoacetogenic spirochete in the gut of *Zootermopsis angusticollis* that requires folate for growth, benefits from the excretion of 5-formyl-tetrahydrofolate by other community members (*Lactococcus lactis* and *Serratia grimesii*).

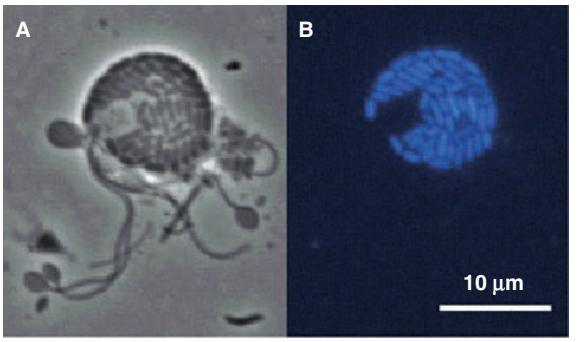

Fig. 10. Phase contrast (A) and epifluorescence (B) photomicrographs of a small trichomonad in *Schedorhinotermes lamanianus* and its attached epibionts, showing the typical F_{420}-autofluorescence of methanogenic archaea. Photomicrographs taken by M. Pester.

Interactions Between Prokaryotes and Protozoa Most of the flagellate protozoa in the guts of lower termites are associated with prokaryotic microorganisms, either as epibionts on their cell surface or as endobionts in the cytoplasm and in the nucleus. The abundance and variety of such associations are documented by numerous electron microscopy studies (for references, see Honigberg [1970], Radek [1999a], Inoue et al. [2000], and Dolan [2001]), but virtually nothing is known about the physiological basis of these associations, especially the metabolic interactions (Brune and Stingl, 2005).

Cook (1932) was the first to observe the emission of a gas other than CO_2 by *Termopsis nevadensis* (syn. *Zootermopsis nevadensis*) and speculated that intestinal protozoa could produce hydrogen, methane, or possibly a mixture of both. Many decades later, termites were shown to emit both hydrogen and methane (Breznak, 1975; Odelson and Breznak, 1983), and axenic cultures of *Trichomitopsis termopsidis* (a gut flagellate from *Zootermopsis*) were shown to produce only hydrogen after methanogenic symbionts were eliminated by treating the cultures with bromoethanesulfonate, an inhibitor of methanogenesis (Odelson and Breznak, 1985a; Odelson and Breznak, 1985b).

Methanogenic symbionts of protozoa can be easily visualized by epifluorescence microscopy (Fig. 10). Lee et al. (1987) reported that methanogenic bacteria in the hindgut of *Zootermopsis angusticollis* are associated only with the small flagellated protozoa *Trichomitopsis termopsidis*, *Tricercomitus termopsidis* and *Hexamastix termopsidis*, whereas they were not observed in the large, hypermastigid protozoa. On the basis of the results of various treatments that selectively eliminated or affected certain protozoa from the gut of this termite, Messer and Lee (1989) concluded that the large protozoa of the genus *Trichonympha* were the most important hydrogen source in the hindgut, whereas the methanogenic symbionts of *Trichomitopsis termopsidis* produced most of the methane.

The large gut flagellates are often colonized by epibiotic bacteria. The presence of special attachment sites on the cell envelope of the flagellates (e.g., Tamm, 1980; Radek et al., 1992; Radek et al., 1996; Dolan and Margulis, 1997; Stingl et al., 2004) indicates a tight association. In some cases, the epibionts seem to be responsible for the locomotion of the host.

The polymastigote flagellate *Mixotricha paradoxa*, which occurs exclusively in the gut of *Mastotermes darwiniensis*, uses its four flagella only for steering. The cell is propelled by the many thousands of spirochetes that cover most of the body surface. The spirochetes are attached to projecting brackets of the cell surface in a manner that allows the helical movement of the individual cells to travel in metachronal waves along the cell surface of the host, resulting in locomotion (Cleveland and Grimstone, 1964). The epibiotic spirochetes were recently identified as members of the *Treponema* cluster by 16S rRNA gene sequence analysis (Wenzel et al., 2003). In addition, a second, rod-shaped epibiont is intimately associated with the cell surface by specific attachment sites (Fig. 11); it is affiliated with other uncultivated Bacteroidales.

The devescovinid flagellate *Caduceia versatilis* (d'Ambrosio et al., 1999) carries two different, rod-shaped and filamentous, epibionts. In this case, the host is propelled by the self-synchronizing movement of the flagella of several thousand rod-shaped bacteria, which are deeply embedded into its the cell surface (Tamm, 1982). The epibionts of *Staurojoenina* flagellates (Fig. 12), recently assigned to the candidate taxon "*Vestibaculum illigatum*" (Stingl et al., 2004), have a similar morphology, although in this flagellate,

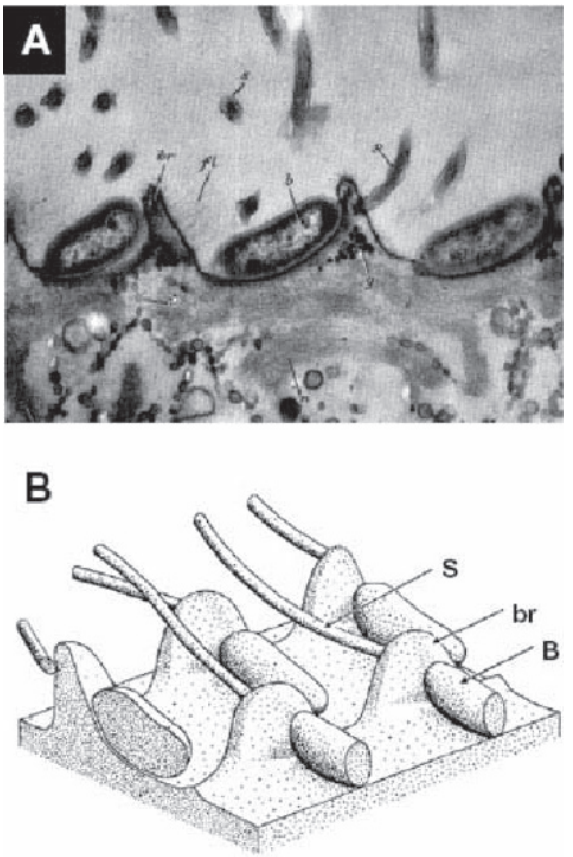

Fig. 11. Transmission electron micrograph (A) of the epibiotic bacteria on the cell surface of *Mixotricha paradoxa*, a large flagellate occurring exclusively in the gut of *Mastotermes darwiniensis* that lives in a motility symbiosis with prokaryotes. The schematic presentation (B) illustrates the regular arrangement of the spirochetal (S) and rod-shaped (B) epibionts and the special attachment brackets (br) at the cell surface. Reproduced from Cleveland and Grimstone (1964).

motility is not due to the bacteria but to their own flagella. Nevertheless, "*Vestibaculum illigatum*" falls into the same cluster of Bacteroidales as the rod-shaped epibiont of *Mixotricha paradoxa* (Stingl et al., 2004), a lineage that also contains numerous clones obtained from other termites (Ohkuma et al., 2002b; Yang et al., 2005).

The larger flagellate species in the gut of *Reticulitermes* species harbor numerous prokaryotic endobionts within their cytoplasm (Bloodgood et al., 1974; Bloodgood and Fitzharris, 1976). The endobionts of *Trichonympha* and *Pyrsonympha* species in *Reticulitermes santonensis* (Fig. 13) belong to the candidate phylum "Endomicrobia", which seem to occur exclusively in termite gut flagellates (Stingl et al., 2005). To date, there is no indication of their possible function. An involvement in hydrogen metabolism is unlikely

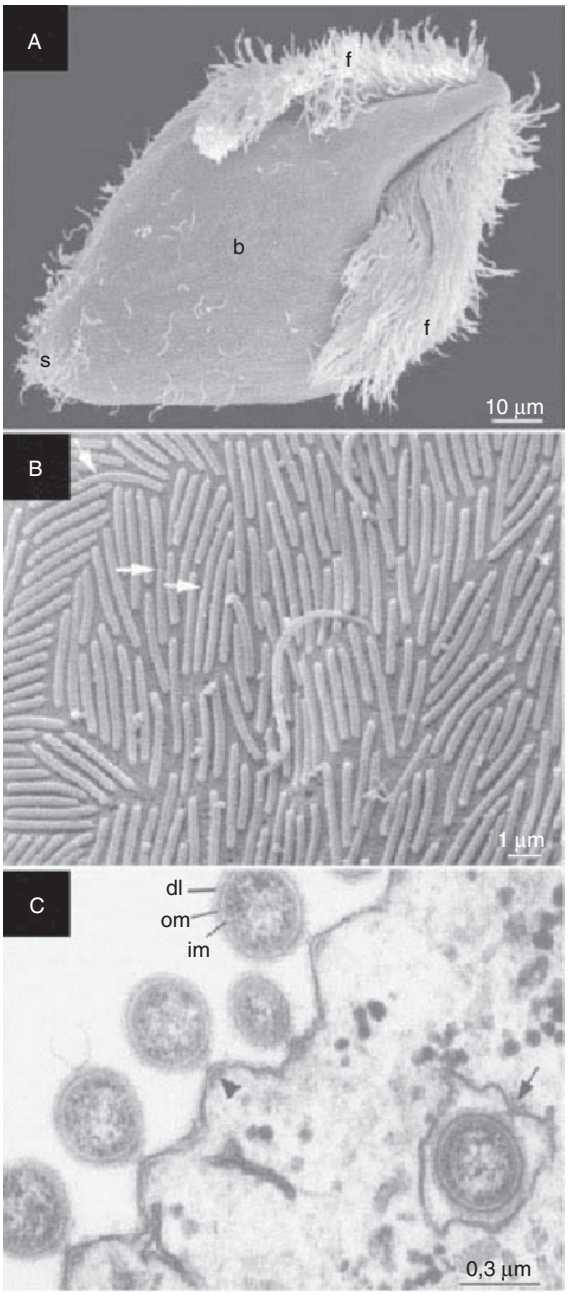

Fig. 12. Scanning (A, B) and transmission (C) electron micrographs of *Staurojoenina* sp. from *Neotermes cubanus*. A) Overview of a cell, showing two of the four flagellar tufts (f), numerous bacterial rods (b), and occasional spirochetes (s) attached to the surface. B) Close-up of the cell surface, showing single spirochetes between the ectobiotic rods. Arrows point to early stages of cell division. C) Cross-section of the epibiotic rods. In addition to an inner membrane (im) and outer membrane (om), the cell is surrounded by a diffuse layer (dl). Electron-dense material supports the plasma membrane of the flagellate below the attachment sites (arrowhead). The arrow points to a phagocytized rod-shaped bacterium with remnants of attachment complex. Reprinted from Stingl et al. (2004).

Transmission-electron micrographs of ultrathin sections of *Trichonympha agilis* (A) and *Pyrsonympha vertens* (B) showing the ultrastructure of the endosymbiotic bacteria in the candidate genus "*Endomicrobium*," which are very abundant in the cytoplasm of these flagellate species. Cells are surrounded by two membranes; the outermost membrane forms tube-like elongations at the tapered cell poles (arrow in A). g, glycogen. Bars = 0.2 µm. Reprinted from Stingl et al. (2005).

since the oxymonadid *Pyrsonympha* species are phylogenetically distant from the hypermastigid flagellates (Moriya et al., 2003; Stingl and Brune, 2003) and do not seem to possess hydrogenosomes (see Brune and Stingl, 2005).

Microbe-Host Interactions

Although the host provides a favorable habitat for the intestinal microbiota and thrives on their metabolic products, there is not always a necessity or clear indication for any specific interactions. However, the intimate associations of bacteria with microvilli of the midgut epithelium or with the epithelial cups in the hindgut cuticle (Breznak and Pankratz, 1977) indicate a closer integration of certain bacteria with the host tissues. Another example suggesting interactions with the gut tissue are the clostridia-related bacteria located in the ectoperitrophic space between the midgut wall and the peritrophic membrane in the mixed segment, closely associated with the mesenteric epithelium (Tokuda et al., 2000; Tokuda et al., 2001).

Pathogens A few reports indicate that the gut microbiota of termites is not always beneficial. *Serratia marcescens*, which has been isolated from the guts of *Reticulitermes hesperus* (Thayer, 1976) and *Mastotermes darwiniensis* (Kuhnigk et al., 1994), causes septicemia in *Coptotermes formosanus* (Osbrink et al., 2001). *Serratia marcescens* seems to form part of the normal microflora of insects since it can be isolated from both healthy and diseased specimens. Usually nonpathogenic when present in the digestive tract in small numbers, it multiplies rapidly once it enters the hemocoel and causes death in 1–3 days (for references, see Lysenko [1985] and Sikorowski and Lawrence [1998]). Also, the fungi associated with *Reticulitermes flavipes* include both cellulolytic species and potential pathogens (Zoberi and Grace, 1990). It is not clear whether entomopathogenic fungi form a part of the natural gut community or are only found among diseased insects (Rath, 2000).

Intracellular Symbionts Termites, like many other insects, are also associated with intracellular prokaryotes that are vertically transmitted via the ovaries (Breznak, 2004). Flavobacteria of the genus *Blattabacterium* reside in specialized cells (bacteriocytes) of cockroaches and the most primitive termite, *Mastotermes darwiniensis* (Bandi et al., 1995). The close phylogenetic relationship between endosymbionts from *Mastotermes darwiniensis* and members of the wood-feeding cockroach genus *Cryptocercus* supports the hypothesis that termites evolved from subsocial, wood-dwelling cockroaches (Lo et al., 2003). All other termites examined carried endocytoplasmic bacteria that are affiliated with the *Wolbachia* group and are located in nonspecialized fat body cells (Bandi et al., 1997). Endonuclear bacteria have been observed in the trophocytes of *Reticulitermes lucifugus* and *Kalotermes flavicollis* (Grandi et al., 1997).

Mutualists or Commensals?

In the hindgut symbiosis, the host creates a rather constant environment for its symbionts, provides a continuous supply of substrates, and by the transfer of the microorganisms to other nestmates, ensures their propagation within the ecosystem. In the symbiosis between lower termites and fiber-digesting flagellates, both partners are indispensable and the mutual advantage is obvious. However, in the case of most prokary-

otic gut symbionts, the symbionts appear to be of little advantage to the host.

If the benefit of the association is unidirectional, a symbiont would be classified as a commensal, and the host might even benefit from its elimination (Brune, 2003). Unfortunately, it is not easy to eliminate specific prokaryotes from the intestinal microbial community of termites selectively, and it is difficult to distinguish between the direct and indirect consequences of their elimination. Removal of the spirochetes from the gut of *Nasutitermes exitiosus* by feeding metronidazole or exposing the termites to pure oxygen kills the termites almost as rapidly as the complete removal of all bacteria by antibiotics (Eutick et al., 1978b).

In view of the constant and massive inoculation with microorganisms in their diet, it is clear that termites cannot keep their gut sterile. The molecular diversity studies have provided ample evidence for a specific microbiota, composed of lineages that occur exclusively in termites (Yang et al., 2005). The absence of a "normal gut microflora" would allow the uncontrolled proliferation of ingested foreign microorganisms and increase the danger of colonization by potential pathogens. *Serratia marcescens* failed to colonize the gut of normal *Coptotermes lacteus*, but transient colonization occurred when the protozoa and spirochetes were killed by exposure to pure oxygen (Veivers et al., 1982).

Under oxygen-limited conditions, the energy loss caused by the activity of the gut microbiota is relatively small (Table 2). The hypothetical, nonsymbiotic oxidation of cellulose to CO_2 would allow the termite to exploit 100% of the free energy of the reaction (Eqn. 1). A homoacetogenic degradation of one glucose equivalent to three acetate molecules by the gut microbiota (Eqn. 2 + Eqn. 3) releases only 10.8% of the free energy contained in the substrate; the rest is still available for the host (Eqn. 4), which also benefits from the nutritionally valuable microbial biomass. However, the situation is quite different if the H_2 formed in the microbial fermentations is converted to methane (Eqn. 2 + Eqn. 5). Although the amount of free energy released in methanogenesis is not much larger than that released in reductive acetogenesis, the host receives only two-thirds of the acetate available under homoacetogenic conditions (Eqn. 6); 28.4% of the free energy in the substrate remains in methane, which cannot be exploited by the host (Eqn. 7) and is lost to the environment.

Such energetic considerations suggest an obvious advantage if a termite uses reductive acetogenesis as the hydrogen-consuming process, and why especially the more highly evolved termites (Termitidae) show a tendency towards increasing methane emission rates is still a mystery (Brauman et al., 1992; Bignell et al., 1997). Nevertheless, considering the added value of metabolic properties such as nitrogen fixation, ammonia assimilation, and provision with vitamins, the advantages for the host may be well worth the investment. The exploitation of the nutritive resources contained in the microbial biomass requires the digestion of the gut symbionts, which is realized by proctodeal trophallaxis (Machida et al., 2001), a behavioral trait that was probably fundamental to both the establishment of the gut microbial community and the evolution of sociality in termites (Nalepa et al., 2001).

Conclusions

Termite guts are minute but efficient bioreactors for the conversion of lignocellulose to short-chain fatty acids and microbial biomass. However, termite guts are not simply anoxic fermentors, but axially and radially structured environments with physicochemically distinct microhabitats, and we are just beginning to understand the complex interactions within the intestinal microbial communities. Microbial diversity in the termite gut is enormous, and the existing isolates represent only a negligible fraction of the untapped diversity of prokaryotes in

Table 2. Free energy of important reactions involved in symbiotic digestion.[a]

Reaction	$\Delta G^{\circ\prime}$ (kJ/mol)[b]	Relative change[c] (%)
(1) Glucose + 6 O_2 → 6 CO_2 + 6 H_2O	–2872	100
(2) Glucose + 2 H_2O → 2 Acetate$^-$ + 2 H^+ + 2 CO_2 + 4 H_2	–216	7.5
(3) 4 H_2 + 2 CO_2 → Acetate$^-$ + H^+ + 2 H_2O	–95	3.3
(4) 3 Acetate$^-$ + 3 H^+ + 6 O_2 → 6 CO_2 + 6 H_2O	–2561	89.2
(5) 4 H_2 + CO_2 → CH_4 + 2 H_2O	–131	4.6
(6) 2 Acetate$^-$ + 2 H^+ + 4 O_2 → 4 CO_2 + 4 H_2O	–1707	59.5
(7) CH_4 + 2 O_2 → CO_2 + 2 H_2O	–818	28.4

CHAPTER 2.5

Marine Chemosynthetic Symbioses

COLLEEN M. CAVANAUGH, ZOE P. MCKINESS, IRENE L.G. NEWTON AND FRANK J. STEWART

Introduction

Bacteria and marine eukaryotes often coexist in symbioses that significantly influence the ecology, physiology and evolution of both partners. De Bary (1879) defined symbiosis as "the living together of differently named organisms," implying that the term encompasses both positive (e.g., mutualism) and negative (e.g., parasitism) associations. Many researchers now view symbiotic interactions as those that persist over the majority of the lifespan of the organisms involved and that provide benefits to each partner beyond those obtained in the absence of association. This chapter describes such symbioses, specifically those between marine invertebrate and protist hosts and chemosynthetic bacterial symbionts.

These bacteria, which cluster primarily within the Gammaproteobacteria (Fig. 1), are chemoautotrophs or methanotrophs. In both chemoautotrophic and methanotrophic symbioses, the hosts, through an astonishing array of physiological and behavioral adaptations, provide the symbiont access to the substrates (i.e., electron donors and acceptors) necessary for the generation of energy and bacterial biomass. In exchange, a portion of the carbon fixed by the symbiont is used, either directly or indirectly, for host energy and biosynthesis. These symbioses thereby increase the metabolic capabilities, and therefore the number of ecological niches, of both the host and the bacterial symbiont.

In those symbioses for which the electron donor has been explicitly identified, sulfide and other inorganic reduced sulfur compounds (e.g., thiosulfate) fuel energy generation by the chemoautotrophic symbionts, serving as electron sources for oxidative phosphorylation. In these symbioses, the ATP produced in electron transport fuels autotrophic CO_2 fixation via the Calvin cycle. In contrast, bacteria in marine invertebrate-methanotroph symbioses use methane (CH_4) as an energy, electron, and carbon source. Unlike their protist or metazoan hosts, chemoautotrophs and methanotrophs share the ability to use reduced inorganic compounds or methane for energy generation and carbon dioxide or methane for carbon fixation and utilization. On the basis of these unique biosynthetic capacities, notably the ability to synthesize C_3 compounds from C_1 compounds, we refer collectively to these bacterial symbionts as "chemosynthetic."

Given the sulfide-rich habitats in which chemoautotrophic symbioses occur, researchers infer that the bacterial symbionts oxidize reduced inorganic sulfur compounds to obtain energy and reducing power for autotrophic carbon fixation. While some endosymbionts (such as those in the protobranchs *Solemya velum* and *S. reidi*; Cavanaugh, 1983; Anderson et al., 1987) utilize thiosulfate ($S_2O_3^{\mu}$), an intermediate in sulfide oxidation, hydrogen sulfide is inferred to be the preferred energy source in a variety of symbioses (see review in Van Dover, 2000). But for many symbioses the actual energy source has not been identified definitively; rather, only an autotrophic metabolism has been confirmed. Indeed, chemosynthetic bacteria utilizing other energy sources (e.g., hydrogen or ammonia) could also serve similar nutritional roles in symbiotic associations. In this review, bacterial symbionts that have been shown to use reduced sulfur compounds (H_2S, HS^{μ}, $S^{\mu 2}$, $S_2O_3^{\mu}$, S^o) for energy metabolism are referred to as thioautotrophs, while the more general term "chemoautotroph" is used to describe symbionts for which data supporting autotrophic CO_2 fixation exist but for which the lithotrophic energy source is unknown.

History

The discovery of deep-sea hydrothermal vents and the flourishing ecosystems associated with them significantly advanced scientific understanding of chemosynthetic symbioses. Oceanographers in the research submersible *Alvin* discovered hydrothermal vents along the Galapagos Rift in 1977. In stark contrast to perceptions of the deep benthos as a cold, food-limited habitat incapable of supporting substantial biomass, hydrothermal vents are oases, characterized by high concentrations of free-living

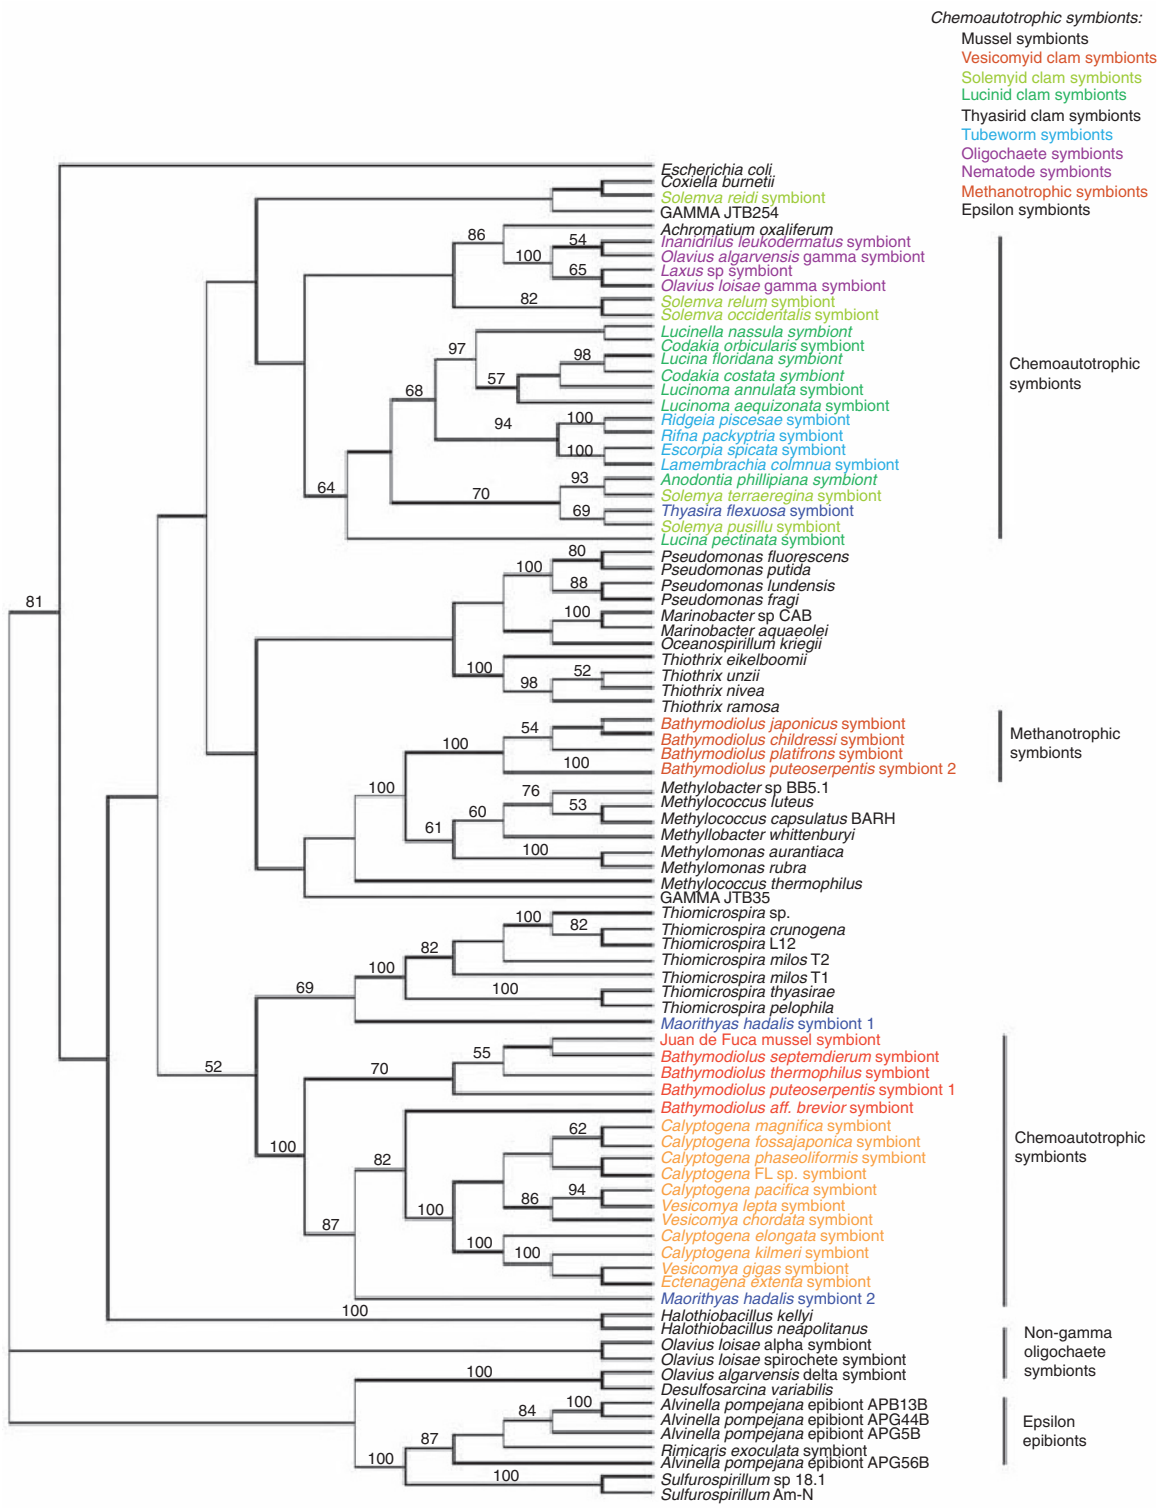

Fig. 1. Phylogeny showing the strict consensus of 46 trees obtained via parsimony analyses of 16S rRNA gene sequences (1456 bp) from symbiotic and free-living bacteria. Results greater than 50% from a 500 replicate bootstrap analysis are reported above respective branches. Chemosynthetic symbiont taxa are color-coded (see key on Figure).

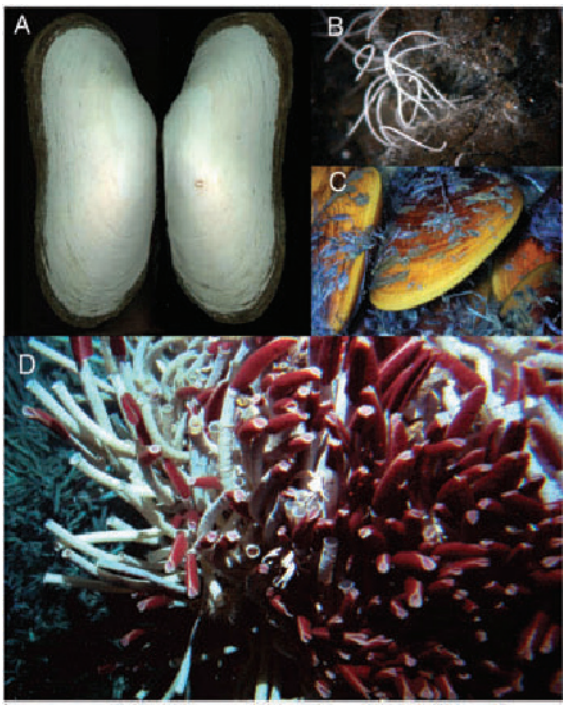

Fig. 2. Symbiont-containing host organisms from hydrothermal vents and cold seeps. (A) *Calyptogena magnifica* shell; courtesy of Emilio Jorge Power. (D) Riftia pachyptila at the East Pacific Rise.

microorganisms and dense aggregations of invertebrates (Lonsdale, 1977; Grassle, 1985; Van Dover, 2000). Researchers first argued that vent invertebrates achieved high densities by filtering organic matter, which was presumably transported to vent sites in hydrothermally-driven convection cells (Lonsdale, 1977). A second hypothesis suggested that the invertebrate community fed directly on locally dense populations of free-living chemoautotrophic bacteria (Lonsdale, 1977; Corliss et al., 1979).

However, studies of the giant tubeworm, *Riftia pachyptila* (Fig. 2), whose lack of mouth and gut precludes suspension feeding, suggested that sulfide-oxidizing endosymbiotic bacteria might contribute substantially to the vent food web. Cavanaugh et al. (1981) proposed that symbiotic chemosynthetic bacteria occurred in *R. pachyptila*. Microscopic and biochemical evidence indicated Gram-negative bacteria were present, packed within the tubeworm trophosome (Cavanaugh, 1981; Fig. 3), a highly vascularized organ in the tubeworm trunk in which activities of enzymes involved in sulfide oxidation and carbon fixation were also detected (Felbeck, 1981a). In addition, Rau (1981) used stable isotope signatures to show a nonphotosynthetic carbon source for *R. pachyptila*, implying a role for chemoautotrophy in tubeworm metabolism. Following confirmation of a chemosynthetic endosymbiosis within the giant tubeworm, researchers questioned the putative reliance on filter feeding by other vent invertebrates. Ultimately, anatomical, enzymological, and isotopic analyses revealed the presence of sulfur-oxidizing bacterial symbionts either within the tissues (endosymbiotic) or attached to the surfaces (episymbiotic) of most vent taxa, including vesicomyid clams, mytilid mussels, shrimp, and polychaete worms (Cavanaugh, 1994; Nelson and Fisher, 1995a; Van Dover, 2000).

Recognizing the ubiquity of chemoautotrophic symbioses at hydrothermal vents, researchers searched for and discovered similar symbiotic associations in other marine habitats, including coastal and subtidal reducing sediments (e.g., Felbeck et al., 1981b; Southward et al., 1981; Southward, 1982; Cavanaugh, 1983; Giere, 1985; Bauer-Nebelsick et al., 1996), brine and hydrocarbon seeps (Sibuet and Olu, 1998), and whale skeletons (Bennet et al., 1994; Smith and Baco, 2003), thereby extending the host taxa to include solemyid and lucinid bivalves, pogonophoran tubeworms, echinoids and ciliates. In addition, methanotrophic bacteria were detected in a marine sponge (Vacelet et al., 1995), a pogonophoran tubeworm (Schmaljohann and Flügel, 1987), and in vent and seep mussels, sometimes co-occurring with sulfur-oxidizing chemoautotrophs in a "dual symbiosis" (Childress et al., 1986; Cavanaugh et al., 1987; Cavanaugh, 1993).

Habitat Chemistry

The seemingly disparate ecological niches where these symbioses are found all possess a chemical gradient, or chemocline, which chemosynthetic bacteria exploit for energy production. Chemoclines form where reduced, high-energy compounds such as sulfide or methane (typically produced in anoxic habitats, including vent fluids and sediments) underlie an oxic water column. Chemosynthetic microorganisms must bridge the oxic-anoxic interface to access both the reduced compounds (e.g., H_2S) used as an energy source and the oxygen to which electrons are shuttled in aerobic energy metabolism.

The source of reduced compounds used in chemoautotrophic energy metabolism differs among habitats. In marine sediments microbial sulfate reduction (in which $SO_4^{\mu 2}$ is used as an electron acceptor during the oxidation of organic matter) dominates, and the sulfide utilized by thioautotrophic symbioses (e.g., involving lucinid clams or solemyid protobranchs) in these habitats is of biogenic origin. In contrast, sulfide at

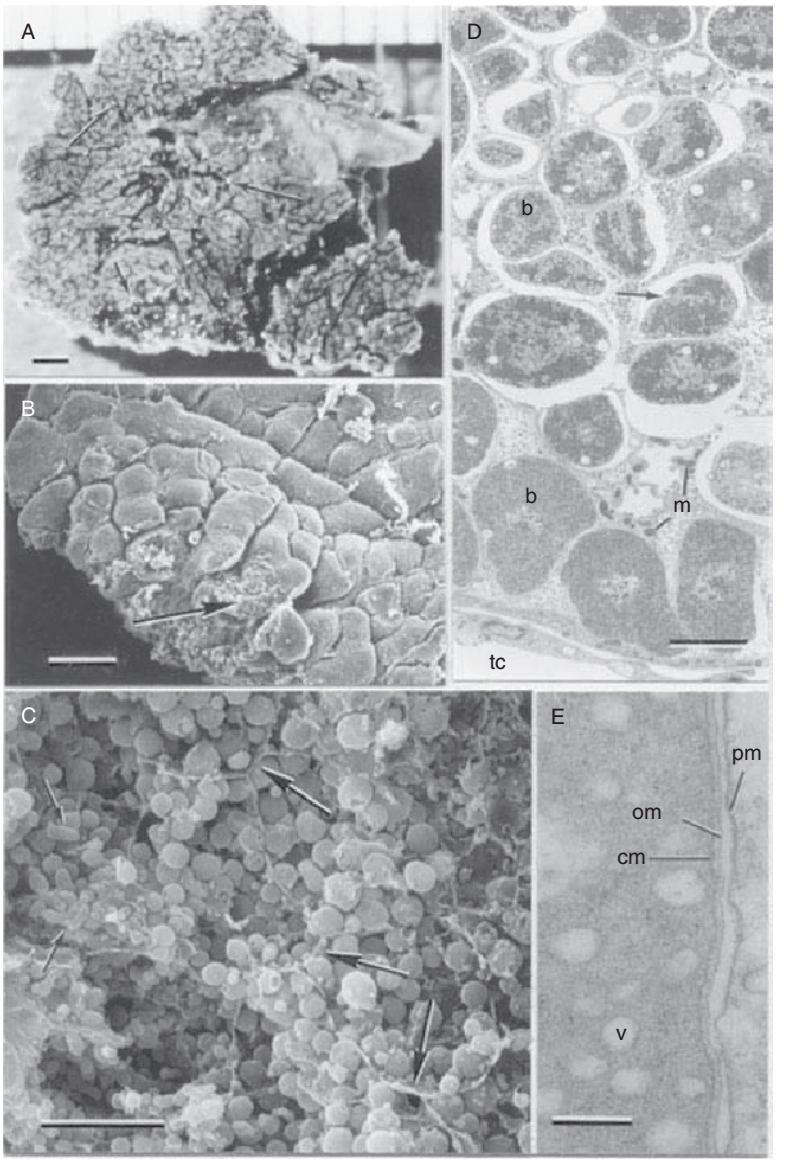

Fig. 3. *Riftia pachyptila* Jones (A–C: Galapagos Rift; D, E: 21°N, East Pacific Rise). (A) Photograph showing elemental sulfur crystals (arrows) scattered throughout trophosome; courtesy of M. L. Jones. (B) Scanning electron micrograph showing lobules of trophosome; arrow indicates area of C (below) where surface epithelium was removed to reveal symbionts within trophosome. hydrothermal vents is produced by the geothermal reduction of seawater sulfate and by the interaction between geothermally heated water and sulfur-containing rocks (e.g., basalt; Alt, 1995; Elderfield and Schultz, 1996; Rouxel et al., 2004). Seawater that percolates into the developing crust becomes heated and reacts with oceanic basalt, becoming enriched with metals and sulfide and charged with volcanic gases such as methane and carbon dioxide. Heated vent water then exits with concentrations of reduced compounds orders of magnitude higher than in ambient seawater. Hydrothermal effluent is hot (temperatures up to 350–400°C), acidic (pH ~ 3), anoxic, and can contain 3–12 mmol/kg of H_2S, 25–100 μmol/kg of CH_4, and 0.05–1 mmol/kg of H_2, as well as 360–1140 μmol/kg of Mn and 750–6500 μmol/kg of Fe (Elderfield and Schultz, 1996). As it exits the seafloor and mixes with the ambient bottom oxygenated seawater (pH, ca. 8; temperature = 1.8°C; [O_2], ca. 110 μM), metallic sulfides precipitate out resulting in "black smokers" (reviewed in Elderfield and Schultz, 1996). Vent organisms are typically found clustered around more diffuse or low flow vents, which are caused by ambient seawater mixing in the shallow subsurface with vent fluid. These vents are characterized by a higher pH (ca. 6), lower temperatures (1.8 to ca. 40°C), and, consequently, lower concentrations of reduced chemicals (Van Dover, 2000).

The relative acidity of vent fluid (black smokers: pH, ca. 3; diffuse flow vents: pH, ca. 6) significantly impacts the concentration of inorganic

chemicals available to chemosynthetic symbioses. For example, carbon dioxide (CO_2), bicarbonate (HCO_3^{μ}), and carbonate ($CO_3^{\mu 2}$), the three distinct chemical species of the dissolved inorganic carbon (DIC) pool, vary in relative abundance depending on pH; pK_a values for these compounds are 6.4 for $CO_2 : HCO_3^{\mu}$ and 10.3 for $HCO_3^{\mu} : CO_3^{\mu 2}$ at 25°C (Stumm and Morgan, 1996). Thus CO_2, which diffuses freely across biological membranes and is the DIC species fixed by chemoautotrophic symbionts utilizing the Calvin cycle, is readily available at vents (Cavanaugh and Robinson, 1996; Goffredi et al., 1997b). In addition, sulfide exists at three levels of dissociation (H_2S, HS^{μ}, and $S^{\mu 2}$) depending on pH, with pK_a values of 7.0 for $H_2S : HS^{\mu}$ and 12.9 for $HS^{\mu} : S^{\mu 2}$ at 25°C (Stumm and Morgan, 1996). Therefore, in the relatively acidic vent fluids sulfide occurs predominantly as H_2S. In such effluent, total sulfide (H_2S, HS^{μ}, and $S^{\mu 2}$) concentration correlates positively with temperature (Johnson et al., 1988); conversely, higher temperatures (>30°C) may facilitate reactions between sulfide and other dissolved elements (such as iron) that reduce free sulfide availability (Luther et al., 2001). The chemical environment (i.e., concentrations of CO_2, O_2, H_2S, CH_4, H^+, and dissolved metals) is therefore expected to significantly influence the ecology and evolution of chemosynthetic symbioses.

Methods for Studying Chemosynthetic Symbioses

To date, the bacteria involved in these symbiotic associations have not yet been isolated and grown in pure culture—perhaps because the unique environment encountered in situ by chemosynthetic symbionts has not been recreated or because a reduced genome, characteristic of many endosymbionts, has precluded growth outside of the host. Symbiotic bacteria are therefore studied indirectly, using methods to assess their physiology, ecology and phylogeny within the context of the intact symbiosis. Traditionally, researchers identify chemosynthetic symbioses using a combination of microscopy (light, confocal, scanning and transmission electron), which provides visual information on the location, morphology and ultrastructure of symbionts, and enzyme assays, which detect and quantify the activity of key proteins involved in chemoautotrophic (e.g., ribulose 1,5-bisphosphate carboxylase-oxygenase) or methanotrophic (e.g., methanol dehydrogenase) metabolism. In addition, tracing the incorporation of radiolabeled substrates (e.g., carbon dioxide, methane and nitrogen species) within the host helps define the physiology of the host-bacteria partnership. Such physiological assays, in conjunction with analyses of stable isotope signatures of symbiont-containing and symbiont-free host tissue, provide valuable insight into the trophic dynamics of symbiont-based communities. Molecular approaches, such as polymerase chain reaction (PCR)-based gene probing, 16S rRNA gene analysis, and fluorescent in situ hybridization (FISH), are increasingly used to characterize the systematic relationships of symbiont and host species (e.g., Distel et al., 1995; Peek et al., 1998; Dubilier et al., 1999) and the metabolism and gene flow of the bacterial symbionts (Robinson et al., 1998; Lee et al., 1999; Millikan et al., 1999; Podar et al., 2002). Molecular techniques have also been used to detect symbiont transmission modes (Cary and Giovannoni, 1993a; Krueger, 1996a) as well as symbiont abundance (Polz and Cavanaugh, 1995).

Summary

This chapter reviews symbiotic associations between chemosynthetic bacteria and marine invertebrate and protist hosts. A bias toward symbioses between chemoautotrophic bacteria and hydrothermal vent invertebrates is evident, primarily because our knowledge of marine bacterial symbioses stems largely from studies of vent fauna done in the 27 years following the discovery of these unique organisms. But despite this impressive body of research, much about these marine symbioses remains to be revealed. In conjunction with several earlier reviews that provide a thorough and thoughtful treatment of symbioses occurring at hydrothermal vents and cold seeps (Fisher, 1990; Felbeck and Distel, 1991; Childress and Fisher, 1992; Cavanaugh, 1994; Nelson and Fisher, 1995a), the following chapter presents an overview of the ecology, physiology and evolution of chemosynthetic symbioses.

Host Diversity

Chemosynthetic bacteria are known to associate with a diversity of invertebrate hosts (six phyla), as well as with ciliate protists (Table 1 and references therein). To date, the majority of the symbionts characterized via 16S rRNA phylogenetic analyses fall within the Gammaproteobacteria division (Fig. 1; discussed further below). The intimacy of these associations varies among taxa. The bacterial partners may be episymbionts living on the surface of the host (e.g., on shrimp, nematodes, sponges, limpets and ciliates; Figs. 4–6), or endosymbionts living either extracellularly within host tissue (e.g., in oligochaetes; Fig. 7) or in specialized host cells and organs (e.g., in bivalves and

Table 1. List of invertebrate taxa hosting chemoautotrophic or methanotrophic bacterial symbionts.[a]

Group	Common name	Symbiont-containing tissue	Location	Habitat	Symbiont type	References
Protozoa						
Class Ciliata	Ciliate	NA	Epibiotic	Cold seeps, mangrove swamp	Chemoautotroph	Bauer-Nebelsick et al., 1996 Ott et al., 1998 Buck et al., 2000 Fenchel and Finlay, 1989
Porifera

Abbreviation: NA, not applicable.

[a]Chemosynthetic status of symbionts inferred from ultrastructural, physiological, enzymatic, and molecular data.

[b]A solemyid protobranch, *Acharax alinae*, has been described from the Lau Basin hydrothermal vents, but the symbiosis has not been characterized (Metivier and Voncosel, 1993).

[c]Solemyid clams have been collected from cold seeps in the eastern Pacific, and lucinid and thyasirid clams have been collected from cold seeps in the Gulf of Mexico, Sagami Bay, and Barbados Prism, though the presence of symbionts has not been formally described (Sibuet and Olu, 1998).

[d]Though it is now accepted that the pogonophoran and vestimentiferan worms are not separate phyla but members of phylum Annelida, they are listed as separate groups for identification purposes.

[e]The oligochaete *Olavius algarvensis* has been shown to have an additional symbiont which is a sulfur reducing bacterium and member of the delta Proteobacteria (Dubilier et al., 2001). *Olavius loisae* has been shown to host an alpha proteobacterium and a spirochete as well as a chemoautotroph (Dubilier et al., 1999).

[f]This symbiont has been described as *Thiothrix*-like on the basis of morphology, physiology, and immunological assays (Temara et al., 1993; Brigmon and de Ridder, 1998).

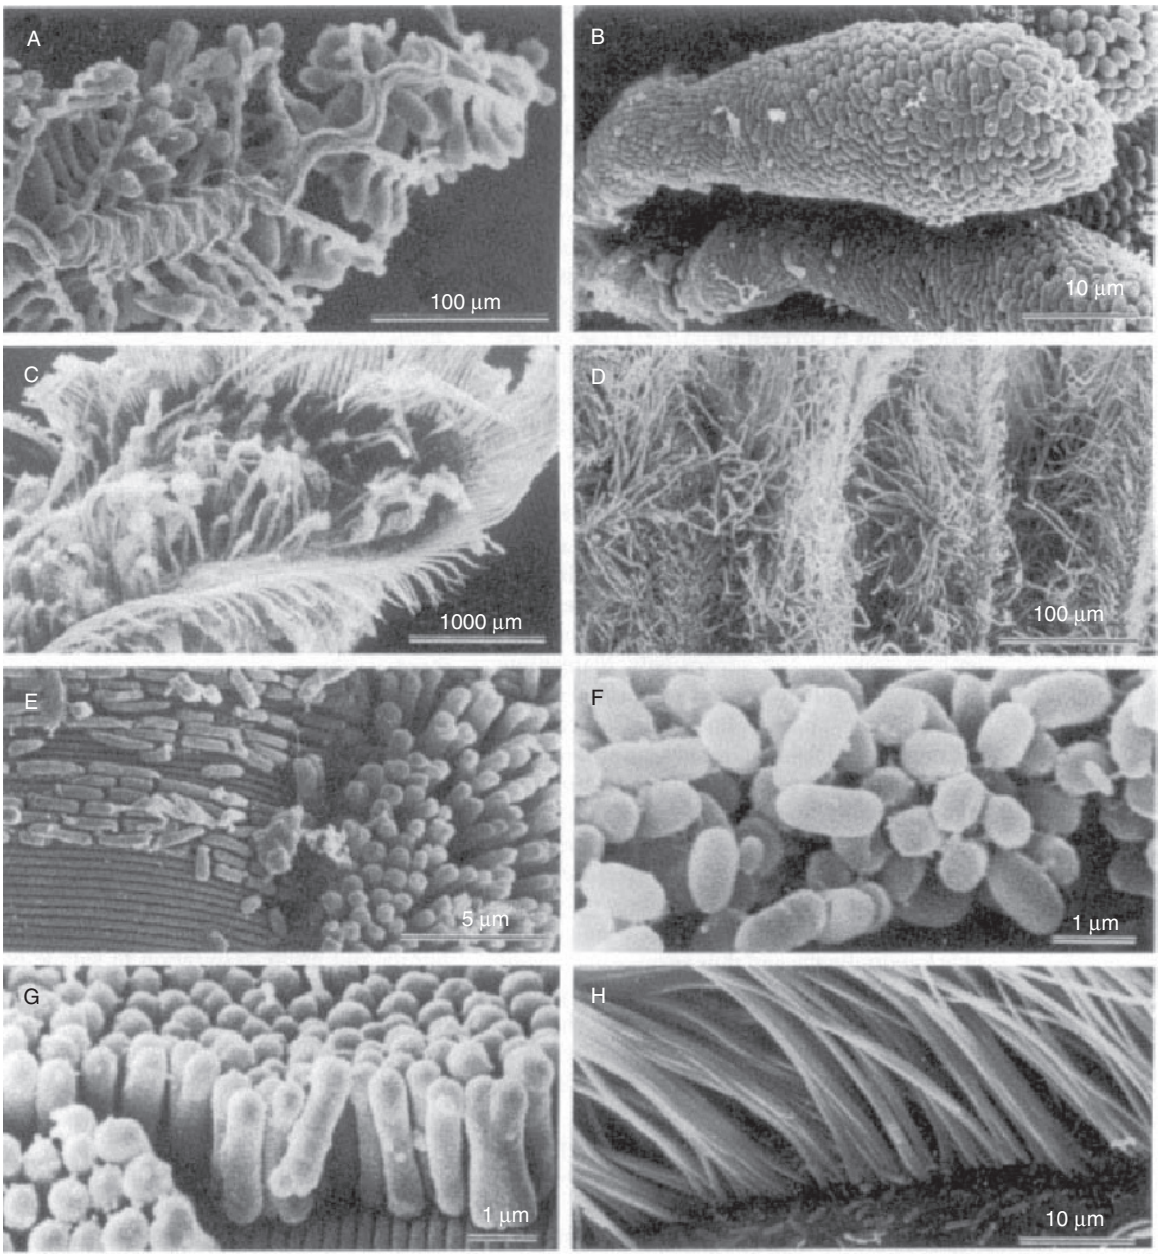

Fig. 4. Scanning electron micrographs showing the morphological diversity of ectosymbiotic bacteria on the colonial ciliate *Zoothamnium niveum* (A, B), the shrimp *Rimicaris exoculata* (C, D), and the nematodes within the subfamily Stilbonematinae (E-H). (A) Entire ciliate colony with zooids attached to a common stem, and (B) bacterial epigrowth on an individual zooid. (C) Shrimp appendage covered by dense arrays of filamentous bacteria, and (D) detail of the hair-like bacterial covering. Epigrowth on different species of nematodes showing (E) irregular epigrowth of two morphological types on *Robbea* sp., (F) coccoid bacteria forming multilayers on *Stibonema* sp., (G) upright standing, longitudinally dividing rods on *Laxus oneistus*, and (H) dense array of nonseptate filaments that can reach up to 100 mm in length on *Eubostrichus dianae*. From Polz et al. (2000), with permission.

vestimentiferan tubeworms; Figs. 2, 3, and 8). In intracellular endosymbioses the symbionts are housed within specialized host cells called "bacteriocytes" and are contained within a host-derived membrane bound vacuole (Cavanaugh, 1983; Cavanaugh, 1994; Fisher, 1990). Host morphology clearly suggests a nutritional benefit from these intimate associations. Indeed, as in the giant vent tubeworms, the digestive system of many endosymbiont-containing marine invertebrates is either reduced (e.g., in coastal solemyid protobranchs) or absent altogether (e.g., in oligochaetes and vestimentiferan and pogonophoran tubeworms), consistent with

host dependence on the symbiont for part or all of its nutrition.

All of the members of the tubeworm family Siboglinidae examined to date, including the vestimentiferan and the smaller pogonophoran tubeworms, contain intracellular symbionts. Most of these symbionts are inferred to be chemoautotrophic, but methanotrophs have been found in one host species (*Siboglinum poseidoni*; Schmaljohann and Flügel, 1987). The vent tubeworm *Riftia pachyptila* and other vestimentiferan and pogonophoran tubeworm species possess a unique morphological adaptation to accommodate their symbionts. Tubeworm bacteria reside within a lobular and highly vascularized organ (the trophosome) that occupies most of the tubeworm trunk and functions specifically to house bacteria (Cavanaugh, 1981; Felbeck, 1981a; Figs. 3 and 9). The symbiosis is obligate for these worms, as they are mouthless and gutless as adults and depend on their internal bacteria for their nutrition.

Chemosynthetic symbioses are widespread within the Mollusca and have been detected in five bivalve and two gastropod families (Table 1). In mollusk symbioses the bacteria occur only in the gills; bacteria have been found within gill epithelial cells of solemyid protobranchs (Cavanaugh, 1983; Krueger et al., 1996b; Figs.

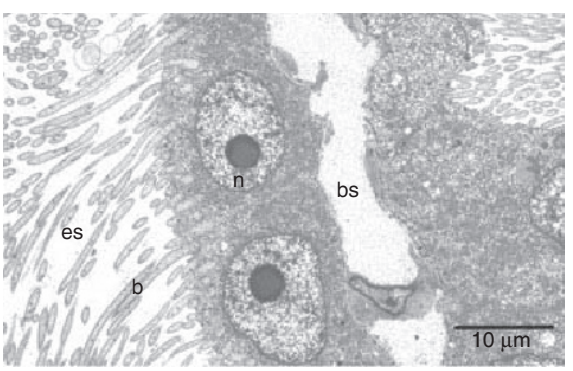

Fig. 5. *Lepetodrilus fucensis*. Transverse section of gill tissue from the hydrothermal vent limpet showing episymbiotic filamentous bacteria partially embedded in the host epithelium. b, bacteria; es, extracellular space; n, nucleus; bs, blood space. Courtesy of Amanda Bates.

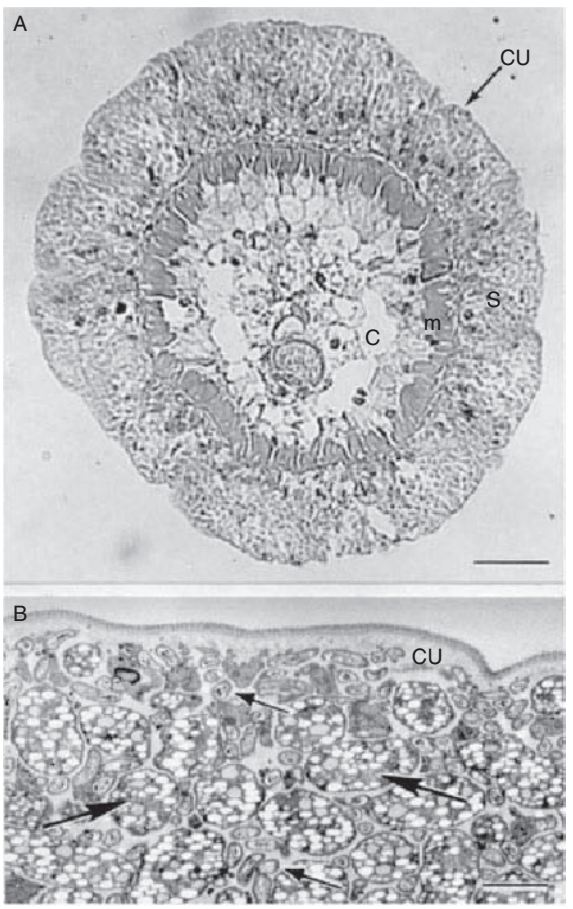

Fig. 7. *Inanidrilus leukodermatus*. (A) Light micrograph of a cross section of an oligochaete worm. (B) Transmission electron micrograph of symbiont-containing region just below the cuticle. Note smaller and larger symbiont morphotypes (smaller and larger arrows, respectively). c, coelomic cavity; m, muscle tissue; s, symbiont-containing region between cuticle and epidermis; cu, cuticle. Scale bars: A, 20 µm; B, 2 µm. From Dubilier et al. (1995), with permission.

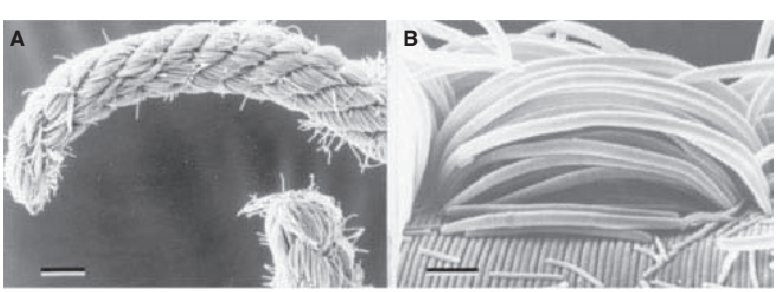

Fig. 6. *Eubostrichus* cf. *parasitiferus*. Scanning electron micrographs showing the symbiotic bacteria on the surface of the nematode. (A) Anterior (bottom) and posterior (top) end with symbionts arranged in a characteristic helix. (B) Higher magnification. Bacteria are attached with both ends to the worm's cuticle. Note the increasing length of the cells from proximal to distal along the worm's surface. Scale bars: A, 20 µm; B, 2 µm. From Polz et al. (1992), with permission.

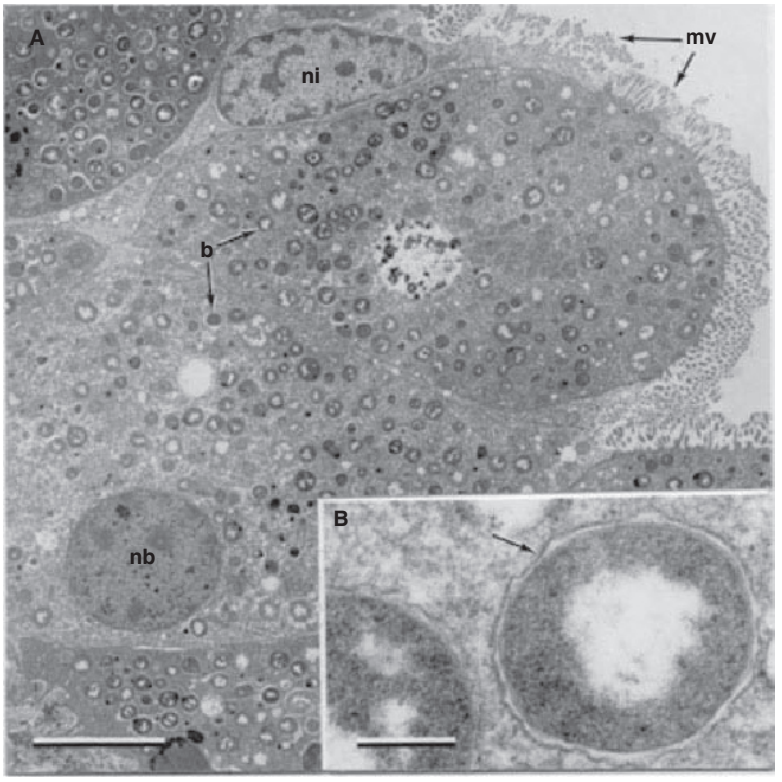

Fig. 8. *Calyptogena magnifica* Boss and Turner (21°N East Pacific Rise). (A) Transmission electron micrograph of slightly oblique transverse section of gill filament, showing coccoid-shaped bacteria within gill bacteriocyte and intercalary cells lacking symbionts; b: bacteria; mv: microvilli (of both cell-types); nb: nucleus of bacteriocyte; ni: nucleus of intercalary cell. (B) Same, higher magnification, transverse section of coccoid-shaped symbionts, showing cell ultrastructure typical of Gram-negative bacteria and peribacterial membrane (arrow). Scale bars: A, 5 μm; B, 0.25 μm. From Cavanaugh (1985), with permission.

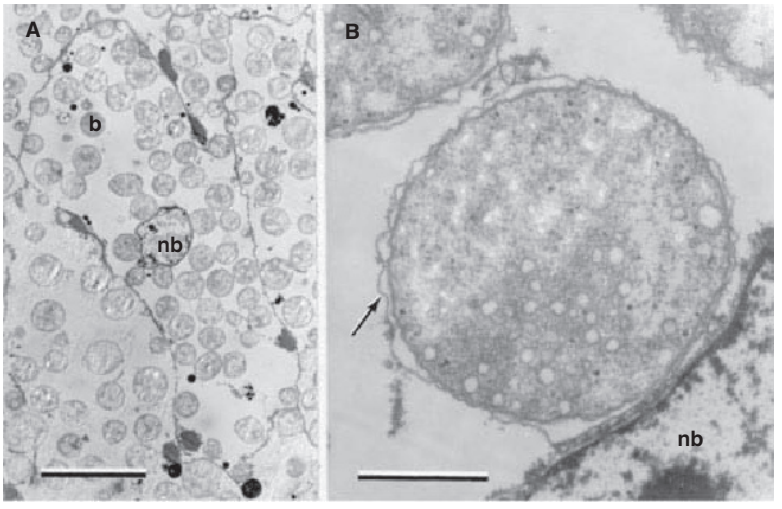

Fig. 9. Escarpia spicata Jones (San Clemente Fault). (A) Transmission electron micrograph, portion of trophosome lobule showing numerous coccoid- to ovoid-shaped bacterial symbionts, some of which appear intracellular. (B) Same, higher magnification, showing bacterial cell envelope (resembling that of Gram-negative bacteria) and intracytoplasmic membrane-bound vesicles; arrow: peribacterial membrane; b: bacteria; nb: nucleus of bacteriocyte. Scale bars: A, 10 μm; B, 1 μm. From Cavanaugh (1985), with permission.

10–13), lucinid clams (Cavanaugh, 1983; Felbeck, 1983a), thyasirid clams (Felbeck et al., 1981b; Cavanaugh, 1983; Arp et al., 1984), vesicomyid clams (Boss and Turner, 1980; Rau, 1981; Arp et al., 1984; Fig. 8), mytilid mussels (Fiala-Médioni, 1984; Le Pennec and Hily, 1984; Figs. 2 and 14), and provannid gastropods (Stein et al., 1988; Windoffer and Giere, 1997). Within certain mollusk families (e.g., Solemyidae, Lucinidae and Thyasiridae), all species examined form symbioses with chemoautotrophic bacteria. In other families, such as the Mytilidae, chemoautotrophic symbionts have been detected only in members of the subfamily Bathymodiolinae, which are found exclusively in the deep-sea. Further, dual symbioses involving both methanotrophs and chemoautotrophs are restricted to species of deep-sea bathymodioline mussels collected from methane seeps and hydrothermal vents (Cavanaugh, 1994; Nelson and Fisher, 1995a; Van Dover, 2000; Fig. 14).

Chemosynthetic bacteria also occur as episymbionts on marine invertebrates (Table 1; Fig. 4). These symbionts include the Epsilonproteo-

Fig. 10. *Solemya* sp. (right hand) collected from deep-sea vent sites (2380 m depth) along the subduction zone off Oregon, and *Solemya velum* (left hand) collected from subtidal reducing sediments (<1 m depth, mean low tide) of Massachusetts eelgrass beds. Photo courtesy of Dr. Ruth D. Turner.

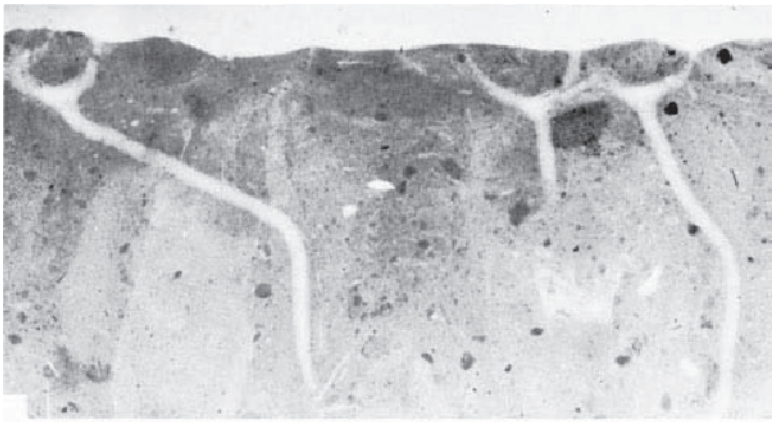

PLATE 3. SOLEMYA

Fig. 11. *Solemya velum*. Characteristic Y-shaped burrows dug by the coastal protobranch clam to bridge the oxic-anoxic interface and access both reduced sulfur (from below) and oxygen (from above). From Stanley (1970), with permission.

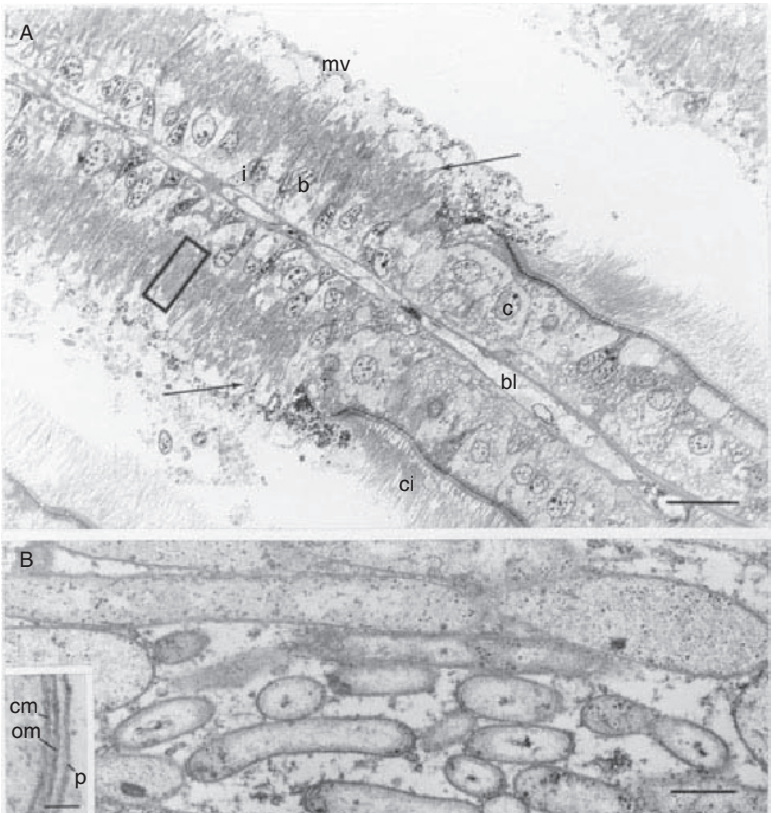

Fig. 12. Solemya borealis. (A) Transverse section of gill filaments showing intracellular rod-shaped bacteria (arrows, rectangle). Bacteriocytes are confined to the region proximal to the ciliated edge of the gill and are flanked by symbiont-free intercalary cells that appear to comprise the microvillar surface of the gill filament. Light micrograph. b: bacteriocyte nucleus; c: ciliated cell nucleus; i: intercalary cell nucleus; bl: blood space; ci: cilia; mv: microvilli. (B) Higher magnification of symbionts showing cell ultrastructure typical of Gram-negative. Inset: Detail of symbiont cell envelope and peribacterial membrane. p: peribacterial membrane; cm: cell membrane; om: outer membrane. Scale bars: A, 20 µm; B, 1 µm; inset, 0.05 µm. From Conway et al. (1992b), with permission.

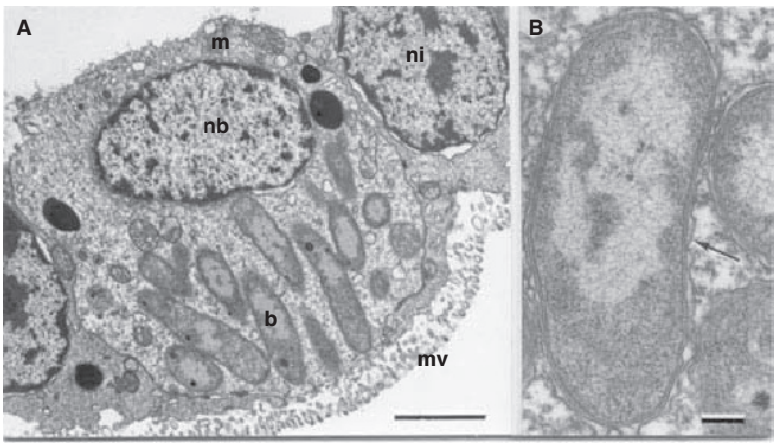

Fig. 13. *Solemya velum*. (A) Transmission electron micrograph, transverse section of gill filament, showing rod-shaped bacteria within gill bacteriocyte and intercalary cells lacking symbionts; b: bacteria; mv: microvilli; nb: nucleus of bacteriocyte; ni: nucleus of intercalary cell. (B) Same, higher magnification, transverse section of rod-shaped bacterium, showing cell ultrastructure typical of Gram-negative bacteria and peribacterial membrane (arrows). Scale bars: A, 3 μm; B, 0.2 μm. From Cavanaugh (1985), with permission.

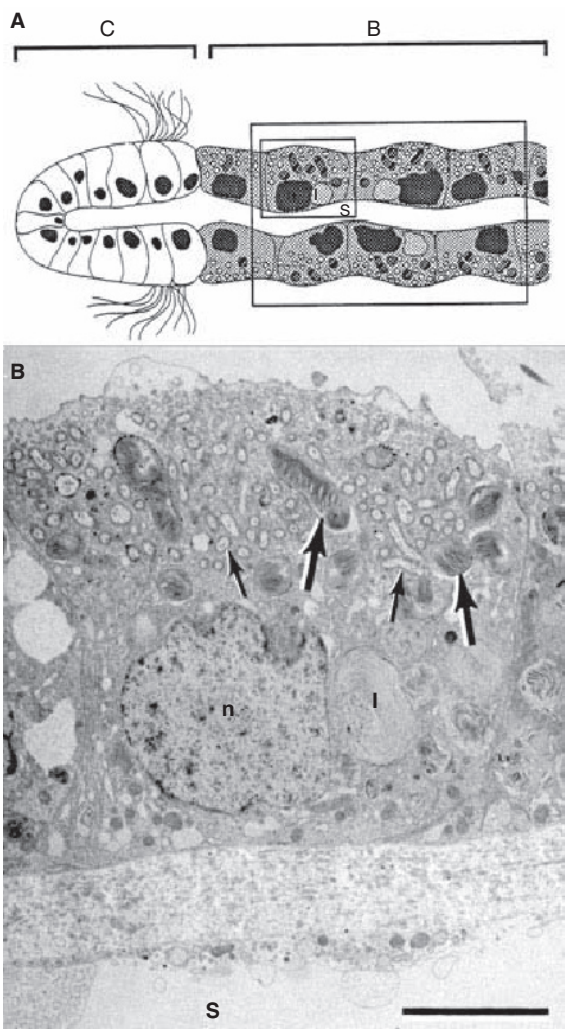

Fig. 14. *Bathymodiolus puteoserpentis*. Transverse section of Mid-Atlantic Ridge (MAR) mytilid gill filament, showing symbiont-containing gill epithelial cells (bacteriocytes). (A) Diagram of gill filament. Bacteriocytes are confined to the region proximal to the ciliated border of the gill. Small box shows positions of Figs. 14B. B: symbiont-containing bacteriocyte region; and C: symbiont-free ciliated region. (B) Transmission electron micrograph. Large and small symbionts (large and small arrows, respectively) are located in the apical region of the cells, while nuclei and lysosomal residual bodies occupy the region closest to the blood sinus. Note centrally stacked intracytoplasmic membranes in large symbionts. 1, Lysosomal residual body; n, bacteriocyte nucleus; and s, blood sinus. Scale bar: 5 μm. From Distel et al. (1995), with permission.

bacteria that cover the cuticle of *Rimicaris* shrimp, dominant members of the metazoan fauna at vents on the Mid-Atlantic Ridge (MAR; Polz et al., 1998) and the Central Indian Ridge (CIR; Van Dover et al., 2001; Van Dover, 2002a), and the surfaces of alvinellid polychaetes (Desbruyères et al., 1985; Cary et al., 1997). Chemosynthetic episymbionts also associate with nematodes (Weiser, 1959; Ott et al., 1991; Polz et al., 1992; Polz et al., 1994) and ciliates

(e.g., Fenchel and Finlay, 1989; Bauer-Nebelsick et al., 1996). In addition, methanotrophic episymbionts have been found living on a deep-sea sponge (Vacelet et al., 1995; Vacelet et al., 1996). Vent limpet-bacteria associations seem to be an intermediate between epi- and endosymbioses; bacteria exist partially embedded in the limpet gill epidermis and may be endocytosed or fed on by the host (de Burgh and Singla, 1984; Bates et al., 2004; Fig. 5). Some epibiont communities, like those residing on the *Rimicaris* shrimp and the nematode *Laxus* sp., are dominated by a single phylotype (Polz et al., 1994; Polz and Cavanaugh, 1995), while others are quite diverse (Polz et al., 1999; Campbell et al., 2003). But given that morphological plasticity often belies the phylogenetic identity of symbionts (Polz et al., 1999; Giere and Krieger, 2001), symbiont diversity estimates are only appropriate when putative symbiont phylotypes are confirmed using hybridization methods (e.g., FISH).

Symbiont Diversity

Morphology and Ultrastructure

Symbiont morphology varies among functional types (chemoautotroph vs. methanotroph), among phylotypes within the same functional group, and among individuals in a population of a single phylotype. The symbionts all have a Gram-negative cell envelope but range from small (ca. 0.25 μm diameter) coccoid endosymbionts within mussel gills (Cavanaugh, 1985; Dubilier et al., 1998) to large (>10 μm length) rod-shaped and filamentous episymbionts on vent shrimp (Hentschel et al., 1993b; Polz and Cavanaugh, 1995; Fig. 4). Some bathymodioline mussels host two metabolically distinct symbionts: small (<0.5 μm) chemoautotrophs and larger (1.5–2.0 μm) methanotrophic bacteria possessing stacked intracytoplasmic membranes, which are typical of Type I methanotrophs (e.g., Childress et al., 1986; Cavanaugh et al., 1987; Cavanaugh et al., 1992; Fiala-Médioni et al., 2002; Pimenov et al., 2002; Fig. 14). Morphological diversity can also occur throughout monospecific populations within a single host animal. For example, populations of sulfur-oxidizing chemoautotrophic symbionts in the tubeworm *Riftia pachyptila* contain distinct morphotypes that vary in abundance depending on location within the trophosome lobule (Bright et al., 2000); small, rod-shaped bacteria occur primarily in the innermost zone of the lobule nearest the host's axial blood vessel, while small and large cocci (1.6–10.7 μm diameter) occupy zones nearer the periphery of the trophosome (Bright et al., 2000). Such variability may relate to differences in the lifecycle stage and metabolism among symbiont cells (Bright et al., 2000).

Symbiont Phylogeny

While chemoautotrophic symbionts have consistently evaded culture, the suite of cellular and molecular methods used to characterize these bacteria has revealed startling evolutionary trends. Investigators have successfully sequenced 16S rRNA genes from symbiont-containing tissue and subsequently confirmed the symbiont origin of these sequences via hybridization with symbiont-specific probes. In contrast to the wide diversity of host taxa involved in these symbioses, chemosynthetic symbionts cluster primarily within a single bacterial division, the Gammaproteobacteria, on the basis of 16S rRNA gene sequences (Distel and Cavanaugh, 1994; Dubilier et al., 1999; McKiness, 2004). Such analyses have also shown that most host species typically form a relationship with a unique symbiont phylotype. But this clearly is not always the case. For example, while strain level variation may occur, vestimentiferan tubeworms belonging to the genera *Riftia*, *Tevnia*, and *Oasisia* appear to share a single, or very similar, symbiont phylotype based on 16S rRNA gene sequences (Feldman et al., 1997; Laue and Nelson, 1997; Di Meo et al., 2000; Nelson and Fisher, 2000; McMullin et al., 2003), as do some species of tropical lucinid clams (Durand and Gros, 1996a; Durand et al., 1996b).

Recently, McKiness (2004) reported phylogenetic analyses of 16S rRNA gene sequences from chemosynthetic symbionts within the Gammaproteobacteria. This study represented the most comprehensive analysis of chemoautotrophic symbionts to date. It included 39 symbiont sequences and over 30 sequences from free-living bacteria representatives of chemoautotrophs, methanotrophs, and marine bacterioplankton. Here, an expanded phylogenetic analysis is presented that includes the Epsilonproteobacteria symbionts of shrimp and alvinellid worms (Fig. 1). This consensus tree illustrates the strong level of resolution afforded by the 16S rRNA gene and shows that almost all of the chemosynthetic symbionts for which sequence data are available cluster into two main clades. The first clade includes symbionts of lucinid and thyasirid clams, solemyid protobranchs, tubeworms, nematodes, and oligochaetes, and the second clade includes the mytilid mussel and vesicomyid clam symbionts.

Though the first clade as a whole has relatively low bootstrap support, smaller clusters within the first clade are strongly supported. For example, the monophyletic cluster of nematode and oligochaete symbionts has 100% bootstrap sup-

port. Similarly, the vestimentiferan tubeworm symbiont clade also has high bootstrap support, corroborating prior evidence that these worms share a single or very similar symbiont phylotype, which is consistent with environmental transmission of symbionts (Feldman et al., 1997; Laue and Nelson, 1997; Di Meo et al., 2000; Nelson and Fisher, 2000; McMullin et al., 2003; see the section Ecology and Evolution in this Chapter). In contrast, the clam symbionts exhibit a more complicated relationship. The lucinid clam symbionts form a paraphyletic group; some are sister to the tubeworm symbionts while others group with thyasirid and solemyid symbionts. The solemyid symbionts show similarly complicated relationships, as they are polyphyletic and scattered throughout the first clade. *Solemya velum* and *S. occidentalis* symbionts cluster with the nematode and oligochaete symbionts, while *S. terraeregina* and *S. pusilla* symbionts cluster with lucinid and thyasirid clam symbionts. Thus, this disjointed distribution does not suggest cospeciation between host taxa and symbionts in this first clade and indicates that there were multiple initiations of symbiosis within the solemyid and lucinid clams.

The position of the *S. reidi* symbiont within this first main group is curious; this symbiont falls at the base of this first main group, clustering with an intracellular pathogen, *Coxiella burnetti*, and an environmental clone from a Japanese cold seep, Gamma JTB254 (discussed further below). This symbiont sequence has held a basal position in other analyses (see Bayesian analysis in McKiness, 2004) and provokes questions concerning the nature of symbiosis in protobranch bivalves. As additional sequences become available, it will be necessary to reassess the position of the *S. reidi* symbiont with respect to other chemoautotrophic symbionts.

The second clade of symbionts, which includes the mytilid mussel and vesicomyid clam symbionts from vents and cold seeps, shows 100% bootstrap support (support for the mussel and vesicomyid clades being 70% and 99%, respectively). The symbiont from the Central Indian Ridge mussel, *Bathymodiolus* aff. *brevior*, falls at the base of the vesicomyid clam symbionts, with 82% bootstrap support. In contrast to the first symbiont clade (Fig. 1, top), evidence suggests that an ancestral symbiont initiated symbioses with both the vesicomyid clams and the bathymodioline mussels and predated the split between these bivalve lineages. On the basis of 16S rRNA gene sequence data, the divergence of the clam and mussel symbionts has been dated to 125–300 million years ago (Mya). This is corroborated by the fossil record, which dates the bathymodioline mussel hosts to 150 Mya and the vesicomyid clams to 100 Mya (Distel, 1998).

The symbionts of the thyasirid clam *Maorhithyas hadalis* occupy unique positions in this phylogenetic framework. On the basis of 16S rRNA sequence data and in situ hybridization, Fujiwara et al. (2001) described two different symbionts within this clam. One of the symbionts shows evolutionary relatedness to the bathymodioline mussel and vesicomyid clam symbionts, occurring basal to the clade containing these bacteria, and the other symbiont clusters with the free-living *Thiomicrospira* spp. This free-living "symbiont" phylotype, however, may be a contaminant. Difficulties with in situ hybridization have precluded attempts to describe the microdistribution of the two symbiont types (Fujiwara and Uematsu, 2002), bringing into question the phylogenetic identity of the clam symbionts.

The phylogenetic positions of the methanotrophic endosymbionts and the filamentous epibionts are shown also in Fig. 1. The methanotrophic symbionts characterized to date all belong to the Gammaproteobacteria, forming a clade with 100% bootstrap support. The sister group of this clade consists of free-living Type I methanotrophs (*Methylococcus*, *Methylobacter* and *Methylomonas* spp.). Given their monophyly, the mussel symbionts apparently arose from a common ancestor. But the question of whether these symbionts subsequently cospeciated with their hosts remains unanswered.

The episymbionts in this analysis include the sulfur-oxidizing Epsilonproteobacteria found on the Mid-Atlantic Ridge shrimp *Rimicaris exoculata* and the eastern Pacific polychaete *Alvinella pompejana.* Interestingly, the shrimp epibiont clusters with the polychaete epibionts despite the fact that *R. exoculata* occurs on the Mid-Atlantic Ridge while alvinellid polychaetes inhabit vents in the eastern Pacific Ocean.

Free-living microorganisms can potentially provide insight into the ancestral form of endosymbionts. For instance, the evolution of insect endosymbionts (e.g., *Wolbachia* and *Buchnera* spp.) is commonly studied by comparative analyses with free-living, closely related microbes (Wernegreen, 2002; Moran, 2003). But until recently, the chemoautotrophic symbiont clades have not included any free-living bacteria. Figure 1 includes two species of bacteria that are not chemoautotrophic symbionts (*Coxiella burnetti* and *Achromatium oxaliferum*) and an environmental clone (JTB254). All three of these sequences fall within the first symbiont clade. *Coxiella burnetii* is an intracellular pathogenic bacterium (Woldehiwet, 2004) and the Gamma JTB254 clone was recovered from a deep-sea cold seep in the Japan Trench (Li et al., 1999). They both fall in a cluster with the *S. reidi* symbiont. Both *C. burnetii* and the *S. reidi* symbionts are able to maintain an intracellular existence in

eukaryotic hosts. *Coxiella burnetii*, however, is capable of growth in animal cell lines (e.g., Woldehiwet, 2004) and pathogenically infects a wide range of hosts (Niemczuk and Kondracki, 2004; Watanabe, 2004; Woldehiwet, 2004). In addition, *A. oxaliferum*, a freshwater sulfur-oxidizing bacterium, falls out with the nematode and oligochaete symbionts clade. *Achromatium oxaliferum* occurs in freshwater sediments along the redox zone where it has access to sulfide and oxygen (Head et al., 1996; Glockner et al., 1999; Gray et al., 1999). As cultivation methods improve and sequences are added to the 16 rRNA gene database, other free-living bacteria that are closely related to symbionts will likely be identified. Indeed, recent studies incorporating 16S rRNA gene sequences from unidentified environmental clones into phylogenetic analyses of free-living and symbiotic bacteria suggest that chemosynthetic symbionts may in fact resolve into three distinct clades (N. Dubilier, personal communication; Duperron et al., 2004). Free-living relatives of chemosynthetic symbionts should reveal much about the ecological and evolutionary constraints on the symbiont as well as about the potential for gene loss during the transition from the free-living to the symbiotic state.

Symbiont Characterization

Enzyme Activities

Researchers routinely demonstrate chemoautotrophy or methanotrophy in symbionts by the activity or presence of diagnostic enzymes. Indeed, given the inability to culture chemoautotrophic symbionts, detection of such enzymes is often the only evidence used to infer symbiont metabolism. This characterization often involves physiological assays using tissue or purified protein extract, immunodetection, or PCR-based gene probing. Such studies were initially conducted on the tubeworm *Riftia pachyptila*. For example, Felbeck (1981a) assayed tubeworm trophosome tissue for the activities of key enzymes of the Calvin cycle, the CO_2-fixing enzyme, ribulose 1,5-bisphosphate carboxylase-oxygenase (RubisCO), and phosphoribulose kinase (PRK) as well as enzymes associated with the oxidation of reduced inorganic sulfur compounds. The activity or presence of RubisCO has subsequently been used to diagnose symbiont autotrophy in a diversity of host species, including all of the chemoautotroph-harboring invertebrates listed in Table 1 (excluding alvinellid polychaetes; see below): shallow water solemyid and lucinid bivalves, vent and seep tubeworms and bivalves (including mussels hosting both methanotrophic and chemoautotrophic symbionts), nematodes, oligochetes, shrimp, sea urchins, and ciliates (Felbeck et al., 1981b; Cavanaugh, 1983; Cavanaugh et al., 1988; Polz et al., 1992; Johnson et al., 1994; Nelson et al., 1995b; Bauer-Nebelsick et al., 1996; Krieger et al., 2000; Elsaied et al., 2002; Fiala-Médioni et al., 2002). While RubisCO has not been detected in the alvinellid epibionts, genes encoding citrate lyase, a key enzyme of the reductive tricarboxylic acid (TCA) cycle, recently have been detected via analyses of symbiont DNA sequences, suggesting that the Epsilonproteobacteria symbionts of alvinellid worms fix carbon via this pathway (Campbell et al., 2003).

Enzymes involved in chemosynthetic energy generation have also been used to characterize these symbionts. Although the sulfur metabolism enzymes are not unique to sulfur oxidation, certain enzymes such as ATP sulfurylase, when detected in high activities, have been used to infer sulfur-based chemolithotrophy (Felbeck, 1981a; Fisher et al., 1993b; Laue and Nelson, 1994). As methane monoxygenase, the enzyme that catalyzes the first step in the oxidation of methane in aerobic methanotrophs, is notoriously labile (Prior and Dalton, 1985; Cavanaugh, 1993), methanol dehydrogenase (MeDH), the enzyme that catalyzes the second oxidation step (i.e., methanol to formaldehyde) and is known to occur only in methylotrophs, has been used extensively to diagnose methanotrophy. MeDH has been detected in gill extracts of mussels hosting methanotrophs or both methanotrophs and thioautotrophs (Cavanaugh et al., 1992; Fisher et al., 1993b; Robinson et al., 1998; Fiala-Médioni et al., 2002; Pimenov et al., 2002; Barry et al., 2002) and in a deep-sea sponge (Vacelet et al., 1996). Such enzymatic evidence strongly suggests methanotrophy, particularly when coupled with ultrastructural observations showing symbionts with the complex intracytoplasmic membranes that are characteristic of Type I methanotrophs.

Stable Isotope Signatures

Carbon Isotopes In addition to enzymology, stable isotope data provided some of the first evidence in support of chemoautotrophy in marine invertebrate-bacteria symbioses (e.g., Rau and Hedges, 1979; Spiro et al., 1986) and continue to be useful in assessing symbiont metabolism and tracking energy and carbon transfer in chemosynthetic symbioses (Colaco et al., 2002; Levin and Michener, 2002; Van Dover, 2002a; Robinson et al., 2003; Scott et al., 2004). Because enzymes involved in distinct carbon fixation pathways discriminate differently against the use of the heavier carbon isotope (^{13}C), the stable

carbon isotope ratio comparing ^{13}C to ^{12}C ($\delta^{13}C$) can be used to help distinguish different autotrophic metabolisms. For example, whereas $\delta^{13}C$ values of marine phytoplankton typically vary between µ18‰ and µ28‰ (Fry and Sherr, 1984; Gearing et al., 1984; Goericke et al., 1994), carbon derived chemosynthetically at vents is either considerably lighter (enriched in ^{12}C), with $\delta^{13}C$ values from µ27‰ to µ35‰, or heavier (depleted in ^{12}C), with values from µ9‰ to µ16‰ (Childress and Fisher, 1992; Robinson and Cavanaugh, 1995; Robinson et al., 2003). Depending on the source of methane, symbioses between mussels and methanotrophic bacteria may be even more depleted in ^{13}C, with $\delta^{13}C$ ranging from µ37‰ to µ78‰ (Cavanaugh, 1993; Nelson and Fisher, 1995a; Barry et al., 2002).

Because consumers generally retain the carbon isotopic signature of their food (i.e., "you are what you eat"; DeNiro and Epstein, 1979), comparisons between $\delta^{13}C$ signatures of symbiont-containing host tissue and symbiont-free host tissue can be used to study the transfer of symbiont-derived carbon to the host. For example, $\delta^{13}C$ values (µ30.8‰ to µ35.8‰) in symbiont-containing gill tissue from the western Pacific vent mussel *Bathymodiolus brevior* were significantly lower than values from symbiont-free foot tissue, suggesting that *B. brevior* supplements its diet via filter feeding on photosynthetically derived carbon (Dubilier et al., 1998). In contrast, other studies show a high dependence on symbiont carbon by host species, including coastal solemyid protobranchs (Fisher and Childress, 1986; Conway and Capuzzo, 1991), thyasirid clams (Dando and Spiro, 1993; Fiala-Médioni et al., 1993), and vestimentiferan tubeworms (Kennicutt et al., 1992), as well as suggest differences in the contribution of methanotrophs and chemoautotrophs to host carbon in mussels containing dual symbioses (Cavanaugh, 1993; Trask and Van Dover, 1999; Fiala-Médioni et al., 2002; Yamanaka et al., 2003).

Stable carbon isotope signatures have also been used to detect chemosynthetic symbioses in fossil bivalves of the clam family Lucinidae, whose extant members all host chemosynthetic symbionts. CoBabe (1991), by determining the $\delta^{13}C$ values of organic matrix material extracted from lucinid fossils dating to ca. 120,000 ya, showed that fossilized lucinid (*Epilucina* sp.) shells ($\delta^{13}C$ = µ25‰) were about 5‰ lighter than values from other bivalves collected in the same deposit (Pt. Loma, CA). Also, the organic matter of lucinid fossils was similar to that from modern samples, implying that the fossil organic matrix did not decay or change significantly over time. These results, along with strong evidence showing that shell $\delta^{13}C$ values are reasonable proxies for tissue values in extant species, suggest that the fossil lucinid hosted chemosynthetic symbionts ca. 120,000 ya (CoBabe, 1991). Thus, stable carbon isotope analysis may be an effective tool for tracing the evolution of chemosynthetic symbioses in the fossil record.

One of the main factors affecting stable carbon isotope signatures of chemoautotroph-invertebrate symbioses appears to be the form of RubisCO used by the symbionts. While $\delta^{13}C$ values for vent bivalves hosting sulfide-oxidizing symbionts cluster between µ27‰ and µ35‰ and resemble values for free-living chemoautotrophic bacteria, values for vent tubeworms, shrimp episymbionts, and many free living bacterial mats at vents are significantly heavier, ranging from µ9‰ to µ16‰ (Childress and Fisher, 1992; Van Dover and Fry, 1994; Robinson and Cavanaugh, 1995; Cavanaugh and Robinson, 1996; Robinson et al., 2003). The difference between these groups relates to the form of RubisCO used to fix CO_2 by the symbionts, with form I RubisCO occurring in most members of the isotopically lighter group and form II in all members of the heavier tubeworm group (Robinson and Cavanaugh, 1995). Corroborating this hypothesis, Robinson et al. (2003) showed that the kinetic isotope effect (ε value), the relative rate of $^{13}CO_2$ to $^{13}CO_2$ fixation ($^{12}k/^{13}k$) and a measure of discrimination against ^{13}C by the purified RubisCO enzyme in vitro, is significantly lower for form II RubisCO from *Riftia pachyptila* symbionts (ε = 19.5‰) than for the form I enzyme (ε = 22–30‰). Such variation may have arisen from evolution under differing concentrations of CO_2 and O_2 (Robinson et al., 2003).

But isotopic discrimination by RubisCO does not fully account for ^{13}C-enrichment in these symbioses. For example, to explain the discrepancy in *R. pachyptila* biomass $\delta^{13}C$ values, Scott (2003) used a mass balance model to show that steep gradients in [CO_2] among symbiont, host, and environmental pools may drive ^{13}C enrichment. RubisCO, which occurs in the symbiont cytoplasm, preferentially fixes $^{12}CO_2$, leaving $^{13}CO_2$ behind. If fixation is rapid, CO_2 equilibration between the isotopically lighter host cytoplasm and the isotopically heavier symbiont cytoplasm cannot occur, causing RubisCO to draw from a more enriched $^{13}CO_2$ pool and accounting for the relatively heavy $\delta^{13}C$ of tubeworm biomass. Further, stable carbon isotope values are also affected by the $\delta^{13}C$ of the environmental carbon pool (Fisher, 1995; Colaco et al., 2002). Scott et al. (2004) demonstrated that the "light" $\delta^{13}C$ values of the symbionts of the coastal protobranch clam *Solemya velum* are explained not only by the kinetic isotope effect of symbiont form I RubisCO (ε = 24.5‰) but also by the $\delta^{13}C$ value of the CO_2 in the sediment.

Similarly, the source of methane production can significantly impact the isotopic signature of methanotroph symbioses (Fisher, 1995; MacAvoy et al., 2002). The $\delta^{13}C$ of methane varies considerably depending on whether it is produced thermogenically ($\delta^{13}C$ of CH_4 >μ45‰) or biologically by methanogens ($\delta^{13}C$ of CH_4 <μ60‰; Lilley et al., 1993; Fisher, 1995), and this variability is reflected in the $\delta^{13}C$ values of chemosynthetic symbioses (Fisher, 1995). Therefore, in instances where the $\delta^{13}C$ of the source methane is unknown, conclusions about the contribution of methanotrophic symbionts to host $\delta^{13}C$ values should be interpreted with caution (Fisher, 1995). In addition, interpreting $\delta^{13}C$ signatures may be especially problematic for dual symbioses in which both methanotrophic and thioautotrophic symbionts co-occur in the same host cell. In these symbioses the $\delta^{13}C$ values of the symbionts and the host reflect a mix of methanotrophic and thioautotrophic metabolism (Fisher, 1995). These signatures are potentially confounded in instances when the thioautotrophic symbionts use the CO_2 respired by the methanotrophs, resulting in a second discrimination against an already light pool of CO_2 and an anomalously light tissue $\delta^{13}C$ value (Fisher, 1993a).

Thus, while $\delta^{13}C$ values often provide the first evidence that chemoautotrophic or methanotrophic symbioses occur in certain animal species, researchers must recognize that $\delta^{13}C$ is inherently responsive to physical, environmental and enzymatic factors. Stable carbon isotope signatures therefore should not be used apart from other corroborating evidence (e.g., physiological and enzyme activity assays and genetic characterization) to identify carbon fixation pathways or methane oxidation in chemosynthetic symbioses (Fisher, 1995; Scott, 2003; Scott et al., 2004).

Sulfur and Nitrogen Isotopes In addition to carbon isotopes, stable isotopes of sulfur and nitrogen are also used to study sources and metabolism of these elements in symbioses. The extent to which different sources of reduced sulfur—geothermal production in vent fluid or microbial sulfate reduction in bottom sediment—support thioautotrophic metabolism has been inferred from the $\delta^{34}S$ value of biological samples. Such analyses revealed hydrothermally derived sulfide as the dominant sulfide source for deep-sea vent symbioses (Fry et al., 1983; Yamanaka et al., 2003). In contrast, symbiotic bacteria within a shallow water vestimentiferan tubeworm, *Lamellibrachia satsuma* (Miura et al., 2002), and the protobranch, *Solemya velum* (Conway et al., 1989), rely predominantly on sulfide derived from microbial sulfate reduction.

Similarly, $\delta^{15}N$ values, because they vary predictably and largely between producer and consumer trophic levels (increase of ca. 3.4 per level), are particularly useful markers for studying aquatic food web interactions (Minagawa and Wada, 1984). In general, $\delta^{15}N$ values of chemoautotrophic organisms are significantly lighter (<0‰; Van Dover and Fry, 1994) than values for photosynthetic organisms (>6‰; see Michener and Schell [1994] and Fisher [1995]). Researchers have used this discrepancy and the predictable trophic level fractionation of ^{15}N to show host reliance on symbiont-derived organic matter in a number of symbioses including the coastal clams *Solemya velum* and *S. borealis* (Conway et al., 1989; Conway et al., 1992b) and in vent mussels from the Mid-Atlantic Ridge (MAR) and the Galapagos Rift (Fisher et al., 1988; Trask and Van Dover, 1999). In addition, $\delta^{15}N$ values have been used extensively in conjunction with $\delta^{13}C$ values to show the flow of chemosynthetically derived organic matter through vent food webs, including those on the MAR (Vereshchaka et al., 2000; Colaco et al., 2002), the Central Indian Ridge (Van Dover, 2002a), and the Galapagos Rift (Fisher et al., 1994). As with $\delta^{13}C$ data, $\delta^{15}N$ values vary considerably among sites; $\delta^{15}N$ may depend in part on the $\delta^{15}N$ of the dissolved inorganic nitrogen (DIN) pool, the proportions and $\delta^{15}N$ values of different components (NH_4^+, $NO_3^{\mu 2}$, NO_2^{μ}, and urea) in the DIN pool (Waser et al., 1998; Colaco et al., 2002), the uptake kinetics of different DIN assimilation pathways (Waser et al., 1998; Krueger, 1996a), and, as shown for vent shrimp (Vereshchaka et al., 2000) and mussels (Trask and Van Dover, 1999), the ontogenetic stage of the host. Therefore, as noted above with stable carbon isotopes, in the absence of additional enzymatic, genetic and environmental data, caution must be used when comparing $\delta^{15}N$ values from different habitats and species.

Ecophysiology

Symbioses between chemosynthetic bacteria and marine invertebrates must acquire all of the substrates necessary for chemosynthetic metabolism: reduced sulfur or methane, oxygen, dissolved inorganic carbon (DIC, as CO_2 or CH_4), and other nutrients (e.g., nitrogen and phosphorus) for use in biosynthesis. In particular, to support energy generation, these symbioses must obtain substrates from both oxic and anoxic environments. To meet these demands, the host-symbiont association relies on specialized biochemistry, physiology and behavior. These adaptations are best studied in thioau-

totrophic endosymbioses and are discussed primarily within this context below.

Spanning the Oxic-Anoxic Interface

Access to both oxygen and reduced chemicals is necessary for aerobic respiration by chemosynthetic symbionts. Specifically, thioautotrophs shuttle electrons from reduced sulfur (e.g., sulfide) to a terminal electron acceptor during oxidative phosphorylation, generating a proton gradient that drives ATP synthesis. Though some thioautotrophic symbionts (such as those in the tubeworm *Riftia pachyptila* [Hentschel and Felbeck, 1993a] and the clam *Lucinoma aequizonata* [Hentschel et al., 1993b]) may use nitrate as an electron acceptor during periods of anoxia, most thioautotrophic symbionts typically use molecular oxygen for respiration. Similarly, methanotrophs must obtain oxygen for respiration as well as methane for both energy generation (via methane oxidation) and carbon assimilation (Anthony, 1982).

This dual requirement for oxygen and reduced compounds poses unique problems for thioautotrophs and methanotrophs. First, these organisms must obtain energy substrates from mutually exclusive environments—oxygen is absent or at very low levels in the anoxic zones from which sulfide or methane is typically obtained. Second, sulfide, the predominant energy source for thioautotrophy, spontaneously reacts with oxygen to form less-reduced sulfur compounds (S^0, $S_2O_3^{\mu 2}$, or $SO_4^{\mu 2}$; Zhang and Millero, 1993), thereby decreasing the availability of substrates for thioautotrophy. Though such abiotic oxidation may be several orders of magnitude slower than biological sulfide oxidation (Millero et al., 1987; Johnson et al., 1988), thioautotrophic symbioses must still compete with oxygen for free sulfide. Also, in habitats containing both sulfide and methane, abiotic oxidation of sulfide may limit the oxygen available for methanotrophy. These limitations force free-living thioautotrophs and methanotrophs into microaerophilic zones at the interface, or chemocline, between oxic (e.g., water column) and anoxic (e.g., vent fluid and sediment pore water) habitats. Such free-living bacteria demonstrate unique mechanisms to support life at the oxic-anoxic interface; these adaptations may be behavioral (e.g., tracking the chemocline via gliding by *Beggiatoa*), anatomical (e.g., keeping cells in the chemocline via "veil" formation by *Thiovulum* or creation of a filamentous sulfur matrix by *Arcobacter*), biochemical (e.g., internal or external sulfur deposition that serves as an electron source or sink when sulfide or oxygen is limiting, as by *Beggiatoa* and *Arcobacter*), or developmental (e.g., resting stage formation by methanotrophs; Table 2 and references therein).

Table 2. Adaptations of thioautotrophs and methanotrophs for life at oxic-anoxic interfaces.[a]

Adaptation	Example
Attachment	*Thiothrix*
Motility, chemotaxis	*Beggiatoa Thioploca*
Elemental sulfur deposition	*Beggiatoa Thiothrix*
Nitrate and sulfur storage	*Thiomargarita Thioploca*
Create own interface	*Thiovulum*
Filamentous sulfur production	*Arcobacter* sp.
Resting cysts	Methanotrophs
Associate with eukaryote	Thioautotroph and Methanotroph symbionts

[a]From Anthony (1982), Jørgensen and Postgate (1982), Cavanaugh (1985), Schulz et al. (1999), and Wirsen et al. (2002).

Symbiosis thus may be viewed as an adaptation to simultaneously obtain sulfide (or methane) and oxygen from anoxic-oxic interfaces, allowing thioautotroph or methanotroph symbionts, via association with a eukaryotic host, to circumvent many of the problems of sulfide acquisition (Cavanaugh, 1985). Similarly to free-living sulfur bacteria, thioautotrophic symbioses use specialized behavioral, anatomical or physiological mechanisms, either to spatially or temporally bridge sulfidic and oxic zones or to simultaneously sequester sulfide and oxygen (Cavanaugh, 1994; Fisher, 1996; Polz et al., 2000). For instance, the cold seep vestimentiferan tubeworm *Lamellibrachia* cf. *luymesi* acquires oxygen via its anterior plume while extending a posterior section of its tube (the root) deep into the sediment to acquire sulfide (Julian et al., 1999; Freytag et al., 2001). Similar burrowing tactics occur in some species of symbiont-containing thyasirid clams, which possess a superextensile foot (up to 30 times the length of the shell) that burrows into the sediment to access hydrogen sulfide (Dufour and Felbeck, 2003), and in protobranchs of the genus *Solemya*, which dig Y-shaped burrows in reducing sediments to allow simultaneous pumping of oxygenated water from above and sulfide-rich pore water from below (Stanley, 1970; Cavanaugh, 1983; Fig. 11). Also, shrimp, nematodes and oligochaetes migrate vertically along the oxygen-sulfide gradient or between separate oxic and anoxic zones, thereby enabling their symbionts to simultaneously access both energy substrates or to store reduced sulfur compounds for later oxidation (Polz et al., 2000).

The vent tubeworm *Riftia pachyptila* possesses a remarkable biochemical adaptation to simultaneously acquire sulfide and oxygen. *R. pachyptila* produces coelomic and vascular hemoglobins that, in contrast to most invertebrate and verte-

brate hemoglobins, can bind oxygen in the presence of sulfide (Arp et al., 1985; Arp et al., 1987; Childress et al., 1991; Zal et al., 1996). *R. pachyptila* appears to preferentially take up HS^{μ} from the surrounding fluid, despite a large H_2S gradient from tubeworm blood to the environment (Goffredi et al., 1997a). The HS^{μ} diffuses across the plume of the worm (Goffredi et al., 1997a) and then binds reversibly and independently of O_2 at two free cysteine residues, each located on a distinct globin type (Zal et al., 1997; Zal et al., 1998; Bailly et al., 2002). These residues are well conserved in both symbiont-containing and symbiont-free annelids from sulfidic environments but are absent in annelids from sulfide-free habitats (Bailly et al., 2002; Bailly et al., 2003). Bailly et al. (2003) suggest that the sulfide binding function may have been lost via positive selection, if the sulfide-binding cysteine residues react disadvantageously with other blood components in the absence of sulfide.

Extracellular hemoglobins that simultaneously bind sulfide and oxygen are absent in most other marine invertebrates that host sulfide-oxidizing symbionts (Weber and Vinogradov, 2001); such organisms have evolved other mechanisms for regulating sulfide toxicity and delivery. For instance, the vesicomyid clam *Calyptogena magnifica* synthesizes a di-globular, non-heme molecule that readily binds free sulfide within the blood serum, perhaps via zinc residues (Arp et al., 1984; Zal et al., 2000). Also, several thioautotroph-containing species, including the vent mussel *Bathymodiolus thermophilus* and the coastal clam *Solemya velum*, appear to mediate detoxification in part by storage of sulfur in amino acids (e.g., taurine and thiotaurine; Conway and Capuzzo, 1992a; Pruski et al., 2000a; Joyner et al., 2003; Pruski and Fiala-Médioni, 2003). Indeed, thiotaurine may be used effectively as a biomarker of thioautotrophic symbioses (Pruski et al., 2000b).

Other host organisms, including some bivalve mollusks, apparently avoid sulfide toxicity via mitochondrial oxidation of sulfide. Powell and Somero (1986) first demonstrated mitochondrial sulfide oxidation in the coastal protobranch *S. reidi*. The authors showed that mitochondria isolated from the gill and foot of *S. reidi* exhibit ADP-stimulated oxygen uptake and ATP synthesis following the addition of sulfide. On the basis of the effects of cytochrome and reduced nicotinamide adenine dinucleotide (NADH) oxidase inhibitors, electrons from sulfide oxidation appear to enter the respiratory chain at cytochrome *c* in *S. reidi* mitochondria (Powell and Somero, 1986). Further characterization of this system using ^{35}S showed that sulfide is oxidized exclusively to thiosulfate (O'Brien and Vetter, 1990), a nontoxic intermediate that can function as the energy source in symbiotic carbon fixation. Subsequently, researchers have demonstrated mitochondrial sulfide oxidation across a wide range of organisms, including polychaete worms, clams, fishes and chickens (Grieshaber and Volkel, 1998; Yong and Searcy, 2001). These data lend credence to the hypothesis that mitochondria evolved from sulfide-oxidizing endosymbiotic bacteria (Searcy, 1992).

Readers should consult several additional reviews (e.g., Cavanaugh, 1994; Fisher, 1996; Polz et al., 2000) for a more extensive discussion of the remarkable adaptations used by chemoautotrophic symbioses to sequester both oxygen and reduced chemicals across oxic-anoxic zones.

Carbon Uptake and Transport

In addition to oxygen and reduced sulfur compounds, thioautotrophic symbionts utilizing the Calvin cycle require CO_2 for autotrophic carbon fixation. Acquisition of CO_2 is not trivial given that relative concentrations of the three distinct chemical species (CO_2, HCO_3^{μ} and $CO_3^{\mu 2}$) in the dissolved inorganic carbon (DIC) pool can vary considerably depending on pH (pK_a of 6.4 for $CO_2 : HCO_3^{\mu}$ at 25°C; see the section Habitat Chemistry in this Chapter). In general, the majority of DIC in seawater (pH ~ 8.0) is HCO_3^{μ}. But at vents the typically lower pH of the mixed vent fluid and ambient bottom water generates higher concentrations of CO_2, giving organisms that use the Calvin cycle a distinct advantage.

The tubeworm *Riftia pachyptila* provides an interesting model in which to study the uptake and transport of DIC. Goffredi et al. (1997b) demonstrated that for *R. pachyptila*, pH plays an important role in DIC uptake. The acidity of diffuse vent fluid (pH ca. 6) around tubeworms ensures that CO_2 (pK_a of 6.1 at in situ temperature and pressure of ca. 10°C and 101.3 kPa; Dickson and Millero, 1987) is the dominant DIC form in the vent environment. This contrasts with the vascular fluid of the worm, which has an alkaline pH of 7.1–7.5, apparently because of the action of H^+-ATPases (Goffredi et al., 1999; Goffredi and Childress, 2001; Girguis et al., 2002). The alkaline pH inside *Riftia* results in rapid conversion of CO_2 to HCO_3^{μ}, which, because of its negative charge, cannot diffuse out of the worm; this in effect creates a bicarbonate "trap" (Childress et al., 1993). Thus, a gradient of higher external [CO_2] to lower internal [CO_2] develops across the tubeworm plume and drives diffusion of DIC into the blood (Childress et al., 1993; Goffredi et al., 1997b; Scott, 2003). Following diffusion into the plume, DIC (as CO_2 and HCO_3^{μ}) is transported by the vascular system to the symbiont-containing trophosome. Here, carbonic anhydrase, the enzyme that reversibly con-

verts CO_2 into HCO_3^{μ} in both prokaryotes and eukaryotes, may play a role in converting HCO_3^{μ} into CO_2, the DIC species used by RubisCO (Kochevar and Childress, 1996; De Cian et al., 2003a; De Cian et al., 2003b). As discussed above for *Riftia*, DIC incorporation into symbiont biomass occurs via CO_2 fixation by a form II RubisCO of the Calvin-Benson cycle. Rapid CO_2 fixation rates create steep internal [CO_2] gradients between symbiont and host cytoplasm that may, in combination with the relatively low discrimination of form II RubisCO against ^{13}C, result in a ^{13}C-enriched signature of symbiont and host biomass (Robinson et al., 2003; Scott, 2003).

In chemosynthetic endosymbioses the host benefits by obtaining part or all of its nutrition from the symbiont, via two potential transfer mechanisms: the host may assimilate autotrophically fixed carbon that has been released by the symbiont and translocated to host cells in the form of soluble organic molecules, or the host may directly digest bacterial cells. Radiotracer analysis and microscopy have proven particularly useful in studying host nutrition. For example, Fisher and Childress (1986) showed a rapid (within hours) appearance of radiolabeled carbon in the symbiont-free tissues of the host clam *Solemya reidi* following exposure to ^{14}C-labeled bicarbonate, suggesting release of fixed carbon by the symbiont population. In contrast, a slow (1–5 days) transfer of labeled organic carbon from methanotroph-containing tissue to symbiont-free tissue of a seep mussel exposed to ^{14}C-labeled methane was inferred to be due to initial $^{14}CH_4$ incorporation by the symbionts with host digestion of symbionts occurring later (Fisher and Childress, 1992). Electron microscopy showing symbionts being degraded in the basal region of bacteriocytes in other methane-based and dual chemoautotroph-methanotroph mussel symbioses supports this interpretation (Cavanaugh et al., 1992; Barry et al., 2002), as does the detection of lysosomal enzymes in the gills of the vent bivalves *Calyptogena magnifica* and *Bathymodiolus thermophilus* (Fiala-Médioni et al., 1994; Boetius and Felbeck, 1995) and the shallow water clam *Lucinoma aequizonata* (Boetius and Felbeck, 1995).

In the *R. pachyptila* tubeworm symbiosis, the transfer of carbon from symbiont to host appears to occur via both translocation and digestion (Bright et al., 2000). Felbeck (1985) and Felbeck and Turner (1995) documented a rapid (within seconds) appearance of labeled succinate and malate in trophosome tissue and in vascular and coelomic blood following exposure of whole worms (in pressure vessels) and plumes to ^{14}C-bicarbonate. Subsequently, Felbeck and Jarchow (1998) showed that succinate, malate, and several other organic acids and sugars were excreted by purified suspensions of *R. pachyptila* symbionts, suggesting that these simple organic compounds might be important intermediates in the transfer of fixed carbon from symbionts to host. Corroborating these data, Bright et al. (2000), using pulse labeling analysis, showed that the bulk of organic carbon assimilated into *R. pachyptila* tissue is first released by metabolically active bacteria at the center of a trophosome lobule. However, these authors also showed that a smaller fraction of host carbon is obtained by digestion of bacterial cells at the lobule periphery (Bright et al., 2000). This evidence for digestion is supported by prior studies showing degenerative stages of bacteria within the *R. pachyptila* trophosome (Bosch and Grassé, 1984; Hand, 1987). In addition, relatively high lysozyme activity in *Riftia* tissue further suggests that digestion of symbionts plays a role in tubeworm nutrition (Boetius and Felbeck, 1995).

Nitrogen

The partners in a symbiosis must also acquire all of the other macro- and micronutrients, particularly nitrogen and phosphorus, for use in the biosynthesis of organic compounds. Currently, very little is known about how various forms (inorganic and organic) of phosphorus are transferred to and among different pools within chemoautotrophic endosymbioses. Most studies have focused on nitrogen metabolism, using a combination of enzyme characterizations and physiological experiments to elucidate nitrogen assimilation pathways. Nitrate ($NO_3^{\mu 2}$), which is abundant at vents (in situ concentrations of ~40 μM; Johnson et al., 1988), appears to be the predominant nitrogen source for vent symbioses. For example, Lee et al. (1999) demonstrated the activity of nitrate reductase, a bacterial enzyme involved in converting nitrate to ammonia for either assimilatory or respiratory purposes, in the vent tubeworms *Riftia pachyptila* and *Tevnia jerichonana* and the mussel *Bathymodiolus thermophilus*. In addition, the ammonia assimilation enzymes glutamine synthetase (GS) and glutamate dehydrogenase (GDH) were detected in these symbioses, and almost all GS activity in symbiont-containing tissue was shown to be due to enzyme produced by the bacterial symbiont and not the host (Lee et al., 1999). Supporting these data, physiological experiments on *R. pachyptila* kept in pressurized chambers showed that the symbiont population reduces nitrate to ammonia not for respiratory purposes but for incorporation into both symbiont and host biomass (Girguis et al., 2000). However, in *R. pachyptila,* high GS activity also occured in symbiont-free branchial plume tissue, suggesting

that the host may also be involved in assimilation of ammonia from the vent environment (Minic et al., 2001). But further enzymatic characterization of *Riftia* tissues demonstrated that the tubeworm depends on its symbionts for the de novo synthesis of pyrimidine nucleotides (Minic et al., 2001) as well as for the biosynthesis of polyamines (Minic and Herve, 2003), suggesting that the trophosome is a primary site for nitrogen assimilation and metabolism.

In contrast, in the thioautotrophic symbiosis involving the shallow-water clam *Solemya reidi*, inorganic nitrogen is readily assimilated in the form of ammonia (Lee and Childress, 1994), which is abundant in the shallow water, nutrient-rich habitats of the clam (e.g., sewage outfalls). Ammonia incorporation rates are highest in the symbiont-containing gill tissue, and the sulfur-containing amino acid taurine appears to be a major end product of ammonia assimilation (Lee et al., 1997). The mechanisms by which chemosynthetic symbionts, particularly those contained within the cells of invertebrate hosts (such as *Solemya* and *Riftia*), acquire all of the other macro- and micronutrients for biosynthesis have yet to be characterized.

Ecology and Evolution

History

Prior to the use of molecular techniques, researchers considered vent taxa to be relic species. These organisms, whose strange morphologies suggest a primitive state, purportedly survived past extinction events due to the relative isolation of vents from the photic zone (McArthur and Tunnicliffe, 1998). This perception of vents as ancient ecosystems is supported by the fossil record, which shows that over 80% of vent species are found only at vent sites (Tunnicliffe, 1991; Tunnicliffe, 1992; Little et al., 1997; Little and Vrijenhoek, 2003) and that the oldest vent site dates to the Silurian (~430 Mya; Little et al., 2004). But the fossil record for vents is relatively poor. There are only 19 known fossilized vent sites on the planet, perhaps because calcium carbonate structures dissolve relatively quickly in vent fluids (Hunt, 1992; Kennish and Lutz, 1999). Also, studying vent fauna evolution based on the morphological characters of fossils is problematic if much of the specimen has degraded or if the preserved character is plastic or isomorphic. In particular, vestimentiferan tubeworms are known for the phenotypic plasticity of their tubes (Southward et al., 1995; Black et al., 1998).

In contrast, molecular evidence suggests that vent taxa evolved more recently (22–150 Mya; later-Mesozoic and Cenozoic) and suggests an alternative hypothesis to vent taxa as living relics: vents were recently populated from shallow seeps or whale falls (Van Dover et al., 2002b; Hurtado, 2002). Indeed, the communities most similar to those of vents occur at seeps. Compared to the spatially and temporally patchy distribution of vent fossils (with most being concentrated in the Silurian and Devonian rocks of the Ural mountains), seep fossils are ubiquitous (Little and Vrijenhoek, 2003). At least 50, and perhaps as many as 200, fossilized seep sites dating from the Devonian to the Pleistocene have been uncovered. These specimens are much better preserved than most vent fossils and include extant vent taxa not yet uncovered at fossil vent sites (e.g., vesicomyids, thyasirids, mytilids and solemyids; Little and Vrijenhoek, 2003). This greater diversity supports the seeps-to-vents hypothesis. However, opponents argue that the vent fossil record has been greatly affected by high calcium carbonate dissolution rates (Little and Vrijenhoek, 2003).

While the discrepancy between the evolutionary histories suggested by the fossil and molecular evidence needs to be resolved, it must also be stressed that these data are not evidence for chemosynthetic symbioses. In a unique study, CoBabe (1991) was able to deduce a chemosynthetic symbiosis by analyzing the organic matrix from fossil lucinid shells using stable carbon isotopes. This result is encouraging and suggests that both the age of these organisms and their symbiosis can be addressed using current methods.

Organism Interactions

In the relatively featureless and nutrient poor deep sea, vent and seep environments are ecological oases (Laubier, 1989). Initially, free-living chemoautotrophic bacteria were hypothesized to provide the bulk of primary production in these communities (Lonsdale, 1977). Indeed, at some vent sites, suspended bacteria or bacteria in surface-attached mats are a large food source for higher trophic levels (Humes and Lutz, 1994; Van Dover, 2000). But the dominant strategy for the major vent and seep fauna is symbiosis with chemoautotrophic bacteria (Cavanaugh, 1994), and these symbioses significantly influence the ecology of the nonsymbiotic community. Not only are chemosynthetic symbioses a major and stable source of organic carbon (Sarrazin and Juniper, 1999), but as biogenic structures, they also provide living space for a diversity of species in an otherwise two-dimensional landscape of basalt or sediment (Bergquist et al., 2003). For example, the tubes of chemosynthetic vestimentiferans support mussels, sponges and limpets,

many of which host their own chemosynthetic symbionts (Yamamoto et al., 2002; Bergquist et al., 2003; Bates et al., 2004).

Vent symbioses may also significantly impact the free-living bacterial community by providing increased surface area for attachment. Free-living bacteria that cluster phylogenetically with known chemoautotrophic and heterotrophic groups have been isolated from tubeworm surfaces (Lopez-Garcia et al., 2002; Yamamoto et al., 2002). On the Mid-Atlantic Ridge, a single phylotype of shrimp episymbionts, which appear to be transmitted among hosts via the environment, represented over 60% of the free-living bacteria (Polz and Cavanaugh, 1995). This suggests that the host inoculates inanimate surfaces continuously, increasing the probability of symbiont attachment relative to the free-living community (Polz and Cavanaugh, 1995). Such environmental inoculation may also occur in tubeworm and lucinid clam symbioses, in which the symbionts also appear to be transmitted environmentally (Durand and Gros, 1996a; Durand et al., 1996b; Di Meo et al., 2000; Nelson and Fisher, 2000; McMullin et al., 2003).

Transmission Strategies and Effects on Symbiosis

The transmission strategy of a symbiosis reveals much about the evolutionary dynamics between host and symbiont. Symbiont transmission can occur environmentally (through a free-living population of symbiotic bacteria), horizontally (between contemporary organisms sharing the same habitat), or vertically (from parent to offspring). Vertically transmitted endosymbionts are effectively disconnected from their free-living counterparts. These symbionts experience elevated rates of mutation and fixation of slightly deleterious alleles because of genetic drift (Wernegreen, 2002). For the most part, these evolutionary effects are due to a vastly different selective regime inside the host and a severely depreciated population size (Ohta, 1973); endosymbionts undergo a population bottleneck upon host colonization and another upon transmission (Mira and Moran, 2002). But the asexuality and lack of recombination in endosymbionts exacerbate these genetic problems through what is known as "Muller's rachet" (Muller, 1964; Moran, 1996). In Muller's ratchet, wildtype recombinants cannot be introduced into the endosymbiont population (Moran and Baumann, 1994; Dale et al., 2003); genetic drift therefore occurs quickly, and the population cannot recover after fixation of deleterious alleles.

In contrast, symbiont populations that are environmentally transmitted are effectively larger and more genetically heterogeneous than populations transmitted vertically. Comparisons of 16S rRNA gene evolution between free-living bacteria, in which significant recombination occurs (Dykhuizen and Green, 1991; Levin and Bergstrom, 2000), and symbiotic chemosynthetic bacteria revealed unexpected differences in rates of evolution depending on mode of transmission (Peek et al., 1998). While chemoautotrophic, maternally transmitted endosymbionts did exhibit rapid evolutionary rates, consistent with their small population sizes, environmentally transmitted symbionts evolved more slowly than their free-living counterparts (Peek et al., 1998). The authors suggest that this slower rate of evolution could be caused by purifying selection in a large population. These results, however, were based on one gene across many lineages; a true genomic analysis of evolution in chemosynthetic endosymbionts is necessary to extend these findings.

Because chemosynthetic symbionts have yet to be cultured and their hosts are difficult to maintain in the laboratory, the transmission strategy of a symbiosis has been inferred by phylogenetic analysis or PCR-based detection of bacteria in host reproductive tissues or gametes. If the symbionts are maternally transmitted and the symbioses stable, congruence of host and symbiont phylogenies should occur (e.g., Chen et al., 1999; Thao et al., 2000; Degnan et al., 2004) and bacterial symbionts should be found in ovaries or oviducts of the host. Using these techniques, vertical transmission has been proposed for the solemyid protobranchs (Cary, 1994; Krueger et al., 1996b) and vesicomyid clams (Endow and Ohta, 1990; Cary and Giovannoni, 1993a; Peek et al., 1998; Hurtado et al., 2003). Interestingly, although bacteria have been detected via PCR in the gonads of female hosts, this does not necessarily imply direct bacterial endocytic localization in host eggs. Indeed, in *Solemya reidi*, the internal contents of oocytes do not contain bacteria, and instead the transmission mechanism is thought to occur via ingestion; the larvae ingest the bacteria, which are then engulfed by hemocytes in the larval perivisceral cavity and transported to the developing gill (Gustafson and Reid, 1988). The oligochaetes also exhibit an interesting mechanism of vertical transmission. During oviposition, the eggs appear to be infected with the symbiotic bacteria via the adult's genital pad (Giere and Langheld, 1987). During the development of the larvae, many of the bacteria exist intracellularly, but as the animal matures, the symbionts take their primarily extracellular form.

However, of the putatively vertically transmitted symbioses, only associations involving vesicomyid clams show phylogenetic congruence

between host and symbiont (Peek et al., 1998; Hurtado et al., 2003). Cospeciation does not appear to have occurred in the solemyid protobranchs (Durand et al., 1996b; Krueger and Cavanaugh, 1997) or in the mytilid mussels (McKiness, 2004). When evaluating phylogenetic congruence, however, other factors that influence a phylogenetic reconstruction, such as geographic constraints, must be taken into account. Also, robust phylogenies with adequate taxa sampling for both host and symbiont are necessary; incomplete phylogenies may be hindering analyses of the solemyid and mytilid symbioses.

Lack of PCR-based evidence and phylogenetic incongruence has been used to infer an environmental mode of transmission for several of the chemosynthetic symbioses. For instance, the lucinid clams exhibit environmental transmission (Durand and Gros, 1996a; Gros et al., 1996; Gros et al., 1998; Gros et al., 2003a; Gros et al., 2003b). Researchers have even been able to exchange symbionts between lucinid species without affecting the development of the juvenile animal (Gros et al., 2003a). In addition, vent tubeworms appear to acquire their symbionts from the environment (Distel and Cavanaugh, 1994; Feldman et al., 1997; Laue and Nelson, 1997; Di Meo et al., 2000; Nelson and Fisher, 2000; McMullin et al., 2003), as evidenced in part by the presence of functional genes for sensing and responding to the environment as well as a flagellin gene in the *Riftia* symbiont (Hughes et al., 1997; Hughes et al., 1998; Millikan et al., 1999). Indeed the 16S rRNA phylotype has been detected in vent environments via both PCR and in situ hybridization, suggesting the vent tubeworm symbionts are environmentally transmitted (Harmer et al., 2004). While environmental transmission of tubeworm symbionts seems to be a potentially risky strategy, given the stochastic nature of environmental transmission and the complete dependence of the adult tubeworms on their symbionts for nutrition, detection of "wild" symbionts in conjunction with the phylogenetic evidence supports environmental transmission in this species.

The mechanism of transmission for the mytilid mussels remains largely unresolved; on the basis of varying evidence, researchers have suggested both vertical and environmental transmission. Vertical transmission in *Bathymodiolus thermophilus*, the thioautotroph-hosting mussel, was suggested in 1993, but evidence supporting this report is not yet published (Cary and Giovannoni, 1993a). In contrast, a recent study based on genetic and ultrastructural data of the chemoautotrophic symbionts of *B. azoricus*, a MAR mussel hosting both thioautotrophs and methanotrophs, indicated environmental acquisition of the chemoautotrophic symbionts (Won et al., 2003a; DeChaine et al., 2004). In addition, McKiness (2004) provided the first assessment of cospeciation between symbiont and host in *Bathymodiolus* mussels, analyzing molecular data for both methanotrophic and chemoautotrophic symbionts and testing phylogenetic congruence with the hosts. The results showed weak support for vertical transmission of the chemoautotrophic symbionts but provided no evidence for vertical transmission of the methanotrophs.

Biogeography and Population Genetics

The view of hydrothermal vents as deep-sea islands frames questions of vent biogeography and population genetics. Compared to the relatively uniform and stable environment of the abyssal deep sea, hydrothermal vents are ephemeral, dynamic and geographically fragmented. A chain of vents along a mid-ocean ridge resembles a chain of islands in an archipelago. However, genetic data for many vent species do not cleanly fit an "island" or "stepping-stone" model of biogeography (Vrijenhoek et al., 1998). Some host taxa do exhibit a decline in gene flow with increasing distance between sites (Black et al., 1994), as a stepping-stone model would predict (Kimura and Weiss, 1964), while others show a more widespread gene flux (Karl et al., 1996) or appear to encounter barriers to dispersal other than distance (Black et al., 1998). These differences should be resolved with a greater understanding of the major variables affecting vent biogeography, including larval development and dispersal, symbiont distribution, oceanic flow, and past and current bathymetry. This section focuses predominantly on host biogeography because research on the population genetics and biogeography of bacterial symbionts is lacking. Understanding host population dynamics, however, does provide valuable insight into the distribution of the chemosynthetic symbionts to which most vent fauna are tightly linked.

Vent habitats are highly ephemeral and sensitive to variations in tectonic activity, hydrothermal inputs, and geologic events. Consequently, the persistence of vent organisms, which are predominantly sessile as adults, depends on successful larval dispersal to new sites. The dispersal strategy of larvae can significantly impact the biogeography of the adult organism (Lalou and Brichet, 1982; Fustec et al., 1987). On the basis of laboratory studies and comparisons with shallow water species, researchers infer that some vent larvae are planktotrophic while others are lecithotrophic (Lutz et al., 1980; Turner et al., 1985; Young et al., 1996; Marsh et al., 2001). Although both forms are pelagic, planktotrophic larvae are positively buoyant and feed in the

water column while lecithotrophic larvae are negatively buoyant and nonfeeding (Poulin et al., 2001). Larvae of the large vesicomyid clam *Calyptogena magnifica* typify a planktotrophic dispersal strategy successfully exploiting the vent plume to carry them many kilometers (Pradillon et al., 2001; Mullineaux et al., 2002). Although planktotrophic larvae risk being carried off the ridge axis by cross currents, *C. magnifica* apparently encounters no significant barriers to dispersal across the equator on the East Pacific Rise (EPR; Karl et al., 1996). Conversely, lecithotrophic larvae are less affected by cross currents but, because they are non-feeding, have relatively short larval stages and therefore limited time for dispersal. For example, in laboratory studies, larval *Riftia pachyptila* exhibit a lecithotrophic strategy, surviving a maximum of 38 days (Marsh et al., 2001). Assuming flow rates characteristic of EPR currents, this interval suggests a maximum dispersal distance of 100 km (Marsh et al., 2001); however, the in situ dispersal distance is unknown given that *Riftia* larvae have not been detected in the wild.

The geology and tectonic activity associated with mid-ocean ridges also impact the biogeography of vent organisms. For instance, Iceland, an active site of crust formation, rises out of the ocean along the northern MAR, forming a barrier that prevents dispersal along the ridge axis (Tyler and Young, 2003). Given that Iceland interrupted the MAR approximately 55 Mya, the ridge axis north of Iceland constitutes one of the most isolated vent systems on the planet, perhaps representing a new biogeographic province (Bilyard and Carey, 1980; Dunton, 1992; Svavarsson et al., 1993). Similar dispersal barriers are seen among vent fields abutting the Azores Rise in the Atlantic (Tyler and Young, 2003) and also evident between the EPR and the Northeast Pacific vent fields (Tunnicliffe, 1988; Tunnicliffe and Fowler, 1996). These barriers are insurmountable and may provide the conditions for allopatric speciation of both host and symbiont.

Research on EPR bathymodiolid mussels and their symbionts provides a good example of how larval dispersal strategy, current regime, and bathymetry interact to structure biogeography (Lonsdale, 1977; Corliss et al., 1979). Except at Northern Pacific sites, which are separated from the EPR by the North America landmass, vent communities on the Pacific ridge axis appear relatively uniform. For example, the mussel *Bathymodiolus thermophilus*, which undergoes a planktotrophic larval stage, occurs over a distance of 4900 km (from 13°N to 32°S) on the EPR. Mussel populations along 13°N and 11°S are genetically indistinguishable, indicating no population subdivision (Craddock et al., 1995; Won et al., 2003). Deep ocean currents that flow primarily NNW and SSE along the axis (Marsh et al., 2001) may facilitate dispersal of larval *B. thermophilus*, contributing to the homogeneity observed along the EPR. However, there is some genetic structure in the EPR mytilid populations; the westward currents across the ridge axis at 15°N and the Easter Microplate are obstacles for planktotrophic larvae. At 15°N, a westward current flows across the ridge axis, partially isolating the 17°S population from the other northern populations. Further south, at the Easter Microplate, mussel populations are severely divergent (Won et al., 2003). Although morphologically indistinguishable, mussels north and south of the Microplate are genetically distinct (Won et al., 2003). The Easter Microplate therefore appears to be a significant topographic obstacle for larval dispersal. Such a feature can produce cross-axis currents, like those at 15°N, that may sweep bathymodiolid larvae (which are positively buoyant) off the ridge axis (Fujio and Imasato, 1991; Mullineaux et al., 1995). The degree to which such barriers also impact the genetic diversity and biogeography of chemosynthetic symbiont populations remains an open question.

Summary

Scientific understanding of chemosynthetic symbioses continues to expand. The spectacular discovery of hydrothermal vents highlighted the importance of chemosynthetic bacteria both in food webs and in symbioses with eukaryotes and provided the impetus to examine less exotic environments for such associations. As other oxic-anoxic environments (e.g., freshwater) and the invertebrates and protists that inhabit them are explored, new symbioses will undoubtedly be discovered. Further, chemosynthetic bacteria that use other sources of energy (e.g., hydrogen) may be found in similar associations.

Current studies of these fascinating symbioses involve a range of experimental and diagnostic tools, including physiological assays in specialized growth chambers, enzyme characterizations, immunodetections, and stable isotope analyses. Increasingly, molecular techniques, such as PCR-based gene probing, FISH, and 16 rRNA phylogenetic analysis, are used to complement traditional methods. These studies provide valuable insight into the population dynamics, evolutionary history, and carbon and nutrient metabolism of symbionts. In addition, projects are currently underway to sequence the genomes of some of the chemosynthetic symbionts described in this review (e.g., symbionts of *Riftia pachyptila* and *Solemya velum*). Genomic analysis, in conjunction with new technologies to manipulate symbioses under in situ conditions

(e.g., via vascular catheters; Felbeck et al., 2004) and to sample the physical environment (e.g., electrochemical sampling; Luther et al., 2001), will contribute significantly to our understanding of symbiont biology. Scientists are now poised to reveal how interactions with the host and the abiotic environment impact symbiotic chemosynthetic bacteria over both ecological and evolutionary timescales.

Acknowledgments. We thank our colleagues and collaborators for active discussions on chemosynthetic symbioses and for their scientific contributions. Without the Chief Scientists, Captains and crews of the research vessels (including R/V Atlantis II, R/V Atlantis, and R/V Knorr), and the Expedition Leaders and crews of Deep Submergence Vehicle (DSV) Alvin and the remotely operated vehicles, we could not explore the vast unknown deep sea—to them we are grateful. Research in my laboratory (CMC) on chemosynthetic symbioses has been supported by grants from NSF (Biological Oceanography, RIDGE, Cell Biology), the Office of Naval Research, NOAA National Undersea Research Center for the West Coast and Polar Regions, and NASA (Exobiology) and by graduate fellowships from the NIH, NSF (IGERT), and Howard Hughes Medical Institute, which we gratefully acknowledge.

CHAPTER 3.1

Organic Acid and Solvent Production Part I: Acetic, Lactic, Gluconic, Succinic and Polyhydroxyalkanoic Acids

PALMER ROGERS, JIANN-SHIN CHEN AND MARY JO ZIDWICK

In Memorium

Shortly before the completion of this chapter, Palmer Rogers passed away suddenly. Palmer was the one who motivated and shepherded us to the completion of this work. He had a lifelong dedication to education of students and helped them attain the satisfaction that achieving in-depth understanding of science through hard work can bring. Palmer was kind, creative, energetic and uncompromising in his scientific integrity and will be remembered with fondness by the many people whose lives he touched.

General Introduction

The objective of this chapter is to present the ways bacteria are effectively harnessed as biocatalysts to perform the synthesis of bulk organic acids and solvents. Prior to the development of the petroleum-based chemical industry, microbial fermentations of agricultural biomass were a major source of a number of useful bulk organic chemicals. Commercial chemical production often emerged from a much earlier food processing technology where grains, corns, milks and fruits were fermented to wines, beers, cheeses and vinegars. Beginning at the end of the 19th century and continuing to the present, specific bacterial strains were selected from nature to produce commercially needed bulk chemicals such as lactic acid, acetic acid, acetone and butanol and more recently gluconic acid and polyhydroxyalkanoates. With the advent of genetic engineering, bacterial strains are being altered for production of propanediols, butanediol and succinic acid at higher yields and productivity than are possible using natural strains.

Table 1 lists a selected number of organic acids and solvents (covered in detail in this chapter) produced by prokaryotes. The topical products are selected based on the following properties of the production process that are either well-known or under development:

1) Bacteria-catalyzed processes convert cheap biomass into the desired products at high yield and low cost.
2) Downstream separation and purification technologies have been applied successfully to the process.
3) The product, as a commodity chemical, has diverse applications and the promise of a strong future market.

Each section includes the following information about the product:

1) introduction and history of the process;
2) scientific background such as microbiological principles, physiology, biochemistry, genetics, and product chemistry;
3) commercial fermentation and bioprocess technologies, economics, and competitive processes;
4) research and development, such as approaches to strain improvement and new process technologies;
5) patent and regulatory issues;
6) prospects for the process; and
7) a reference list.

In today's world, the biotechnology industry, which includes the bacterial production of compounds listed in Table 1, accounts for a mere US $30 billion in chemical compounds produced by fermentation or other bioconversion processes. The total chemical market is greater than US $1,200 billion (Wilke, 1995), which includes all organic chemicals mostly produced from petroleum, natural gas, and coal feedstocks. Indeed, most of the organic acids and solvents listed in Table 1 are also synthesized today by chemical processes from these nonrenewable feedstocks. An exception is the polyhydroxyalkanoates, produced only by bacteria. However, cheap, petroleum-derived plastic polymers dominate the present-day market where the polyalkanoate products are designed to compete.

With this situation in mind, what are the needs for and advantages of developing processes for

Table 1. The major organic acids and solvents produced by prokaryotes.

8.	Acetone/isopropanol/butanol
9.	1,2- and 1–3-Propanediol
10.	2,3-Butanediol

producing fermentation-derived bulk organic acids and solvents? As the cost of nonrenewable feedstocks increases, the need for production of these high-volume organic chemicals from renewable alternative feedstocks is growing. For example, acetic acid, acetone and isopropanol are on the list of the top 50 organic chemicals produced worldwide (Wilke, 1995), and today they are largely products of chemical synthesis. However, there are active research efforts to develop new technologies to reduce costs in fermentation, bioconversion, and downstream processing—subjects to be covered in the following sections of this chapter. For producing essential organic acids and solvents, these efforts have the potential of adding a product stream based on renewable resources to existing chemical synthesis routes. In this chapter, the best example of a bulk process with this potential is the production of bioethanol from agricultural biomass and even municipal wastes. At present, however, the role of bacterial systems in bioethanol production is relatively minor.

Biosynthetic routes often have product-specific advantages over chemical synthesis, which are important for extending and adding value to some bulk products listed in Table 1. For example, optically active compounds, such as lactic acid, can be produced as either L- or D-lactic acid employing specific species of lactobacilli as biocatalysts, whereas chemical synthesis produces a racemic mixture of D, L-lactic acid. Specific properties of polylactide polymers and chemical derivatives of lactic acid differ importantly depending upon the chirality of the monomer (stereospecificity).

Biodegradability of final products such as plastic bottles and films has become an important environmental concern. Where biodegradability is a desirable property, polyhydroxyalkanoate- and polylactide-based plastics produced from bacterial processes are under development for replacement of poorly biodegradable polyvinyl, polyethylene, and other petroleum-based plastics.

As the world population increases beyond the 6-billion mark, urban, food processing and agricultural wastes become an overwhelming problem. However, microbiologists and bioprocess engineers have developed processes for utilizing wastes as alternative feedstocks. An example is the production of the deicer Ca-Mg-acetate from gasified municipal solid wastes or from waste cheese whey by bacterial fermentation covered in section 1 of this chapter. A second example is the planned facility for conversion of waste bagasse from sugar cane refineries into millions of gallons of ethanol by bacterial fermentation (McCoy, 1998). Thus, the future of bioethanol production from waste biomass may well depend upon development of bacterial fermentations.

Using genetically altered bacteria, chemical companies are developing single-step fermentation/conversion processes for carrying out multistep synthesis of bulk solvents or organic acids. Bacteria-catalyzed conversions of glucose into 1,2- or 1,3-propanediol are examples of processes presently in the experimental stage, which may be developed commercially in the future (Alpers, 1999).

Research into the bacterial production of 2,3-butanediol (summarized in a section of this chapter) also has been considerable. The future prospects of large-scale fermentative production of 2,3-butanediol as a fuel or as a major chemical feedstock will depend on the need to substitute for present petroleum-based products such as 1,3-butadiene and methyl ethyl ketone (Maddox, 1996).

Although the emphasis of this chapter is upon the development of bacteria-based fermentations to produce organic acids and solvents, we have pointed out the parallel role of fungal-based processes where relevant in some sections. For example, the yeast fermentation is of overwhelming importance in bioethanol production. Yet, the bacterial fermentation route has been developed to play important roles in the future utilization of major carbon sources. On the other hand, the lactic acid fermentation is dominated by bacterial processes, and yet a major commercial project employs a fungal fermentation (see Lactic Acid in this Chapter). Industrial production of gluconates and gluconic acid has been based on *Aspergillus niger* fermentations in the past. Yet much research and development predicts that fermentations using *Acetobacter methanolicus* and *Zymomonas mobilis* may become dominant in the future.

In the following sections, we try not only to indicate the major bacterial systems developed for the production of the specific organic acids or solvents but also to give a realistic assessment of the relative impact of competing processes.

Section 1: Acetic Acid

Introduction

Until the late 19th century, all acetic acid was derived from the classical process of sugar fermentation to ethyl alcohol followed by a second-stage microbial oxidation to acetic acid. The dilute solution of acetic acid produced by microbial metabolism is called "vinegar." Wine-souring leading to a variety of vinegars has been known as long as the practice of wine making, probably before 6000 BCE (Nickol, 1979). Early Babylonian writings (4000 BCE) report in great detail the production of vinegar and wine from date palms. Vinegar was used early in Babylonian, Greek and Roman culture for food flavoring, food preservation, pickling, for medicinal purposes such as wound healing, and as a popular drink for soldiers and peasants (Swings, 1992). The New Testament reports that Roman soldiers offered Jesus vinegar to drink during the crucifixion.

A number of natural sugar-containing juices or mashes that are first converted by fermentation to alcoholic solutions can serve as raw materials for vinegar production. The vinegar is named after the original raw material, such as wine vinegar, peach vinegar, apple cider vinegar, rice vinegar, malt vinegar, etc. Until about the early 1950s, most of the world supply of acetic acid was manufactured utilizing the microbial oxidation of raw alcoholic mixtures by a vinegar production process (Ghose and Bhadra, 1985). Perhaps the earliest vinegar manufacturing method was the "slow process," or "Orleans process," employed in the Orleans region of France even before the 17th century (Allgeier and Hildebrandt, 1960). Wooden casks were partly filled with a "good vinegar" as a source of inoculum followed by weekly additions of fresh wine. After five weeks some of the vinegar was replaced by more fresh wine. A thick bacterial mat develops on the surface, known as the "mother of vinegar." Air was supplied through holes in the cask above the surface of the mat. Thus a slow, continuous vinegar process was developed.

Vinegar was produced by the Orleans process or French method long before the discovery of the microbial basis for the oxidation of ethanol to acetic acid, and for that matter, the fermentation of sugars to alcohol. In 1732, Berman Boerhaave first suggested the biological nature of the "mother of vinegar;" then Persoon, in 1822, reported evidence of bacteria in this surface mat and named it "Mycoderma" (Ghose and Bhadra, 1985). Kutzing (1837) found that small microscopic organisms in the mother inoculum were necessary for the conversion of alcohol to acetic acid. Pasteur (1868) discovered that the cause of deterioration of wines was due to bacterial contamination during and after the yeast fermentation process, resulting in conversion of alcohol to acetic acid. Almost simultaneously, he made the observation that during vinegar manufacture similar bacteria, which he called "*Mycoderma aceti*," were responsible for production of the acetic acid by oxidation of ethanol. Subsequently, Pasteur showed that partial sterilization or "Pasteurization" of wine at 55°C prevented the spoilage process, and his discovery made him a hero of the French wine industry (Dubos, 1988).

The "quick process" or "German process" was invented in the early 1800s. Wine is added at the top of and allowed to trickle through a generator that consists of a tank packed with beechwood shavings. Bacterial cells grow attached to the beechwood shavings and catalyze the conversion of alcohol to acetic acid. Air is blown through holes from the bottom of the tank. In 1929 the "Frings process" was introduced as a major improvement of the quick process (Fig. 1). The Frings generator included both forced aerations and temperature control features. This trickle bed process yielded 98% conversion of a 12% ethanol solution to acetic acid in 5 days. It was also low cost and easy to control.

Hromatke and Ebner introduced the submerged reactor with an aerator fixed at the bottom of the reactor for oxidation of ethanol to acetic acid by *Acetobacter* species (Hromatke and Ebner, 1949). Today the Frings Acetator® is the most common reactor for the production of all types of vinegar by the submerged fermentation method (Ebner et al., 1996). The submerged cultivation reactor (Fig. 2) has the following advantages over the trickling bed reactor for commercial production:

1) alcohol oxidation to acetic acid is 30 times faster;
2) a smaller total reactor volume is required to achieve a given level of productivity;
3) between 5–8% higher yields are obtained; and
4) the process is easily automated. It was discovered that Acetobacter is very sensitive to short periods of low O_2 levels in submerged-culture conditions. Therefore, the success of this process depends upon continuous high rates of aeration of the broth (Agreda and Zoeller, 1993).

Most production of acetic acid from dilute sugar solutions is carried out by the two-step vinegar process, using the submerged reactor technology; however, during this decade, a one-step microbial fermentation of sugar to acetic acid production has been under development (Cheryan et al., 1997). This fermentation is carried out by acetogenic *Clostridium* species and has two major advantages over the two-step vin-

egar process. First, the fermentation is anaerobic, which saves energy required for aeration during the process; secondly, the single bacterium converts sugar directly and almost stoichiometrically to acetic acid, with a theoretical yield of almost 100%, which reduces raw material costs. This bioprocess, when developed, may become competitive with chemically produced acetic acid for specific uses, such as calcium magnesium acetate for deicing roadways (Cheryan et al., 1997).

A third biological source of acetic acid is the distillation of wood by a process that was developed in the late 19th century (Agreda and Zoeller, 1993). It probably provided an additional source of acetic acid up to the early 20th century.

The first commercial plant for the chemical production of acetic acid came on line about 1916. Clearly this was the beginning of the expanding market for acetic acid as an important commodity chemical in industry (Agreda and Zoeller, 1993). Chemical synthesis of acetic acid is dependent upon petrochemicals from nonrenewable crude oil resources. There are three major processes in use today: oxidation of acetylene-derived acetaldehyde; catalytic butane oxidation; and the carbonylation of methanol (the Monsanto process; Agreda and Zoeller, 1993). Production by the Monsanto process provides the major source of glacial acetic acid used in industry worldwide. In the United States, chemical synthesis of acetic acid was reported as 2.34×10^6 tons/yr in 1995 (Kirschner, 1996), which demonstrates the importance of acetic acid as a commodity chemical in industry.

Scientific Background

THE AEROBIC PROCESS A two-step microbial process yields a dilute 5–12% solution of acetic

acid (vinegar) from a crude carbohydrate-containing mash. The first step is the production of ethanol from sugars by an anaerobic fermentation, usually by the yeast *Saccharomyces cerevisiae* or alternatively by a bacterium such as *Zymomonas mobilis*:

$$C_6H_{12}O_6 \rightarrow 2CO_2 + 2CH_3CH_2OH \quad (1)$$

The second step is the oxidative conversion of ethanol to acetic acid carried out by an *Acetobacter* strain. These bacteria catalyze an interesting incomplete oxidation where characteristically their capacity to oxidize ethanol and lactate far exceeds the oxidation of acetic acid to CO_2. During the incomplete oxidation of ethanol, the reducing equivalents are transferred to oxygen:

$$2CH_3CH_2OH + 2O_2 \rightarrow 2CH_3COOH + 2H_2O \quad (2)$$

Surprisingly, the microbiology of the modern vinegar fermentation is not entirely worked out as to the exact taxonomy of the participating *Acetobacter* species. It is still state of the art to start a new fermentation process with a "seed vinegar" which is a microbiologically undefined sample drawn from a running Frings-acetator (Ebner et al., 1996). For example, ten strains of *Acetobacter* were isolated from a series of running industrial acetators in southern Germany. Using 16S rRNA oligonucleotide probes to hybridize with DNA from these strains, four strains were identified as members of the *Acetobacter europeus/xylineum* species; six strains could not be identified as to species (Sokollek et al., 1998).

Table 2 lists some of the identified species of *Acetobacter* that have been isolated from various vinegar production processes. Phenotypic differentiation of *Acetobacter* from the closely related genera *Gluconobacter* and *Frateuria* is presented by Swings (1992).

But regardless of how these *Acetobacter* strains are classified, the vinegar producers' first interest is to use a strain of bacteria that produces a high concentration of acetic acid (12–14%). Also the strain chosen must tolerate a high acetic acid concentration; it should require small amounts of nutrients; it should not overoxidize the acetic acid formed; and it should maintain a high productivity (2.5–4% every 24 h; Ebner and Follmann, 1983). There are two reasons for the lack of defined pure starter cultures of preserved strains that embody the desired qualities for commercial acetic acid production. First, the successful preservation and cultivation of isolated production strains has been described only recently (reviewed by Sokollek and Hammes, 1997). Secondly, high frequencies of spontaneous mutations in the acetic acid bacteria cause deficiencies in alcohol oxidation, lowered resistance to acetic acid and loss of other important physiological properties of production strains (Beppu, 1993). IS elements have been identified as being the cause for some of these mutational events in *Acetobacter* species (Iversen et al., 1994; Takemura et al., 1991; Kondo and Horinouchi, 1997). To avoid the possible selection of mutants in preparation of starter cultures, a suggested procedure has been developed (Sokollek et al., 1998). Basically, the pure cultures are isolated on agar plates. A colony is selected, grown and tested in a pilot acetator to verify high productivity, maximum yield and tolerance to acetic acid. An aliquot of the test acetator is prepared and frozen or lyophilized as a starter culture (Sokollek and Hammes, 1997). After recovery, these cultures were found to be reliable inocula for starting fermentation in pilot acetators.

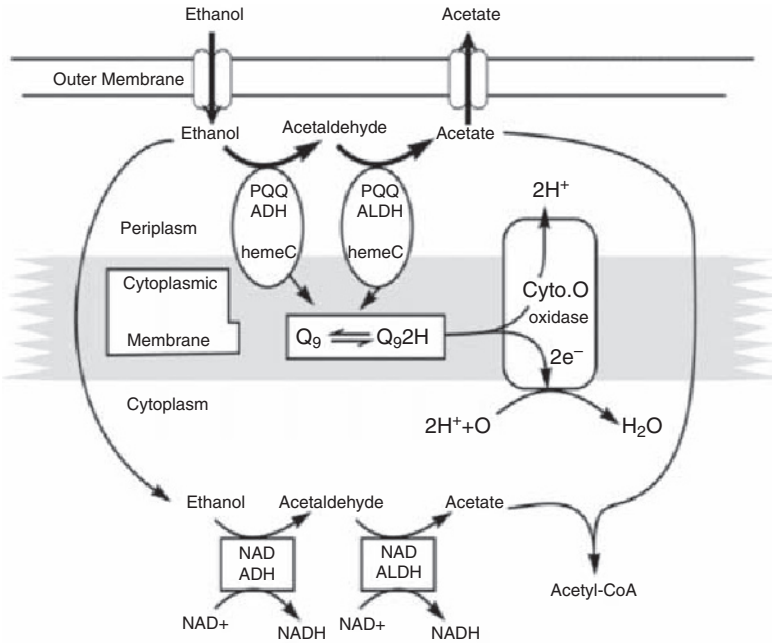

Fig. 3. Alcohol oxidizing systems in *Acetobacter* sp. See text for descriptions. Redrawn from Matsushita et al. (1994), with permission.

Oxygen deprivation during acetic acid production by *Acetobacter* in a submerged-culture reactor causes rapid loss in productivity. Muraoka et al. (1982) showed that when a submerged reactor with *Acetobacter aceti* reached 6% acetic acid, blocking aeration for 10 s completely inhibited further acid production. Loss of production was correlated with observed damage to bacterial cells shown by morphologic changes such as irregularly shaped cells. Yet, at less than 4% acetic acid in the reactor, oxygen limitation for 12 min had little effect on cell appearance or on acid production when aeration was started again. Thus, the sensitivity to oxygen depletion is related to sensitivity of the *Acetobacter* cells to accumulated acetic acid. Further, when all ethanol is used up in an active running acetic acid reactor, the acetic acid bacteria will be irreversibly damaged if addition of fresh ethanol is delayed (Ebner and Follmann, 1983). Mesa et al. (1996) modeled the death rate of *A. aceti* due to lack of O_2 in submerged culture as a function of acetic acid concentration. Also they included data showing the protective effect of increasing concentrations of ethanol.

Apparently, Acetobacter is protected from the toxic effects of high concentration of acetic acid by its own ethanol-oxidizing system, through maintenance of pH homeostasis. As the acetic acid concentration increases, the pH outside approaches 2–4, whereas the pH inside the cells must be maintained at pH 6.5–7. Thus for survival a ΔpH of 4–2.5 must be maintained very much as for other acidophiles (White, 1995).

The biochemistry and proposed bioenergetics of the alcohol-oxidizing systems together with the alcohol-oxidizing respiratory chains have been elucidated (Matsushita et al., 1994).

The acetic acid bacteria produce acetic acid from ethanol by two enzyme-catalyzed reactions of membrane-bound alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH). In addition, some acetic acid bacteria can oxidize various sugars and sugar alcohols. These reactions are all "incomplete oxidations" because the oxidation products are usually accumulated in large amounts in the bacterial beers. Both ADH and ALDH have pyrroloquinoline quinone (PQQ) bound as a prosthetic group and are linked to the respiratory chain in the cytoplasmic membrane (Fig. 3). A second set of NAD(P)$^+$-dependent ADHs and ALDHs is found in the cytoplasm of acetic acid bacteria. These latter two enzymes have much lower specific activities than those of the PQQ-enzymes and are not involved in acetic acid production (see Fig. 3).

The quinoprotein dehydrogenases, ADH-PQQ and ALDH-PQQ, are tightly bound to the periplasmic side of the cytoplasmic membrane. Electrons from alcohol and aldehyde are donated to ubiquinone (Q_9) embedded in the membrane. The ubiquinol oxidase, either cytochrome O (Cyto.O) or cytochrome *a*, transfers electrons from Q_9 and generates an electrochemical proton gradient by reduction of oxygen with $2H^+$ or by pumping H^+ into the periplasmic space (Fig. 3). The major role of this alcohol respiratory system is to maintain homeostasis by consuming cytoplasmic protons and thus balancing the DpH. This permits the *Acetobacter* to grow slowly and survive on ethanol and acetic acid in the presence of high acetic acid concentrations.

The observed low biomass yield compared to the high rate of O_2 uptake is supported by experiments with ^{14}C-ethanol utilization by *A. rancens* (Mori and Terui, 1972). The O_2 uptake and ethanol oxidation were in agreement; but the growth yield was only 10% of that expected compared to other bacteria. Biomass yield was studied with *A. pasteurianus* using an ethanol-limited chemostat with about the same result (Luttik et al., 1997). These workers also measured proton translocation coupled to O_2 uptake for acetate oxidation by the same ethanol-limited cells and found that a very low proton translocation stoichiometry might explain the low biomass yield. Apparently production strains of *Acetobacter* are selected for very low rates of acetate oxidation. But how acetate oxidation is regulated is still incompletely understood (Saeki et al., 1997a).

The Anaerobic Process During studies with the anaerobic acetogenic clostridia, it was recognized that these bacteria can ferment sugars such as glucose, fructose and xylose almost exclusively to acetic acid by the following reactions:

$$C_6H_{12}O_6 \rightarrow 3CH_3COOH \quad (3)$$

or

$$2C_5H_{10}O_5 \rightarrow 5CH_3COOH \quad (4)$$

In 1940, Wieringa described *Clostridium aceticum*, the first acetogenic anaerobic spore-forming bacterium (Adamse, 1980). It was discovered to grow on hydrogen and carbon dioxide, forming acetic acid (Braun et al., 1981), according to the following equation:

$$2CO_2 + 4H_2 \rightarrow CH_3COOH + 2H_2O$$
$$\Delta G^\circ = -107\,kJ \quad (5)$$

These organisms have been called "homoacetogens" because on most substrates they produce very little if any organic product, other than acetic acid. Alternatively, Drake (1994) prefers the name "acetogens," defined as "obligately anaerobic bacteria that can use the acetyl-CoA pathway as: 1) their predominant mechanism for the reductive synthesis of acetyl-CoA from CO_2, 2) their major terminal electron-accepting, energy-conserving process, and 3) their mechanism for the synthesis of cell carbon from CO_2." Acetogen (as defined above) distinguishes a process by which acetyl-CoA rather than acetate is formed as the final product. Also these bacteria often can produce products other than acetate under certain conditions using alternate pathways (Misoph and Drake, 1996). Acetogen (as defined above) also distinguishes these bacteria from the ethanol oxidizers, *Acetobacter* sp. In 1986, the acetogens were represented by 14 different species within five genera, three of which are thermophilic (Ljungdahl, 1986). By 1994, there were 40 species classified and 19 unclassified isolates reported (Drake, 1994). A selected list is presented in Table 3.

In addition to growth on H_2 and CO_2, some acetogens also grow on other one-carbon compounds, such as formate, carbon monoxide and methanol (equations 6–10):

Table 3. Characteristics of some acetogens.

Organism	Optimal growth temperature (°C)	Growth substrates Organic	One-carbon	References

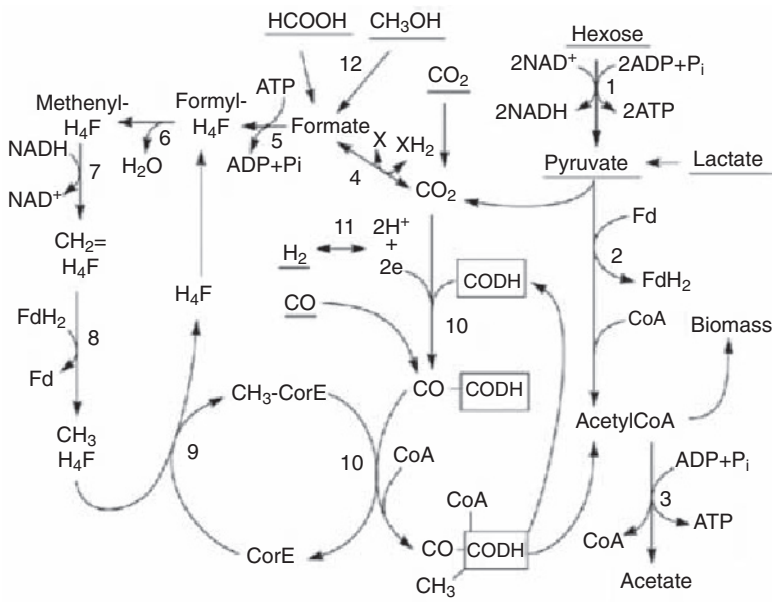

Fig. 4. Biochemical pathway used by acetogens for fermantation of sugars and utilization of one-carbon precursors for biomass and acetate production: 1, hexose oxidation to pyruvate by the Embden-Meyerhof pathway; 2, pyruvate-ferredoxin oxidoreductase; 3, phosphotransacetylase and acetate kinase; 4, formate dehydrogenase; 5, formate tetrahydrofolate synthetase; 6, methenyl tetrahydrofolate cyclohydrolase; 7, methylenetetrahydrofolate dehydrogenase; 8, methylenetetrahydrofolate reductase; 9, methyl transferase; 10, carbon monoxide dehydrogenase (CODH); 11, hydrogenase(s); 12, methanol dehydrogenase and formaldehyde dehydrogenase; Cor-E, corrinoid protein; and H_4F, tetrahydrofolate. Underlined compounds are substrates used by various acetogens. The Wood/Ljungdahl Pathway consists of reactions 4 through 10.

$$4CO + 2H_2O \rightarrow CH_3COOH + 2CO_2 \quad (6)$$

$$4HCOOH \rightarrow CH_3COOH + 2CO_2 + 2H_2O \quad (7)$$

$$4CH_3OH + 2CO_2 \rightarrow 3CH_3COOH + 2H_2O \quad (8)$$

$$2CO + 2H_2 \rightarrow CH_3COOH \quad (9)$$

$$2HCOOH + 2H_2 \rightarrow CH_3COOH + 2H_2O \quad (10)$$

Thus, most of this versatile group of anaerobic organisms can grow on one-carbon compounds as both a sole carbon and energy source (equations 6–8) or by utilizing energy from the oxidation of H_2 (equations 5, 9 and 10). Acetic acid is the primary product during growth on selected sugars, alcohols, organic acids or one-carbon compounds.

It is immediately obvious that the fermentation carried out by this group of bacteria (Table 3) has three advantages over the aerobic process for acetic acid production using *Acetobacter*. First, this is an anaerobic process, so the energy and equipment costs for providing large amounts of oxygen during the fermentation are unnecessary. Second, the theoretical yield of the anaerobic process is 3 moles of acetic acid per mole of glucose used, or 100%. The theoretical yield of the aerobic process is only 67% acetic acid per g of glucose because one-third of the carbon is lost as CO_2 (see equation 2). Third, the ability of some of these bacteria to utilize CO_2 and other one-carbon precursors for growth and acetic acid production permits their use in biological conversion of synthesis gases produced from waste biomass to acetic acid. However, Busche (1991) concluded that the higher acetate concentration tolerated by *Acetobacter suboxydans* used in the aerobic process might outcompete the advantage of the one-step process with the high yield of three acetates per glucose by the anaerobic acetogens.

The biochemical pathway that permits the fermentation of glucose to three moles of acetate by these bacteria includes the enzyme-catalyzed reactions also essential for the fixation of CO_2 and other one-carbon precursors into cell material. But acetogens do not use the Calvin cycle for CO_2 fixation because the enzyme ribulosediphosphate carboxylase is not present in their cytoplasm. Rather, acetyl CoA is the first intermediate formed during CO_2 or CO fixation by homoacetogenic bacteria. The pathway (now established for both the acetate fermentation and growth on CO_2/H_2) is a combination of the Embden-Meyerhof pathway and the "Wood/Ljungdahl pathway" diagrammed in Fig. 4 (Ljungdahl, 1986; Drake, 1994).

Fermentation of hexose yields two pyruvates, and pyruvate is further oxidized to 2 acetyl-CoA and 2 CO_2 by the enzyme pyruvate:ferredoxin oxidoreductase. Then the 2 acetyl-CoAs are converted to 2 acetates. The 4 moles ATP per hexose produced are used for further metabolism. The oxidation-reduction balance is achieved by reduction of both CO_2 molecules to a third acetyl CoA and finally to acetate by the Wood/Ljungdahl pathway. The NADH and reduced ferredoxin generated from the oxidized forms during fermentation of hexose are the source of reducing power. One CO_2 is reduced to 5-methyltetrahydrofolate. The first reaction in this pathway (reaction 4, Fig. 4) is the formation of formate catalyzed by an unusual tungsten-

selenoprotein, formate dehydrogenase (Yamamoto et al., 1983). For *C. thermoaceticum*, the electron donor is NADPH. The methyl group of 5-methyltetrahydrofolate is transferred through a corrinoid-protein intermediate (CH_3-CorE) to carbon monoxide dehydrogenase (CODH) for the final condensation reaction with coenzyme A and CO to form acetyl CoA (reactions 9 and 10, Fig. 4). Also, CODH has been purified and characterized from a number of anaerobic bacteria such as *A. woodi* and *C. thermoaceticum* (Ragsdale, 1994). The enzyme from acetogens contains 6 Ni, 3 Zn and a number of FeS centers. Thus, the primary functions of the CODH of acetogenic bacteria are the reduction of CO_2 to a nickel-bound CO and the synthesis of acetyl CoA. Because the former function is the first step in the synthesis function, it has been suggested that the name of the enzyme should be "methyl-CO-CoA condensing enzyme" or just "acetyl CoA synthase" rather than CODH (Ljungdahl, 1986).

During autotrophic growth with CO_2/H_2 (equation 5) or with reduced one-carbon compounds such as CO, HCOOH, or CH_3OH (equations 6–8), energy must be derived from H_2 via hydrogenase or alternatively by an enzymatic transfer of electrons from the one-carbon compounds to electron transport proteins. *Clostridium thermoaceticum* contains membrane-bound cytochrome *b*, menaquinone, as well as two rubredoxins and two ferredoxins. *Clostridium thermoaceticum* also has an H^+-translocating ATPase, indicating that these anaerobes must utilize a proton-electrochemical gradient ($D\mu_{H^+}$) created by an electron transport system to produce ATP (Ljungdahl, 1994). This mechanism is essential for ATP synthesis during autotrophic growth inasmuch as the only other source of ATP is acetyl CoA to acetate.

Some acetogens, such as *A. woodi*, develop a sodium-electrochemical gradient ($D\mu_{Na^+}$) coupled to acetogenesis from growth with $H_2 + CO_2$ rather than a $D\mu_{H^+}$ formed by *C. thermoaceticum* (Müller and Gottschalk, 1994). Experiments with inverted vesicles suggested that the sodium-pump is a function of one of the membrane-bound enzymes, methylene-H_4F reductase or the methlytransferase (see Fig. 4, reactions 8 and 9). That ATP synthesis is driven by a membrane-bound, Na^+-translocating ATP synthase was demonstrated in *A. woodii*. Sodium ions also play a major role in the acetogens *A. kivuii* and *P. productus* during acetogenesis with H_2 and CO_2. Homoacetogens growing with sugars can produce adequate ATP from their conversion to pyruvate and then to acetate through acetyl CoA (Fig. 4, reactions 1 and 3). However, the observation of high growth yields of some homoacetogens when fermenting sugars together with the observed formation of some hydrogen gas suggests that an electron transport-induced proton-gradient may produce additional ATP under fermentation conditions as well.

When acetogens grow on one-carbon compounds using the Wood/Ljungdahl pathway, all cellular carbon compounds must be produced from acetyl CoA (Fig. 4). The incorporation of acetyl CoA carbon into lipids, amino acids, nucleotides, carbohydrates and thus all biopolymers has been demonstrated for *C. thermoaceticum* and *A. woodii* (Eden and Fuchs, 1982; Eden and Fuchs, 1983). Similar pathways are found for other strict anaerobes such as the sulfur-reducing bacteria growing on acetate and the methanogenic Archaea growing on CO_2 and H_2 or on acetate (Thauer, 1989).

The maintenance of pH homeostasis by acetogens during accumulation of acetic acid in the medium has not been carefully studied. The undissociated acetic acid in the medium freely diffuses into the cells where it dissociates into acetate and H^+ dependent on the cytoplasmic pH (~pH 6.0). When the H^+ concentration inside the cell is greater than or equal to the H^+ concentration outside in the medium, then the cell membrane potential is neutralized or reversed. How the acetogen cells deal with this situation is unknown; however, they are tolerant to only about 2.0–3.0 g of acetic acid per liter during batch fermentation. Experiments demonstrate that continuous control of the pH (6.6–6.9) during batch or fed-batch fermentation increases the yield of acetate to 46–56 g per liter (reviewed by Wiegel, 1994).

The production of acetic acid by acetogens is coupled to growth of their biomass. When growth is rapid, production of acetic acid increases, and when growth is limited or slowed, the production of acetic acid decreases. The nutritional requirements for maximum acetate yield and productivity by *C. thermoaceticum* growing on glucose are reviewed by Cheryan et al. (1997). The optimum concentrations of the metal iron, cobalt, molybdenum, selenite, zinc and nickel have been determined for maximum growth and acetate production by this bacterium. Cheap sources for the organic nitrogen, which are required for growth, have been studied for low-cost media development.

The availability of acetogens that are thermophilic (Table 3) certainly adds versatility when considering an organism for a production process (Wiegel, 1994). Costs of cooling a large volume of medium following sterilization and dissipation of heat generated during mixing and stirring, as well as the risk of contamination by foreign bacteria, are much reduced when operating a commercial-level fermentation system at the higher temperatures of 60–70°C. Thus, the thermophilic species, *C. thermoaceticum*, *C. ther-*

moautotrophicum and *Acetogenicum kivii*, are attractive candidates for new process development.

Commercial Applications

INDUSTRIAL ACETIC ACID There are two major areas of commercial application of acetic acid today: food-grade vinegar, which is largely the product of bacterial oxidative conversion of diluted purified alcohol or alcoholic mashes from various fruits and grains, and chemically synthesized industrial acetic acid, 62% of which is produced by carbonylation of methanol and the rest by oxidation of *n*-butane. Chemically synthesized acetic acid is a commodity chemical that has become a major feedstock for the United States and worldwide chemical industry. Figure 5 displays the major chemicals derived from acetic acid and their commercial applications.

Petrochemically produced acetic acid reached a level of 4.68×10^9 lbs/yr in the United States by 1995 and was ranked 35th in abundance of all chemicals produced (Kirschner, 1996). Worldwide production in 1998 was estimated at 11.9×10^9 lbs/yr (Layman, 1998).

Bioderived acetic acid does not compete economically with acetic acid produced by chemical synthesis. This is because glacial acetic acid is the preferred starting material for most synthetic routes leading to other products. The cost of petroleum derived 100% acetic acid by the methanol carbonylation process (Monsanto) is from \$0.15 to \$0.35/lb, whereas the cost of 100% acetic acid from the *Acetobacter* aerobic oxidation of ethanol is estimated at \$0.35 to \$0.45/lb (quoted by Cheryan, 1999). The chemical processes have the advantages of initially high acetic acid concentrations (35–45%) and high production rates. The disadvantages are high cost of catalysts and dependence on nonrenewable petroleum for raw materials.

Industrial acetic acid could be synthesized by either of two microbial processes: 1) from sugars in the two-step vinegar process via ethanol using *Acetobacter* species, or 2) from sugars or syngas (CO, H_2, and CO_2) by the anaerobic fermentation process using *Clostridium thermoaceticum* or related organisms (see "Scientific Background" in this Chapter). These bioprocess routes have the advantage of using a variety of renewable raw materials, which presently are more expensive than petroleum-based resources. The major disadvantage is the cost of recovery of low concentrations of acetic acid (4–12%) from the fermentation beers, which are mostly water. A great deal of research and development effort is underway to improve the technology of product recovery and improve bacterial strains. These experimental efforts and improvements in the two microbial processes and separation processes are reviewed in the next section (see "Areas of Research and Development" in this Chapter).

VINEGAR ACETIC ACID A submerged fermentation is the most common technique used today for the production of all kinds of vinegar. The Frings Acetator® is the best-designed equipment capable of automated operation (Ebner et al., 1996). It is mainly used for production of alcohol vinegar but also can be used for conversion of alcoholic mashes of fruits and grains. By 1993, more than 600 acetator units were in operation worldwide with a total vinegar production of about 135×10^9 liters per yr (Ebner et al., 1996).

Figure 2 is a diagram of the Frings Acetator. The Frings Alkograph® is an automatic detector

that measures the amount of ethanol in the acetator. The Alkograph® automatically activates the vinegar discharge pump when the level of ethanol approaches zero. A level switch in the acetator stops this pump and starts the mash pump, which refills the fermenter slowly with fresh mash back to the original volume (Ebner and Follmann, 1983). New biosensors and modern membranes have permitted development of devices, such as the Frings Alkosens®, that measure alcohol levels without time delay (Ebner et al., 1996).

To produce vinegar with from 12–15% acetic acid in the acetator, Ebner (1985) developed a semicontinuous process. Each fermentation cycle (about 24–40 hours depending on the conditions) starts with 7–10% acetic acid and about 5% ethanol. When the alcohol concentration drops to between 0.05 and 0.3%, a volume of the fermentation beer is rapidly discharged. The acetator is recharged slowly with a volume of new mash containing 0–2% acetic acid and 12–15% ethanol, until the starting conditions are again reached. Then a new cycle begins again.

Ebner et al. (1996) reported that since 1994 the single-stage process could be modified to produce vinegar up to 19% acetic acid. Also a two-stage process has been developed to produce vinegar with 18.5% acetic acid (Ebner and Enenkel, 1978). Since 1993, vinegar of more than 20% acetic acid was produced by this process, and an automatic control arrangement for the process has been described (Ebner et al., 1996). The canning industry has a high demand for vinegar with very high acetic acid levels (19–20%). Thus the vinegar industry has developed plants that utilize the two-stage submerged-fermentation process to produce this product (Ebner and Follmann, 1983).

A factory for production of glacial acetic acid using the vinegar process was built in Turkey in 1962. This factory had operated for 20 years before production was discontinued in 1981. It produced 2 tons/day of glacial acetic acid from molasses (Ebner and Follmann, 1983). The process included: alcoholic fermentation of a diluted molasses medium; separation of the purified ethanol; submerged-process vinegar production; extraction of acetic acid from vinegar with ethyl acetate; separation of anhydrous acetate from ethyl acetate by distillation; and recovery of the ethyl acetate. Other similar factories erected in other countries have been shut down. The future of such factories depends upon competing oil prices and further developments of the vinegar process.

The total production volume of vinegar output in the European Union and Japan can be fairly well estimated. However, the United States vinegar production figures have not been published since 1987, and production levels in China and Russia are unknown. Excluding China and Russia, a 1996 estimate of worldwide vinegar of 10% acetic acid is given as about 1.9×10^9 liters per yr or 190,000 tons of pure acetic acid (Ebner et al., 1996).

Research and Development

STRAIN IMPROVEMENT: *ACETOBACTER* Odd as it may seem, the vinegar industry has always worked with acetic acid bacteria that are not properly characterized. Industrial submerged fermentations are normally started by inoculation with an undefined sample from a previous running fermentation called "inoculation vinegar." The lack of defined pure starter cultures is due to problems of isolation, cultivation and preservation of the vinegar bacteria. Entani et al. (1985) developed a double-layer agar technique using an acetic acid-ethanol (AE)-medium that permitted cultivation of the *Acetobacter* species capable of producing 10–15% acetic acid in the commercial acetator. Sievers et al. (1992) and Sokollek and Hammes (1997) have perfected techniques for isolation and cultivation of pure colonies of production strains that now can be preserved and identified. In 1992, Sievers et al. described a new species, *A. europaeus*, claimed to be the major component in industrial vinegar "fermenters" in Central Europe (Sievers et al., 1992). However, using the new isolation technology and hybridization with olignuclotide probes constructed on the basis of the 16S rDNA sequences published by Sievers et al. (1994a), only four of ten strains isolated from running industrial acetators in Southern Germany were identified as *A. europaeus* (Sokollek et al., 1998). The other six acetic acid bacteria (presumably *Acetobacter* species) could not be identified by hybridization with the DNA probes available. Starter cultures prepared from both an identified (*A. europaeus*) and an unidentified *Acetobacter* strain when inoculated into a pilot acetator achieved the acetate production characteristic of the industrial process. Thus, it is now possible to carry out useful experiments incorporating genetic technology to improve industrial strains of *Acetobacter*.

The desirable characteristics of acetic acid bacterial strains useful to the vinegar industry are: tolerance to high concentrations of acetic acid and to "total concentration" (acetic acid + ethanol); requirement for low concentrations of nutrients; absence of acetic acid overoxidation; and high productivity. Genetic techniques have been developed over the past 15 years directed toward strain improvement and understanding of the physiology of these characteristics. Also the perceived problems of strain stability as well

Table 4. Comparison of acetic acid productivity between two transformants of *Acetobacter aceti* NBI2099.

Indicators of production and yield	*A. aceti* NBI2099 (pMV24)[a]	*A. aceti* NBI2099 (pAL25)[a]

as development of bacteriophage resistance are being addressed. Development of genetic systems for DNA transfer and expression in acetic acid bacteria has been reviewed (Beppu, 1993; Fukaya et al., 1992). A great deal of work has resulted in the construction of a number of useful chimeric plasmids composed of *Escherichia coli* vectors and cryptic plasmids from *Acetobacter aceti* or *Gluconobacter suboxidans*. Drug-resistant markers on *E. coli* plasmids, such as resistance to ampicillin, kanamycin, chloramphenicol and tetracycline, are expressed in acetic acid bacteria; some of the chimeric plasmids are stable in both hosts without selective pressure. Genetic transformation of acetic acid bacteria has been demonstrated by conjugal transfer from other species of Gram-negative bacteria carrying hybrid conjugal plasmids. In vitro transformation of *A. aceti* by plasmid DNA has been carried out on cells pretreated with calcium ions or polyethylene glycol. Efficiencies of 10^5 transformants per μg plasmid DNA are reported. Electroporative transformation of *A. xylinum* with plasmid DNA is also successful. Insertional inactivation was achieved by transforming a wild-type strain of *A. aceti* using a chimeric plasmid containing a cloned *leuB* gene with an inserted kanamycin resistance gene within the *leuB* sequence. Transformant cells were produced that were both *leuB*-negative and KmR. This work demonstrated both gene disruption and a method for foreign gene insertion (insertional inactivation) as a result of homologous recombination in the *A. aceti* host (Okumura et al., 1988). A third method, spheroplast fusion, has been developed for *Acetobacter* strains. After mixing of spheroplasts of two different strains, regeneration of cells yields a fusion frequency of about 10–5. The purpose here is to obtain fused cells that express desired properties of both the "mother strains" (Fukaya et al., 1989).

Cloning and sequencing of the two *Acetobacter* genes for the two membrane-bound dehydrogenases (alcohol dehydrogenase [ADH] and aldehyde dehydrogenase [ALDH]) have been reported. Characterization of these genes in a number of *Acetobacter* species and in *Gluconobacter suboxydans* is still under study (Beppu, 1993). In a preliminary report, *A. aceti* showed improved acetic acid production and yield after being transformed with a multicopy plasmid carrying the ALDH gene (Table 4). These results suggest that genetic manipulation may lead to improved production strains.

Research on the causes of spontaneous mutation of strains of *A. aceti* and *A. pasteurianus* is underway to determine the nature of the genetic instability of ethanol oxidation during industrial vinegar production. Genetic analysis has implicated insertion of IS element IS1380 into the ADH gene or into the cytochrome *c* gene as being responsible for some cases of mutation. The direction of research on strain instability and on the genetics of tolerance to acetic acid and ethanol has been reviewed (Beppu, 1993).

Strain Improvement: Acetogens The use of the acetogenic bacteria in the anaerobic process of acetic acid production presents three serious problems. The first major concern is low tolerance to acid. The bacterial species listed in Table 3 have been studied in enough detail to indicate that no growth and little acetate production occur at less than pH 4.7. Research over the past 15 years on adaptation or selection of mutants of homoacetogens that tolerate lower pH values has been only partially successful. For example, one strain (mutant C5-3 of *C. thermoaceticum*) grew in continuous culture and (at pH 5.3–5.8) produced up to 3.5–4.5 g of acetic acid/liter. Most recent research on mutation and strain selection has concentrated on *C. thermoaceticum* (Wiegel, 1994). A promising mutant of *C. thermoaceticum* (ATCC49707 or DSM6867) produced up to 55 g/liter, under controlled pH 6.2–6.8, during fed-batch fermentation of glucose. This strain also tolerated dolime (high-magnesium lime) up to 60 g/liter (Parekh and Cheryan, 1991; Parekh and Cheryan, 1994b). This strain is presently under development for

production of calcium-magnesium acetate (CMA; Cheryan et al., 1997).

The second problem for the acetogenic production process is low productivity. In the batch process, rates of 0.5–0.8 g/liter · h are considered unacceptable (Busche, 1991). Only technological advances in the fermentation process, covered below, can improve low productivity. The third problem is that the rate of acetic acid production by acetogens is closely coupled with the rate of growth. *Clostridium thermoaceticum* under fed-batch fermentation conditions and with higher acetate-producing mutants seems to exhibit some uncoupled acetic acid production. However, higher yields of acetic acid and decreased biomass waste would result with an increase in growth-uncoupled acetic acid production (Weigel, 1994).

PROCESS DEVELOPMENT: *ACETOBACTER* Research on development of the acetic acid production process involves many types of bioreactors. In Table 5, the characteristics of some of these experimental bioreactors and processes are compared to three industrial bioreactors in use for vinegar production. The focus of this research is to develop a process that yields a high production rate with a high exit concentration of acetic acid, while maintaining a long period of stable operation. All of these objectives must be realized if the *Acetobacter* process is to be eventually incorporated into a commercial glacial acetic acid production system that will be competitive with the chemical manufacturing processes. Using the commercial submerged vinegar fermentation with a Frings acetator in a semicontinuous mode, the process output is 120–150 g of acetic acid/liter (Table 5). A 64,000-liter unit can produce more than 6,000 lbs of acetic acid in 24 h and is stable for 360 days. The experimental processes listed in Table 5 have achieved much higher productivities than present commercial processes, but in general sacrifice the high acetic acid output. The cell-recycle continuous bioreactors with hollow fiber filtration modules have achieved the highest productivity in the laboratory setting, producing 5–50 times more acetic acid (g/liter · h) than the Frings acetator. However, the output acetic acid is two to three times more dilute (45.7–60 g/liter), thus placing the greater burden on the final separation processes.

Park et al. (1991) investigated a semicontinuous reactor with ethanol fed to maintain 20–30 g/liter for about 50 h when acetic acid accumulated to about 85–90 g/liter (see Table 5). Oxidation of ethanol slowed to zero at this time and the cell culture was rapidly recycled through a hollow fiber filter. The concentrated cells were then diluted with fresh medium and a new cycle started. It was found that the *Acetobacter* cells lost much viability but the nonviable cells continued to oxidize ethanol during the later cycles. A high acetic acid output of about 85–90 g/liter was maintained through six cycles or for about 300 h.

[c]Cell density (0.8 g-dry/liter) and dilution rate, 0.5 h^{-1}.

Upon scale-up, the engineering of these cell-recycle bioreactors promises to be more costly and more complex to operate than the commercial semicontinuous submerged Frings acetators. The experimental shallow-flow bioreactor is designed to give a continuous horizontal flow of medium under a bacterial film with a large surface area of a few hundred cm^2. The liquid depth is less than 10 mm, resulting in high oxygen absorption and an acetic acid output of 57.6 g/liter (Table 5). This apparatus is technically simple and has been shown to yield very high rates of production of acetic acid (31.7 g/liter · h) without the energy required for forced aeration (Toda et al., 1989). Furthermore, the high productivity is dependent on the high surface-to-volume ratio of the shallow liquid flow and the exit acetic acid concentration (50–66 g/liter) does not change very much over a ten-fold variation in liquid residence time.

There have been a great many reports of experimental bioreactors based on the immobilized cell technology. Some of these are listed in Table 5. Many difficulties have been encountered with immobilized cell systems such as poor oxygen exchange and breakdown of gels and beads with consequent bleeding of attached bacteria. The advantage of these bioreactors is that the productivity is three to four times that of commercial processes. None of these immobilized approaches has gone beyond the small pilot-plant bioreactor stage and much more engineering development is necessary for practical commercial application of this technology (Mori, 1993).

Research has demonstrated efficient production of acetic acid from glucose in a coculture of *Zymomonas mobilis* and *Acetobacter* strains (Kondo and Kondo, 1997). Normally, in the vinegar process, the anaerobic ethanol fermentation is carried out separately from the oxidative conversion of ethanol to acetic acid, which requires highly aerobic conditions. Even though *Z. mobilis* grows and produces ethanol from glucose more rapidly in anaerobic culture and *Acetobacter* spp. grow and produce acetic acid under aerobic conditions, the two organisms in fact can coexist in natural settings such as fermentation of plant juices and beers. Also both of these bacteria are tolerant to low pH and high ethanol concentrations (Swings and deLey, 1977). The culture of two bacteria with 100 g of glucose/liter was initially operated at low aeration and low agitation until the glucose reached 5 g/liter, and then the shift to acetic acid production was started by operating at high aeration. The acetic acid yield from glucose was 0.64 g/g (95.5% of theoretical) and thus 62–70 g of acetic acid/liter was produced in about 60 h in these experiments. Further research and scale-up may yield a coculture method for direct manufacture of acetic acid from inexpensive sources of sugar with acetic acid outputs of 120–150 g/liter, similar to production achieved by the Frings acetator (Table 5).

Process Development: Acetogens Development of processes for production of acetic acid by the anaerobic acetogenic bacteria has focused mainly on fermentation of sugars. The advantage of these bacteria (such as *C. thermoaceticum*) is that they are homofermentative, with almost quantitative conversion of substrate to acetic acid. However, as outlined above (see "Strain Improvement: Acetogens"), they are sensitive both to high sugar concentration and to inhibition by acid conditions, resulting in limited acetic acid output (less than 20 g/liter) in batch culture.

The acid tolerant mutant of *C. thermoaceticum* ATCC49707 (see "Strain Improvement: Acetogens") when grown in batch culture with pH controlled at pH 6.3–6.8 showed a much improved acetic acid output of 30–40 g/liter and a productivity of 0.3 g/liter·h (see Table 6). Experimental fermentations have been con-

[a]All results were obtained using *C. thermoaceticum* ATCC47909 fermentation of glucose at pH 6.3 to 6.8, except for immobilized cell results, which were *C. formicoaceticum* ATCC 27076 fermentation of fructose at pH 7.6.

ducted to replace expensive additives like yeast extract (YE) with low-cost nutrients. The best source of nutrients found for sugar fermentation using *C. thermoaceticum* is corn steep liquor (CSL), which has been used in industrial ethanol fermentations and for production of pharmaceuticals. This research is summarized by Cheryan et al. (1997). Because *C. thermoaceticum* and other acetogenic anaerobic bacteria are sensitive to high sugar concentrations, experimental fed-batch mode fermentations resulted in higher acetate outputs (see Table 6). Here additional substrate is added as a concentrate at intervals during the fermentation. However, the productivity still remained very low. Continuous fermentation and immobilized whole cell systems have been used to increase productivity in acetogenic fermentations (Table 6).

Several experimental cell recycle bioreactors using a membrane module as a separation device have been developed that yield up to five-fold greater productivity in anaerobic fermentations (Cheryan et al., 1997; see Table 6). Figure 6 is a diagram of a continuous cell-cycle membrane bioreactor. The reactor is connected in a continuous closed loop with the S ultrafiltration membrane module. Product is removed in the permeate and feed is added and volume adjusted in the reactor. Because acetate production is "growth-associated," excess cells must be bled from the retentate. The entire system runs at a high cell density permitting the same high output of fed-batch fermentations with four to five times the productivity. These bioreactors have retained stable operation for greater than 50 days (Table 6). Experiments with the cell-cycle continuous reactors show that (at high dilution rates of 0.03 h^{-1}) the productivity is 1.7 g/liter · h, but the output was only 25 g/liter; at a low dilution rate of 0.007 h^{-1}, productivity dropped to 0.4 g/liter 7 · h, with a high output of 45 g/liter. Thus, a compromise must be set dependent on the other process elements. Variations such as the two-stage continuous cell-recycle and the continuous cell-recycle with fed-batch draw and fill bioreactors are being developed and have both higher output of acetic acid and the higher productivity (see Table 6). Acetic acid production from fructose at pH 7.6 by *C. formicoaceticum* immobilized in a fibrous-bed bioreactor is under development. Both fed-batch and continuous processes were examined (Table 6). Inasmuch as both a higher maximum production rate and higher inhibition rate constant were observed in the fibrous-bed reactor, it was concluded that immobilized cells were less sensitive to acetic acid inhibition than were unattached suspended cells. This improved cell behavior predicts that a fibrous bed reactor may be a tool for adapting these bacteria to acetate-tolerance (Huang et al., 1998b).

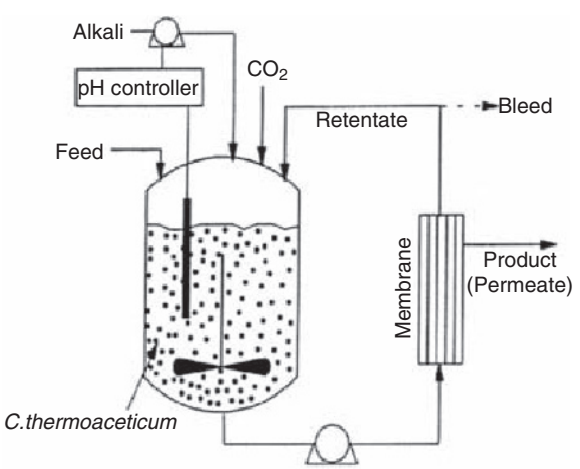

Fig. 6. Production of acetic acid from glucose by *Clostridium thermoaceticum* in a continuous bioreactor. The schematic shows the use of membrane separation for product recovery and cell recycle. From Cheryan et al. (1997), with permission.

Extractant Systems for Acetic Acid Recovery

Fermentation beers are mostly water with a small amount of acetic acid, usually 1.2–3.5%. Recovery costs are significant and they become a major economic consideration for any successful process. The commercial choice for acetic acid recovery has been solvent extraction. Busche (1985) presented an example of an extractive fermentation process along with a cost analysis for a glacial acetic acid plant producing 250×10^6 lbs/y. It is clear from this analysis that recovery costs make up a significant contribution to the overall cost of production. Most important is that product recovery costs are very sensitive to the acetic acid concentration of the fermentation liquor. Busche (1991) compared the economics of manufacture of glacial acetic acid by extractive fermentation using Acetobacter suboxydans with extractive fermentation using *Clostridium thermoaceticum*. A model was designed based on continuous production of acetic acid in fluidized bed bioreactors with recycling beginning with corn syrup-glucose. The ethanol is prepared from corn syrup by fermentation in a continuous bioreactor using *Zymononas mobilis*, and the ethanol beer is directly sent to the *Acetobacter* bioreactor after removal of the *Z. mobilis* cells. Even though the *C. thermoaceticum* fermentation of corn syrup-glucose has a 90% yield, the low output of 3.6% acetic acid results in a higher cost of product purification. The extraction process involves treatment of the broths in a continuous countercurrent multistage extractor using a high-boiling

solvent such as trioctyl phosphine oxide at 50% in 2-heptanone (with a K of 2.5 and a low solubility in water of 1 ppm). The extract is then treated in distillation columns to purify the glacial acetic acid product. The entire technoeconomic analysis showed that the combined *Acetobacter-Zymomonas* scheme for glacial acetic acid production is slightly less costly than the *Clostridium* direct high-yield fermentation ($0.38 versus $0.42/lb). However, neither was competitive with the price at that time of $0.29 to $0.31/lb for synthetic glacial acetic acid. Improvements in bioreactor design were covered in the sections above for oxidation of ethanol by Acetobacter (see "Process Development: *Acetobacter*" in this Chapter) and for sugar fermentation by *Clostridium* (see "Process Development: Acetogens" in this Chapter). These improvements, which produce a higher acetic acid output at an acceptable productivity when combined with downstream organic extractant methods, may eventually result in glacial acetic acid production from biomass competitive with synthetic acetic acid production. Althouse and Tavlarides (1992) made an analysis of 50 organic extractant systems for acetic acid removal. Two candidate extractants (Adogen 381 [40% in cyclohexanone] and Adogen 381 [Xy-Mix]) were selected based on a number of criteria. Either was suggested for the extraction of dilute acetic acid from the outflow of a fermenter. The membrane techniques electrodialysis (ED) and nanofiltration (NF) have been found useful for downstream separation and partially concentrating acetates (Cheryan et al., 1997). Several NF membranes were screened for separation of acetic acids and the technique appeared to be economically sound for consideration in processing fermentation broths (Han and Cheryan, 1996).

Development of Processes for Production of Calcium Magnesium Acetate

The thrust of research and development for production of acetic acid by acetogenic bacteria such as *Clostridium thermoaceticum* and *C. formicoaceticum* is the manufacture of acetate salts. Calcium magnesium acetate (CMA) and potassium acetate (KAc) have been approved by the U.S. Federal Highway Administration as environmentally safe and noncorrosive deicers for winter roadways and for airport runways (Yang et al., 1997). Acetate salts are considered a commodity chemical. Presently, CMA is made from petroleum-derived glacial acetic acid at a cost of about $1,000/ton. Two processes for the production of CMA requiring acetogenic bacteria as biocatalysts have been analyzed to demonstrate technical and economic feasibility.

In a demonstration project report (Basu et al., 1999), a process was outlined whereby municipal solid waste (MSW) coal or sewage sludge was converted to syngas (CO, CO_2 and H_2) by well-known technologies. For example, lignocellulosic biomass may be gasified by the approximate reaction:

$$8CH_2O + 2O_2 + (8N_2) \rightarrow 6CO + 2CO_2 + 6H_2 + 2H_2O + (8N_2) \quad (11)$$

The cooled gas mixture of CO, CO_2, and H_2 was then converted by a new proprietary acetogenic bacterium, ER12, to acetic acid/acetate. As was presented above (see "Scientific Background" in this Chapter), members of acetogenic bacteria such as *A. kivui*, *P. productus*, and *A. woodii* produce acetic acid from either CO or H_2 and CO_2 (see Table 3). Strain ER12, isolated by Bioengineering Resources, Inc. (BRI), is a mesophilic acetogen that rapidly utilizes CO, CO_2 and H_2, has a high tolerance to acetate/acetic acid, and can accumulate 15–20 g of product/liter at pH 4.5–5.0. Production of acetic acid was tested in a continuous stirred tank reactor, with both continuous gas and liquid feed, and with cell recycle. The liquid product stream was fed to an extraction column where a solvent (proprietary) extracted acetic acid to a concentration of 50 g/liter. Dolime was added to produce CMA, the solvent was separated for recycle, and the CMA water stream was fed to a dryer. Figure 7 is a diagram of the process of CMA production from waste biomass.

Economic projections for a facility to produce 100,000 tons/year of CMA from MSW were presented. With no charge or credit for the waste materials used, the operating cost with an included 30% investment return was estimated at $200/ton. This price is less than 28% of the price of the CMA deicer.

Also a detailed process has been developed for production of CMA from cheese whey lactose (Yang et al., 1999). Whey, a byproduct from the manufacture of cheese and casein, contains about 4.5% lactose, 1% protein and some salts and lactic acid. The cheese industry in the United States produces more than 57 billion lbs/year of liquid whey with only one-half used in human food and animal feed. Disposal of the excess cheese whey remains an important problem for the dairy industry. A novel fibrous bed bioreactor has been developed for fermentation of whey lactose to produce acetic acid by a coculture of immobilized cells of *Lactobacillus lactis* and *Clostridium formicoaceticum* (Huang and Yang, 1998a). The coculture consists of a homolactic bacterium and a homoacetic bacterium. These two bacteria sequentially convert lactose to lactate and then lactate to acetate, with an acetate yield from lactose greater than 90%. The perfor-

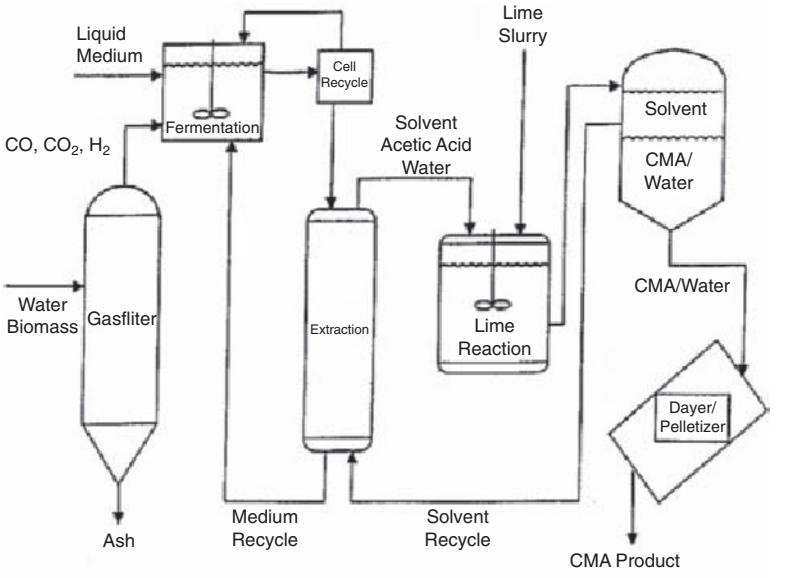

Fig. 7. Process for production of calcium magnesium acetate (CMA) from municipal solid wastes (MSW), sludge or other biomass. Following gasification of the waste, the synthesis gas (CO, CO_2 and H_2) is cooled and fed to a continuously stirred tank reactor containing a liquid stream with nutrient salts and vitamins. The gasses are fermented by an anaerobic acetogenic bacterial culture to form acetic acid. A cell separation system is used to recycle cells back to the reactor, maintaining a high cell concentration and a high production rate and yield of acetic acid. The product stream (15–20 g) acetic acid is fed to an extraction column for solvent extraction of acetic acid yielding 50 g/liter. In a stirred reaction tank, Mg-lime is added to form CMA. The CMA-water stream is fed to a dryer/pelletizer. From Basu et al. (1999), with permission.

mance of *C. formicoaceticum* in the fibrous bed bioreactor was excellent owing to the high cell density (30 g/liter) maintained. In fed-batch operation with corn steep liquor as nutrient at 37°C and pH 7.6, the productivity was about 0.2 g/liter · h and the acetate output was 70 g/liter. Thus, the *C. formicoaceticum* in this bioreactor became tolerant to high acetic acid concentration compared to free cells. The comobilization with the homolactic bacterium, *L. lactis*, in the fibrous bed removed the requirement for purging O_2 from the whey medium to allow growth of the strictly anaerobic *C. formicoaceticum*. *Lactococcus lactis* is not as sensitive to O_2 and removes the residual O_2 from the medium.

Two processes for production of 24 tons/day of CMA from 10^6 lbs of cheese-whey-permeate per day utilizing the fibrous bed bioreactors were evaluated for product quality and manufacturing costs (Yang et al., 1999). Figure 8 diagrams both processes.

In Process 1, the whey is subjected to two tandem fermentations yielding acetic acid, which is then partially extracted from the beer before mixing with dolime to obtain CMA; in Process 2, the whey is fermented by coculture with CaO/MgO added to adjust the pH of the beer. The beer is then evaporated and dried. The CMA produced by both processes had properties very similar to commercial CMA prepared from glacial acetic acid, with a product cost for Process 2 of $291/ton and for Process 1 of $328/ton. The market price for commercial CMA is about $1,000/ton, which is due to the present market price of about $700/ton of synthetic glacial acetic acid (Yang et al., 1999).

Prospects for Bacterial Acetic Acid Production

Specialized Product Areas For the immediate future, chemical synthesis of acetic acid as a commodity chemical from petrochemicals is the major method for production throughout the world. Figure 5 diagrams the major chemical intermediates (precursors of the major industrial products) formed from acetic acid. Production of vinyl acetate, chloroacetic acid, acetic anhydride, and acetate esters requires glacial acetic acid, which is most inexpensively produced by the carbonylation of methanol, the Monsanto process, or by catalytic oxidation of butane (Agreda and Zoeller, 1993). More than 95% of all acetic acid production is directed toward these four precursors.

Is there a niche in which the bacterial processes can be focused on for profitability in the immediate future? First of all, the vinegar industry employing *Acetobacter* species as biocatalysts will certainly continue as a viable presence in the future. Production of vinegar from an expanding variety of fruits and grain sources will always

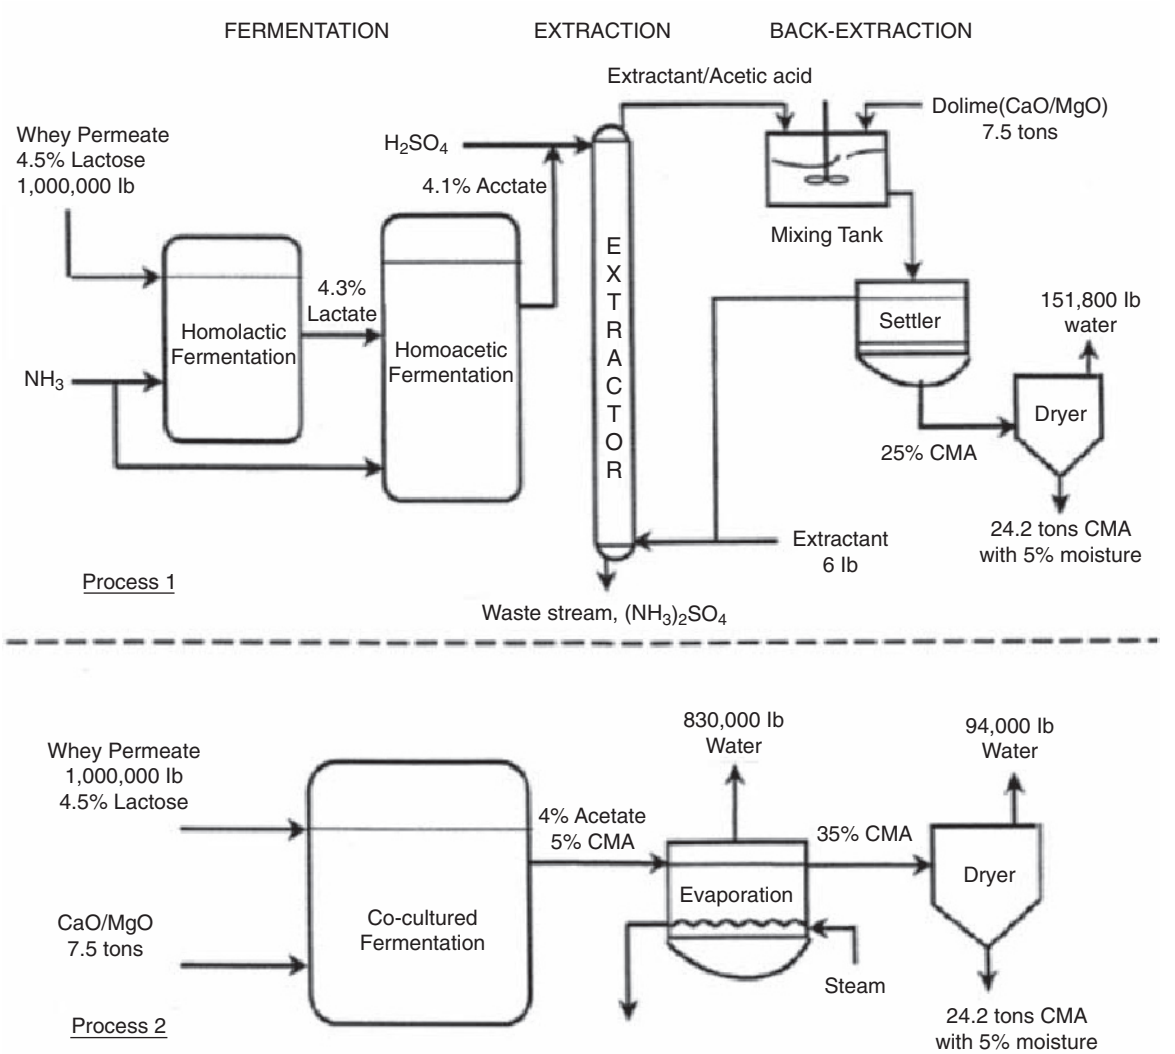

Fig. 8. Two processes for production of calcium magnesium acetate (CMA) from cheese-whey-permeate. In Process 1, the homolactic fermentation of whey-lactose by *Lactococcus lactis* and the homoacetic fermentation of lactic acid by *Clostridium formicoaceticum* are carried out in tandem to produce 4.1% acetate. Acetic acid is concentrated using solvent extraction. Dolime (CaO/MgO) is added to the extractant-acetic acid mixture in a mixing tank. Extractant is recovered. CMA-water is fed to a dryer/pelletizer. In Process 2 the whey-lactose is converted to acetic acid by a simultaneously fermenting coculture of *L. lactis* and *C. formicoaceticum*. Because CaO/MgO is added during the fermentation, the product is 5% CMA (4% acetate). The entire culture beer is steam evaporated to a 35% CMA-water mixture, which is fed to a dryer/pelletizer. From Yang et al. (1999), with permission.

maintain a strong market position in the food industry. The Frings Acetator-based process, utilizing dilute alcohol mashes, remains the most efficient and profitable production method in the food and canning industry (Ebner et al., 1996).

Secondly, the developed bacteria-catalyzed production of inexpensive calcium magnesium acetate (CMA) and potassium acetate (KA) from gasified municipal solid wastes (MSW) or from waste cheese whey is an important product area (see "Development of Processes for Production of Calcium Magnesium Acetate" in this Chapter). The superiority of CMA and KA as deicers for roads and airport runways as well as the economic advantage of the bacteria-based production processes predicts an important area for profitable industrial development for the future. It has been estimated that if only 10% of rock salt is replaced with CMA, the projected annual use of CMA deicer would be $2–2.8 \times 10^9$ lbs/yr. There are also a number of other important industrial uses for acetate salts listed in Fig. 5, such as for heat transfer liquids, meat preservation, and fungicides.

Acetic Acid Production from Bacteria-Based Processes A major decrease in the capacity to synthesize industrial acetic acid from methanol and CO or by other chemical processes may occur at the end of the next century due to depletion of natural gas and petroleum resources together with an increasing demand for these materials worldwide. With price increases accompanying this situation, bacteria-based processes can certainly become major players in the glacial acetic acid market.

Which bacterial process is most attractive for acetic acid production within this future scenario? Ethanol oxidation to acetic acid by the *Acetobacter* process has major advantages over the sugar fermentations to acetic acid by the various acetogens such as *Clostridium thermoaceticum*. Comparing Tables 5 and 6 (see "Current Research and Development"), the former process yields higher output (g/liter) and higher productivity (g/liter · h). In addition, industrial production of glacial acetic acid has been carried out using the *Acetobacter* process (Ebner and Follmann, 1983). Along with the future depletion of petroleum reserves, industrial ethanol production would certainly increase, providing a major source of fuel as well as commodity chemicals. The capacity for fuel ethanol production in the United States as of 1991 was 19×10^9 lbs/yr (Kosaric, 1996). Acetic acid production plants using the Frings Acetator® and new extraction technologies could produce industrial glacial acetic acid directly from the ethanol streams of future ethanol production plants.

A second prospect for acetic acid production is the direct conversion of gasification products, CO, CO_2 and H_2, to acetic acid by anaerobic acetogens. Table 3 (see "Commercial Applications" in this Chapter) is a list of acetogenic bacteria that utilize these gases in addition to methanol, producing almost exclusively acetic acid. The demonstration of acetic acid production from gasified MSW and other carbon sources by the acetogen ER12 showed that these waste sources can be utilized to produce acetate salts efficiently and profitably (see "Development of Processes for Production of Calcium Magnesium Acetate" in this Chapter). Production of glacial acetic acid on a large scale would require development of additional extraction and distillation technologies to separate acetate from the dilute beers. Research efforts focused on increasing acid tolerance of the anaerobic acetogenic production strains by mutation or by immobilization methods will be important to the success of these processes. A future goal will be to develop acetogens that utilize waste sugar sources and/or degrade cellulosic polymers while producing a high proportion of acetic acid (>90%) in the product steam.

Section 2: Lactic Acid

Introduction

With the development of agriculture, at about four to five thousand BCE, the problem of food storage for future use emerged. It was recognized early that fermentation of foods such as milk, vegetables, fruits and meats resulted in both enhanced flavors and better preservation. Food containers dating from 2300 BCE discovered in Egypt with cheese-like residues suggest that lactic acid fermentations have been used for at least four to five thousand years (McGee, 1984). The manufacturing processes applied in these ancient "lactic acid" fermentations were household or small-scale and craft-centered, so improvements were small and slow. But the development of a true technology of the fermentation process had to await the Industrial Revolution in the 18th century, bringing with it the advent of the science of chemistry. Lactic acid (2-hydroxypropionic acid), the major acid in these fermentations, was first identified as a chemical substance in sour milk whey by Carl Wilhelm Scheele in 1780. Scheele was a gifted experimentalist and probably the first organic chemist in history (Benninga, 1990). Besides lactic acid, he also discovered tartaric acid, citric acid, malic acid, and a number of other organic acids.

In 1857, Louis Pasteur was the first to recognize that a lactic fermentation was due to a peculiar gray substance he called a "lactic yeast," which he found was responsible for production of lactic acid. Further, he showed that the lactic yeast was distinctly different from the brewer's yeast that converted sugars to alcohol and CO_2. Later, in 1877, the careful experiments of the famous surgeon, Joseph Lister, demonstrated that only a single bacterium, "*Bacterium lactis*," was sufficient to bring about souring or fermentation of cows' milk. Lister's landmark experiments established not only that one bacterium would cause the lactic acid fermentation, but also that his dilution method made it possible to prepare pure cultures of a single bacterial type. Following Lister's discovery, isolation of pure cultures of lactic acid bacteria became a vital stage in developing a scientific approach to any microbial fermentation process.

The early development of microbial processes for industrial production of ethanol or lactic acid occurred in Berlin at the "Research Institute for Fermentation Industries," directed by Max Delbrück. The major accomplishments of this institution were the preparation of pure cultures of bacteria or yeasts for industrial fermentations and the application of the principle of "natural pure culturing." In "natural pure culturing," the characteristic properties of the desired microbe

are used (in an industrial process) to suppress the growth of undesirable bacteria, thereby allowing its growth to dominate. This principle was applied to lactic acid production by raising the fermenter temperature to 45–50°C, which permitted growth of the lactic acid bacteria while preventing growth of most contaminant microorganisms.

The first industrial fermentation for lactic acid production was at the Avery Lactate Co. in Littleton, Massachusetts. Charles Avery, a chemist who attended Massachusetts Institute of Technology (MIT), discovered that (to produce baking powder) calcium lactate would act as an acidulant in place of the more expensive cream of tartar (potassium bitartrate) when added to sodium bicarbonate. At that time, baking powder had been introduced into the baking industry. However, the new product was a commercial failure owing to both technical problems and economic competition from another effective acidulant, exsiccated alum (Benninga, 1990). Pure cultures of "*Lactobacillus delbrueckii*" and "*Lactobacillus bulgaricus*" were prepared for industrial use by Max Delbrück's Institute for the Fermentation Industries in Berlin from about 1896. Taking advantage of these pure cultures, Albert Boehringer established the first commercially successful large-scale lactic acid production plant in Ingelheim. It came on line in the late 1890s, producing technical grade lactic acid (50 and 80%), which was sold for use in the textile and leather industries, replacing tartaric acid and tartrates. Prior to 1914, five lactic acid production plants emerged in the United States. However, imported German technical grade lactic acid was of the higher quality required for textile, leather and pharmaceutical uses and thus it competed successfully in the United States market. During World War I, the lactic acid industry in the United States expanded rapidly to a total production of 4.6×10^6 lbs/year by 1919, as a result of the disappearance of German competition. However, during the 1920s, the lactic acid fermentation industry in Germany (e.g., Boehringer and E. Merck) recovered and their prewar export markets were rapidly reestablished. Because of the high quality and low prices resulting from new scientific and technical advances and production efficiency, the German exports of lactic acid almost wiped out production in the United States. This lactic acid production (along with worldwide production) again increased, growing to a peak of $7.2–9.0 \times 10^6$ lbs/year during World War II. During this war, sodium and potassium lactate were used as a coolant for armored vehicles in place of glycerol. Between World War II and 1963, lactic acid production in the United States leveled off at about 4.6×10^6 lbs/year.

In 1963, synthetic lactic acid production began on a commercial scale. The chemical synthesis route for synthetic lactic acid yields a racemic mixture of DL-isomers. The commercial process is based on lactonitrile (Holten et al., 1971). Lactonitrile is produced by the base-catalyzed addition of hydrogen cyanide to acetaldehyde. Lactonitrile is then hydrolyzed by strong acid to yield lactic acid, which is purified and recovered. Today, synthetic lactic acid is produced mostly in the United States and Japan, and it accounts for about 50% of total worldwide production. Industrial fermentations also yield about half the world's lactic acid production, and thus are very competitive.

Scientific Background

The physical and chemical properties of lactic acid are extensively covered by Holten et al. (1971). Some of these properties are listed in Table 7.

The two optically active enantiomeric forms are L(+) dextrorotary and D(−) levorotary:

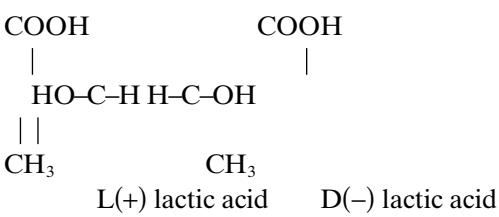

Table 7. Selected properties of lactic acid enantiomers.

Property	Enantiomer and chemical abstracts service registry no.		
	L(+) 79-35-4	D(−) 10326-41-7	DL 598-82-3
Molecular weight	90.08	90.08	90.08
Melting point (°C)	52.8–53.6	52.8–53.6	16.8–33
Boiling point (°C)		103	82–85
Optical rotation $[\alpha]_D^{20}$, in degrees:			
Acid	+2.5	–2.5	
Zinc salt	–8.2	+8.18	
Dissociation constant	1.90×10^{-4}		1.38×10^{-4}
pK (25°C)	3.79	3.83	3.73

From Litchfield (1996), with permission.

Table 7 (from Litchfield, 1996) shows that the zinc salts of the two enantiomers have the reverse optical activity of the free acid. Esters of the two isomers also show the same optical activity shift. Vick Roy (1985) citing Lockwood et al. (1965) states that although the L(+) form appears to be dextrorotatory, it may actually be levorotary as are the salts and esters. The apparent (+) optical rotation may be due to formation of an ethylene oxide bridge between carbons 1 and 2, with a tautomeric shift of the hydroxyl group from carbon 1 to the carbonyl group. Salts and acids cannot form the epoxide ring and are levorotary. Lactic acid is infinitely soluble in water and has low volatility. In solutions of 20% or more, lactic acid polymerizes into linear dimers of lactoyl lactate or higher polymers as well as cyclic dimers of D, D-, L, L-, or D, L-lactides. Lactic acid is both an organic acid and alcohol and therefore can participate in many chemical reactions. The lactic acid bacteria used in industrial fermentations or under development for commercialization are listed in Table 8. The various bacterial strains produce either almost pure lactic acid enantiomers, L(+) or D(−), or a racemic mixture of DL-lactic acid. The present nomenclature (Kandler and Weiss, 1986) lists *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Lactobacillus rhamnosus* (formally *Lactobacillus delbrueckii*) as producers of D(−) and L(+) lactic acid, respectively (see Table 8). In earlier industrial fermentations producing L(+) lactic acid, *L. delbrueckii* was the specified species used. Thus, it is important to be aware of improper identification of strains in the literature, owing to frequent reclassifications. Because of the new markets for specialty polylactic acid polymers, there is a need for L,L-, D,L- and D,D-lactide dimers as precursors of polymers with different physical properties (Datta et al., 1995). Strain selection for commercial scale fermentation focuses on: 1) rapid fermentation of inexpensive carbon sources with low nitrogen content; 2) high yield of stereospecific lactic acid with low amounts of cell mass and other products; and 3) tolerance to low pH (below pH 5) and high temperature (about 45°C). The industrially important organisms are "facultative anaerobes" in that they tolerate oxygen but do not use it as a final electron acceptor in respiration to generate a proton gradient for ATP synthesis. In addition, the fermentation process characterized by high temperature (above 40°C), low oxygen, high lactic acid and low pH tends to restrict contamination by unwanted bacteria.

Lactobacillus rhamosus (formerly *L. delbrueckii*) produces high yields of L(+)-lactic acid from sucrose and glucose at 45°C, making it an excellent commercial production strain (Table 8). But this bacterium will not utilize lactose, so it cannot make use of cheese whey. *Lactobacillus delbrueckii* subsp. *bulgaricus* and *L. helveticus* both ferment lactose from cheese whey, producing high yields of lactic acid. *Lactobacillus delbrueckii* produces the D(−) enantiomer and *L. helveticus* a racemic mixture of DL-lactic acid. Because most commercial fermentations are developed for L(+)-lactic acid production, strains of *L. casei* and *Lactococcus lactis* are being developed for fermentation of lactose sources such as cheese whey.

There are two pathways for the uptake and metabolism of lactose by the lactose-fermenting lactic acid bacteria summarized in Fig. 9 (Davidson et al., 1995). One pathway transports lactose into the cell using a proton symporter, which is a classical lactose permease. Hydrolysis of lactose is catalyzed by a β-galactosidase to D-glucose and D-galactose. D-Galactose is converted to glucose-1-phosphate by the Leloir pathway (Gottschalk, 1986), and both glucose and glucose-6-phosphate are further metabolized by the Emb-

Table 8. Selected lactic acid bacteria: their fermentation pathways, lactic acid enantiomer produced, and major carbon sources used.

Bacteria	Fermentation pathway	Lactic acid enantiomer	Carbon sources substrates and complex
Lactobacillus delbrueckii subsp. *bulgaricus* (formerly *L. bulgaricus*)	Obligate homolactic	D(−)	Lactose, cheese whey, casein whey, and cheese whey permeate
Lactobacillus rhamnosus (formerly *L. delbrueckii*)	Homolactic-inducible heterolactic	L(+)	Glucose, sucrose and potatoes
Lactobacillus helveticus	Obligate homolactic	D, L	Cheese whey permeate and lactose
Lactobacillus amylophilus	Obligate homolactic	L(+)	Starch
Lactobacillus amylovorus	Obligate homolactic	D, L	Starch
Lactobacillus casei subsp. *casei* and subsp. *rhamnosus*	Homolactic-inducible heterolactic	L(+)	Lactose and cheese whey
Lactococcus lactis subsp. *lactis* and subsp. *cremoris* (formerly *Streptococcus lactis*)	Obligate homolactic	L(+)	Lactose and cheese whey permeate
Streptococcus thermophilus	Obligate homolactic	L(+)	Lactose

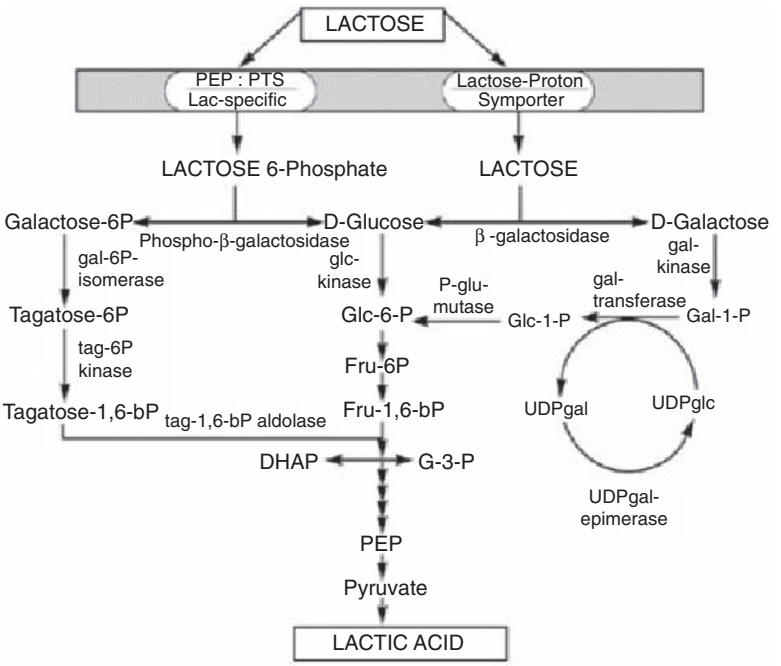

Fig. 9. Pathways for uptake of lactose and metabolism to lactic acid.

den-Meyerhof pathway to lactic acid. The second pathway uses a phosphoenolpyruvate-dependent phospho-transferase system (PEP:PTS, Lac-specific) to form lactose-6-phosphate from lactose as it is transported through the cytoplasmic membrane. The lactose-6 phosphate is hydrolyzed by phosphoryl-β-galactosidase to glucose and galactose-6-phosphate. The galactose-6-phosphate is converted to tagatose-6-phosphate, then tagatose-1, 6-biphosphate, and finally triose-phosphates by a series of enzymes. The triose-phosphates and glucose then enter the Embden-Meyerhof pathway as shown in Fig. 9. *Lactobacillus delbrueckii* and *L. helveticus* contain the lactose-permease-β-galactosidase pathway, whereas *L. casei* and the *Lactococcus lactic* have only the PEP:PTS and phospho-β-galactosidase pathway (Arihara and Luchansky, 1995).

Two species of *Lactobacillus* that utilize starch as a substrate are listed in Table 8. Although starch is not normally utilized by lactic acid bacteria, two species, *L. amylophilus* (Mercier et al., 1992) and *L. amylovorus* (Cheng et al., 1991; Zhang and Cheryan, 1994a), have been isolated and are able to produce a high yield of lactic acid from liquified starch in experimental fermenters.

The industrial strains of lactic acid bacteria can completely ferment a medium of 12–15% sugar in 2–4 days with greater than a 90% yield of lactic acid. All of these bacteria are considered homofermentative in that they utilize a homolactic fermentation pathway, producing two molecules of lactic acid for each molecule of hexose. As

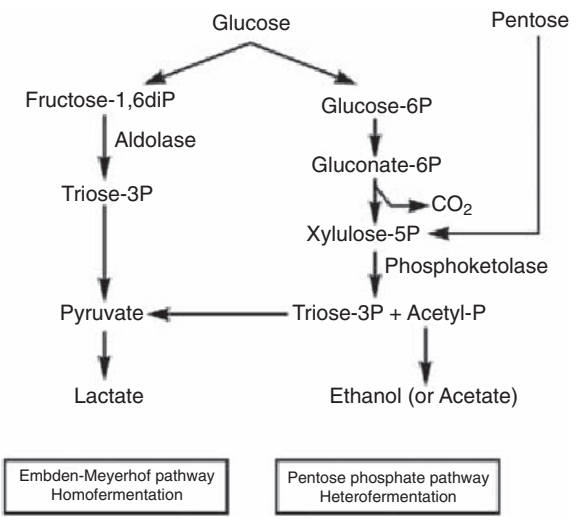

Fig. 10. Metabolic pathways of carbohydrates used by lactobacilli. From Bigelis and Tsai (1995), with permission.

diagrammed in Fig. 10, the Embden-Meyerhof pathway is used in the homolactic fermentation.

The fructose 1,6-diphosphate (FDP) is the key intermediate, and the two enzymes, fructose-6-phosphate kinase and FDP aldolase, are diagnostic for this pathway. In some lactic acid bacteria, the L-lactic dehydrogenase (LDH) is allosterically activated by FDP and/or Mn^{++} ion. The obligate homolactic strains listed in Table 8 ferment sugars (usually hexoses) only by this pathway. Table 8 also lists two homolactic-inducible heterolactic strains, *L. rhamnosus* and *L. casei*. These lactic acid bacteria can use the pentose

phosphate pathway shown in Fig. 10 by inducing the enzyme phosphoketolase. All of the other enzymes needed for this pathway are present in all these bacteria. Induction of this pathway usually requires very low hexose concentrations (and thus lower internal FDP) and/or added pentose. This pathway produces one mole each of lactate, acetate (or ethanol) and CO_2 for each mole of hexose, or one mole each of lactate and acetate for each mole of pentose. A few lactic acid bacteria use exclusively the pentose phosphate pathway because they do not produce the enzyme FDP aldolase. However, these strains are not useful in commercial lactic acid production. The production of a stereospecific product, D(−)- or L(+)-lactic acid, by these bacteria is due to the stereospecific lactic dehydrogenases, L-LDH and D-LDH. It was thought that bacteria such as *L. plantarum* or *L. helveticus* that produce D, L-lactic acid contains a racemase. However, it was shown that *L. plantarum* contains both enzymes, D-LDH and L-LDH, and thus can easily equilibrate added lactic acid enantiomers by catalysis through pyruvate (Dennis and Kaplan, 1960). The two enzymes have quite different properties. Cloning and sequencing of the L-LDH and D-LDH genes revealed no significant homology between them. However, the D-LDH genes from other lactobacilli were found to be homologous (Taguchi and Ohta, 1991).

Lactic acid bacteria are well known for their complex nutrient requirements for growth. An array of vitamins, nucleotides, and amino acids or peptides is essential, and the minimum requirements for growth of each strain can vary (Buchta, 1983). Further, many of the growth factors significantly increase the rate of lactic acid fermentation. Because of the large number of essential and stimulatory factors, it is impractical to cultivate these organisms in chemically defined medium. In large commercial-scale fermentations, complex nutrient sources such as corn steep liquor, malt extracts, malt sprouts or soybean extract are added. Although cheap, the crude materials also may contain specific inhibitors of the fermentation and also increase the cost of lactic acid purification downstream (Bigelis and Tsai, 1995). Thus, a balance must be established between the high rate and yield of a fermentation and the purification costs. Because carbon dioxide (CO_2) fixation is required for many biosynthetic pathways in bacteria, it is not surprising that CO_2 is shown to stimulate growth of many lactic acid bacteria. During a pure homolactic fermentation of sugars, no CO_2 is produced. To prevent a CO_2 limitation, calcium carbonate may be added to neutralize lactic acid for pH control during a fermentation (Bigelis and Tsai, 1995). Some lactic acid bacteria require added fatty acids or fatty acid esters (Tweens). Often fatty acids can be synthesized by these organisms when the vitamin, biotin, is added to the fermentation broth (Bigelis and Tsai, 1995).

The different lactic acid bacterial strains show pronounced differences in proteolytic capacities allowing them to grow on protein sources from meats, vegetables and milks for a supply of amino acids and small peptides. Because these bacteria have multiple amino acid requirements and cannot utilize ammonia as a sole nitrogen source, their growth is dependent upon an efficient system for protein and peptide degradation and transport. The lactic acid bacterial strains selected for a specific industrial fermentation (e.g., sucrose with added corn steep liquor) must have optimal proteolytic characteristics as well as lactic fermentation abilities for the particular set of raw materials used. The efficiency of the fermentation is intimately dependent on the cascade of proteolytic reactions that occur during growth and fermentation. The genetics and physiology of the proteolytic system of lactic acid bacteria have been reviewed (Kok and deVos, 1994). Peptides are sometimes more effective than free amino acids for growth and fermentation. For example, whey protein with an average peptide length of six amino acids (700 kDa) was found most effective for high production rates of lactic acid in *L. delbrueckii* subsp. *bulgricus* (Leh and Charles, 1989).

Microbial production of lactic acid is vulnerable to bacteriophage attack. Industrial fermentations as well as food and dairy fermentation using *Lactobacillus* spp., *Lactococcus* spp. and *Streptococcus* spp. are subject to disruption by bacteriophage infection. Because of the size of this problem and its economic impact, much research has been carried out over the past six decades on the biology of the bacteriophages and the resistance mechanisms mounted by these bacteria to prevent phage infection. Klaenhammer and Fitzgerald (1994) have reviewed and evaluated this research. They point to factors that contribute to the onset of bacteriophage infection in the fermentation process, such as reliance on specialized strains and increasing pressure of manufacturing schedules. The classification of the known lactic acid bacteriophages, how they adsorb to cells, and phage lysogeny and lytic development are fairly well known. The genetics and biochemistry of bacteriophage resistance of lactic acid bacteria suggest some practical applications (Klaenhammer and Fitzgerald, 1994).

The major mechanisms of phage resistance which have been identified in the lactic acid bacteria include blocking of virus adsorption, restriction endonucleases and modification methylases, and abortive infection systems. Over the past ten years, genetic studies of *Lactococcus*

sp. show that these bacteria often carry the genes for these resistance devices on a variety of plasmids. The other lactic acid bacteria have also been shown to carry plasmid-borne resistance mechanisms as well. In their review, Klaenhammer and Fitzgerald (1994) outline "genetic addition strategies" for using these plasmids (carrying restriction systems for transfer and "stacking" into commercial strains) to improve bacterial resistance to multiple phage attack. Advances in the molecular biology of *L. lactis* and its phages have encouraged the emergence of novel recombinant phage defense systems which complement the mechanisms described above. For example, a suicide system has been developed that consists of a cassette with a promoter from a lytic phage (031) linked to a lethal gene (the *LlaI* restriction site; Djordjevic et al., 1997). When the cassette is inserted in the *L. lactis* chromosome, the phage-specific inducible promoter is activated by phage 031 infection, causing expression of the linked lethal gene, which results in death of the host cell and degradation of the phage genome.

Another example of a phage defense system employs antisense mRNA technology as a barrier to phage expression. Production of a specific antisense mRNA may act by competing with normal mRNA at the initiation of translation on the surface of the ribosome. Secondly, the direct binding of antisense RNA to the normal RNA may make it susceptible to degradation by double-stranded RNases in the cell. Walker and Klaenhammer (2000) produced antisense constructs of "late genes" of phage 031 with *ori*31 as a promoter, which were inserted into recombinant plasmids. When *L. lactis* carrying these plasmids are infected with bacteriophage 031, they produce large amounts of late 031 antisense mRNA. This results in significant protection of *L. lactis* against 031 infection. Clearly, in any large-scale commercial fermentation, a carefully planned, long-range phage defense program must be in place.

Commercial Applications

FERMENTATION For commercial scale production of lactic acid by fermentation, there are choices of feedstock, fermentation methods, product recovery, and final uses and applications that must be addressed. The feedstock-carbohydrate to be fermented as well as the enantiomeric form of lactic acid desired (D–, L+, or DL) will determine the organism selected to catalyze the process (see "Scientific Background" and Table 8). The choice of feedstock should be optimized considering 1) low cost, 2) low levels of contaminants, 3) fast fermentation rate, 4) high lactic acid yield, 5) little or no by-product formation, 6) little or no pretreatment required, and 7) year-round availability (Vick Roy, 1985). Long distance transport of feedstocks to the fermentation plant can be costly and should be avoided. Litchfield (1996) stresses that ideally a fermentation of cheese whey to lactic acid should be located close to cheese manufacturing plants because cheese whey is very dilute (4–4.5% lactose) and easily infected with bacteria. Also, refrigeration during storage or transport allows lactose to crystallize out of the whey owing to its low water solubility. Yet cheese whey and cheese whey permeate are low cost available feedstocks. In 1994, in the United States about 57×10^6 lbs (25.9×10^9 Kg) of liquid whey (4–4.5% lactose) was a by-product from dairy product manufacture. Only one half is converted commercially to dried products such as lactose. The rest is waste and has been used in large-scale commercial fermentations for lactic acid by companies such as Sheffield Product Co., Norwich, NY. Complex carbohydrates containing starch or sugar can be used as feedstocks. In early fermentations, beet molasses was used, but a high quality lactic acid was produced only after an added step of solvent extraction during product recovery (Buchta, 1983). Thus, crude feedstocks should be avoided because added chemical contaminants are often difficult to remove during the downstream recovery stage. Purified sucrose from sugar beets and sugar cane, glucose from hydrolyzed starch sources such as corn, and wheys containing lactose are the major raw materials used today. The use of purified feedstocks in the fermentation ensures lower cost of the final product recovery. In the United States, glucose from enzyme-hydrolyzed cornstarch produced in wet-milling is the major substrate for commercial lactic acid formation. Direct fermentations of liquid cornstarch by the amylolytic *Lactobacillus* strains, such as *L. amylophilus* (Mercier et al., 1992) and *L. amylovorus* (Cheng et al., 1991), have been carried out in the laboratory; however, no commercial processes are presently in use. The availability of purified sucrose as a feedstock from beets in Europe and from sugar cane in Brazil permits commercial production of high quality lactic acid in these regions. Nevertheless, sugar prices vary considerably and thus the economics of lactic acid production may be strongly affected.

The major fermentation method used to produce lactic acid on an industrial scale is the batch fermentation process. The factors affecting the batch process have been reviewed (Litchfield, 1996; Vick Roy, 1985). Because of the very corrosive properties of lactic acid, construction materials used for the fermenter and downstream processing equipment are a major cost item. Copper, copper alloys, steel, chrome steel,

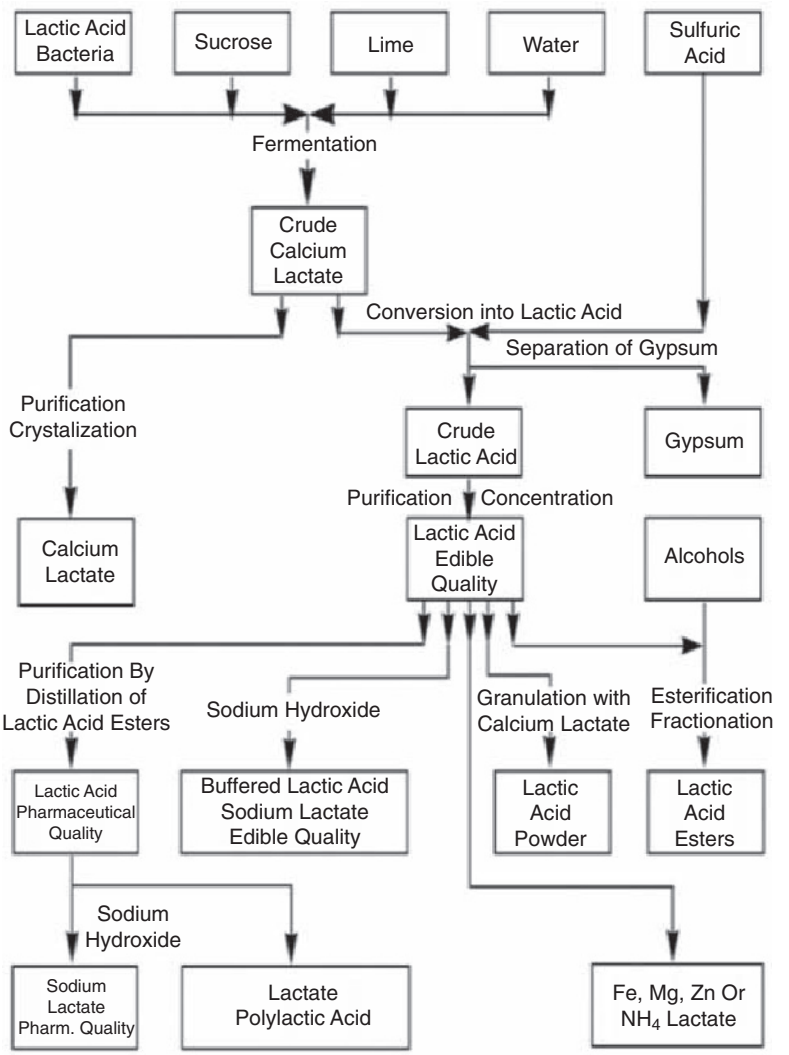

Fig. 11. Flowchart for production of lactic acid and its derivatives by the Purac fermentation process. From Bigelis and Tsai (1995), with permission.

and high nickel steels are all unsatisfactory. High molybdenum stainless steel like SS316 is satisfactory. Plastic linings of fermentation tanks have been used successfully, and new developments in ceramics and plastics may provide future choices (Vick Roy, 1985).

Contamination with other bacteria is not a big problem in commercial fermentation if fermenters are steam-treated or chemically sterilized prior to filling with a heated medium. A pure-culture inoculum is usually used, and the fermentation is run at a high temperature (43–50°C) and with very low oxygen. Eventually a high concentration of lactic acid accumulates. All of these conditions tend to inhibit growth of many potential contaminants. Specific conditions vary with the industrial process. For example, during the fermentation of 15% glucose by *L. rhamnoses* in 30,000-gallon reactors, a temperature of 45–60°C and a pH of 5.0–6.0 were maintained for 4–6 days, producing an 80–90% yield of lactic acid (Inskeep et al., 1952). For fermentation of cheese whey (4–5% lactose) by *L. delbrueckii* subsp. *bulgaricus* in a 5,000-gallon reactor, 43°C and a pH of 5.5 were maintained for 1–2 days with a yield of 85–90% lactic acid (Campbell, 1953). A flow chart of the Purac fermentation process for lactic acid production is diagrammed in Fig. 11. However, companies in the United States starting lactic acid production by fermentation use newly developed proprietary processes (Datta et al., 1995).

Calcium carbonate is usually added during the batch fermentation to control the pH, and the highest concentration of lactic acid (12–15%) is limited by the precipitation of calcium lactate from the broth. Temperature control is maintained with heat transfer coils using circulating water, and the cells are retained in a mixed suspension by mechanical agitators or pump circulation. The productivity of large batch commercial reactors is low, at 1–3 gms/liter · hr.

The final biomass of cells is lower than 30 wt % and usually about 15 wt % of the amount of sugar added initially. The fermentation rate is initially high, but then slows down as nitrogenous sources are depleted and lactic acid accumulates. Litchfield (1996) has reviewed work that shows a significant effect of inoculum size on lactic acid yields obtained with *L. delbrueckii* subsp. bulgaricus, *L. casei* and *L. helveticus* in laboratory-scale fermentation. However, little is reported on the effect of inoculum sizes for commercial-scale lactic acid fermentation.

Product Recovery The recovery of lactic acid from the fermentation medium is a major cost item for the entire process (Vick Roy, 1985; Datta et al., 1995). The product is available in four grades: 1) technical, 2) food (FCC), 3) pharmaceutical (USP) and 4) "heat stable" lactic acid that will not discolor when heated to 200°C for a few hours. The greater the purity, the more complex and expensive the recovery process.

The first step in the conventional recovery processes is heating the fermentation beer to 80–100°C and increasing the pH to 10 to kill the bacteria, coagulate proteins and maintain calcium lactate's solubility in the beer. The crude calcium lactate solution is then filtered, decolorized with activated carbon, and concentrated by evaporation. Lactic acid is recovered by addition of sulfuric acid and then further purified by one of the following routes (Fig. 11):

1) crystallization of calcium lactate (technical);
2) filtration, carbon treatment, and concentration of lactic acid (food quality);
3) formation of lactate esters and fractionation (pharmaceutical quality); and
4) distillation of lactic acid esters (highest purity, heat stable lactic acid).

These purification processes are often combined with liquid-liquid extraction, ion-exchange, and adsorption on solid adsorbants. However, for every ton of fermentation lactic acid produced by the conventional recovery process, about one ton of gypsum ($CaSO_4 \cdot 2H_2O$) by-product is also produced. Ecological and economical disposal thus becomes a problem for a large-scale production facility.

Developments in membrane-based separation and purification of lactic acid have been made. The use of ultrafiltration and electrodialysis provides a new approach for lactic acid recovery that would be low cost and simultaneously avoid the formation of the problem by-product, gypsum (Datta et al., 1995). Advances in membrane technology allowing low-energy desalting-electrodialysis have led to a proprietary method for production of fermentation lactic acid from carbohydrates without calcium salt production (Datta, 1989). This new technology can be operated as a continuous process and scaled up to large-volume recovery of lactic acid from the fermentation beer and manufacture of lactide polymers (Gruber et al., 1992; Gruber et al., 1994). A major commercial effort for lactic acid production and conversion to polylactide by a United States agriprocessor, Cargill Dow, incorporates this technology (Datta et al., 1995; Jarvis, 2001).

Application and Uses The major application of lactic acid and lactic compounds is for food additives. Table 9 presents a list of applications for lactic acid, lactate salts, and various lactylated fatty acid esters in the food industry.

Lactic acid and the lactate salts are generally recognized as safe by the Food and Drug Administration (FDA) in the United States. The stearoyl lactates and other esters used as emulsifiers and bread dough conditioners have also been approved by the FDA. More than 50% of the lactic acid destined for food uses goes into producing these emulsifying agents for bakery goods. The four most important esters of lactate salts are calcium and sodium stearoyl-2-lactylate, glyceryl lactostearate, and glyceryl lactopalmitate (Datta et al., 1995). These products have specific uses in the formulation of cake mixes, dips, and other prepared foods (Table 9). Because production of all of these emulsifiers requires the highest quality "heat stable" lactic acid, only synthetic lactic acid or heat stable fermentation lactic acid grades can be used.

Technical grade lactic acid has been used for a long time in the leather tanning industry as an acidulant. It is used in the finishing of textiles and acid dying of wool. Inorganic acids are used competitively in these processes, but lower cost lactic acid together with environmental regulations against dumping waste salts may favor extensive use of lactic acid in the future.

Lactic acid is used in many small-scale applications such as resin production, solder fluxes, lithographic and textile printing, adhesives, electroplating and electropolishing baths, and detergent formulations. These uses may account for 5–10% of consumption of lactic acid.

There are numerous pharmaceutical and cosmetic applications and formulations containing lactic acid, sodium and calcium lactates, and a range of acyl lactates. Calcium lactate is widely used for treating calcium deficiency. Lactates are added to many cosmetic products as moisturizers, emulsifiers and stabilizers. Lactates have been promoted in skin care products for improving skin texture and appearance (Smith, 1993). Ethyl lactate is an active ingredient in anti-acne preparations (Datta et al., 1995).

There are important medical applications for polylactides prepared from the lactide dimer as

Table 9. Food applications of lactic acids and lactic acid compounds.

Compound (Chemical Abstracts Service Registry no.)	Food application	Code of Federal Regulations[a] reference
L(+)-Lactic acid (79-35-4) > D(−)-Lactic acid (10326-41-7) > DL-Lactic acid (598-82-3)	Antimicrobial agent, curing and pickling, flavoring, enhancer, adjuvant pH control, solvent and vehicle	21 CFR 184.1061

well as for lactide-glycolide copolymers synthesized from lactide and glycolide dimers. These polymers are used for procedures requiring surgical sutures, implants, bone plates, and controlled drug release, inasmuch as they are biocompatible, biodegradable, and resorbable materials.

Concern over the negative environmental impact of accumulating nondegradable plastic films and containers has been increasing. Replacement of these petroleum-based plastics with biodegradable plastics may be inevitable within the next 50 years. Lactic acid based bio-plastics will play an important role in future potential products (see "Areas of Research and Development" in this Chapter).

Economics The major commercial producers of lactic acid are listed in Table 10. The worldwide market for lactic acid and lactic acid esters was estimated at 60–65,000 tons/yr (54.5–59 10^6 kg/yr) (Litchfield, 1996). Producers of synthetic and fermentation lactic acid are both included, considering they share the market about equally. The United States consumes almost 40% of annual production (Bigelis and Tsai, 1995). The major producer of fermentation lactic acid in the United States is Archer Daniels Midland, Co., with a capacity of 10–20,000 tons/yr (9.1–18.2 × 10^6 kg/yr; Anonymous, 1993). This proprietary fermentation process is presently nonbacterial. In contrast, Sterling Chemicals, a major producer of synthetic lactic acid in the United States, had an annual capacity of 9.5–10,000 tons (8.6–9.1 × 10^6 kg; Bahner, 1994). The competitive position of fermentation lactic acid over synthetic lactic acid depends upon the ability to selectively produce desired stereoisomers of lactic acid (D– or L+) instead of a racemic mixture produced by the synthetic route. Use of inexpensive carbohydrate feedstocks and advances in separation technologies keep production costs low.

Example prices in 1994 for both fermentation and synthetic food grade 50% and 88% lactic acid were $0.71 and $1.15 per pound (Litchfield, 1996).

The technological and thus economic potential of lactic acid and polylactic acid suggest that the market will expand. A large United States agriprocessing company, Cargill, has constructed a new fermentation facility with a capacity of

125,000 tons/yr of lactic acid, incorporating new separation technologies.

Research and Development

Microbial Genetics and Strain Improvement

Mutants of the lactobacilli can be selected following spontaneous or induced mutagenesis. For example, following mutagenesis with ethyl methane sulfonate, three mutants of *L. delbrueckii* ATCC 9649 were selected, which produced a higher yield of lactic acid than the parent strain in a stirred-tank batch fermentation with 12% glucose. Also, the rate of lactic acid production by the mutant strains was more than twice that of the wild-type (Demirci and Pometta, 1992). *Escherichia coli*, a mix acid fermenter, was converted by mutation to a homolactic strain. A double mutant strain of *E. coli* RR1 was produced which was deficient in both phosphotransacetylase (mutation in *pta*) and in phosphoenolpyruvate carboxylase (mutation in *ppc*). This strain did not produce significant amounts of acetate or succinate, and thus fermented glucose to primarily D(–) lactic acid (Chang et al., 1999). Certainly, mutagenesis followed by selection for properties such as growth at high temperature or high lactic acid concentration remains a standard method for improvement of production strains.

However, since about 1987 there have been dramatic advances in genetic technology and in understanding genetics of the lactic acid bacteria. Reviews of research and applications of genetic technology to lactic acid production have appeared (Gasson and DeVos, 1994; Bigelis and Tsai, 1995; Arihara and Luchaasky, 1995; Davidson et al., 1995; Wang and Lee, 1997a). Research predicts that the tools for genetic engineering of lactic acid bacteria provide for an almost unlimited potential for strain development.

Developing a genetic system for lactic acid bacteria was initially dependent upon optimizing a DNA transfer method. The most significant advancement was the use of electroporative (high voltage) transformation first shown in *Lactococcus lactis* (Harlander, 1987) and then extended to Lactobacillus sp. and other Gram-positive bacteria (Cauvin and Luchansky, 1992; Luchansky et al., 1988). Genetic research with *Lactobacillus* utilizes electrotransformation to transfer plasmid vectors for cloning, expression, integration, and transposon mutagenesis. Often electroporation techniques must be optimized for each bacterial species and new strain under study.

Most plasmid vectors used for cloning, expression, integration, and transposon mutagenesis were initially developed for *Lactococcus lactis* (DeVos and Simons, 1994). Shuttle vectors with lactococcal replicons and staphylococcal resistance markers were initially electroporated into strains of lactobacilli with some success. However, consistent high frequency transformation of lactobacilli has been achieved with several cloning and mutagenesis vectors based on *Lactobacillus* replication regions from cryptic, endogenous plasmids. For example, plasmids pPSC20 and pPSC22 replicated and were stably maintained in *L. lactis*, *Bacillus subtilis*, *E. coli* and a number of Lactobacillus species (Cocconcelli et al., 1991). Table 11 lists some *Escherichia-Lactobacillus* shuttle vectors and their applications.

A list of the plasmids of *Lactobacillus* and construction of useful vectors for commercial applications was reviewed (Wang and Lee, 1997b).

There is a considerable research effort directed toward stabilizing gene expression in both the lactococci and lactobacilli by integrating desired foreign genes into the bacterial genome. Chromosomal insertion of plasmid-carried genes could prevent segregational instability that may be a problem during large-scale or continuous fermentations. The use of integrative gene cloning and nonreplicative integration vectors with

Table 11. *Escherichia-Lactobacillus* shuttle vectors and their applications.

lactococcal strains is reviewed in detail by Gasson and DeVos (1994). Studies demonstrated that integration occurs via homologous single crossover recombination. Using similar nonreplicative vectors in *L. lactis*, it has been shown that chromosomal genes can be insertionally inactivated and that gene replacement recombination is also feasible. The use of insertional vectors for strain stabilization, gene replacement and gene disruption has been developed for *Lactobacillus* (Arihara and Luchansky, 1995). In *Lactobacillus* stabilization of cloned genes is usually achieved by chromosomal integration based on homologous recombination with a randomly cloned DNA fragment as the integration target inserted in a nonreplicating plasmid. Using this technique, stable chromosomal integration of α-amylase from *Bacillus stearthermophilus* and a cellulase gene from *Clostridium thermocellum* was achieved in *Lactobacillus plantarum* (Scheirlinck et al., 1989). An integrative "food-grade" cloning vector for *L. acidophilus* was constructed using a piece of chromosomal DNA as an integration target (Lin et al., 1999). A second important technique for generation of stable recombinant lactic acid bacterium strains is the use of a bacteriophage integrase-mediated site-specific insertion into the host chromosome (Auvray et al., 1997; Martin et al., 2000). A third innovation is the development of an integrative vector which allows stable gene insertion specifically into the chromosomal lactose operon of *L. casei* (Gosalbes et al., 2000). The integrated foreign genes followed the same expression pattern as for the lactose genes in that they were repressed by glucose and induced by lactose.

Expression studies are encouraging in that more than 65 *Lactobacillus* genes have been cloned and expressed in *E. coli*. Many *Lactobacillus* genes have been expressed in other lactobacilli, and several heterologous genes have been transferred and expressed in *Lactobacillus* strains (Table 11). As lactic acid emerges as a major commodity chemical, research efforts are focusing on direct utilization of inexpensive carbon substrates, such as lactose-containing cheese whey, or starchy and cellulosic biomass sources. Expanding the substrate range of production strains of *Lactobacillus* or building entirely new production strains is now possible by transfer, integration, and expression of the genes for lactose metabolism from *L. casei* combined with other genes essential to catalyze a specific lactic acid production process.

The genes for both of the lactate dehydrogenase enzymes, L-LDH and D-LDH, that control lactic acid stereospecificity in the lactobacilli have been cloned and sequenced. The L-LDH enzyme from a variety of lactic acid bacteria forms a closely related class entirely distinct from the D-LDH enzymes which form a second closely related group of proteins. With broad host-range integration vectors now available, it is possible to alter the LDHs in lactobacilli by gene replacement or gene disruption. Thus, a production strain of *L. helveticus*, which normally produces a mixture of (D, L)-lactic acid, can be converted to produce exclusively either (D–) or (L+)-lactic acid (Bhowmik and Steele, 1994).

Growth of lactic acid bacteria is dependent upon a complex source of organic nitrogen compounds. All of these bacteria are fastidious organisms with multiple amino acid requirements. Thus rapid growth is dependent upon efficient proteolysis of proteins and transport of amino acids and small peptides. Hydrolysis of proteins may be by protease treatment of the medium prior to fermentation or by the action of proteolytic enzymes produced by the lactobacilli or lactococci during fermentation. In all cases, it is essential that the selected fermentation strain and the protein source be compatible for optimal cell growth and fermentation as well as low accumulation of by-products that will interfere with downstream separation of lactic acid. As a consequence, the proteolytic systems of lactic acid bacteria have been the subject of research efforts over the past 15 years. Most of the detailed biochemistry, cell location of enzymes, and genetic engineering of proteolytic enzymes that have been determined for the lactococci is reviewed by Kok and DeVos (1994). The research on proteolytic systems of *Lactobacillus* strains used in fermentation is more limited but developing rapidly (Arihara and Luchansky, 1995).

Overcoming and understanding host-bacteriophage interactions is a major topic of research with the lactic acid bacteria. For example, in *L. helveticus* a plasmid-linked restriction-modification system was identified that blocks fruitful infection by two bacteriophages (Reyes-Gavilan et al., 1990), and in *L. lactis* subsp. *cremoris*, four phage-resistance plasmids have been identified (Forde et al., 1999). Both lytic and lysogenic phages of the lactococci and lactobacilli have been and continue to be under study; genetic strategies for constructing phage-insensitive strains of the lactococci have been formulated (Klaenhammer and Fitzgerald, 1994). Walker and Klaenhammer (2000) reported combining two genetic stratagies to inhibit infection of *L. lactus* by bacteriophage ø31. The bacteria carrying a low-copy-number plasmid, pTRK360, containing the phage ø31 origin of replication, trigger an explosive production of this plasmid upon phage infection. The large number of plasmid-carried *ori31* genes compete with and inhibit phage ø31 DNA repli-

cation, resulting in an efficiency of plaquing of only 0.3. However, these workers combined this strategy with a second strategy employing antisense RNA. To produce a high level of phage ø31 antisense mRNA relative to normal sense mRNA during phage infection, the antisense cassettes containing the late-expressed phage genes (ORF 3 through ORF 6) were subcloned into pTRK360. Infected *L. lactis* carrying this plasmid produced high levels of antisense transcripts later in the lytic cycle. Growth studies at various levels of phage ø31 infection showed that using the dual strategies of competing *ori31* copies and antisense mRNAs of phage ORFs was more effective than using either method alone (Walker and Klaenhammer, 2000). The research on the lactococci is being applied to improving phage resistance of *Lactobacillus*, although presently little is known about phage resistant strategies and phage-coded counter defense mechanisms for this group of lactic acid bacteria.

Advances in Fermentation and Separation Technologies Direct fermentation of starch to lactic acid by lactobacilli is not possible when employing the preferred industrial strains of lactobacilli, considering they use sugars such as glucose or lactose efficiently but do not effectively hydrolyze starch. Although a well established two-enzyme treatment for starch hydrolysis is applied in the corn wet-milling process to produce glucose, such a process may not be usable for other starchy feedstocks used on a smaller scale. Two approaches to this problem are under development. First, lactic acid production using two starch-hydrolyzing strains, *L. amylophilus* (Mercier et al., 1992) and *L. amylovorus* (Cheng et al., 1991), has been demonstrated. Laboratory scale results in batch reactors provided conditions for rather good productivity and a greater than 90% yield of lactic acid. A second approach is an integrated method of simultaneous saccharification and fermentation (SSF) of potato starch by *Lactobacillus delbrueckii* with added glucoamylase (Tsai and Moon, 1998). Prior to SSF the crude starch was mixed with α-amylase and liquefied for 20 min at 103.5°C. The authors predict that the process which eliminates the two-step starch hydrolysis and sterilizer steps will reduce both capital cost and process time.

The productivity of the classical batch-reactor for lactic acid fermentation is lower than desirable for economically viable large-scale production. A great deal of research has been carried out on continuous fermentation processes over the past 10–15 years that promises to raise productivity. The research on continuous processes up to 1995 has been reviewed (Litchfield, 1996).

Added productivity of lactic acid fermentations can be achieved by combining continuous systems with mechanisms that allow higher bacterial cell concentrations. Research is concentrated on two mechanisms: 1) membrane recycle bioreactors (MRBs) and 2) immobilized cell systems (ICSs). The MRB consists of a continuous stirred-tank reactor in a semi-closed loop with a hollow fiber, tubular, flat, or cross-flow membrane unit that allows cell and lactic acid separation and recycle of cells back to the bioreactor. The results of a number of laboratory studies with various MRB systems demonstrate the effect of high cell concentrations on raising lactic acid productivity (Litchfield, 1996). Table 12 lists examples of published results employing various MRB systems.

The volumetric productivity (g of lactic acid/liter · h) is usually greater than 10-fold that of batch or continuous processes. Ceramic tubular membranes have been used which are both steam sterilizable and resistant to mechanical stress (Xavier et al., 1995). Fermentation production of lactic acid directly from starch was optimized in an MRB using *L. amylovorus* (Table 12). No saccharification or pre-liquefication of starch was found necessary (Zhang and Cheryan, 1994a). In summary, the research with MRB systems demonstrates that this is a successful approach to fermentation because both a high productivity is achieved and a high concentration of lactic acid is removed in the final permeate. Long-term performance of these units at high cell densities, however, has been limited to about 10 days owing to filtration-membrane clogging, which requires a cleaning operation or replacement of the membrane unit.

Research has been carried out employing immobilized cell systems (ICSs) with the goal of improving lactic acid production. Bacteria are immobilized either by entrapment in gels such as alginate beads or carrageenan beads or, alternatively, by adsorption as a biofilm on the surface of supports such as porous glass, ceramic beads or polypropylene composites (Table 13).

The results of the major investigations up to 1994 have been reviewed by Litchfield (1996). Normally the immobilized cells are exposed to the substrate-containing medium in a bioreactor where the high concentration of cells catalyzes the production of lactic acid. The spent medium with the lactic acid then passes to a recovery unit to remove the lactic acid. The medium is then renewed by adding back substrate and other nutrients and finally is recycled back to the bioreactor. Both the added sugars and the lactic acid recovered are at relatively high concentrations. In practice the various gels used for entrapment of cells have softened, leaked cells, or prevented rapid outward diffusion of the lactic acid, thus blocking cell metabolism. Also plugging and clogging of column-shaped bioreactors often

occurred. In addition, contamination of difficult-to-sterilize natural gels can be a problem. The use of lactic acid bacterial biofilms adsorbed on inert supports has been more successful (Table 13). Research trials with a composite support of 75% polypropylene and 25% agricultural materials and *L. casei* in a repeated batch fermentation showed excellent biofilm stability for up to 72 days (Demirci and Pometto, 1995). Using a different bioreactor configuration, *L. casei* cells on polyethyleneimine-coated foam glass beads yielded excellent results in a recycle batch fermentation. Both systems can produce an average of 4.3–4.6 g of lactic acid/liter · h (Ho et al., 1997a).

In general, the productivity of the ICSs is far lower than that of the MRB systems. However, the ICSs apparently have the advantage of long-term stability over the MRB systems. The advances in membrane-based separation and purification technologies combined with electrodialysis and ion exchange separation form the basis for scale-up large-volume production. A proprietary process employing these technologies for continuous fermentation of sugar for lactic acid production is under development by a major company in the United States (Datta et al., 1995).

Preliminary research has appeared demonstrating extractive lactic acid fermentation based on aqueous two-phase systems (ATPS). The idea is to provide a technology that simultaneously prevents product inhibition and enhances volumetric productivity. Basically, an ATPS involves an extractive step for removal of the product (lactic acid) at the same time it is being formed during the fermentation stage. For the extractive bioconversion to be effective the product must be partitioned into the phase opposite the one preferred by the microbial cells. Using a two-phase system composed of polycation, polyethyleneimine (PEI) and a neutral polymer, hydroxyethylcellulose (HEC), successful lactic acid partitioning and fermentation by *L. lactis* was demonstrated (Kwon et al., 1996). Following batch fermentation, 75–85% of the lactic acid was in the PEI layer and 90% of the cells were in HEC layer under optimal conditions. Good product yields (0.7–0.85 g/g) and productivity (8–10 g of lactic acid/liter · h) were reported in both batch and continuous fermentations. Other polymer pairs have been tested for a two-phase fermentation-extraction system (Planas et al., 1996). However, no scale-up fermentations or economic analyses of application of these approaches for commercial production have appeared.

Prospects

New Products and Future Demand for Lactic Acid

Up to 1994, the world demand for lactic acid reached about 60–65 $\times 10^3$ tons/yr, with a predicted growth of about 12–15% per year (Bahner, 1994). The major use for lactic acid in the United States is for food applications (about 85%), whereas the remainder is for industrial uses (Datta et al., 1995). Most likely, this situation will change rapidly during the 21st century.

Lactic acid is now recognized as an excellent feedstock in the chemical industry for new products. Based on the potential products from lactic acid (see Table 14), the demand for lactic acid in the future could reach 2.5–3.4 $\times 10^6$ tons/yr. New technologies are under development for manu-

facturing lactic acid and for industrial scale processes for product synthesis (Fig. 12).

Research on membrane-based separation methods combined with electrodialysis forms the basis for new processes for lactic acid production. These technological improvements have led to proprietary large-scale production methods for obtaining purified concentrated lactic acid from carbohydrates without excess calcium sulfate (gypsum) or other salts in the waste stream. United States agriprocessing companies are building large-capacity production plants for simultaneous fermentation and separation of lactic acid based on this technology (Datta et al., 1995).

Both DuPont and Cargill are developing large-scale manufacturing processes for conversion of lactic acid to lactides, glycolides and prepolymers. Eventually, the goal is to develop commercial-scale processes for production of biodegradable polymers for a variety of uses. The lactide copolymers have a range of properties and promise to compete well with petroleum-based polymers such as polystyrene, polyvinyl chloride and vinylidine (Tables 15a and 15b).

Lactic acid also may be converted into a variety of other chemicals such as propylene glycol, propylene oxide, and acrylic acid by known technologies (Fig. 12). If potential uses and market volumes appear as predicted (Table 14), then commercial-scale manufacturing processes also must be developed. In the future, lactic acid esters, which are nontoxic and less volatile, may replace more toxic solvents now in use as plasti-

cizers and films (Table 14). Consumer demand and regulatory agencies already favor safer aerosol-forming solvents.

Competitive Processes Chemical synthesis of lactic acid from lactonitrile is the major alternative process for manufacture in competition with fermentation lactic acid. In 1995, synthetic lactic acid accounted for about 50% of the total world lactic acid production (Litchfield, 1996). The advantage of the chemical synthesis route is the ease of obtaining a highly purified lactic acid which is required for many industrial products. The synthetic lactic acid is a racemic mixture (DL), whereas fermentation lactic acid may be selectively D(−) or L(+) or DL depending on the organism catalyzing the conversion. Controlled optical purity as well as chemical purity of lactic acid is vital for commercial production of lactide polymers with specific properties required for the desired applications and potential uses of the polymers. Also, optically active lactic and lactate esters may be applied to new chiral synthesis routes for specialty chemicals such as drugs and agrichemicals (Datta et al., 1995).

Fungal fermentation of carbohydrates to lactic acid is potentially competitive with the classical *Lactobacillus* fermentation. Presently, Archer Daniels Midland's fermentation facility in Illinois, in the United States, is producing lactic acid

from enzyme-converted corn starch, using a "nonbacterial" propriety fermentation process. The production capacity is reported as 10–20 × 10^3 tons/yr of lactic acid, but details of the process are not available. *Rhizopus* spp. grow aerobically utilizing glucose or sucrose to produce L(+)-lactic acid. Some species, such as *R. oryzae* and *R. arrhizus*, can convert starch or starch-containing complex substrates to L(+)-lactic acid. *Rhizopus* spp. are obligate aerobes and heterolactic. Thus, the highest theoretical yield of lactic acid is about 0.75 g per g of glucose. Practically, experimental yields of 0.5–0.72 g/g are observed, compared to 0.85–0.9 g/g for the *Lactobacillus* fermentations (Litchfield, 1996). However, the yield of lactic acid can be improved and production of side products reduced by the application of genetic engineering to the metabolic pathways. The advantage of the *Rhizopus* spp. is that they grow and produce lactic acid in an inorganic mineral medium containing only ammonia or nitrate as a nitrogen source and no amino acid or vitamin requirements. This property greatly simplifies the downstream separation and purification of the lactic acid product.

Future Lactic Acid Bacteria The future commercial emphasis is on production of lactic acid as a bulk chemical converted from biomass by microbial fermentation. Clearly, future research employing genetic engineering will be aimed at converting bacteria into more efficient chemical reactors for this process. The desired properties of a future engineered lactic acid bacteria are listed in Table 16. Only the first four of these properties are characteristic of the present industrial strains of *Lactobacillus* and related lactic acid producers. The problems of productivity and product tolerance are limiting factors in batch fermentations. The desired high productivity and tolerance to lactic acid are now being dealt with using new continuous membrane-based fermentation-separation technology (FST), applied to commercial production. The last three properties listed (Table 16) limit the effective use of the *Lactobacillus* strains.

Transfer of metabolic pathways and phage-resistance properties between bacteria using genetic engineering technologies (GET) is available for developing future super bacteria. This new set of industrial lactic acid bacteria will probably not be based on the present *Lactobacillus*, inasmuch as overcoming the complex growth requirement is an enormous task. Conversion of a chosen bacterium into a true homolactic L(+)- or D(−)-lactic acid producer strain is now achievable through genetic engineering technology (GET).

Section 3: Gluconic Acid

Introduction

Two reviews cover the microbial production processes for conversion of glucose to gluconic acid and its calcium and sodium salts (Milson and Meers, 1985; Roehr et al., 1996). Hlasiwetz and Habermann (1870) first identified gluconic acid as a major product of the chemical oxidation of glucose. Boutroux (1880), while studying the microbial fermentation of glucose in the presence of calcium carbonate, isolated calcium gluconate. The gluconic acid-producing organism was later identified as a strain of *Mycoderma aceti*, most probably a *Gluconobacter* sp. Forty-two years later, Molliard (1922) reported that gluconic acid was produced by *Sterigmatocystis nigra* (probably *Aspergillus niger*) during growth with sucrose. Within a few years, gluconic acid production was associated with many fungi, such as *Penicillium* species, strains of *A. niger*, and strains of aerobic bacteria such as *Pseudomonas*, *Gluconobacter*, and *Zymomonas*.

The list of uses of gluconic acid and its derivatives is astoundingly diverse and has continued to grow in the food, pharmaceutical, and metal treatments industries throughout the 20th century (see "Commercial Applications" in this Chapter). As a result, much attention has been focused on processes for production of gluconic acid and its salts by oxidation of glucose. There

Table 16. Future lactic acid bacteria.

Desired properties	Present bacteria (Lactobacillus)	Developing technologies
High yield, >0.9g of lactic acid/g of substrate	Homolactic	GET
Optical purity D(−) or L(+) options	Yes	GET
High temp. (42–55°C)	Grow and ferment	FST
Anaerobic metabolism	Yes	FST
Product tolerance	About 10%	FST
High productivity >10g of lactic acid/liter · h	Low	FST
Broad substrate use (cellulose, starch, etc.)	Limited	GET
Grow in mineral salts	Complex requirements	GET
Virus infection control	Liable to infection	GET

Abbreviations: GET, Genetic Engineering Technologies; and FST, Fermentation and Separation Technologies.

are four categories of commercial processes: chemical processes; the *A. niger* process and other fungal processes; the *Gluconobacter* process and other bacterial processes; and the immobilized enzyme processes.

The chemical conversion of D-glucose to D-glucono-δ-lactone and thence to D-gluconic acid has been used in manufacturing processes. Electrochemical oxidation in the presence of bromide (Isbell et al., 1932) and oxidation with air or oxygen (employing a catalyst; deWilt, 1972) are examples of methods in use. However, because of the appearance (during chemical production) of unwanted side-products that require difficult downstream purification, the more specific microbial "fermentations" and other biochemical processes are definitely competitive.

Aspergillus niger was the major organism in the development of microbial processes for conversion of glucose to gluconic acid. Bernhauer (Bernhauer, 1924; Bernhauer, 1928) demonstrated that selected strains of *A. niger* carried out this conversion in high yields when the acid produced was neutralized, usually by calcium carbonate. Research on the technology of gluconic acid production started in the United States Department of Agriculture (USDA) in 1926. About this time at the USDA, a pilot plant process was developed for gluconic acid production using selected strains of *Penicillium luteum purpurogenum* in a surface-type "fermentation" (Herrick and May, 1928). But the critically important development was the production of gluconic from glucose by the submerged culture technology using stirring and forced aeration in the reactor (May et al., 1934). With either *A. niger* or *P. luteum* used in the oxidation process, a 90% yield in only 48–60 h was reported. Employing a strain of *A. niger* (strain 67) with the modern submerged reactor technology, pilot plant studies yielded 95% conversion of glucose (in a 15–20% solution) in 24 h (Moyer et al., 1937). The commercial-scale technique utilizes a 25% glucose solution, achieves a 95% conversion in the submerged reactor, and involves neutralization by calcium carbonate as well as reuse of mycelium in 24-h cycles. Sodium gluconate is the product desired for most commercial uses. Blom et al. (1952) developed the basic process for sodium gluconate production in which gluconic acid is neutralized (~pH 6.5) with sodium hydroxide during the microbial conversion. This process is essentially that used by most production plants today. A continuous gluconic acid production process was developed in Japan by Fujisawa Pharmaceutical Group (Yamada, 1977). This process employed *A. niger* and was carried out using conventional fermentation techniques. In 1977, production of gluconic acid in Japan had reached 8,500 tons/yr.

Production methods employing the bacterial strains *Acetobacter* (*Gluconobacter*) were developed and patented early in the last century (Currie and Carter, 1930; Verhave, 1930). The genus *Gluconobacter* and the genus *Acetobacter* are closely related and are accepted as two separate genera in the family Acetobacteraceae, primarily based on the proposal by Asai (1968). The main distinction is that the *Acetobacter* sp. rapidly oxidize ethanol to acetic acid and only slowly oxidize glucose to gluconic acid, whereas *Gluconobacter* sp. rapidly oxidize glucose to gluconic acid. The *Gluconobacter oxydans* ATCC621H (formerly *A. oxydans*) was the most frequently used strain in early gluconic acid production processes. The family grouping Acetobacteraceae is supported by 16S ribosomal DNA sequence similarities of eight species (Sievers et al., 1994b). However, this molecular analysis does not present a convincing case for separation of *G. oxydans* from the species *Acetobacter*. The first production techniques employed a modified "quick vinegar" process used early in production of acetic acid (see the "Acetic Acid" in this Chapter). However, a more modern submerged fermentation process utilizing *Gluconobacter oxydans* was also developed (Currie and Finlay, 1933). This process is very much like the present method used for vinegar acetic acid production by *Acetobacter* (see the "Acetic Acid" in this Chapter). Increases in gluconic acid concentration and in productivity have been achieved in continuously performed processes combined with immobilization of *Gluconobacter* cells on carriers (Shiraishi et al., 1989a). Research on process development has proceeded and is covered in "Areas of Research and Development."

Interest in a gluconic acid production process using a novel acetic acid bacterium, *Acetobacter methanolicus*, has emerged (Uhlig et al., 1986). *Acetobacter methanolicus* is a facultative methylotrophic bacterium that can grow on methanol as a sole carbon and energy source. Several patents document the possible future use of this organism (Babel et al., 1986; Babel et al., 1987; Babel et al., 1988; Babel et al., 1991).

Acetobacter diazotrophicus is an isolated aerobic nitrogen-fixing acetic acid bacterium (Gilles et al., 1989). It grows well in simple mineral salts medium and oxidizes glucose at high rates in acid conditions (pH 3.5) and (unlike *G. oxydans*) in the presence of high concentrations of gluconic acid (Attwood et al., 1991). Because of these characteristics, the use of *A. diazotrophicus* is of interest for bulk production of gluconic acid.

A fourth bacterial candidate, *Zymomonas mobilis*, can rapidly convert mixtures of glucose and fructose to gluconic acid and sorbitol with almost a 100% yield. This coupled oxidation-reduction process depends upon the *Z. mobilis*

enzyme glucose-fructose oxidoreductase present in cells grown with these sugars (Zachariou and Scopes, 1986). Several protocols for cell treatment and cell immobilization are under study for development of commercial processes leading to large-scale production of the two products sorbitol and gluconic acid (see "Areas of Research and Development" in this Chapter).

A fourth process for gluconic acid production is the direct use of the enzyme glucose oxidase (GO) as a catalyst to carry out the rather simple reaction:

$$\text{D-glucose} + O_2 \xrightarrow{GO} \delta\text{-gluconolactone} + H_2O_2$$

Glucose oxidase isolated from *Aspergillus* or other fungi has been immobilized on a number of supports, and studies show that it is quite sensitive to the hydrogen peroxide formed during glucose oxidation. Therefore, a number of methods for co-immobilizing GO together with catalase have been developed (e.g., Bucholz and Goedelmann, 1978). This approach is, in theory, similar to the immobilization of *A. niger* mycelia, either flocculated (as pellets) or covalently bound to various supports (Sakura et al., 1989). Systems employing other enzymes that oxidize glucose also have been studied. A coupled system that simultaneously oxidizes glucose to gluconic acid and transfers electrons via NAD(H) to reduce fructose to mannitol has been proposed. Bacterial glucose dehydrogenase (GH) and mannitol dehydrogenase (MH) from different organisms have been immobilized to carry out the following reactions:

$$\text{D-glucose} + NAD^{+GH} \rightarrow \text{D-gluconolactose} + NADH + H^+$$

$$\text{D-fructose} + NADH + H^{+MH} \rightarrow \text{D-mannitol} + NAD^+$$

Membrane reactors have been employed that allow retention and recycling of NAD (Howaldt et al., 1988; Howaldt et al., 1990; Oben et al., 1996). This approach is probably technologically too complex to permit scale-up for bulk commercial production. A more likely candidate for commercial production by an immobilized enzyme process is the use of the single enzyme glucose-fructose oxidoreductase (GFOR) of *Zymomonas mobilis* (Nidetzky et al., 1997; Silva-Martinez et al., 1998).

In summary, considering the production of gluconic acid, the *A. niger* process appears to dominate present-day manufacturing methods. Likewise, the continuing research and development efforts utilizing the *Gluconobacter* process are clearly evident. In addition, the emergence of two new bacterial processes employing *A. methanolicus* and particularly *Z. mobilis* has opened promising new routes for production that may be competitive in the future. These bacterial processes are emphasized in the sections below.

Scientific Background

D-Gluconic acid is one of the oxidation products of D-glucose. There are three major reactions catalyzed by microorganisms for oxidation of D-glucopyranose to yield D-glucono-δ-lactone by removing two hydrogens (Fig. 13).

D-Glucono-δ-lactone is in equilibrium with gluconic acid in water solution. Also gluconic acid is in equlibrium with D-glucono-γ-lactone; in addition, gluconic acid ionizes in water to yield a gluconate anion and a hydrogen ion. Thus, a water solution of gluconic acid is a rather complex system depicted at the bottom of Fig. 13. The equilibria shown influence the apparent acid dissociation constant with an approximate pKa of 3.7. Thus, gluconic acid acts as a weak acid in solution and is highly soluble in water. The equilibria between the gluconolactones and the free gluconic acid are attained very slowly. However, a lactonase, produced by most glucose-oxidizing bacteria and fungi, catalyzes a rapid hydration of the lactones (Fig. 13). The sodium salt of gluconic acid has the property of

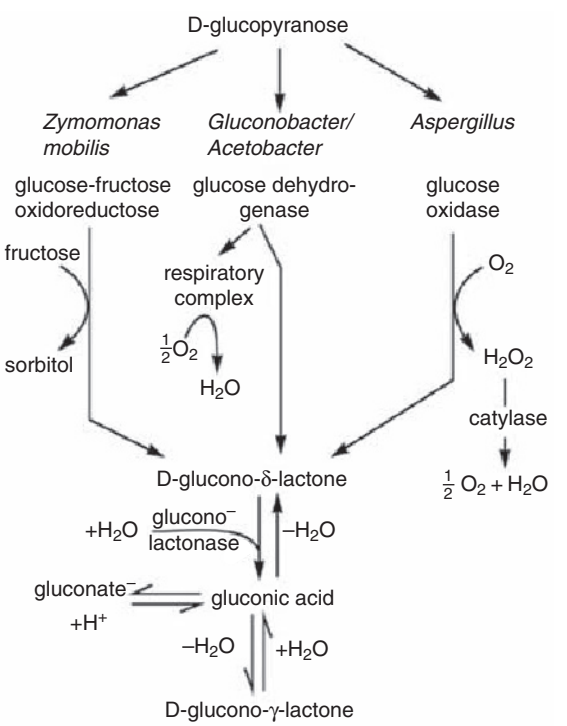

Fig. 13. Major routes of enzymatic oxidation of glucose to gluconolactone by bacteria and fungi. Gluconolactonase, present in all of these organisms, catalyzes formation of gluconic acid. Gluconic acid is in equilibrium with the lactones and gluconate in water solution.

forming complexes with various metal ions. The high metal sequestering action of sodium gluconate has led to important commercial uses in many varied processes and products (see "Commercial Applications" in this Chapter).

The biochemical pathway of glucose oxidation to gluconic acid by *Aspergillus niger* and most other fungi is catalyzed by glucose oxidase followed by a catalase which in turn removes H_2O_2 (Fig. 13). The details of the physiology and biochemistry of the fungal process for gluconic acid production were reveiwed by Roehr et al. (1996) and will not be covered here.

The bacteria employed or in processes under development for gluconic acid production are listed in Table 17. *Gluconobacter oxydans*, *A. methanolicus* and *A. diazotrophicus* are closely related strains (Sievers et al., 1994b). All three species utilize the membrane bound D-glucose dehydrogenase enzyme pathway for oxidation of D-glucose to D-gluconic acid (Fig. 13).

The biochemistry and suggested bioenergetics of the glucose-oxidizing system and respiratory chain for *Gluconobacter* and *Acetobacter* have been extensively studied and reviewed (Matsushita et al., 1994). Figure 14 is a cartoon of the

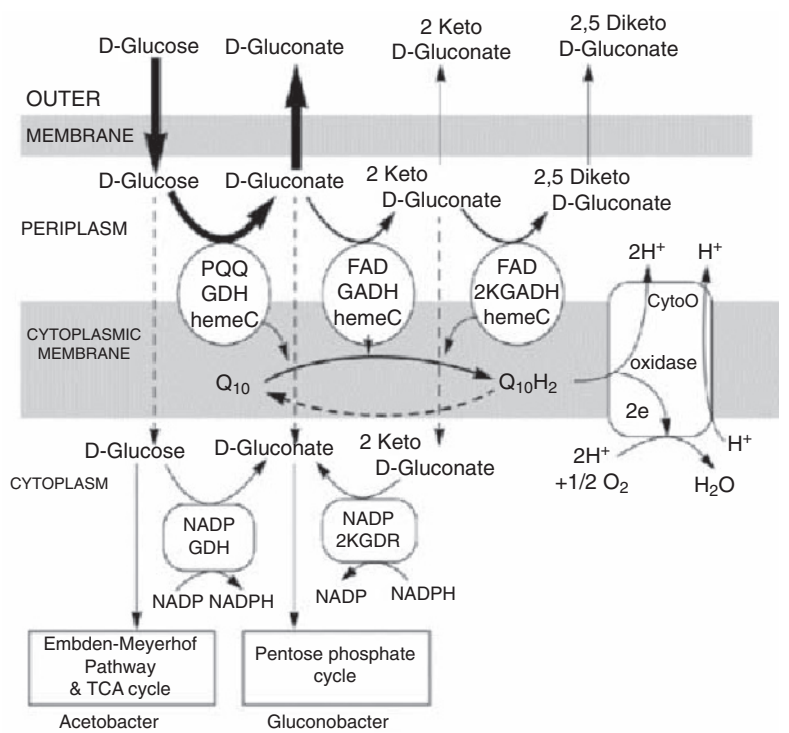

Fig. 14. Oxidation of glucose to gluconic acid by *Gluconobacter* and *Acetobacter*. Quinoprotein D-glucose dehydrogenase (GDH) and flavoproteins D-gluconate dehydrogenase (GADH) and 2-keto-D-gluconate dehydrogenase (2kGADH) are located on the outer surface of the cytoplasmic membrane. Cytochrome *o* (Cyto *O*) accepts electrons from the dehydrogenases via ubiquinone (Q_{10}) and cytochrome *c* (hemeC). Ubiquinol ($Q_{10}H_2$) is oxidized by cytochrome *o* oxidase (or Q oxidase) to generate a proton gradient. NADP-dependent D-glucose dehydrogenase (GDH) and NADP-dependent 2-keto-D-gluconate reductase (2KGR) work in the cytoplasm. Redrawn from Matsushita et al. (1994), with permission.

proposed arrangement of the elements of the glucose-oxidizing system.

These bacteria produce gluconic acid from glucose mainly via a membrane-bound enzyme, D-glucose dehydrogenase (GDH), with pyrroloquinoline quinone (PQQ) attached as a prosthetic group. *Gluconobacter oxydans* also produces varying amounts of 2-keto-D-gluconate and 2,5-diketo-D-gluconate by further oxidation of gluconic acid catalyzed by the two enzymes gluconate dehydrogenase (GADH) and 2-keto-D-gluconate dehydrogenase (2KGADH). These two enzymes are also membrane bound, each containing three subunits: a cytochrome *c*; a flavoprotein with a covalently bound FAD; and a third subunit. These oxidations take place on the outer surface of the cytoplasmic membrane. Mostly gluconic acid together with smaller amounts of the other two oxidation products accumulates in the beers. The dehydrogenases are linked to the respiratory chain through ubiquinone (Q_{10}) in the cytoplasmic membrane (Fig. 14). A set of $NADP^+$-dependent GDH and GADH enzymes is located in the cytoplasm, where it functions to interchange glucose and the gluconates. D-Glucose is metabolized primarily through the Embden-Meyerhof pathway and tricarboxylic acid (TCA) cycle by most *Acetobacter* sp. Alternatively, *Gluconobacter* sp. convert glucose to gluconate, which is metabolized through the pentose phosphate pathway (Fig. 14). Gluconate production by *G. oxydans* is largely catalyzed by the membrane-bound GDH which has 30 times the activity of the cytoplasmic $NADP^+$-dependent GDH (Pronk et al., 1989). *Gluconobacter* and some species of *Acetobacter* can accumulate high concentrations of gluconic acid and smaller amounts of ketogluconates outside the cells. The oxidative reactions carried out by the sugar-oxidizing systems are coupled to the respiratory chain in which the electron transfer can develop a proton-electrochemical gradient across the cytoplasmic membrane, as diagrammed in Fig. 14. The proton gradient is used for ATP production and energetic events for cell growth and maintenance. But it has been shown that the coupling of glucose oxidation to the growth yields for *G. oxydans* is very inefficient at pH values less than 5.0 and at high glucose concentrations (Olijve and Kok, 1979b). Thus, a property of the respiratory chains of both *Gluconobacter* and *Acetobacter* is the rapid oxidation of high concentrations of alcohols and sugars while not permitting a high rate of energy generation. How is the potential for producing or utilizing the proton gradient (shown in Fig. 14) somehow uncoupled? In the case of *Gluconobacter* a bypass, cytochrome δ oxidase system, is apparently induced at low pH, which allows a high rate of sugar (or alcohol) oxidation without producing a large proton gradient (Matsushita et al., 1994). But many *Acetobacter* spp. do not produce the bypass cytochrome oxidase system, and it remains unclear how uncoupling of energy production occurs. These acetic acid bacteria have evolved to live in specific environments, such as surfaces of fruit and flower parts, where high concentrations of sugars and alcohols exist under aerobic conditions.

The further oxidation of gluconic acid to the ketogluconic acids by *Gluconobacter* or *Acetobacter* (illustrated in Fig. 14) is a potentially undesirable reaction when using these organisms for gluconic acid production. Suppression of most ketogluconate formation has been achieved by maintaining the pH at low levels (Roehr et al., 1996). The best results for gluconate production by *G. oxydans* depend upon the presence of high glucose concentrations, low pH and high aeration.

Uhlig et al. (1986) described a novel acetic acid bacterium (*A. methanolicus*) that is a facultative methylotroph (Table 17). This pink-pigmented bacterium grows well on methanol or glycerol or glucose in a mineral medium containing only pantothenic acid as a growth factor. More important, glucose is strongly oxidized to gluconate, but 2-, 5-, or 2,5-ketogluconates are not formed. Based on 16S-rRNA sequences, *A. methanolicus* was found to be closely related to other species in the genus *Acetobacter* and also to *G. oxydans* (Sievers et al., 1994c). *Acetobacter methanolicus* is different from other acetic acid bacteria in that it contains a methanol oxidase respiratory chain, as do other methylotrophs, in addition to sugar and alcohol oxidase respiratory chains. The methanol oxidase system consists of methanol dehydrogenase, which is a quinoprotein dehydrogenase (PQQ), and cytochromes c_L and c_H located free in the periplasm together with a membrane-bound cytochrome *c* oxidase which is either cytochrome *co* or aa_3 (Matsushita et al., 1994). In contrast, as depicted in Fig. 14, all of the primary dehydrogenases that are part of the sugar- and ethanol-oxidizing systems are membrane-bound and donate electrons to ubiquinone and a terminal ubiquinol oxidase such as cytochrome *o*, *a* or *d*. Methanol is assimilated as formaldehyde using the ribulose monophosphate pathway through fructose-1, 6-biphosphate.

An interesting aerobic nitrogen-fixing bacterium, *A. diazotrophicus*, was isolated from sugar cane in Brazil. DNA-rRNA hybridization placed this organism in the genus *Acetobacter* (Gilles et al., 1989). Additional characteristics of *A. diazotrophicus* include growth on a simple mineral media, high rates of gluconic acid formation, growth and gluconic acid production at high glu-

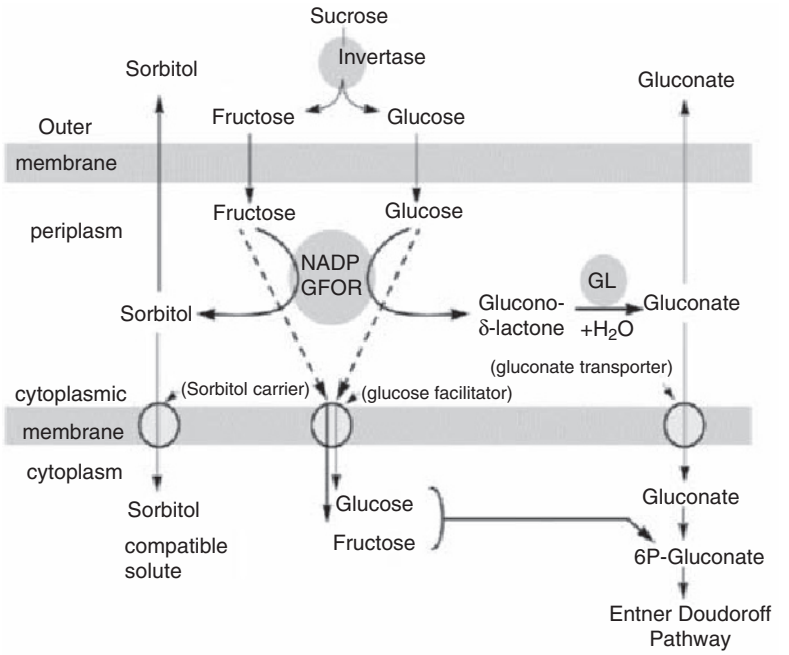

Fig. 15. Zymomonas mobilis production and utilization of gluconate and sorbitol from glucose and fructose. Sucrose may be hydrolyzed to glucose and fructose by an extracellular invertase. The periplasmic enzyme glucose fructose oxidoreductase (GFOR) with a tightly bound NADP converts the two sugars to D-gluconolactone and D-sorbitol. Gluconolactone is hydrolyzed to gluconate (gluconic acid) by a periplasmic gluconolactonase (GL). During normal metabolism, gluconate is utilized for carbon and energy via the Entner-Doudoroff pathway. Some glucose and fructose also are utilized. The sorbitol taken into the cell acts as an osmoprotectant. When normal metabolism is blocked, gluconate and sorbitol are manufactured and exit the cell's periplasm in equimolar amounts. Redrawn from Loos et al. (1994), with permission.

cose concentrations of 15% and at low pH, down to pH 3.5. These properties indicate that *A. diazotrophicus* may be of interest in commercial production (Attwood et al., 1991). In nature, *A. diazotrophicus* forms a symbiotic association with the sugar cane plant. During bacterial nitrogen-fixation, about one half of the fixed nitrogen is exported and made available as an organic nitrogen source for the host. The plant provides mainly sugars that are oxidized by the bacterium, some of which provide carbon and energy for growth. Glucose metabolism in *A. diazotrophicus* (like in *G. oxydans*) proceeds exclusively by the pentose-phosphate pathway. No enzymes peculiar to the Embden-Meyerhof or Entner-Douderoff pathways were detected (Attwood et al., 1991). However, the major portion of the glucose is oxidized via the membrane-bound PPQ-GDH and cytochrome quinoloxidase system. This oxidation pathway must provide a means to maintain an anaerobic environment within the cell so that the O_2-sensitive nitrogenase remains active. When bacteria are grown at low NH_3 (1 mM) the glucose dehydrogenase activities are 6.8- to 10-fold higher than when cells are grown in high NH_3 (40 mM). Isolated membranes from bacteria grown with low NH_3 showed an equivalent higher glucose oxidase activity (Flores-Encarnacion and Contreras-Zentella, 1999). Thus the respiratory system appears to be adjusted for scavenging oxygen to protect the nitrogenase, considering nitrogenase activity is much higher in cells with low NH_3 and growth is N_2-dependent.

The well-known ethanologenic bacterium, *Zymomonas mobilis*, has attracted attention as a candidate for development of processes for gluconic acid production (Table 17). Using glucose-fructose oxidoreductase (GFOR), an enzyme with a tightly coupled NADP as a hydrogen carrier (Fig. 15), this organism can convert a mixture of glucose and fructose, or sucrose, into gluconono-δ-lactone and sorbitol.

In addition, the enzyme glucono-δ-lactonase (GL) ensures rapid hydrolysis of the lactone to gluconic acid (Zachariou and Scopes, 1986). Under normal conditions the gluconate is taken up by these cells, phosphorylated, and utilized via the Entner-Doudoroff metabolic pathway for energy and carbon compounds required for growth. However, procedures are under development to permeabilize pregrown cells for production of gluconic acid and sorbitol, beginning with high concentrations of glucose and fructose (Roehr et al., 1996). Permeabilized cells leak their cofactors such as ATP and NADH, and thus the gluconic acid produced is not further metabolized. Silveira et al. (1999) reported that they obtained high yields of gluconic acid and sorbitol with untreated cells of *Z. mobilis* when high concentrations of glucose plus fructose (650 g/liter) were present. The high yields of gluconic acid were found to be due to inhibition of normal metabolism, permitting diversion of most substrates through the GFOR/GL pathway (Silveira et al., 1999).

Zymomonas mobilis can grow anaerobically in media containing very high concentrations of

sugars, such as glucose and sucrose. In natural habitats, such as fruit juices, plant saps and honey, the bacteria may encounter dry periods producing environments with high concentrations of sugars. It was demonstrated that sorbitol promotes growth of *Z. mobilis* in high-sugar solutions. It was proposed that probably sorbitol functions to counteract osmotic stress by acting as a compatible solute (Loos et al., 1994). The enzyme, GFOR, is located in the periplasm of *Z. mobilis* and makes up about one percent of the total cell protein (Fig. 15). The GFOR/GL system has a dual role. It converts fructose into sorbitol, which acts as a compatible solute permitting growth and survival of *Z. mobilis* in solutions of 30% sugar or higher. Simultaneously, glucose is converted into gluconic acid, some of which may be transported into the cell, phosphorylated and become available to the Entner-Doudoroff metabolic pathway for cell growth (Fig. 15). Clearly the bulk of both sorbitol and gluconic acid exits the cell under conditions where metabolism is blocked and fructose plus glucose concentrations are high.

Commercial Applications

Uses of Gluconic Acid and Gluconates Brief summaries are found in Milson and Meers (1985) and Roehr et al. (1996). D-Gluconic acid is a nontoxic and noncorrosive weak acid that is very soluble in water. It also forms water-soluble complexes with heavy metal and alkaline metal cations. Because gluconic acid is considered either a safe food additive or even a "food" in most countries, it has been of use in many processes related to the food industry. In the dairy industry, gluconic acid added to cleaners prevents calcium salt deposition in milking machinery and milk storage vessels. It is used in gentle metal-cleaning operations for aluminum and steel containers and equipment in food processing plants. Gluconic acid addition to various foods and beverages prevents cloudiness, complexes trace amounts of heavy metals and improves the food by adding a mild sourness to the taste. Gluconic acid is usually marketed as a 50% water solution, whereas the D-glucono-δ-lactone is commercially available as a crystalline solid. The glucono-δ-lactone is added as a slow-acting acidulant in baking powders for prepared instant cake mixes or instant bread mixes. Glucono-δ-lactone also is added during production of cured meat products such as in sausage preparations.

Sodium gluconate is the major commercial product used today, available either as a solid or in solution. The multiple uses of sodium gluconate depend upon its sequestering action with calcium, magnesium and iron in the presence of alkaline solutions of sodium carbonate or sodium hydroxide. For example, cleaning solutions are marketed to remove oxide scales or paint and lacquer residues from metal or glass surfaces. Also, sodium gluconate solutions are used in the textile industry to prevent iron deposition. Sodium gluconate acts as a plasticizer and a retardant of the setting process when mixed into concrete. Calcium gluconate is widely used for antacid and calcium supplement preparations. Ferrous gluconate is used in dietary iron supplement preparations. Pharmaceutical preparations containing nitrogen bases are often marketed as gluconates, as are disinfectants such as chlorohexidine gluconate.

Industrial Production The total world production of gluconic acid and gluconate in 1996 was estimated as $100–120 \times 10^6$ lbs/yr, of which 80% was sodium gluconate (Roehr et al., 1996). The standard for commercial production of gluconic acid or gluconates is the *Aspergillus niger* process. Although this process is basically a biochemical conversion, it is presently competitive with chemical, electrochemical, or catalytic oxidation techniques because of their lower yields and side reactions.

The *A. niger* process is presently superior to the older *Gluconobacter* and *Acetobacter* processes for a number of reasons summarized here and previously mentioned (Milson and Meers, 1985; Roehr et al., 1996). First, the requirements for *A. niger* growth are only mineral salts, a carbon source (such as glucose) and aerobic conditions. In contrast, the *Gluconobacter* species usually require a number of vitamins for growth. Secondly, for *A. niger*, the theoretical yield of gluconic acid from glucose is 100%, although a practical yield is usually between 90 and 95%. The yield for *Gluconobacter* is usually lower (about 75–80%) because of further enzymatic oxidation of gluconic acid to 2-keto-gluconate and 2,5-diketogluconate (Fig. 14). By careful attention to maintaining a moderately high glucose concentration and controlling the pH, the appearance of ketoacids can be minimized to less than 10% of the product (Noury and Van der Lande, 1962). But these ketoacids must then be removed during downstream processing. Thirdly, pregrown *A. niger* mycelia suspended in production media with glucose (250–380 g/liter) at pH 6.5 will produce almost 95% gluconic acid at a productivity of 13 g/liter · h, whereas strains of *Gluconobacter* are usually sensitive to glucose concentrations greater than 100 g/liter. Ziffer (1971) described a fed-batch method by which *A. niger* converted glucose (600 g/liter) to gluconic acid in 60–70 h. Crystallization of the sodium gluconate was prevented by allowing the pH to slip down to 3.2–3.5 during the process. In sum-

mary, the *A. niger* process is used for commercial production because it can produce (at a high productivity) a high yield of gluconic acid or gluconates in a relatively pure state requiring a minimum of downstream processing or purification. However, the competitive position of the *A. niger* process has been challenged by two new bacterial processes (see "Areas of Research and Development" in this Chapter).

The selling price of gluconic acid (50% solution, technical grade) was \$0.50–0.56 per lb and of sodium gluconate (powder, technical grade) \$0.66–0.70 per lb (Anonymous, 2000).

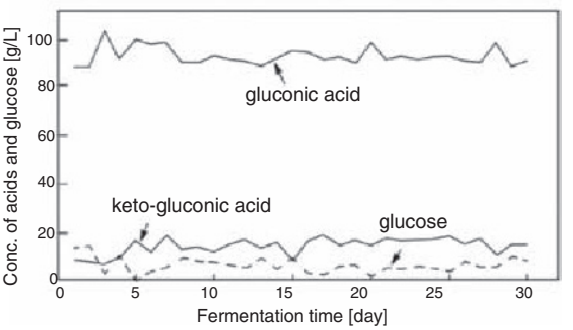

Fig. 16. Continuous production of gluconic acid from glucose by *Gluconobacter suboxydans* immobilized by adsorption on a ceramic honeycomb monolith reactor. Production was for one month at glucose, 100 g/liter; reactor residence time, 3.5 h; and aeration rate, 900 cm^3/min. The high productivity was 26.3 g/liter · h, with a yield of 84.6% gluconic acid. From Shiraishi et al. (1989b), with permission.

Areas of Research and Development

GLUCONOBACTER AND ACETOBACTER STRAINS AND PROCESS DEVELOPMENT The bacterial strains presently being considered for incorporation into future processes for gluconic acid production are listed in Table 17. Initially, *G. oxydans* was used for production; it became evident that this organism presents important barriers to commercial process development.

First, the rapid growth requirement for vitamins and (for some strains) other organic nitrogen sources complicates the growth medium and later the downstream purification of the final product. Second, this bacterium is sensitive to low pH and to high concentrations of glucose and gluconic acid, resulting in low productivity and low final concentrations of gluconic acid in the beer. Third, the significant further oxidation of gluconic acid to 2-keto and 2,5-diketogluconate lowers the final yield and adds by-products that must be removed in later purification.

Process development and employment of alternative bacterial strains have bypassed some of these problems. Shiraishi et al. (1989b) investigated continuous production of gluconic acid with *G. suboxydans* IFO 3290 immobilized by adsorption on ceramic honeycomb monoliths. This type of ceramic with uniform 1- or 2-mm channels was found to be ideal for allowing rapid gassing (up to 900 cm^3/min) as well as effective immobilization and metabolism by aerobic bacteria. Using a laboratory-scale ceramic reactor (immobilized *G. suboxydans*), a continuous conversion of glucose (100 gm/liter) was performed for 30 days, during which time the adsorbed cells remained stable (Fig. 16).

A gluconic acid yield of 84.6% and glucose conversion of 94% were achieved. The calculated productivity of 26.3 g/liter · h was the highest ever reported for *Gluconobacter*. Unfortunately, the production of keto-gluconic acid was about 9%. Attempts to reduce the ketogluconate concentration using this continuous immobilized-cell method (changing the system to a three-stage reactor) were only partially successful (Shiraishi et al., 1989a).

Transposon, Tn*5*-induced mutagenesis of *G. oxydans* was demonstrated (Gupta et al., 1997). Using this method, Gupta et al. (1999) have produced a mutant of *G. oxydans* ATCC 9937 (mutant C11) that is defective in gluconic acid dehydrogenase (GADH) and thus produces only gluconic acid from glucose without further oxidation of gluconic acid to 2-ketogluconate or 2,5-diketogluconate (see Fig. 14). Mutant C11 will certainly be attractive for development of a gluconic acid production process free of ketogluconate synthesis.

During the 1980s and 1990s, the Institute of Biochemistry in Leipzig began developing a process for gluconic acid production carried out with a methanol-utilizing strain Acetobacter methanolicus MG58 (IMET 10945T; Babel et al., 1986; Babel et al., 1991). The organism was grown on methanol and the growth process ended owing to a deficiency of nitrogen and phosphorous. Cells (5–20 g of dry biomass per liter; BM) were suspended in the reactor vessel (F) and 150–250 g of glucose/liter was added. During the batch phase (10–20 h), glucose was converted into gluconic acid and the pH dropped to about 1.5–2.0. A continuous process was started, adding glucose (G) to the recycled permeated stream to maintain a level of gluconic acid at 200 g/liter (CGA) in the reactor (Fig. 17).

Even at this high concentration of gluconic acid, the *A. methanolicus* cells, when continuously fed glucose, maintained a synthesis rate of gluconic acid at 20–30 g/liter · h for seven days (Poehland et al., 1993). The medium retention time in the reactor (F) and the permeate stream

rate were controlled by pumps in the recycle circuit, which runs through a microfiltration module (MF). This arrangement continuously removes gluconic acid and other ingredients from the medium. The ultrafiltration output was passed continuously into a electrodialysis apparatus (ED) to concentrate and purify the gluconic acid (GA). Optimization experiments were carred out in a laboratory-scale system with a 30-liter reactor vessel. Figure 18 illustrates a continuous gluconic acid process employing *A. methanolicus* and lasting more than five days.

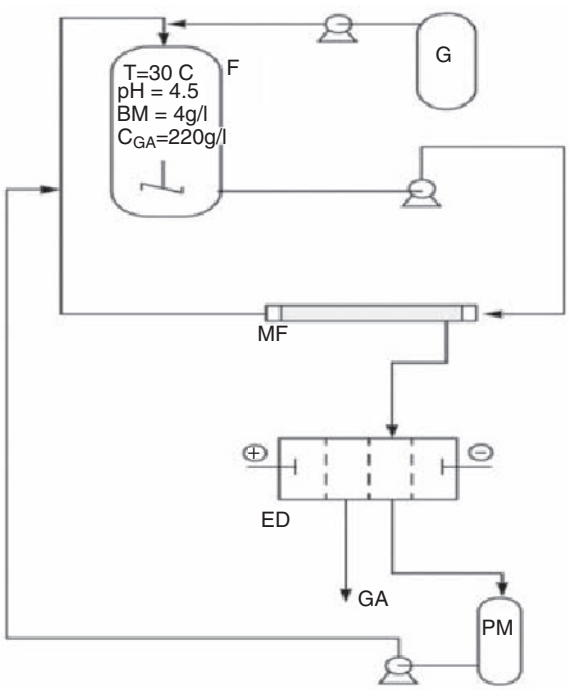

Fig. 17. Flow diagram of the gluconic acid synthesis process utilizing *Acetobacter methanolicus*. See the text for details. Redrawn from Poehland et al. (1993), with permission.

The published results are encouraging for further process development because this organism can withstand high concentrations of gluconic acid and glucose while continuously producing gluconic acid at high rates and at low pH values. Most important, the formation of 2-ketogluconate or 2, 5-diketogluconate does not occur using this organism, so that downstream removal of these by-products is unnecessary (Uhlig et al., 1986).

Acetobacter diazotrophicus, an isolated nitrogen-fixing acetic acid bacterium, shows high rates of gluconic acid production in preliminary studies (Attwood et al., 1991). In contrast to *G. oxydans*, *A. diazotrophicus* grows rapidly on simple mineral medium, tolerates acid to pH 3.5, and also tolerates high glucose and gluconic acid concentrations greater than 150 g/liter. Apparently, aerobic utilization of dinitrogen at low ammonia concentrations depends upon an extremely high rate of respiratory electron transport utilizing glucose oxidation coupled to oxygen uptake (Flores-Encarnacion, 1999). The physiologic conditions for a maximum rate of gluconic acid production using this bacterium may be developed easily, considering a simple batch culture with 150 g of glucose/liter at high ammonia produced an 80% yield of gluconic acid at a productivity of about 15 gm/liter · h (Attwood et al., 1991). Unfortunately, *A. diazotrophicus* produced some 2-ketogluconate during gluconic acid production. However, genetic methods are available to knock out the gluconate dehydrogenase gene or develop mutant strains as reported for *G. suboxydans* (Gupta et al., 1999).

Zymomonas mobilis Process for Gluconic Acid and Sorbitol Production *Zymomonas mobilis* contains the periplasmic enzyme, glucose-fructose oxidoreductase (GFOR),

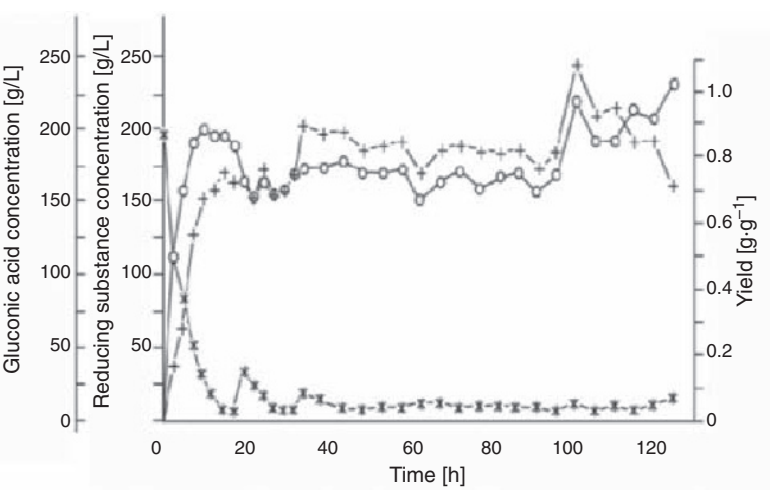

Fig. 18. An example of a continuous process for conversion of glucose to gluconic acid by Acetobacter methanolicus: –o–, yield; –+–, gluconic acid concentration; –∗–, reducing substance concentration (glucose). From Poehland et al. (1993), with permission.

together with gluconolactonase (GL; Zachariou and Scopes, 1986). (See "Scientific Background" of gluconic acid production for a description of the biochemistry and physiology of the *Z. mobilis* system.) Subsequently, it has been shown that this organism can totally convert equimolar fructose and glucose solutions of over 50% into sorbitol and sodium gluconate. The advantages of *Z. mobilis* for process development are:

1) no requirement for high aeration rates in contrast to aerobic processes using *A. niger* or *G. suboxydans*;
2) productivity is enhanced by high concentrations of sugars; and
3) both sorbitol and sodium gluconate have industrial value and can be separated downstream (Chun and Rogers, 1988).

The chemical technology for manufacture of sorbitol requires H_2 gas reduction at high pressure (40–50 atm) and high temperature (140–150°C) of a 70% glucose solution with a Ni^{+2} ion catalyst. The sorbitol syrup produced must be passed through several ion exchangers to reduce the residual nickel below 5 ppm prior to use of the sorbitol in the food industry (Phillips, 1963). In contrast, under the mild conditions, *Z. mobilis* produces equimolar quantities of gluconic acid (or sodium gluconate) and sorbitol at high yields and high productivity. Also, considering selling prices, production of sorbitol (powder, $0.73–0.96/lb, or crystals, $0.73–1.03/lb) from fructose (powder, $0.39/lb) rather than glucose (powder, $0.51–0.54/lb) as a starting material may be more economical (Anonymous, 2000).

Zymomonas mobilis normally utilizes much of the gluconate produced for metabolism via the Entner-Doudoroff pathway (see "Scientific Background" in this Chapter). To develop a process that produces high quantities of both gluconate and sorbitol, the metabolic utilization of gluconate must be suppressed or bypassed. Taking advantage of the perplasmic position of the GFOR and GL enzymes together with methods for preventing metabolism of gluconic acid, three approaches have been used. First, it was found that *Z. mobilis* cells treated with toluene were permeabilized, and thus leaked cofactors such as NAD and NADP. These cells were unable to metabolize gluconate, but retained the full ability to convert glucose to gluconate. This was because the NADP cofactor remains tightly coupled to the GFOR enzyme. Table 18 illustrates data from a number of workers showing that toluene permeabilized cells carry out production of sorbitol and gluconate at high rates and at greater than 90% conversion in a batch reactor. These cells immobilized in calcium-alginate or in carrageenan had similar production characteristics. Using these immobilized cells in continuous or packed-bed continuous recycle reactors resulted in longer running times, up to 75 days (Rehr et al., 1991). However, the productivity and/or the percent conversion was somewhat lower than for batch operation (Table 18). Continuous production of gluconic acid and sorbitol from alternative substrates has been carried out using toluene permeabilized *Z. mobilis* cells co-immobilized with chitin-enzyme complexes in aginate beads (Kim and Kim, 1992a; Ro and

Table 18. Experimental production of gluconic acid and sorbitol by *Zymomonas mobilis*.

Cell treatment	Reactor	Run time	Substrates glucose and fructose g/liter	Production of gluconate-sorbitol Conversion rate		References

[a]The rate applies to each product separately.
[b]Jerusalem artichoke inulin (100 g/liter) added instead of free fructose.
[c]Sucrose added instead of fructose and glucose.

Kim, 1991). With immobilized inulase, Jerusalem artichoke inulin provided fructose, and with immobilized invertase, sucrose substituted for both glucose and fructose. The preliminary results are interesting and may provide a framework for further process development using co-immobilization techniques (Table 18).

A second approach to efficient synthesis of gluconic acid and sorbitol has been the use of cell-free GFOR from *Z. mobilis*. Using a crude extract of *Z. mobilis* in a continuous ultrafiltration membrane reactor, excellent substrate conversion and enzyme stability were maintained for about 10 days (Silva-Martinez et al., 1998). However, it has been concluded that the strict requirements for enzyme stability would be costly for commercial production and downstream processing, which is a strong argument favoring use of permeable cells (Nidetzky et al., 1997).

Finally, a third approach to achieving high production rates and conversion yields was demonstrated using untreated cells of *Z. mobilis* (Silveira et al., 1999). In batch runs for 8 h with 30 g of pregrown cells/liter and glucose plus fructose at 650–750 g/liter, yields reached 91% for both products with productivities of 48 and 45 g/liter · h for gluconic acid and sorbitol, respectively (Table 18). Experiments showed that the main reason for the high yields for batch runs with substrate at 650 g/liter or greater but not at lower concentrations, such as 300 g/liter, was the inhibition of normal metabolism of glucose and gluconates (see Table 18). High concentrations of either substrate or products (gluconate and sorbitol) can cause this inhibition effect, which results in preferential conversion of substrates by the glucose-fructose oxido-reductase/glucono-δ-lactonase system (Silveira et al., 1999). The best conversion yield reported for untreated cells is 91% for gluconic acid and sorbitol, which is lower than 94–98% for permeabilized *Z. mobilis* with or without immobilization (Table 18). However, large-scale permeabilization and immobilization of cells would add to production costs. On the other hand, long runs (up to 75 days) in a two-stage continuous system were achieved with cetyltrimethylammonium bromide (CTAB)-permeable cells immobilized in carrageenan (Rehr et al., 1991). Yet, all of the published continuous processes shown in Table 18 operate with low concentrations of products (about 100 g/liter), increasing costs for water removal.

Although numerous patents have been issued on various methods for the production of sorbitol and gluconic acid using various *Z. mobilis* cell preparations, clearly further process development must occur before a viable commercial process will emerge.

PATENTS The use of *Gluconobacter* (*Acetobacter*) *suboxydans* for production of gluconic acid (by modification of the "quick" vinegar process or by the submerged fermentation process [the Frings process]) is documented in early patents (Currie and Carter, 1930; Currie and Finlay, 1933). However, because of the difficulty in controlling the simultaneous appearance of about 10% ketogluconic acids along with gluconic acids, as well as other serious problems (mentioned in "Scientific Background" and "Areas of Research and Development"), at present, *Gluconobacter* is not considered for development of commercial processes. Thus, *Gluconobacter* spp. do not appear in the patent literature concerning gluconic acid synthesis.

However, numerous patents utilizing *Acetobacter methanolicus* for gluconic acid production have appeared recently. Babel et al. in Germany have been most active in developing the technology for this process described in more than eight patents. Three patents from this group are listed in Table 19. The 1991 patent describes a two-phase process (possibly utilizable for commerical production) culminating in production of a very high yield of gluconic acid (see "Areas of Research and Development" in this Chapter).

There has been a great deal of interest in the possible commercialization of the *Zymonmonas mobilis* catalyzed process for oxidation of glucose to gluconic acid combined with the reduction of fructose to sorbitol. Sorbitol as well as sodium gluconate is used in a varety of industrial applications. The six patents listed in Table 19, from 1988 to 1995, reflect examples of processes employing permeabilized cells of *Z. mobilis*.

Because of the characteristics of this system, permeable cells produce high yields at high productivities of both gluconic acid and sorbitol (see "Scientific Background" and "Areas of Research and Development" in this Chapter). In two of the patents (Rehr et al., 1991; Roehr and Sahm, 1995), immobilization techniques are described that increase the total time duration for a stable process. The last patent listed in Table 19 (Silveira et al., 1994) describes the conditions for use of untreated cells of *Z. mobilis* for production of gluconic acid at high yield.

In addition to the patents emphasizing manufacturing methods for bacterial production of gluconic acid, there are many patents on applications of gluconic acid in industry. A brief survey revealed that over the past ten years, more than 70 U.S. patents appeared for use of gluconic acid and sodium gluconate in pharmaceutical products, food preparations, cleaning of metallic circuits and delicate metal parts, leather treatments, and other products and processes.

Table 19. Selected patents for gluconic acid production.

Patent number	Year	Inventors and (applicants)	Organism and technology
DD 236,754	1986	Babel et al. (Akad.Wissenshaften)	*A. methanolicus* Batch process, high-yield gluconate

Prospects At present, there are no bacterial conversion processes applied to large-scale commercial production of gluconic acid. Industrial manufacture mainly employs the fungal process with *Aspergillus niger* and *Aureobasidium pullulaus* (Roehr et al., 1996; Anastassiadis et al., 1999).

Two bacterial-based processes are under development that may turn out to be competitive in the future. Acetobacter methanolicus supercedes *Gluconobacter suboxydans* and related strains. The attributes of this organism that eliminate the disadvantages of *G. suboxydans* are dealt with in "Scientific Background" and "Areas of Research and Development." A two-phase process has been developed in which *A. methanolicus* cells can be grown on methanol in phase one, and then high glucose concentrations can be converted rapidly to pure gluconic acid during the production phase (Poehland et al., 1993; Babel et al., 1991). In experimental reactors with continuous-feed recycle, high yield and high productivity were maintained for 7 days (see "Areas of Research and Development" in this Chapter).

The *Zymomonas mobilis* production system described above (in "Areas of Research and Development") has the advantage of producing both sodium gluconate and sorbitol under anerobic conditions. The lack of an aeration requirement during the production process certainly lowers costs when compared to other bioprocesses. Secondly, both sodium gluconate and sorbitol are marketable chemicals with a number of applications. The development of processses using permeabilized cells, untreated cells, or immobilized cells in continuous or fed-batch reactors is still in the experimental stage. The results promise high yields of gluconic acid at high productivities under conditions that may be cost-effective and competititve with other processes for gluconic acid manufacture.

Section 4: Succinic Acid

Introduction

Succinic acid (1,4-butanedioic acid) is a four-carbon acid which occurs as a constituent of almost all plant and animal tissues and microorganisms. It has been of considerable interest in recent years as a renewable feedstock for various petrochemical-based large-volume chemicals, owing to the reactivity of its functional groups. Succinic acid received its name from the Latin name "Succinum" meaning "amber," from which it was first isolated. National Aniline began production in the United States in 1929 using an electrolytic reduction of maleic anhydride. The fermentative production of succinic acid was studied in Japan in the 1970s utilizing a variety of feedstocks such as paraffins, sucrose and isopropyl alcohol (Kirk-Othmer, 1983).

Succinic acid also is produced as a by-product of adipic acid manufacture and can be sold as a mixture with other organic acids from this process. Annual world production of adipic acid exceeds a billion pounds and a large amount of by-product succinic acid is obtained. Succinic acid is also sold as a purified product and sells in the range of $2.50 to $2.80 per lb, as listed in a

Chemical Prices section of the Chemical Marketing Reporter of January 10, 2000.

The fermentation processes of *Escherichia coli* and other enterobacteria have been studied since the time of Pasteur, and much is known about fermentative metabolism and the generation of fermentation end products. In the oxidation of hexose, the fermentation products of *E. coli* are made up of a mixture of ethanol, acetic, formic, lactic and succinic acids. *Escherichia coli* adjusts the proportion of products to attain redox balance and generally succinic acid makes up only 5–10 mol% of the fermentation products (Bock and Sawers, 1996). Progress in metabolic engineering has helped raise the interest of various groups in a biological-based industrial process for the overproduction of succinic acid that might compete with petrochemical processes generating comparable four-carbon feedstocks.

Owing to the reactivity of succinic acid, it can be converted to a variety of products, including large volume chemicals such as 1,4 butanediol and tetrahydrofuran. The use of renewable resources and carbohydrates derived from agricultural materials such as corn has increased the interest in making intermediates such as succinic acid in an industrial fermentation process. The potential for industrial succinic acid fermentation was discussed as long as 20 years ago by Zeikus (1980). The various biotechnological methods for production and the markets for succinic acid and its various derivatives were reviewed (Zeikus et al., 1999).

Succinic acid was identified as a target chemical by the United States Department of Energy Alternative Feedstocks Program. Their initial activity focused on the development of decision-making tools, which led to the commencement of process development research in 1993 for succinic acid (Schilling, 1995). A consortium of industry, academic and government scientists in conjunction with the National Corn Growers put together "Vision 2020," based on the use of renewable material for chemical production. One of the projects listed in Vision 2020 is a biocatalyst for the production of succinic acid from biomass (Reisch, 1999). The future need to replace petrochemically derived chemicals for more green technologies will be a driving force in advancing technology for the production of fermentation-derived chemicals such as succinic acid, as well as push the process development for catalytic conversion of succinic acid to other products.

Scientific Background

Succinate, along with a mixture of other products, is produced during fermentative metabolism by a variety of microorganisms. In *Escherichia coli*, glucose is transported into the cell via the phosphotransferase system and metabolized to pyruvate. The NADH produced during glycolysis must be recycled by conversion of pyruvate to fermentation products so that glycolysis may continue. Pyruvate dehydrogenase, which oxidatively decarboxylates pyruvate, is negatively regulated by NADH and is repressed during fermentative growth. Pyruvate formate lyase, which is functional only under anaerobic conditions, converts pyruvate to acetyl CoA and formate. The cell only turns on one of these enzymes at a time, dependent on the redox status of the cell, allowing the cell to balance NADH during aerobic or anaerobic growth (Bock and Sawers, 1996).

During anaerobiosis, the enzyme pyruvate formate-lyase is used by *E. coli* to form one molecule of formate and one molecule of acetyl CoA from one molecule of pyruvate. Formate can either be excreted from the cell or decomposed to carbon dioxide and dihydrogen. Two NADH molecules are consumed through the reduction of acetyl CoA to ethanol, which is the most highly reduced major fermentation product of *E. coli*. This conversion occurs through two dehydrogenation reactions catalyzed by alcohol dehydrogenase (Clark, 1989).

The production of lactate also uses reducing equivalents, and lactic acid is formed by the enzyme lactate dehydrogenase. Lactate is not

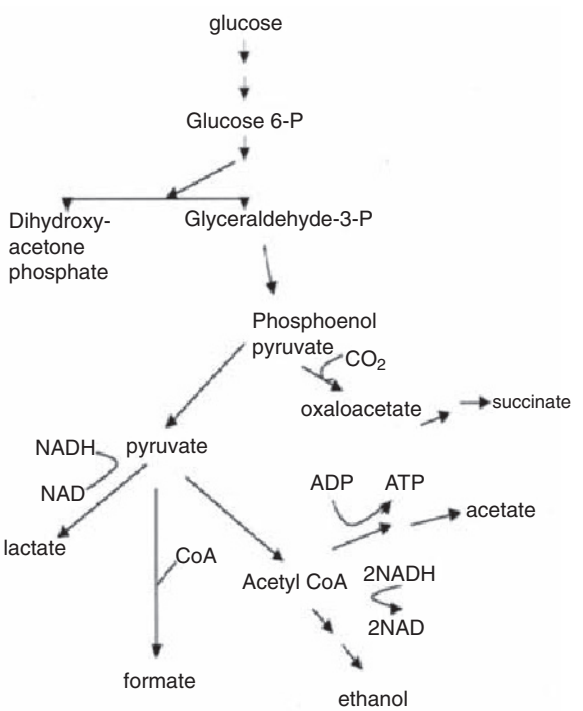

Fig. 19. Mixed acid pathways of *Escherichia coli*.

essential to balance fermentative growth, and the fermentative NADH-dependent lactate dehydrogenase does not appear to be necessary for anaerobic growth (Mat-Jan et al., 1989).

The production of succinate and the enzymatic reactions of malate dehydrogenase and fumarate reductase use two reducing equivalents per succinate formed. The carboxylation of phosphoenolpyruvate (PEP) is the first step in this reaction, with metabolically generated CO_2 limiting the amount of succinate formed (Bock and Sawers, 1996). The reactions below show the mixed acid pathways of *E. coli*.

Typically wild type *E. coli* generates fairly small amounts of succinic acid. Under "Research and Development," the development of *E. coli* strains that produce large quantities of succinic acid will be discussed in greater detail.

Many succinate-producing bacteria so far described have been isolated from the rumen. Propionic acid, which is used by the animal for biosynthetic precursors and for energy, is produced by the decarboxylation of succinic acid. A review written by Gokarn et al. (1997b) covers in more detail the diversity of microorganisms that can be isolated. The most predominant cellulolytic organism in the rumen is *Fibrobacter succinogenes*. It can use a variety of complex substrates and fixes CO_2 during succinate production. Other succinate producers in the rumen include but are not limited to *Ruminobacter amylophilus* and *Wolinella succinogenes* (Gokarn et al., 1997b).

The productivity of selected rumen bacteria for organic acid production was investigated using a variety of cellulosic substrates. The rumen bacteria *Fibrobacter succinogenes* S85 was shown to produce succinate with a yield of 0.38 g/g of glucose and with an acetate yield of 0.11 g/g of glucose consumed. This organism could use cellobiose to produce succinic acid but at slightly lower yields. Because succinate has been found to be a major end product of cellulosic substrates (Walseth cellulose, microcrystalline cellulose, pulped paper and steam-exploded yellow poplar), the use of cellulosic materials for succinic acid production is promising. In contrast, the major end product of *Ruminococcus flavefaciens* on cellobiose, Walseth cellulose, and microcrystalline cellulose was acetate, whereas on pulped paper and steam-exploded yellow poplar, succinate was the major end product. In general, the *Fibrobacter* strain produced more succinate at a higher rate than did the *Ruminococcus* (Gokarn et al., 1997a).

Selenomonas ruminantium, a Gram-negative anaerobe and one of the major species present in the rumen, accumulates succinate as a major end product in the presence of lactate, if malate is added to stimulate lactate uptake. Without malate present, the major end products are acetate and propionate. When succinate reached the concentration of the added malate, malate utilization ended. From a practical standpoint, malate could be added to ruminant diets high in rapidly fermentable carbohydrates. Because high rumen lactate is undesirable, the presence of malate could stimulate lactate utilization (Evans and Martin, 1997).

Actinobacillus sp. 130Z, a facultative anaerobic microorganism that was isolated from the rumen, produces high levels of succinate, and also accumulates some formate and acetate. This strain was classified as *Actinobacillus succinogenes* sp. nov. (Guettler et al., 1999), and owing to its ability to make high levels of succinate under a variety of conditions, it has been the subject of intensive work as well as patent activity. Studies involving this strain will be discussed in greater detail under "Research and Development."

Propionibacterium can ferment glucose or glycerol to make fairly high levels of succinic acid (Gottschalk, 1985), which is a characteristic component of Swiss-type cheese. High concentrations of CO_2 promote this activity (Wood and Werkman, 1938; Wood and Werkman, 1940). *Propionibacterium freudenreichii* subsp. *Shermanii* metabolizes aspartate primarily to succinate and ammonia during fermentation of lactate. When fed lactate with sparged CO_2, however, only a small concentration of succinate is formed and propionate is the main product. This indicates that propionibacteria may use combinations of pathways such as the citrate and transcarboxylase cycles to generate different mixes of end products (Crow, 1987).

The production of succinate by *Lactobacillus* has not been widely studied. Kaneuchi et al. (1988) screened 86 isolates of *Lactobacillus* that were isolated from fermented cane molasses using de Man-Rogosa-Sharpe (MRS) broth. Approximately one-third of the strains screened produced succinate, which is of interest owing to the importance of succinic acid as a flavor ingredient in dairy products. They determined that the diammonium citrate in the MRS broth was the precursor to succinate.

The metabolism of carbon dioxide is a critical aspect for the successful production of succinic acid. Three enzymes that have been examined in the overproduction of succinate can fix CO_2. They catalyze the reactions listed in Table 20.

Actinomyces viscosus, which is associated with periodontal disease and is a succinate producer, incorporates labeled $NaHCO_3$ into succinate but not lactate. High levels of the enzyme phosphoenolpyruvate (PEP)-carboxykinase were found in cell extracts in this study. This enzyme condenses carbonate and PEP to oxalacetate, which

Table 20. Carbon dioxide utilization reactions involved in succinate production.

Substrates	Enzyme	Products	Cell use

Pyruvate, ATP and HCO_3^-	PYC E.C. 6.4.1.1	OAA, ADP and orthophosphate	Can be used to enhance succinate production

Abbreviations: NTP, nucleotide triphosphate; PCK, phosphoenolpyruvate carboxykinase; NDP, nucleotide diphosphate; PEP, phosphoenolpyruvate; PPC, phosphoenolpyruvate carboxylase; OAA, oxalacetic acid or oxalacetate; and PYC, pyruvate carboxylase.

can then be converted to either succinate through malate dehydrogenase and additional metabolic steps or aspartate catalyzed by the enzyme glutamate aspartate aminotransferase (Brown and Breeding, 1980).

The microorganism *Anaerobiospirillum succiniciproducens* forms succinate in high amounts and can make greater than 30 g/liter (Datta, 1992a). Several studies have focused on the effect of the supply of CO_2-HCO_3^- on succinate production (Samuelov et al., 1991; Nghiem et al., 1997; Lee et al., 1999a). A pH of 6.2 and high CO_2-HCO_3^- levels promote succinate as the major product, and the levels of PEP-carboxykinase are high while lactate dehydrogenase and alcohol dehydrogenase levels decrease. Under high CO_2-HCO_3^-, the growth rate of *A. succiniciproducens* is high and cell yield doubles. Lactate and ethanol are formed as electron sink products if CO_2-HCO_3^- are low, and a lower growth rate is observed (Samuelov et al., 1991).

The PEP-carboxykinase (PCK, EC 4.1.1.49) was purified from *A. succiniciproducens*. High levels of this enzyme are made during succinate production, and roughly 10% of the crude cell protein is PCK. The enzyme has an absolute need for divalent cations and synergistic effects of various cations were demonstrated. Despite the fact that the fixation of HCO_3^- is important in succinate production, the K_m value for HCO_3^- is similar to those in other reported enzymes in vertebrates which function in a reverse direction. The authors speculate that high external concentrations of HCO_3^- in the environment push the reaction towards oxalacetate (Podkovyrov et al., 1993).

The PCK-encoding gene was cloned from *A. succiniciproducens* and expressed in *E. coli*. Sequence analysis showed that it is closely related to other PCKs of Gram-negative bacteria and that it is 67.3% identical to the PCK of *E. coli*. This is surprising in that the PCK gene of *E. coli* is not crucial for succinate production, and one would not expect such high homology. The authors compare kinetic constants with other ATP/ADP-dependent PCKs, although the comparison is not exact because of the differing conditions of analysis. The *A. succiniciproducens* enzyme appears to have a higher V_{max} for CO_2 fixation than those of *E. coli* and Trypanosoma cruzi and a higher K_ms for PEP and ADP. The authors conclude that sequence and structural features are probably not responsible for the differing activities of the various PCKs (Laivenieks et al., 1997).

The PCK of *A. succiniciproducens* requires the nucleoside triphosphate ADP, and a pyruvate kinase-like activity of this enzyme was identified. In gluconeogenesis, PCK catalyzes the irreversible decarboxylation of oxalacetate, and in *A. succiniciproducens*, AMP was shown to activate this oxalacetate decarboxylase reaction (Jabalquinto et al., 1999).

The enzyme PEP-carboxykinase also appears to play an important role in other high-succinate producers besides *A. succiniciproducens*. The availability of CO_2 in the medium affects succinate production, and a direct relationship between CO_2 added and succinate production is observed. In a comprehensive comparison between enzyme activities of Actinobacillus sp. 130Z and *E. coli* K-12 grown anaerobically, the specific activity of the *Actinobacillus* PCK was shown to be thousands-fold higher than that of *E. coli*. This is in contrast to the many other enzymes that showed similar activity and indicates that PEP-carboxykinase is produced constitutively in this microorganism (Van der Werf et al., 1997).

In contrast to the previous two examples on the importance of PCK in succinate production by *A. succiniciproducens* and Actinobacillus, overexpression of PCK in *E. coli* had no effect. This result is surprising in that the *E. coli* PCK enzyme has similar if not better kinetic characteristics than the *A. succiniciproducens* enzyme, and why this enzyme does not play an important role in *E. coli* succinate overproduction is uncertain. In *E. coli*, a different CO_2-fixing enzyme appears to play a role, as overexpression of PEP-

carboxylase, produced during growth on glycolytic substrates, increased succinate production from 3.27 to 4.44 g/liter and did not alter the distribution of fermentation products (Millard et al., 1996).

A similar pathway for the formation of succinate in both *Actinobacillus* sp. 130Z and *A. succiniciproducens* has been proposed. The formation of oxalacetate from PEP via CO_2 fixation is the first key step. The enzymes malate dehydrogenase, fumarase and fumarate reductase, all enzymes of the tricarboxylic acid (TCA) cycle, work in a reductive fashion towards succinate (Van der Werf et al., 1997; Samuelov et al., 1991). The reactions catalyzed are as follows:

$$\text{Phosphoenolpyruvate} + CO_2 + \text{NDP} \rightarrow \text{Oxaloacetate} + \text{NTP} \quad (1)$$

$$\text{Oxaloacetate} + \text{NADH} \rightarrow \text{L-Malate} + \text{NAD} \quad (2)$$

$$\text{L-Malate} \rightarrow \text{Fumarate} + H_2O \quad (3)$$

$$\text{Fumarate} \rightarrow \text{Succinate} \quad (4)$$

Enzymes utilized are 1) phosphoenolpyruvate carboxykinase, 2) malate dehydrogenase, 3) fumarase and 4) fumarate reductase.

The drive towards succinate production is influenced by environmental factors that can be controlled in a fermentation process. This aspect will be discussed under "Areas of Research and Development."

Commercial Applications

Succinic acid is sold into four major existing markets. The largest is as a surfactant and foaming agent. The other uses are as a chelator in electroplating, an acidulant and flavoring agent in food, and in the production of health-related agents. The estimated market size for these four areas is more than $400 million per year (Zeikus et al., 1999).

The promise of large-scale low-cost fermentations from renewable resources, especially corn, has spurred interest in the United States to develop chemical production for large-volume chemicals using bio-based processes. Succinic acid can be converted by hydrogenation to 1,4-butanediol, which has a world market in excess of 500,000 metric tons. Butanediol is used to produce polybutylene terephthalate (PBT) resins that have desirable mechanical and thermal properties and are a high-performance version of polyethylene terephthalate resins (PET). Also, 1,4-butanediol is a precursor of tetrahydrofuran, which can be polymerized to polytetrahydrofuran (PTHF). Gamma butyrolactone (GBL) can also be derived from 1,4-butanediol, and much of GBL is used to manufacture the solvent *N*-methyl-2-pyrrolidone (Szmant, 1989).

Butanediol is manufactured primarily through a process called "the Reppe Process," which reacts acetylene and formaldehyde at high pressure. Alternative chemical technologies such as a maleic anhydride process and a process using ester hydrogenation technology have come on line (Tullo, 1999). The raw materials used in the chemical process are large volume and low cost. For example, maleic anhydride sells in the range of about $0.50/lb. This means that a fermentation process must be very efficient with low raw material costs to be able to compete with a chemical-based process.

A methodology was described to assess the feasibility of success in making commodity chemicals from renewable resources. The methodology uses a five-step process in the assessment. The first step is portfolio selection, and some of the key selection criteria are high theoretical yields from substrate, high market interest and volume. The second phase involves initial economic screening and uses an economic criterion called "the Fraction of Revenue for Feedstock" (FRF). In this calculation, the cost of the feedstock is divided by the value of all the products, and the products that show the most promise are those where the fraction is smallest. This value takes into account the yields of the products derived from the various feedstock components. The third phase is a comparative analysis of bioprocessing routes that uses a raw material cost ratio, which in essence compares the raw material costs for a bioprocess versus those for the petrochemical route. Phase four is a qualitative analysis, and phase five is a detailed economic analysis requiring a significant effort to classify and do economic assessment of the process technologies. A number of products in an initial portfolio were assessed, then narrowed down to a shorter list which includes acetic acid, 2,3-butanediol, malic acid, and propylene glycol to name a few. Succinic acid was identified as a potential near-term opportunity because it had one of the best FRFs and raw material cost ratios (Landucci et al., 1994). Despite the attractiveness of succinic acid, at this writing an industrial-scale bioprocess has not been attained. However, improvements in the process technology and strains (as evidenced in the patent literature) indicate the potential for a succinic acid bioprocess in the near future.

The other important aspect of the development of the succinic acid market is the chemical conversion of succinic acid to other products. Selective and low cost catalyst development is needed to enable lower cost economics. The chemistry of succinic acid catalysis has been reviewed by Varadarajan et al. (1999) and the

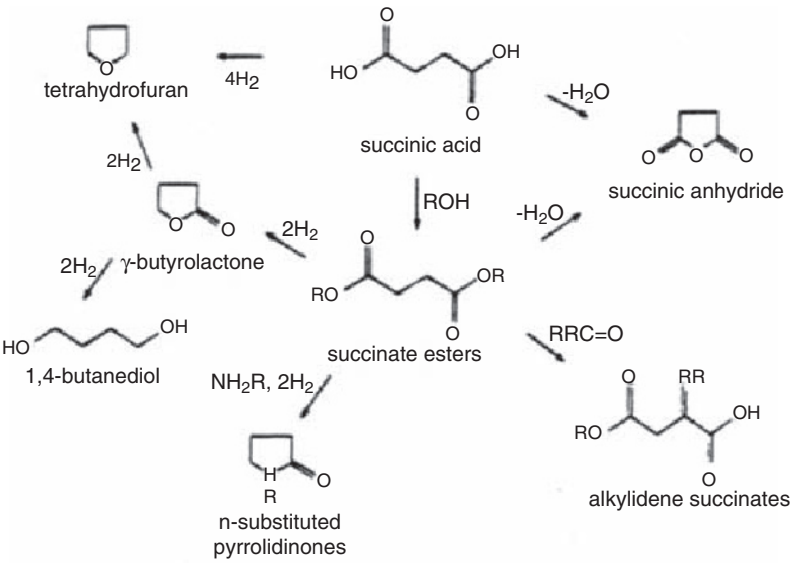

Fig. 20. Summary of catalytic conversion pathways and potential products derived from succinic acid. From Varadarajan et al. (1999), with permission.

summary of the various derived products that follows is from that work. Succinic acid can be readily converted into alkyl esters that have uses as industrial solvents and paint removers. Succinic acid, its anhydride or its esters, can be hydrogenated to the product family of 1,4-butanediol, however, this conversion has not been as well-studied as the hydrogenation of maleic acid or anhydride. A third important product family that can be derived from ammonium succinate, succinimide, or succinic acid is based on 2-pyrrolidinones. They are used for polyvinyl pyrrolidinone (PVP) production, which has an estimated minimum market value of $150 million per year. Other uses for 2-pyrrolidinones include solvents and plasticizers. The commercial production depends upon petrochemical-based materials. A summary of the potential products that can be derived from succinic acid is presented in Fig. 20 (Varadarajan et al., 1999).

The major economic issue in whether succinic acid can compete is the low starting cost of petrochemical raw materials. The target cost for succinic acid from a bioprocess is estimated to be around $0.25/lb for a large-scale plant (Zeikus et al., 1999; Varadarajan et al., 1999). This target cost is necessary to compete with low-cost petrochemical raw materials.

Despite the major interest in the large-volume uses of succinic acid, other new specialty markets of interest should not be ignored. A succinate-based animal feed additive from whey fermentation has been described (Samuelov et al., 1999). The entire fermentation is dried down to a product, which is about one-third succinate, and also contains protein, other organic acids and salts. Succinate is desirable as a feed additive as it is rapidly converted to propionate, which in the rumen improves efficiency and contributes to the overall health of the animal.

Ethylenediamine-*N*,*N*′-disuccinic (EDDS) acid is a chelator that can be used in detergents and is a potential replacement for ethylenediaminetetraacetic acid (EDTA) (Lin et al., 1996). It is also biodegradable and various optical isomers have different susceptibilities to biodegradation (Takahashi et al., 1997). Succinic acid also can be used in the manufacture of biodegradable plastic. A novel biodegradable plastic, called "Bionolle," invented in the early 1990s is based on poly(butylene succinate), poly(butylene adipate succinate), or poly(ethylene succinate). These plastics have been produced on a pilot plant scale and show good processability. They can be processed with conventional equipment and can be made into products such as bottles and foam (Fujimaki, 1998). A copolymer can be made with succinic acid and 1,4-butanediol (Takiyama and Fujimaki, 1994). Bionolle has been shown to be biodegradable in a variety of environments, including activated sludges, soils and compost. Many strains were isolated that can degrade Bionolle (Nishioka et al., 1994).

A novel food use of succinic acid was also identified which is attractive for consumers who would like to reduce their salt consumption. A salt substitute comprised of succinic acid, chloride ion and lysine has been patented (Turk, 1993). The use of organic acids as environmentally friendly promotants of plant growth is an attractive use that bears further exploration. As an example, succinate addition can improve the growth of plants such as potato (Andrianova et al., 1998). Clearly, the growth of succinic acid use as an intermediate in a wide variety of both

specialty and commodity markets shows considerable promise for the future viability of a succinic acid bioprocess.

Research and Development

Although at this time, there is no commercial-scale succinic acid bioprocess, interest remains high, as shown by the activity in the patent and scientific literature. Three different organisms which all show promise have been the focus of the strain improvement research and process development.

Strain Improvement *Actinobacillus* 130Z was isolated from bovine rumen at the Michigan Biotechnology Institute. It was later identified as *Actinobacillus succinogenes* sp. nov., and it is a facultatively anaerobic Gram-negative rod. It is one of the most promising succinic acid producers studied to date, as it can use a variety of sugars and produce greater than 70 g of succinic acid/liter (Guettler et al., 1999). It was isolated in enrichment vials containing an ionophore and fumarate. An atmosphere enriched in carbon dioxide is necessary for rapid fermentative growth (Guettler et al., 1998). The enzyme activities of *Actinobacillus* 130Z and *E. coli* K-12 were compared under the same growth conditions. As described earlier, *Actinobacillus* had increased levels of the CO_2-fixing enzyme PEP-carboxykinase (which appears to be made constitutively) as well as high levels of L-malate dehydrogenase, fumarase, and fumarate reductase, which are all involved in the conversion of PEP to succinate. *Actinobacillus* also had high malic enzyme and oxalacetate decarboxylase activities in contrast to *E. coli* (Van der Werf et al., 1997).

Improvements to *Actinobacillus* were obtained by growing the organism on a source of fermentable carbon as well as sodium monofluoroacetate and by selecting for fluoroacetate-resistant mutants. These mutants give higher succinate production, reduced amounts of acetate and formate, and can produce more than 100 g of succinic acid/liter in 48 h with a yield as high as 97 wt. % on glucose. Presumably carbon flow has been diverted from acetate and formate into the production of succinate (Guettler et al., 1996b).

Anaerobiospirillum succiniciproducens is another high succinate producer that has been the focus of several patents and process development. One patent describes a method for making mutants of *A. succiniciproducens* similar to the method for deriving mutants of succinate-producing *Actinobacillus*. The technique involves the selection of fluoroacetate mutants of *A. succiniciproducens*. The mutant isolated produces less acetate, and in the fermentation, the succinate/acetate ratio is as high as 85 : 1. The lowering of acetate in the fermentation is important in that it is a problem contaminant in the electrodialysis separation process for purifying succinic acid from the fermentation. Reduced toxicity and inhibition of the fermentation by acetate are other advantages of this mutation. It appears that in the mutant, termed "FA-10," pyruvate production has increased while acetate production decreases and succinate levels stay about the same (Guettler and Jain, 1996a).

A metabolic engineering approach towards improvement of *Anaerobiospirillum succiniciproducens* was attempted by cloning and overproducing the PEP-carboxykinase gene. This gene, as described previously, catalyzes the addition of carbon dioxide to PEP to form oxalacetate and can work physiologically in both directions (Laivenieks et al., 1997). This is the first *A. succiniciproducens* gene to be cloned and sequenced. Codon usage is similar to *E. coli* except for a few amino acids, and the putative promoter region also shows many similarities. The gene was overexpressed successfully in *E. coli* so that further kinetic studies could be done. The authors did not look at the effects of overexpression in *A. succiniciproducens*, but now that work has commenced on identifying key genes in this organism, it is likely that future work will focus on improvements of the organism for succinic acid production.

As mentioned earlier, *E. coli* produces succinate but usually at very low levels. One strategy employed by various groups has been the overexpression in *E. coli* of various enzymes that direct carbon flow to succinate. As mentioned previously, uptake and utilization of carbon dioxide is necessary for high yields of substrate and attention has been focused on increasing the level of CO_2-fixing enzymes. Phosphoenolpyruvate carboxylase, which functions aerobically to produce oxalacetate and fermentatively to direct PEP to succinic acid, was overexpressed in *E. coli* and a significant increase in succinate production was seen. The authors cited an average increase from 3.27–4.44 g of succinic acid/liter formed (Millard et al., 1996). When PEP-carboxykinase, which catalyzes the phosphorylation and decarboxylation of oxalacetate to form PEP, was overexpressed in *E. coli*, the distribution of fermentation products remained the same and the amount of succinic acid did not increase. That the overexpression of PEP-carboxykinase did not improve succinate production in *E. coli* is rather surprising, as *A. succiniciproducens* uses a PEP-carboxykinase in its succinate production. The authors speculate that some as yet unknown regulatory control may prevent the *E. coli* PEP-carboxykinase from operating in the reverse direction (Millard et al., 1996).

As *E. coli* does not contain pyruvate carboxylase, a heterologous gene from Rhizobium etli was introduced into *E. coli*. A 50% increase in succinate levels and about a 20% decrease in lactate concentration were observed. Glucose uptake was not affected, and thus this approach may have advantages over increased PEP-carboxylase, which may have undesirable effects in reduction of glucose membrane transport and the phosphotransferase system (Gokarn et al., 1998). The *R. etli* pyruvate carboxylase requires acetyl CoA for activation and is inhibited by aspartate and may be expressed at low levels under typical conditions for succinate production. Use of an alternate pyruvate carboxylase that is not affected by either acetyl CoA or aspartate such as the *pyc* gene from *Pseudomonas fluorescens* was proposed (Gokarn et al., 1999).

Much of the focus on succinate production has been with the use of glucose as a substrate. However, fumaric acid has also been explored as a possible substrate. Fumarate reductase was overexpressed in *E. coli* strains that were fed fumaric acid. High cell density and the presence of glucose were required for increased succinate yield and rate of production. The recombinant strains with enhanced fumarate reductase levels had a succinate molar yield of 120% after four days. Without glucose present, however, mostly malate was produced (Goldberg et al., 1983). Multicopy fumarate reductase genes were also expressed in *E. coli* fed varying concentrations of glucose and fumaric acid. Fumaric acid at 90 g/liter inhibited succinate production, whereas succinic acid production was rapid in the range of 50–64 g/liter. Like the work mentioned in the above paragraph, the authors found that glucose addition in the presence of fumaric acid was necessary and as little as 5 g of glucose/liter could substantially increase the production. The authors speculated that glucose was used as the hydrogen donor for the conversion of fumaric to succinic acid (Wang et al., 1998b).

Another overexpression strategy was tried with the NAD^+-dependent malic enzyme of *E. coli*. Thermodynamically the reduction of pyruvate to malate is favored but in nature this reaction does not occur. A double mutant of *E. coli*, NZN111, which is blocked in both pyruvate:formate lyase (*pfl*) and lactate dehydrogenase (*ldh*), was used as the host. It is unable to grow anaerobically because its pyruvate metabolism is blocked by the fermentation end products acetate, formate, ethanol, and lactic acid. The mutant NZN111 with multiple copies of malic enzyme accumulated succinic acid as a major end product only if the cells were switched to anaerobic metabolism gradually by metabolic depletion of oxygen in a sealed tube (Clark et al., 1988). Mutant strains blocked in either *pfl* or *ldh* did not alter their distribution of fermentation products when overexpressing malic enzyme.

The importance of reducing power was shown for NZN111, as addition of hydrogen gas to the media increased the apparent yield of succinate from 0.65 g per g of glucose to 1.2 g per g of glucose. Although succinate production increased with expression of malic enzyme, NZN111 fermented glucose very slowly, making it less attractive for commercial production (Stols and Donnelly, 1997a). Overexpression of a heterologous malic enzyme from *Ascaris suum* yielded similar results (Stols et al., 1997b).

A novel succinate pathway in *E. coli* was discovered in the NZN111 mutant. Using site-directed mutagenesis, mutations were made in malate dehydrogenase, which catalyzes the interconversion of malate and oxalacetate. These mutant malate dehydrogenases had activity towards pyruvate instead of oxalacetate and provided a low lactate dehydrogenase-like activity. Fermentative growth appeared to be limited by the low lactate dehydrogenase-like activity, so directed evolution was used to select a variant enzyme with improved lactate dehydrogenase activity. After several rounds of subculturing, a mutant termed "AFP111" (named after the Alternate Feedstocks Program of the United States Department of Energy) was isolated based on accelerated glucose catabolism. From one mole of glucose, this mutant yields 1 mole of succinic acid, 0.5 moles of acetic acid and about 0.5 moles of ethanol. This is the first example of an *E. coli* strain that produces succinic acid as its major fermentation product. Donnelly et al. (1998a) proposed that glucose forms two PEPs, one of which is converted to succinate and the other to ethanol and acetate (Fig. 21).

The new strain AFP111 appears to be attractive for commercial use, owing to the lack of strict anaerobic culturing conditions needed, the use of low cost growth medium, and its ability to grow on xylose and other biomass-derived sugars. This strain was shown to produce up to 45 g of succinic acid/liter (Donnelly et al., 1998b).

A similar approach in a different laboratory towards constructing strains of *E. coli* was done by creating a double mutant with mutations in the phosphotransacetylase gene (*pta*) and the *ldh* gene. The *pta* gene catalyzes the conversion of acetyl CoA to acetyl phosphate and a mutation in this gene blocks the fermentative pathway to acetate. When grown under anaerobic conditions, this mutant produced about four times more succinate than the wild type produced as well as significant pyruvate levels. Lactate production was not detected and acetate production was considerably reduced, which may be of interest in light of downstream separation processes (Pan et al., 1999).

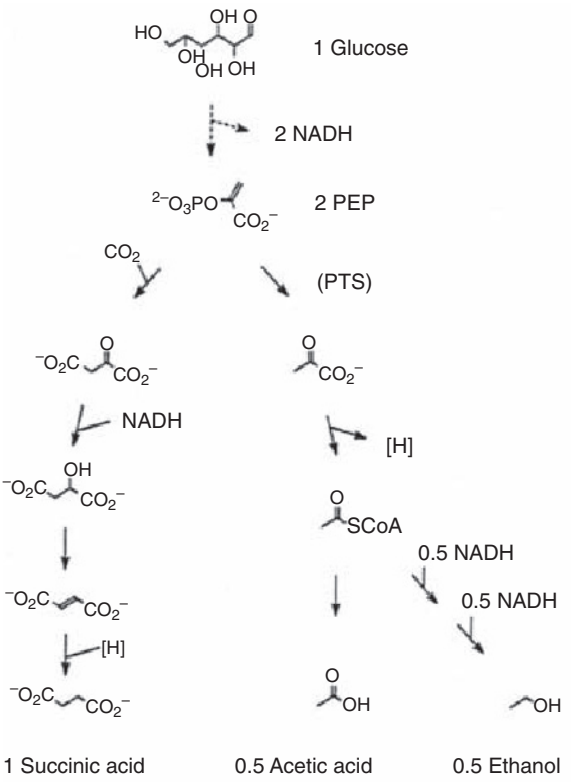

Fig. 21. Pathway for succinic acid production from glucose by *E. coli* strain AFP111. From Donnelly et al. (1998a), with permission.

Process Development There is at this writing no commercial-scale process for the production of succinic acid. There has been activity over the last several years, which is primarily found in the patent literature, to improve the fermentation as well as the downstream process. A great deal of effort was initially spent on *Anaerobiospirillum succiniciproducens*, as this was the first organism observed which could produce succinic acid in levels high enough to envision a commercial process.

Anaerobiospirillum succiniciproducens is a strict anaerobe and grows at an optimal temperature of 39°C. A typical fermentation medium contains dextrose, peptone, yeast extract and salts. The optimal pH range for this organism was determined to be between 5.8 and 6.4. This organism can produce approximately 30 g of succinate/liter from a starting glucose concentration of 50 g/liter. Calcium hydroxide is added to produce a calcium succinate product, which can be precipitated from the broth (Datta, 1992a).

Low cost commercial ingredients can be used as part of an *A. succiniciproducens* fermentation, using dextrose and corn steep solids from a corn wet milling plant. The pH adjustment can be done using high purity industrial grade lime. High initial concentrations of dextrose were inhibitory unless tryptophan was added at 25 ppm. A continuous multistage fermentation with simultaneous precipitation of calcium succinate was shown to be feasible, and a productivity of 2.0 g/liter·hr was observed. Another cost saving measure, the use of spent filtrate from a previous fermentation, was shown to increase fermentation productivity when added to a fermentation up to a level of 50% (Datta et al., 1992b).

The effect of medium components on the production of succinic acid by *A. succiniciproducens* was systematically studied. Sodium ion is essential for glucose transport and an optimal level of 4 g of NaCl/liter was determined. In contrast, magnesium ion did not appear to affect growth or succinic acid production. A variety of complex nitrogen sources were also assessed, and a mixture of polypeptone, yeast extract, soytone and peptone gave better results than any of these ingredients used alone (Lee et al., 1999b).

A large batch was run in an 80-liter fermenter. A high succinate yield of 87 wt. % of added substrate carbon was obtained in a fermentation time of 22.5 h (Datta et al., 1992b). Biotin was shown to be an important microingredient. At 50 mg of added biotin/liter, an increase in glucose consumption was seen and both succinic and acetic acid were increased by 17% and 30%, respectively. Biotin can be found in corn steep liquor, however, the heat treatment needed to sterilize corn steep liquor may inactivate the biotin (Nghiem et al., 1996).

One of the most important factors in the success of succinate fermentation by *A. succiniciproducens* is the addition of carbon dioxide in some form to the media. Using CO_2 supplied as solid magnesium carbonate at pH 6.2 (a molar ratio of CO_2-HCO_3^- to glucose of 1.0 to 0.5), 90% of the glucose was consumed and 65% of the carbon was converted to succinate. When the molar ratio of CO_2-HCO_3^- to glucose was lowered to 0.065, only 45–60% of the glucose was consumed and 8% of the carbon was converted into cell mass. The molar yield of ATP also drops significantly in the lower CO_2-HCO_3^- concentrations. At high CO_2-HCO_3^- levels, PEP-carboxykinase is present in high amounts (Samuelov et al., 1991).

Some uncertainty exists in how the CO_2 should be optimally supplied to the fermenter. Nghiem et al. (1997) found that supply of CO_2 via 1.5 M Na_2CO_3 was adequate and that sparging CO_2 gas into the fermenter at 0.025 liter/min lowered the rate and yield of succinate production, whereas acetate production was not affected. This is in contrast to the work of Datta (1992a), who found that the fermentation did not start as rapidly without a CO_2 sparge. In Datta's patent, increas-

ing the partial pressure of CO_2 produced better results, and at 100% CO_2, which is a partial pressure of 1 atmosphere, the fermentation was finished in 21 h, in contrast to a fermentation time of 42 h at 30% CO_2 (Datta, 1992a). Possibly CO_2 solubility is a factor in the different results, as at pH 6.5, CO_2 is three times more soluble than at pH 6.2 (Jones and Greenfield, 1982).

In comparison to glucose, succinic acid is a highly reduced fermentation product. The effect of supplying hydrogen gas with CO_2 was evaluated. The greatest effect appeared to be on the rate of succinate production. At an optimal H_2/CO_2 ratio of 5:95, the rate of succinate production is 1.8 g/liter · h. Varying glucose concentrations also were studied, as higher substrate concentration would help reduce fermentation costs. The optimal glucose concentration of 20–40 g/liter is in the range of previously observed values, and at the higher glucose concentration of 80 g/liter, rate and yield of succinate were lowered (Lee et al., 1999a).

Not as much work on the process development of an *Actinobacillus* 130Z fermentation has been described. This situation will likely change, as this organism shows very promising attributes for an industrial process. *Actinobacillus* 130Z is not a strict anaerobe and does not require the careful culture conditions as does *A. succiniciproducens*. *Actinobacillus* 130Z is tolerant to very high succinate concentrations and will initiate growth in up to 130 g of magnesium succinate/liter. In contrast, *A. succiniciproducens* will not initiate growth in media with 20 g of disodium succinate/liter. *Actinobacillus* 130Z prefers to obtain its nitrogen from organic sources, and succinate production is increased by eliminating ammonium sulfate. It is more tolerant than *A. succiniciproducens* to pH and can produce succinic acid at high amounts in the pH range of 6.2–7.2. Control of pH can be done with either sodium carbonate or sodium hydroxide. *Actinobacillus* 130Z also can use a wide variety of substrates, including arabinose, fructose, xylose, sucrose and glucose (Guettler et al., 1996c).

Actinobacillus 130Z requires the addition of carbon dioxide to the medium and about 0.3 atmosphere partial pressure is used. Because it is not sensitive to oxygen, pretreatment of the media to remove oxygen need not be done. It is able to use low-cost media ingredients such as corn steep liquor from a corn wet milling plant. Compared to *A. succiniciproducens*, it demonstrates unusually high tolerance to substrate concentrations and can produce succinic acid at glucose levels as high as 150 g/liter (Guettler et al., 1998). This ability to tolerate high glucose concentration is desirable in that less fermentation capital equipment needs to be employed, reducing the overall cost of the process.

Actinobacillus 130Z produces the highest reported amounts of succinic acid. In serum vials, it can produce nearly 80 g/liter and in a fermenter produced more than 60 g/liter in less than 36 h. With continued incubation, it was able to produce 75–79 g of succinate/liter (Guettler et al., 1998).

A novel approach towards supplying reducing power to *Actinobacillus succinogenes* was attempted using electrically reduced neutral red. An electrochemical bioreactor with anode and cathode compartments separated by a cation-selective membrane was constructed. The redox dye mediates electron transfer from the electrode into cellular metabolism. Electrically reduced neutral red enhanced the growth of *Actinobacillus* along with glucose consumption and succinate and ethanol production, whereas formate and acetate production was decreased. Neutral red is not toxic to the cells and can bind to the membrane, providing electrons to fumarate reductase. Neutral red appears to replace quinones in the fumarate reductase complex of *Actinobacillus* (Park and Zeikus, 1999). The approach of using electrical reducing power may have applications in other industrial fermentations besides succinic acid production.

The other succinate process that has been the focus of process development in the patent literature uses *E. coli* AFP111. A two-stage process in which the organism is grown aerobically to generate biomass and switched to anaerobic growth to turn on succinate production has been described. Hydrogen gas can be used as a reductant by the microorganism. The authors report that succinic acid concentration can reach 45 g/liter in a 100% carbon dioxide atmosphere and the weight yield of succinate to glucose can reach 99% (Nghiem et al., 1999).

The typical medium described for *E. coli* consists of tryptone, yeast extract, glucose and salts. A fed-batch fermentation can be run using a glucose and corn steep feed mixture and during the fermentation the glucose concentration is maintained at less than 1 g/liter. *Escherichia coli* could produce succinic acid in the pH range of 6.2–7.4, but the optimal pH appears to be close to 6.6. The microorganism produced high levels of succinic acid in a corn steep liquor medium, with a fermentation time of approximately 99 h (Nghiem et al., 1999).

There appears to be at present three candidates for the industrial production of succinic acid. Each has advantages and disadvantages for commercial production. A simple comparison of the three strains can be made based on yield and fermentation time and is shown in Table 21.

As yet, all examples in the literature have been laboratory or pilot scale, and it is unknown what

Table 21. Summary of high succinic acid producers.

Organism	Succinic acid titer (g/liter)	Fermentation time (h)
Actinobacillus succinogenes 130Z	~100	36–40
Anaerobiospirillum succiniciproducens	~35	36–40
Escherichia coli AFP111	~45	99

challenges will occur when these fermentations are scaled up to greater volumes.

The cost of recovery of succinic acid will be of prime importance in determining whether a cost-effective process will allow succinate-derived chemicals to compete with petrochemicals. Most succinate fermentations need to be run at or near a neutral pH and require the addition of a salt to maintain pH. Removal of the salt to achieve the isolation of the desired acid is one of the challenges of developing a low-cost separation process. Various approaches towards the recovery of organic acids have been tried, but it is beyond the scope of this chapter to review organic acid separation technology. Some work has focused specifically on succinic acid and that is what will be covered here.

As mentioned previously, succinic acid can be precipitated from fermentation broth with calcium hydroxide. A calcium succinate cake can be recovered from the fermentation broth. Acidification of this cake with sulfuric acid yields succinic acid and calcium sulfate solids (gypsum). After this stage, the succinic acid contains many impurities and can be further purified by ion exchange on a strongly acidic cation exchange resin that removes calcium and other cations. Use of a weakly basic anion exchange resin in the next step will remove sulfate and other anionic impurities (Datta et al., 1992b). One drawback of the calcium precipitation process is that it produces gypsum as a by-product.

Another approach to purify succinic acid is the use of electrodialysis technology. One patent describes an integrated process in which the fermentation broth goes through an electrodialysis membrane to concentrate the succinate salt, and then that feed subsequently goes through a water-splitting electrodialysis membrane to form a base and the succinic acid product. The base is recycled to the fermenters for pH control, and the succinic acid is further purified with ion-exchange chromatography to remove residual sodium ion, amino acids and sulfate ions. The other major fermentation product, acetate, is retained through this process with the succinic acid (Glassner and Datta, 1992).

Water-splitting electrodialysis can be improved by using a supersaturated solution of the free acid. Sodium acetate inhibits crystallization of succinic acid, but free acetic acid, which is produced by water-splitting electrodialysis, promotes crystallization of succinic acid (Berglund et al., 1991).

Another separation strategy uses the formation of diammonium succinate, where the ammonium ion is used to control the pH in the fermentation. The diammonium succinate can be concentrated and reacted with a sulfate ion at low pH to yield ammonium sulfate and succinic acid. Succinic acid has very low solubility in aqueous solutions with a pH below 2 and can be crystallized. The succinic acid can be purified with methanol and the ammonium sulfate is thermally cracked into ammonia and ammonium bisulfate. The ammonia can be fed back into the fermenter and the ammonium bisulfate can be recycled for use in succinic acid crystallization (Berglund et al., 1999).

It is likely that process development for succinic acid will continue to be explored. Desirable features of an economic process would include a high yielding fermentation that can tolerate process conditions, low-cost substrate, and an integrated separation process that can recover and purify succinic acid at low cost.

Patents and Regulatory Issues

There are a number of patents on the microorganisms, fermentation process, and downstream separation of succinic acid. In addition, there are patents that cover the further conversion of succinate to other products and many patents on the competitive chemical processes that make large volume chemicals such as 1,4-butanediol. A useful summary of the downstream chemical conversion patents appears in Varadarajan and Miller (1999). While patents have been referenced throughout this section on succinic acid, it is of interest to summarize succinic acid fermentation, strain development, and downstream separation patents here.

Prospects for Succinic Acid Production

At this writing, there is no commercial large-scale process for succinic acid production by fermentation. To make large-scale commodity chemicals derived from succinic acid, the price of the acid needs to be in the range of less than 50

Table 22. Patents for succinic acid production.

cents per pound. This is due to the competition with petrochemically derived raw materials that are also sold in this price range or at an even lower price.

The specialty markets for succinic acid such as surfactants, food uses, and health-related ingredients may benefit from having a "natural" succinic acid produced by fermentation. As the prices of these materials are much higher than commodity chemicals, a fermentation-based process may be able to make product at a cost competitive for these markets (Tsao et al., 1999).

What are some of the technology developments needed to make the production of succinic acid by fermentation an attractive economic option? The theoretical yield of succinic acid is greater than one kilogram of succinic acid per kilogram of glucose. To achieve this theoretical yield, efficient delivery of CO_2 for fixation by the organism is necessary. Also, strains that can use H_2 to supply reducing equivalents may yield economic improvements in the fermentation process.

Strain development is well underway with organisms that can produce as much as 100 g of succinic acid/liter. Certain strains appear to be robust enough to flourish under conditions of high substrate, high final product concentrations, and they do not require special handling, such as total removal of oxygen. Some organisms also can grow on a wide variety of carbon sources and sugars. This opens up the opportunity to use low-cost cellulosic-based materials such as agricultural waste products as a very cheap source of starting raw materials.

The costs of separation of succinic acid will be a critical component in economical production of this acid. As acids are neutralized in the fermentation to maintain an appropriate pH for the microorganism, the salts formed must eventually be removed and can be a waste generation problem. Promising separation technology is the use of liquid-liquid extraction and water-splitting electrodialysis. Key also to lowering separation costs is the development of microorganisms that produce as few by-products as possible which need to be removed from the final product stream.

The other key issue for production of large volume chemicals is the technology needed to further convert succinic acid to other products such as 1,4-butanediol. This process technology must be very competitive with other processes that start with low-cost petrochemical feedstocks. One potential avenue to reducing costs may be the use of crude fermentation broth that is chemically converted and then purified in some further downstream process.

The use of fermentation-derived succinic acid is one of the most promising bio-based processes for large-scale commodity chemical production and may be competitive to petrochemical processes at some future date. The development of this process at a large scale can open up new markets for agriculturally derived raw materials and be a "green" chemical based on renewable resources.

Section 5: Polyhydroxyalkanoic Acids

Introduction

Polyhydroxyalkanoic acids (PHAs) are polyester storage material synthesized by a wide range of microorganisms when their growth in medium containing excess carbon and energy sources is restricted by the lack of an essential nutrient. The PHAs also are formed as reduced end products in some organisms when there is a deficiency in O_2 as the terminal electron acceptor for the cell to achieve a redox balance in metabolism. Some PHAs have physical properties comparable to thermoplastics produced from petrochemicals. The best known PHAs are the homopolymer polyhydroxybutyrate and the copolymer poly (3-hydroxybutyrate-co-3-hydroxyvalerate) or BIOPOL, which was produced by the bacterium *Ralstonia eutropha* (formerly *Alcaligenes eutrophus*) and saw applications in a range of consumer products (Steinbüchel, 1996). The process for BIOPOL production was developed by Zeneca BioProducts (formerly ICI of the United Kingdom) and later sold to Monsanto of the United States (Lee, 1996b; Steinbüchel, 1996). The commercial production of BIOPOL ended in 1998 because of high production cost. However, active research is under way worldwide to improve the physicochemical properties of PHAs as well as the economics of producing better PHAs. Also, novel applications for PHAs have been proposed for the future when PHAs with new properties are synthesized and the commercial importance of their chiral monomers is recognized.

One salient property of PHAs is their biodegradability. Until the introduction of man-made plastics, manufactured goods using materials derived from plants and animals were biodegradable and completely recyclable in the environment. Although plastics have dramatically improved human life, the durability of discarded plastic wares in the environment has created a serious waste-management problem. Use of the biodegradable PHAs as a substitute for the petroleum-based plastics can help preserve the quality of life as well as the natural environment, if PHAs can be produced economically.

Despite their undesirable durability after disposal, plastics are hard to replace because of their low cost and versatility. Plastic wares are inexpensive mainly because they can be mass-produced from historically inexpensive raw materials. The thermoplastics have allowed the use of machines and procedures to mass-produce a very wide range of consumer products. It is thus obvious that if a low-cost, environmentally degradable thermoplastic is available, the new material will allow the continued production of inexpensive but nonpolluting plastic wares for the future generations. This need is the driving force for active research on PHAs.

During the past decade, books (Doi, 1990a; Doi and Fukuda, 1994; Mobley, 1994), a special issue of FEMS Microbiology Reviews (volume 103, pp. 91–364, 1992), and many reviews (Anderson and Dawes, 1990; Aminabhavi et al., 1990; Steinbüchel, 1991; Steinbüchel, 1996; Poirier et al., 1995; Lee, 1996a; Lee, 1996b; Lee, 1997; Ishizaki et al., 1997; Steinbüchel and Füchtenbusch, 1998; Madison and Huisman, 1999) were devoted to PHAs. The following publications may be consulted for a more in-depth coverage of the microbiology of PHA-producing organisms (Steinbüchel, 1991), the biosynthesis and degradation of PHAs (Anderson and Dawes, 1990; Steinbüchel, 1991; Steinbüchel, 1996; Hocking and Marchessault, 1994; Madison and Huisman, 1999), genes for PHA formation (Madison and Huisman, 1999), the physicochemical properties of PHAs (Hocking and Marchessault, 1994; Steinbüchel, 1996), analytical methods for PHAs (Anderson and Dawes, 1990; Hocking and Marchessault, 1994; Steinbüchel, 1996), commercial production and economic considerations (Doi, 1990a; Byrom, 1992; Hrabak, 1992; Hocking and Marchessault, 1994; Lee and Chang, 1995a; Poirier et al., 1995; Lee, 1996a; Lee, 1996b; Steinbüchel, 1996), metabolic engineering of bacteria and plants for PHA production (Madison and Huisman, 1999; Poirier et al., 1995), and patents for PHA production and application (Steinbüchel, 1996).

Scientific Background

History Among the naturally occurring PHAs, the best known is the polyhydroxybutyric acid, which is commonly abbreviated as "poly(3HB)" or "PHB." The discovery of poly(3HB) in bacteria is attributed to Maurice Lemoigne of the Pasteur Institute, who in 1925 reported the presence of 3-hydroxybutyric acid in the autolysate of *Bacillus megaterium* (Lemoigne, 1925) and in 1926 reported the isolation from *B. megaterium* of a polyester with the empirical formula of $(C_4H_6O_2)n$ and identified the material as poly-3-hydroxybutyrate (Lemoigne, 1926). In a note published in 1943, Lemoigne indicated that the occurrence of a PHB-like material in *Azotobacter* was reported by M. W. Beijerinck as early as in 1901, but it had been overlooked until it was reported by Stapp in 1918 (Lemoigne, 1943).

Schlegel et al. (1961) presented a landmark study on the formation and utilization of poly (3HB) by three strains of hydrogen-oxidizing or knallgas bacteria belonging to the genus "*Hydrogenomonas*," which has since been

renamed as "*Alcaligenes eutrophus*" and as "*Ralstonia eutropha*" (Yabuuchi et al., 1995). Electron micrographs of thin sections of *Hydrogenomonas* H16 showed that the inclusions of poly(3HB) could accumulate to occupy the bulk of the intracellular space, and the amount of poly(3HB) reached 65% of the dry weight of these cells. Poly(3HB) purified from *Azotobacter chroococcum*, *Bacillus megaterium* and *Hydrogenomonas* (strains H1, H16 and H20) by these workers had the expected chemical composition and identical infrared spectra. The melting points ranged from 150–155°C (*A. chroococcum*) to 168–173°C (*B. megaterium*), and the variation was attributed to different degrees of polymerization, an explanation that was validated by later studies. The earlier workers found that poly(3HB) is soluble in chloroform but not in ethyl ether, which provides an effective method for the purification of poly(3HB) from lyophilized cells.

Chemical Structure PHAs are hydrophobic linear polyesters with the general structure of

$$-[-O-CHR-(CH_2)-CO-]_{100-30,000}$$

For biosynthetic PHAs, n can vary from 1 (poly-3-hydroxyalkanoate) to 4 (poly-6-hydroxyalkanoate). The hydroxyl-substituted carbon atom (the chiral center) of the acid monomer and the corresponding carbon atom in the PHAs are in the *R* configuration. Over 120 different acid monomers have been found as constituents of PHAs (Anonymous, 1999). Furthermore, the PHAs may be homo- or heteropolymers. The *R* groups or side chains of the acid monomers may be aliphatic or aromatic, saturated or unsaturated, linear or branched, and halogenated or epoxidized. These side chains also can be modified chemically (Madison and Huisman, 1999). A simpler side chain can range from a hydrogen atom to an aliphatic chain of up to 13 carbon atoms, i.e., these PHAs are the condensation product of monomers ranging from 3-hydroxypropionic acid to 3-hydroxyhexadecanoic acid (Steinbüchel, 1996; Madison and Huisman, 1999). Because of the diversity of the side-chains in the PHAs, the physicochemical properties of PHAs vary significantly to allow a broad range of possible applications.

Physicochemical Properties For practical purposes, the most important properties of PHAs are the thermoplasticity and elasticity. The PHAs are thermoplastic materials, meaning that they are resins that become highly viscous and moldable at temperatures close to or above the melting point. The properties of poly(3HB) are often compared to those of polypropylene (Hocking and Marchessault, 1994), as both polymers have similar melting points, degrees of crystallinity, and glass-transition temperatures. However, poly(3HB) is both stiffer and more brittle than polypropylene, resulting from the presence of large crystals in poly(3HB). Poly(3HB) has a lower solvent resistance but a much higher resistance to ultraviolet weathering than polypropylene. The solubility of poly(3HB) in a wide range of solvents has been determined (Steinbüchel, 1996). The crystal structure of PHAs has been discussed in some detail by Hocking and Marchessault (1994).

The material properties of poly(3HB) are greatly improved by the incorporation of 3-hydroxyvaleric acid to form the poly(3-hydroxybutyrate-co-3-hydroxyvalerate) or poly(3HB-co-3HV) copolymer (Hocking and Marchessault, 1994). By manipulating the ratio of the two monomers in the copolymer, a range of physical properties may be obtained. Because organisms other than *R. eutropha* have PHA polymerases that can incorporate a variety of 3-hydroxyalkanoic acids into the copolymer, application of genetic engineering should allow the production of PHAs with superior physical properties as well as biodegradability.

Poly(3HB) and poly(3HB-co-3HV) are piezoelectric materials, whereas the piezoelectric properties of other PHAs have not been investigated (Steinbüchel, 1996). The piezoelectric materials produce electric charges on parts of their surface when mechanical pressure is applied to the crystalline material, and an electric current will result from the charges if the crystal is short-circuited. Conversely, application of a voltage between certain faces of the material produces a mechanical distortion (a deformation) of the material. Piezoelectric materials have important applications in electromechanical transducers, such as microphones. In medicine, chemically synthesized piezoelectric polymers such as polyvinylidone fluoride stimulated bone growth. The piezoelectric property of poly(3HB) may be important for some medical applications (Steinbüchel, 1996).

PHA-Producing Organisms Most genera of bacteria and members of the halophilic Halobacteriaceae of the Archaea synthesize PHAs. A comprehensive listing of PHA-producing organisms can be found in Steinbüchel (1991), which illustrates the wide distribution of the capacity to synthesize PHAs among microbes and also suggests the physiological importance of PHAs to the producing-organisms. Table 23, adapted from Lee (1996b) and Steinbüchel and Füchtenbusch (1998) and also with newer findings, lists the salient features of representative natural and recombinant strains of PHA-producing bacteria. It should be noted that the name of the PHA-

Table 23. Production of polyhydroxyalkanoic acid by natural and recombinant strains of bacteria.

Bacterium	PHA	Carbon source	Cell density (g/liter)	PHA content (%)	References
Alcaligenes latus	Poly(3HB)	Sucrose	112	88	Wang and Lee, 1997
Azotobacter vinelandii	Poly(3HB)	Glucose	40.1	79.8	Page and Cornish, 1993
Chromobacterium violaceum	Poly(3HV)	Valeric acid	41	65–70	Steinbüchel and Schmack, 1995
Escherichia coli, recombinant	Poly(3HB)	Glucose	117	76	Kim et al., 1992b

Ralstonia eutropha	Poly(3HB)	Glucose	164	74	Kim et al., 1994
Ralstonia eutropha	Poly(3HB)	Carbon dioxide	91.3	67.8	Tanaka et al., 1995
Ralstonia eutropha	Poly(3HB-co-3HV)	Glucose + propionic acid	>100	70–80	Byrom, 1992

Abbreviations: PHA, polyhydroxyalkanoic acid; 3HB, 3-hydroxybutyric acid; 3HD, 3-hydroxydecanoic acid; 3HDD, 3-hydroxydodecanoic acid; 3HTD, 3-hydroxytetradecanoic acid; 3HHx, 3-hydroxyhexanoic acid; 3HV, 3-hydroxyvaleric acid; 3HO, 3-hydroxyoctanoic acid; and 4HV, 4-hydroxyvaleric acid.

producing organisms can be a potential source of confusion because bacterial taxonomy is a work in progress. Both the name and the taxonomic position of an organism are subject to change. For example, the name of the best-known PHA-producing organism has been changed from *Hydrogenomonas* H16 to *Alcaligenes eutrophus* to *Ralstonia eutropha*. A literature search based on any one of these names will miss a large amount of pertinent information.

Besides heterotrophic bacteria and archaea, the phototrophic bacteria, including phototrophic purple bacteria and cyanobacteria, are also PHA producers. A study of 15 strains of nonsulfur purple bacteria and 15 strains of sulfur purple bacteria showed that all of them produced poly(3HB) when the growth medium was supplemented with acetate (Liebergesell et al., 1991). When supplemented with propionate, valerate, heptanoate or octanoate, most of the strains produced poly(3HB), and the nonsulfur purple bacteria produced poly(3HB-co-3HV) copolymers even with acetate as the carbon source. The production of PHA by cyanobacteria was first reported by Carr (1966), and the list of PHA-producing cyanobacteria includes species of *Anabaena*, *Aphanothece*, *Chloroglea*, *Gloeocapsa*, *Oscillatoria*, *Spirulina*, *Synechococcus* and *Synechocystis* (Hein et al., 1998; Taroncher-Oldenburg et al., 2000). Production of PHAs by cyanobacteria for commercial purposes has attracted attention lately because the phototrophic organisms use CO_2 instead of the more expensive organic compounds as the carbon source.

Besides the PHA-producing organisms available in pure cultures, various environmental samples, such as the sludge from sewage digesters, contain characteristic PHAs that have not been observed in pure cultures (Steinbüchel, 1996). The biosynthetic capabilities of these not yet characterized PHA-producing organisms may greatly expand the possibility of producing novel chiral monomers for the chemical and

pharmaceutical industries (see "Production of Chiral Monomers" in this Chapter).

Physiological Functions of PHAs The bulk of PHAs is synthesized as a storage material for carbon and energy or as the result of the cell's need to use an alternative route to dispose of excess reducing power under O_2 deficiency. These PHAs occur as granules or inclusion bodies in the cell and contain non-PHA substances for the assembly of such structures (Steinbüchel, 1996). In addition, PHAs also are produced by other organisms, including *Escherichia coli*, but to a much lower level and in complexes with calcium and polyphosphates. It has been proposed that complexes of poly(3HB), calcium ions, and polyphosphates form a helical tubular structure which is located in the cytoplasmic membrane of *E. coli* (Reusch and Sadoff, 1988). Because transformation efficiency correlated with the concentration of poly(3HB) in the membrane, it was speculated that the tubular structure in the membrane might play a role in conferring a cell's competency in taking up extracellular DNA (Reusch, 1992a). However, this model has been challenged (Müller and Seebach, 1993).

Unbound or complexes of PHAs also occur in eukaryotic organisms, including baker's yeast and tissues of various plants and animals, but the concentrations were one or two orders of magnitude lower than those in competent cells of *E. coli* (Reusch, 1992a; Reusch and Sparrow, 1992b). The function of PHA in eukaryotes is not known (Steinbüchel, 1996).

Biosynthesis The biosynthesis of PHAs involves three key reactions:

1) the condensation of two acyl-CoA molecules to form a 3-ketoacyl-CoA, with the release of a CoA,

2) the reduction of 3-ketoacyl-CoA to the chiral (*R*)-(−)-hydroxyacyl-CoA monomer, and

3) the polymerization of the monomers to PHA. Two non-chiral compounds, acetyl-CoA and its condensation product acetoacetyl-CoA, are the most common metabolic intermediates serving as the precursors for the synthesis of poly(3HB) or other PHAs. Stereospecific reductases and hydratases convert acetoacetyl-CoA into chiral (*R*)-(−)-3-hydroxybutyric acid, which is polymerized into poly(3HB). From different starting substrates, different pathways are used for the synthesis of acetyl-CoA, and different organisms may use distinct pathways to form (*R*)-(−)-3-hydroxybutyric acid (Steinbüchel, 1996). Besides acetyl-CoA, longer-chain acyl-CoAs are synthesized via specialized reactions when appropriate substrates are available. The actual composition of the PHA formed thus depends on the types of monomers that are present in the cell, which in turn depends on the carbon substrates that are provided in the growth medium. This flexibility allows one to direct an organism to synthesize PHA copolymers with tailored monomer compositions that confer desirable properties.

Among the different pathways for PHA biosynthesis, the pathways for the formation of poly(3HB) are the best characterized. In *R. eutropha*, the synthesis of poly(3HB) from acetyl-CoA requires only the three reactions described above, whereas in *Rhodospirillum rubrum*, two additional reactions are required to convert (*S*)-(+)-3-hydroxybutyryl-CoA to (*R*)-(−)-3-hydroxybutyryl-CoA to be used by the poly(3HB) polymerase (Steinbüchel, 1996). Formation of the copolymer poly(3-hydroxybutyrate-co-3-hydroxyvalerate) or poly(3HB-co-3HV) in *R. eutropha* requires the condensation of acetyl-CoA and propionyl-CoA to form 3-ketovaleryl-CoA; a 3-ketothiolase different from that catalyzing the formation of acetoacetyl-CoA is required for this reaction (Slater et al., 1998). In Pseudomonas oleovorans and *Pseudomonas aeruginosa*, which synthesize PHAs from medium-chain-length monomers (more than five carbon atoms), a multitude of reactions are involved in converting acetyl-CoA to (*R*)-(−)-3-hydroxyacyl-CoA or (*R*)-(−)-3-hydroxyacyl-ACP (acyl carrier protein) to serve as the substrate for the PHA polymerase (Steinbüchel, 1996).

The enzymes and their structural genes for the three key reactions for the synthesis of PHAs of short-chain-length monomers (three to five carbon atoms) have been extensively studied, and their salient features are summarized below.

3- OR β-KETOTHIOLASE. The thiolase for PHA synthesis is known as the biosynthetic thiolase because its physiological function is in the direction of combining two acyl-CoA molecules into a 3-ketoacyl-CoA molecule, instead of the thiolytic reaction occurring in β-oxidation of saturated fatty acids. Ralstonia eutropha has three or more biosynthetic 3-ketothiolases (enzyme A, enzyme B, and BktC) that differ in their substrate specificity and hence their role in PHA production (Haywood et al., 1988; Slater et al., 1998). The activity of enzyme A (encoded by the *phbA* gene) with 3-ketovaleryl-CoA (3-ketopentanoyl-CoA) is 3% of that with acetoacetyl-CoA and is hence responsible for the formation of poly(3HB). The activities of enzyme B (encoded by the bktB gene) with 3-ketoacyl-CoAs having 5 to 10 carbon atoms are 10–30% of that with acetoacetyl-CoA (Haywood et al., 1988). Enzyme B or BktB is responsible for the formation of the 3HV monomer for the production of

the copolymer poly(3HB-co-3HV) (Slater et al., 1998). Slater et al. (1998) reported the presence of another 3-ketothiolase (BktC) that may serve as a secondary route toward 3HV production. The BktC enzyme was detected in both the wild type and a double mutant for enzymes A and B.

The structural genes for 3-ketothiolase have been cloned and sequenced from over a dozen of PHA-producing bacteria, and they have been designated as either "*pha*" (for PHA metabolism) or "phb" (for poly[3HB] or PHB metabolism) genes (Madison and Huisman, 1999). The *phbA* gene encodes the 3-ketothiolase (enzyme A) for the synthesis of acetoacetyl-CoA, and the gene was first cloned from *Zoogloea ramigera* (Peoples et al., 1987) and then from *R. eutropha* (Peoples and Sinskey, 1989) and a number of other organisms. In *R. eutropha*, the *bktB* gene encodes the second 3-ketothiolase, also known as "enzyme B" or "BktB" (Slater et al., 1998). The *pha* genes are for the synthesis of medium-chain-length PHAs (PHAs composed of 3-hydroxy fatty acids with 6-16 carbon atoms), and at present there are fewer characterized *pha* than *phb* genes. Although the *pha* and *phb* genes were initially found to form operons, it now appears that these genes are not necessarily clustered and that the gene organization may vary from one species to another as these organisms have diverse PHA biosynthetic pathways (Madison and Huisman, 1999).

3- OR β-KETOACYL-COA REDUCTASE. The 3-ketoacyl-CoA reductase catalyzes a crucial reaction for the synthesis of PHA; it introduces the correct chirality into 3-hydroxyacyl-CoA to provide the substrate for PHA polymerase, and by consuming 3-ketoacyl-CoA, the reductase and PHA polymerase together make the 3-ketothiolase-catalyzed condensation reaction energetically favorable. Also, NADPH is the predominant coenzyme and reductant for the characterized 3-ketoacyl-CoA reductase. The availability of reducing power in the form of NADPH is thus considered the driving force for PHA formation (Madison and Huisman, 1999).

In *R. eutropha*, acetoacetyl-CoA reductase is encoded by the *phbB* gene (Peoples et al., 1987). The phb biosynthesis operon in *R. eutropha* consists of the *phbC* (encoding PHA polymerase), *phbA* (encoding 3-ketothiolase), and *phbB* genes in that order. The three enzymes encoded by the *R. eutropha phb* operon are sufficient for the synthesis of PHAs consisting of short-chain-length monomers (3-hydroxyacyl-CoAs with 3–5 carbon atoms).

PHA POLYMERASE OR SYNTHASE. The key enzyme for PHA biosynthesis is the PHA polymerase, also known as the "PHA synthase," which catalyzes the polymerization of the (*R*)-(−)-hydroxyacyl-CoA monomers to PHAs. To date, the structural genes for PHA polymerase have been cloned from about 30 bacteria. Based on the subunit composition and the substrate range, the PHA polymerases can be divided into three classes: the Class I represented by the enzyme of *R. eutropha*, the Class II represented by the enzyme of *Pseudomonas oleovorans*, and the Class III represented by the enzyme of *Chromatium vinosum*. The Class III PHA polymerases are two-component enzymes, encoded by the genes *phaC* and *phaE*, whereas the other PHA polymerases contain one polypeptide encoded by the *phaC* gene. A comparison of the PHA polymerases may be found in Hein et al. (1998) and Madison and Huisman (1999). The Class III PHA polymerases may be further divided into two classes, with the Class IV represented by the enzyme from *Thiocapsa pfennigii*, which has a broader substrate range (including CoA thioesters of medium-chain-length hydroxyalkanoic acids) than that of *C. vinosum* (Steinbüchel, 1996).

The genes for the two-component PHA polymerase of the cyanobacteria *Synechocystis* sp. strain PCC6803 were cloned and characterized (Hein et al., 1998). Because the genome of this organism has been sequenced, it also has allowed the identification of the genes for the PHA-specific 3-ketothiolase and acetoacetyl-CoA reductase in this cyanobacterium (Taroncher-Oldenburg et al., 2000). Transformation of *E. coli* or a PHA-negative mutant of *R. eutropha* with the PHA biosynthesis genes of *Synechocystis* sp. strain PCC6803 conferred the PHA-synthesizing ability to *E. coli* or *R. eutropha* and also allowed the positive identification of genes and enzymes for the complete PHA biosynthesis pathway of cyanobacteria.

In addition to the genes encoding the enzymes for the three key reactions of PHA synthesis, other identified *pha* genes play roles in the assembly of the PHA granules or in the conversion of metabolic intermediates leading to PHA synthesis. The *phaF* and *phaI* genes of *Pseudomonas oleovorans* encode major PHA granule-binding proteins (Prieto et al., 1999a). The *phaD* gene of *P. oleovorans* encodes a protein that is not a major granule-associated protein; however, the PhaD protein seems to be required for the presence of the PhaI protein (Klinke et al., 2000). Inactivation of the *phaD* gene caused the disappearance of the PhaI protein, a decrease in the PHA granule size, and an increase in the number of granules in the cell. The *phaG* gene encodes the 3-hydroxydecanoyl-ACP (acyl-carrier protein):CoA transacylase in *Pseudomonas putida*, which provides a metabolic link between the de novo biosynthesis of fatty acids and the biosynthesis of PHA consisting of C_6 to C_{14} monomers (Rehm et al., 1998).

Transfer of the *P. putida phaG* gene and the *P. aeruginosa phaC1* gene (encoding PHA polymerase) into *Pseudomonas fragi* (a PHA nonproducer) enables the transformant to synthesize PHAs containing primarily C_{10} monomers derived from gluconate, an unrelated carbon source (Fiedler et al., 2000).

Degradation Degradation of PHA is important for two practical reasons: it affects the yield and quality of PHA during commercial production, and it affects the disposal of consumer goods manufactured from PHA. Degradation of PHA can occur as a nonbiological process or as the result of extracellular and intracellular activities of PHA-degrading enzymes. This topic has been reviewed by Dawes and Senior (1973), Anderson and Dawes (1990), Hocking and Marchessault (1994), Steinbüchel (1996), and Jendrossek et al. (1996).

Nonbiological degradation of PHA is the result of spontaneous hydrolysis or thermal decomposition. Spontaneous hydrolysis occurs at a slow rate but is enhanced by acidic and alkaline conditions. There is an apparent initial increase in crystallinity, when the extent of hydrolysis increases, which is followed by a decrease in crystallinity and an elevated rate of hydrolysis. Thermal decomposition of many PHAs occurs at temperatures not far above the melting point, which necessitates the use of additives in the PHAs to minimize structural damages during the molding processes. If the molded articles will be subjected to prolonged heat exposure, cautionary measures are also necessary. The mechanisms of hydrolytic and thermal degradation have been reviewed by Hocking and Marchessault (1994).

Biodegradation in the environment normally proceeds via surface attack by bacteria, fungi and algae. Because the degradation process initiates on the surface, the rate of biodegradation depends in part on the ease of surface colonization. Therefore, the surface area and texture as well as the thickness of the article are important factors in affecting the rate of degradation. The supply of nutrients such as nitrogen and phosphorus as well as oxygen is the other environmental factor that controls microbial growth and hence the rate of biodegradation. Among the different environments, the anaerobe sewage allows the fastest rate of degradation, which is followed by well-watered soil, seawater sediments, aerobic sewage, the rumen of cattle, and seawater. A 1-mm thick molding resin test bar breaks down completely within 6 weeks in anaerobic sewage; this time increases to 60–70 weeks in aerobic sewage and soil at 25°C and to 350 weeks in seawater at 15°C. Packaging films 50 μm in thickness totally degrade in 1–2 weeks in anaerobic sewage, 7 weeks in aerobic sewage, 10 weeks in soil at 25°C and 15 weeks in seawater at 15°C. A molded shampoo bottle made of poly(3HB-co-3HV) is almost completely degraded after 15 weeks in a compost pile; significant degradation in a landfill occurs over 40 weeks. These results clearly indicate that the disposal of PHA-based consumer products must be properly managed or the time required for biodegradation may take years in some environments. The original studies yielding these results are referenced in the review by Hocking and Marchessault (1994).

Biodegradation in the environment involves extracellular enzymes secreted by microorganisms, and these enzymes have been collectively described as PHA depolymerases. Of the characterized depolymerases, most of them hydrolyze the PHA polymer into dimers, and the dimers are further hydrolyzed to the monomers by an extracellular or intracellular dimer hydrolase. The depolymerase from a *Comamonas* species, however, appears to hydrolyze poly(3HB) directly to 3-hydroxybutyrate (reviewed by Hocking and Marchessault, 1994). Not surprisingly, the degree of crystallinity significantly affects the rate of PHA degradation, and it was concluded that poly(3HB) molecules in the amorphous state are more easily hydrolyzed than poly(3HB) in the crystalline state (reviewed by Steinbüchel, 1996).

Extracellular PHA or oligomer depolymerases have been isolated from *Alcaligenes faecalis*, as reviewed by Anderson and Dawes (1990); *Pseudomonas lemoignei* (reviewed by Steinbüchel, 1996); and other organisms (reviewed by Steinbüchel, 1996). From each organism, the distinct depolymerases exhibit different substrate specificity and kinetic properties, and depending on the depolymerase, the dimeric product may be released from either the free hydroxy terminus or the carboxyl terminus of PHA or oligomers derived from the polymer. Structural genes for these depolymerases have been cloned and characterized. The deduced amino acid sequences of the depolymerases all contain the motif Gly-Leu-Ser-Xaa-Gly at the N-terminus, which corresponds to the Alipase box found in lipases and esterases (Jendrossek et al., 1995), and they also share a triad consisting of serine (from the Alipase box) plus histidine and aspartate, which corresponds to the active-site triad of bacterial lipases.

Intracellular degradation of PHAs in the PHA-producing organisms is a physiological process, and this activity can potentially influence the quality and yield of PHAs to be isolated for commercial applications. Research on this aspect of PHA metabolism has been reviewed by Anderson and Dawes (1990), Hocking and

Marchessault (1994), and Steinbüchel (1996), but less is understood about this process than extracellular biodegradation. In *R. eutropha*, biosynthesis and degradation of poly(3HB) have been reported to occur simultaneously, even when poly(3HB) is being accumulated, hence causing a constant turnover of poly(3HB) within the inclusion bodies (Doi et al., 1990b). It was also reported that high molecular weight poly(3HB) was produced in the first stage of accumulation (up to 10 h), and the molecular weight slowly decreased during the remaining period of accumulation (Kawaguchi and Doi, 1992).

Degradation of the native granules of poly(3HB) seems to involve different enzymes and accessory proteins in different organisms. In *R. rubrum* and *Azotobacter beijerinckii*, the native granules are self-hydrolyzing, whereas degradation of native granules isolated from *Bacillus megaterium* required a heat-labile factor associated with the granules together with three soluble components—a heat-stable protein activator, a heat-labile depolymerase and a hydrolase—prepared from the extracts of *R. rubrum* (reviewed by Anderson and Dawes, 1990; Hocking and Marchessault, 1994). Purified poly(3HB) or denatured granules did not serve as substrates. In *R. eutropha*, 3HB monomers are the direct product of depolymerase action, whereas in other organisms, the depolymerases degrade poly(3HB) to dimers and a dimer hydrolase completes the degradation to monomers. The 3HB monomers may be metabolized to acetyl-CoA through reactions formally resembling the reversal of the biosynthetic reactions.

Metabolic Engineering Metabolic engineering of PHAs was reviewed by Madison and Huisman (1999), and literature in this area is expanding at a fast rate because the use of molecular biology tools has been successful in improving the properties of organisms ranging from bacteria to higher plants for PHA production. The need to have better organisms for the production of PHAs became obvious after the commercial introduction of BIOPOL, which was produced by mutant strains of glucose-grown *R. eutropha* converting glucose and propionate into poly(3HB-co-3HV). *Ralstonia eutropha* can accumulate PHA to a high level in the cell; however, the bacterium has a relatively low optimal growth temperature and long generation time, the substrates are expensive, the cell is relatively hard to lyse, and it has enzymes for PHA degradation. Also, the genetics of *R. eutropha* were not well understood, which hindered genetic manipulations of this natural producer. Nevertheless, the *lac* and *gal* operons of *E. coli* were successfully transferred into *R. eutropha* and expressed, hence enabling *R. eutropha* to use lactose (the major carbohydrate in whey) as a less expensive carbon source (Pries et al., 1990). When the PHA-biosynthesis genes of *R. eutropha* were cloned and expressed in *E. coli*, it effectively started metabolic engineering of *E. coli* for PHA production (Schubert et al., 1988). Compared with *R. eutropha*, the recombinant *E. coli* strains have the desired properties of having a faster growth rate, ease of cell lysis when the cell is loaded with PHA, tolerance to propionic acid, and the feasibility to perform a variety of genetic manipulations.

Initially, the effect of added copies of PHA biosynthesis genes on PHA production was examined in several natural and non-natural PHA-producing bacteria. The studies found no dramatic increases in PHA production by introducing additional copies of *phb* or *pha* genes (reviewed by Madison and Huisman, 1999). The results are not surprising in light of the finding that other factors, such as the supply of NADPH (Lee et al., 1996c), limit PHA production. Supplementation of amino acids or oleate, both of which require substantial reducing power for their synthesis, increased poly(3HB) production (Lee et al., 1995c).

Different strains of *E. coli*, including K12, B, W, XL1-Blue, DH5α, HB101, JM 109 and C600, were similarly transformed with the stable high-copy-number plasmid pSYL105 containing the PHA biosynthesis genes of *R. eutropha*, and poly(3HB) production by the transformants was compared (Lee and Chang, 1995b). The rate of poly(3HB) synthesis, the extent of poly(3HB) accumulation, and the yield of poly(3HB) from glucose varied considerably from one strain to another. Strains XL1-Blue and B (harboring the plasmid) produced poly(3HB) at the highest rate. A poly(3HB) concentration of 81 g/liter could be obtained in 41 h from a pH-stat fed-batch culture of *E. coli* (pSYL105).

Following the transfer of the PHA biosynthesis genes from *R. eutropha* into *E. coli*, the recombinant *E. coli* strains were further altered by the introduction of other genes. The transfer of the *prpE* gene, encoding the propionyl-CoA synthetase, from *Salmonella enterica* serovar *typhimurium* enabled the strain to produce poly(3HP-co-3HB) (Valentin et al., 2000a). Inactivation of the ketoacyl-CoA degradation step of the β-oxidation enabled the strain to produce PHAs having different monomer compositions when grown on different alkanoates (Ren et al., 2000). Introduction of genes coding for the enzymes for the conversion of glutamate or 4-aminobutyrate to 4-hydroxybutyryl-CoA (see "Production of PHA Copolymers" in this Chapter) enabled the recombinant strain to produce poly(3HB-co-4HB) (Valentin et al., 2000b).

When the PHA polymerase genes of *Thiocapsa pfennigii* and the genes for butyrate kinase

and phosphotransbutyrylase of *Clostridium acetobutylicum* were transferred into *E. coli*, the recombinant strain produced copolymers and terpolymers of 3HB, 4HB and 4HV when provided with the corresponding hydroxy fatty acids (Liu and Steinbüchel, 2000b). Introduction of the PHA polymerase gene (*phaC1*) from *Pseudomonas oleovorans* into *E. coli* with a stable regulated expression system allowed the recombinant *E. coli* to produce chiral medium-chain-length PHAs (Prieto et al., 1999b). Other examples of expressing the PHA polymerase gene of pseudomonads in *E. coli* to produce medium-chain-length PHAs can be found in the review by Madison and Huisman (1999).

Chromobacterium violaceum produces poly(3HB) or poly(3HB-co-3HV) when grown on a fatty acid carbon source. When the PHA polymerase gene of *C. violaceum* was transferred into *E. coli* or *Pseudomonas putida* and expressed, the recombinants did not accumulate a significant level of PHA. However, similarly transformed *Klebsiella aerogenes* and *R. eutropha* accumulated poly(3HB), poly(3-HB-co-3HV) and poly(3-HB-co-3hydroxyhexanoate). Transfer of the *P. putida phaG* gene (encoding a transacylase) and the *P. aeruginosa phaC1* gene (encoding PHA polymerase) into *P. fragi* enables the recombinant strain to produce PHAs consisting of medium-chain-length monomers (Fiedler et al., 2000). These results illustrate the relationship between the availability of different metabolic intermediates as precursors for PHA synthesis and the composition of the PHA formed. They also show that a PHA polymerase can react with different hydroxyacyl-CoAs within a certain size range, and when metabolic engineering alters the pattern of hydroxyacyl-CoAs present in a cell, the composition of PHAs formed may be similarly altered.

When PHA-producing cells are lysed for processing, the released chromosomal DNA causes a dramatic increase in viscosity. The high viscosity of cell lysate hinders the isolation of PHA during industrial production. To reduce the viscosity, addition of commercial preparations of nuclease or heat treatment is practiced, which adds to the cost of PHA production. The viscosity of cell lysates of *Pseudomonas putida* was reduced by expressing a staphylococcal nuclease in this organism (Boynton et al., 1999). In this study, a nuclease gene from *Staphylococcus aureus* was integrated into the chromosome of several strains of *Pseudomonas putida* and *R. eutropha*, and the expressed nuclease was directed to the periplasm or to the growth medium. During downstream processing, the viscosity of the lysate from a nuclease-integrated *Pseudomonas* strain was reduced to a level similar to that obtained with the wild-type strain after treatment with commercial nuclease.

Metabolic engineering also was performed successfully in eukaryotes including yeast (Leaf et al., 1996) and higher plants (see "Production of PHAs by Transgenic Plants" in this Chapter) for the production of PHAs.

Commercial Applications

Production of BIOPOL After the discovery of the thermoplastic properties of poly(3HB), W. R. Grace and Co. in the United States produced poly(3HB) for the possible commercial applications in the early 1960s, but the process was discontinued because of a low production efficiency and the lack of suitable recovery methods (Lee and Chang, 1995a). In the 1970s, industrial interests in the production of PHB resumed at Imperial Chemical Industries (ICI, United Kingdom). Commercial production of PHA began at ICI Bio Products and Fine Chemicals, which later became Zeneca BioProducts, Billingham, United Kingdom, and was the only producer of PHA on a commercial scale (Byrom, 1992; Byrom, 1994; Lee and Chang, 1995b). The trade name BIOPOL was used to describe the family of PHA polymers manufactured. In 1996, Monsanto of St. Louis, in the United States, purchased the manufacturing technology from Zeneca BioProducts, but Monsanto ended its manufacturing of BIOPOL in 1998 (information provided by Monsanto).

Alcaligenes eutrophus (now *Ralstonia eutropha*) was the organism used in the commercial production of BIOPOL. The ICI process used a fed-batch system on a scale up to 200,000 liters in capacity and produced 300 tons per year. Nutrient limitation was used as the strategy to control the onset of the PHA accumulation phase that follows a period of normal growth to produce cells. The organism grows in a mineral salts medium with glucose as the sole carbon and energy source. At the time of inoculation, the medium in the production-stage fermentor contains a calculated amount of phosphate to allow production of a given amount of cell mass when the other nutrients are in excess. When the concentration of phosphate in the medium decreases to a threshold level so that it becomes limiting (about 60 h after inoculation), the cell begins to store PHA. At this point, more glucose is fed to the culture, if poly(3HB) is the desired product. The fermentation is continued for 40–60 h until the required PHA content is reached. Cell mass in excess of 100 g/liter (dry weight) and a poly(3HB) content of 70–80% are routinely obtained (Byrom, 1992; Byrom, 1994).

To produce the poly(3HB-co-3HV) copolymer, a mixture of glucose and propionic acid, instead of glucose alone, is fed to the culture when cells reach the PHA-accumulating stage under phosphate limitation. The 3HV content of the copolymer is controlled by adjusting the ratio of glucose to propionic acid in the feed. Normally, poly(3HB-co-3HV) copolymers containing 0–30 mol% of 3HV are produced. When the wild-type *R. eutropha* was used for poly(3HB-co-3HV) production, only about 30% of the propionic acid supplied was incorporated into the copolymer because the major proportion of the added propionate was metabolized to acetate, which resulted in poly(3HB), or to CO_2. The problem was solved by the isolation of a mutant that cannot convert propionate to acetate. Use of this mutant reduced the required amount of propionate in the feed for copolymer production, and it not only lowered the cost of production but also alleviated the toxicity problem caused by high concentrations of propionate in the medium (Byrom, 1994). Copolymers having a higher fraction (up to 90 mol%) of 3HV have been produced from butyric or pentanoic acid (Doi et al., 1990b; Lee and Chang, 1995a), but production on an industrial scale has not been reported.

The large-scale commercial production of PHA also required the development of procedures that were not necessary in the laboratory or in the pilot stages. In the laboratory, PHA is effectively extracted from the cell by using organic solvents such as chlorinated alkanes. Environmental considerations preclude the use of such organic solvents in the industrial process, and a water-based extraction procedure was successfully developed. The large size of the fermentor used in the industrial process also requires a much longer time for the harvesting of cells, which can lead to the degradation of the polymer during the harvesting and the extraction stages. These problems had to be solved before commercial production of PHA became feasible. The white powder produced by the industrial process is melted, extruded, and converted into chips, which are supplied to the fabricators. The aqueous effluent generated by the industrial process can be treated in a conventional activated-sludge plant.

Manufacturing BIOPOL-Based Consumer Products BIOPOL can be processed on conventional equipment for polyolefin or other plastics, such as injection molding, extrusion blow molding or fiber-spray gun molding, and therefore was used in the manufacturing of a wide range of consumer products. The first commercial product of PHA utilized BIOPOL and was introduced in 1990. It was a shampoo bottle for the German hair care company AWella, and it was available for some time on a limited market in Germany. Bottles for other cosmetics also came onto the market in Japan. Besides uses in the manufacturing of containers and bags, PHAs also can be used as coatings on items for food service or packaging. In the review by Steinbüchel (1996), many products manufactured from BIOPOL or other PHAs are described, and they include applications in agriculture, medicine, tobacco and foodstuff industry, chemical industry, fishing industry, and other areas.

Areas of Research and Development

Production of PHA Copolymers The homopolymer of 3-hydroxybutyric acid or poly(3HB) is the prototype biodegradable PHA that is naturally produced by many bacteria. Because poly(3HB) is a crystalline and relatively brittle substance, it is not a suitable substitute for the commonly used thermoplastics manufactured from petrochemicals. Copolymers of hydroxyalkanoic acids, on the other hand, are less brittle and more elastic. Therefore, a major area of research on PHA is to develop organisms that can produce PHA copolymers with better mechanical properties and biodegradability.

The three key enzymes for PHA synthesis, 3-ketothiolase, 3-ketoacyl-CoA reductase and PHA polymerase, can usually accommodate substrates with a slightly different chain length. Therefore, two or three kinds of hydroxyalkanoic acids can be incorporated during PHA synthesis to form a copolymer or terpolymer, if the additional kinds of CoA thioesters of hydroxyalkanoic acids can be made available to PHA polymerase through a special feeding regimen or metabolic engineering or a combination of both.

The first PHA copolymer to be produced commercially is poly(3HB-co-3HV), which was produced by *R. eutropha* when fed glucose and propionic acid (Byrom, 1992). The production strain is a glucose-utilizing mutant of *R. eutropha* (*A. eutrophus*) strain H16 that also can assimilate propionate more efficiently than the wild type. Propionic acid is converted to propionyl-CoA first. Condensation of propionyl-CoA and acetyl-CoA yields 3-ketovaleryl-CoA, which is then reduced to 3-hydroxyvaleryl-CoA to serve as a substrate for PHA polymerase. The concentration of poly(3HB-co-3HV) reached 70–80% of the dry weight of the cell. By varying the ratio of glucose and propionic acid, the 3HV content in the polymer can be controlled at particular values in the range of 5–30 mol%. The PHA polymerase of *R. eutropha* accepts CoA thioesters of 3-, 4-, or 5-hydroxyalkanoic acid

with 3 to 5 carbon atoms (Steinbüchel, 1996), and PHA copolymers consisting of these monomers may be produced.

Ralstonia eutropha can produce poly(3HB-co-3HV) to a high concentration. However, this bacterium has a slow growth rate, is sensitive to propionic acid, and is hard to lyse. In addition, it also contains PHA-degrading enzymes, which can lower the yield or quality of PHA. Organisms that do not have these shortcomings were thus developed for the production of copolymers. Through metabolic engineering (see "Metabolic Engineering" in this Chapter) and special feeding programs, numerous recombinant organisms have been constructed to produce a range of PHA copolymers. Progress in this area has been rapid in recent years.

Poly(3HB-co-3HV) can now be produced by recombinant *E. coli* that acquired the PHA biosynthesis genes from *R. eutropha* or *A. latus* (Choi and Lee, 1999b; Choi and Lee, 2000) or by the transgenic plants Arabidopsis and Brassica (Slater et al., 1999). Copolymers consisting of 3-HB and 3-hydroxyalkanoate units of 6–12 carbon atoms can be produced by recombinant Pseudomonas putida and *R. eutropha* that were PHA-negative (Matsusaki et al., 2000). Poly(3-HB-co-4HB) can be produced by a PHA-producing recombinant *E. coli* that also was conferred with the ability to form 4-hydroxybutyryl-CoA from 4-aminobutyrate or glutamate (Valentin et al., 2000a). The genes for four enzymes were introduced into *E. coli* to afford the transformant the capacity to form 4-HB; the four enzymes are glutamate decarboxylase, 4-aminobutyrate:2-ketoglutarate transaminase, 4-hydroxybutyrate dehydrogenase, and acetyl-CoA:4-hydroxybutyrate CoA-transferase. Various copolymers and terpolymers consisting of 3HB, 4HB and 4HV can be produced by recombinant *E. coli* that received the butyrate kinase and phosphotransbutyrylase genes (*buk* and *ptb*) from *Clostridium acetobutylicum* and the PHA polymerase genes (*phaE* and *phaC*) from *Thiocapsa pfennigii* and is fed 3HB, 4HB and 4HV (Liu and Steinbüchel, 2000b). The PHA polymerase of *T. pfennigii* has a broader substrate range than the polymerase of *R. eutropha*.

Poly(3-hydroxypropionate-co-3HB) or poly(3HP-co-3HB) can be produced by a recombinant *E. coli* that acquired the *prpE* gene, encoding a propionyl-CoA synthetase, from *Salmonella* and the PHA biosynthesis genes from *R. eutropha* (Valentin et al., 2000b). The PHAs with medium-chain-length hydroxyalkanoates can be produced by PHA-producing recombinant strains of *E. coli* that are blocked for the ketoacyl-CoA degradation step of the β-oxidation and are fed fatty acids ranging in size from 6 to 18 carbon atoms (Ren et al., 2000). The number of copolymer-producing organisms as well as the kind of copolymer produced can be expected to increase, and many new copolymers with better material properties should result from these efforts.

Production of Chiral Monomers Because PHAs are polymers composed of chiral building blocks, hydrolysis of PHAs leads to the release of the chiral monomers, which are valuable starting material for the synthesis of pharmaceuticals and specialty chemicals. An efficient method has been reported for the production of enantiomerically pure (*R*)-(-)-hydroxyalkanoic acids by in vivo depolymerization of PHAs (Lee et al., 1999c). Those (*R*)-(-)-3-hydroxyalkanoic acids of 4–12 carbon atoms and (*R*)-(-)-3-hydroxy-5-phenylvaleric acid were prepared by providing the environmental condition under which cells possess a high activity of intracellular PHA depolymerase and a low activity of a key enzyme that could convert the chiral monomer into another compound. Monomer (*R*)-(-)-3-hydroxybutyric acid could be produced at a high yield in 30 min by in vivo depolymerization of poly(3HB) accumulated in *Alcaligenes latus*.

In Vitro Biosynthesis of PHA Poly(3HB) is present as granules in bacterial cells and can reach sizes of up to 1 μm. When isolated by chloroform extraction, Poly(3HB) is highly crystalline and has molecular mass as large as 2×10^6 daltons (see "Physicochemical Properties" in this Chapter). However, nuclear magnetic resonance (NMR) and wide-angle X-ray diffraction studies showed that in vivo the poly(3HB) polymer is in a mobile, amorphous state (Barnard and Sanders, 1989; Kawaguchi and Doi, 1990). It was also suggested that additional agents, such as lipids and surfactants, may be needed as plasticizers if the poly(3HB) granule is assembled in vitro (Kawaguchi and Doi, 1990). Any insight into these fundamental aspects of PHA biosynthesis can influence the development of an innovative approach for improving the industrial production of PHA.

Using purified PHA polymerase from *R. eutropha* and synthetically prepared (*R*)-3-hydroxybutyryl-CoA, macroscopic poly(3HB) granules were produced in vitro, and the procedure established the minimal requirement for poly(3HB) granule formation (Gerngross and Martin, 1995). To make the in vitro biosynthesis practically useful, it is necessary to recycle coenzyme A, which is a product of the polymerization reaction. This has been accomplished by incorporating additional enzymes into the in vitro reaction (Jossek and Steinbüchel, 1998; Liu and Steinbüchel, 2000a). The use of butyrate kinase and phosphotransbutyrylase produced from

cloned genes of the anaerobic bacterium *Clostridium acetobutylicum* allowed not only the recycling of CoA but also the in vitro synthesis of 3- and 4-hydroxyacyl-CoA, which then are converted to homo- or copolymers of PHA by the PHA polymerase from *Chromatium vinosum* (Liu and Steinbüchel, 2000a). In this butyrate kinase-linked in vitro system, ATP is the energy-rich compound that must be replenished to sustain the reaction.

Production of PHAs by Genetically Engineered Bacteria In addition to the search for better PHA-producing organisms from nature, much effort has been devoted to the use of mutagenesis and recombinant DNA techniques to confer desired properties to selected bacteria for PHA production. These genetically engineered bacteria can produce PHAs of specific compositions for better material properties or can use less expensive substrates. The sections on metabolic engineering (see "Metabolic Engineering" in this Chapter) and production of PHA copolymers (see "Production of PHA Copolymers" in this Chapter) describe the construction of these recombinant bacteria and the novel PHAs produced by them. These recombinant organisms have been extensively used in fermentation studies (Table 23) to maximize their productivity.

At the Korea Advanced Institute of Science and Technology (Taejon, South Korea), Dr. S. Y. Lee and coworkers have conducted extensive studies with recombinant strains of *E. coli* engineered for PHA production (Lee and Chang, 1995b; Lee, 1996a; Lee, 1996b). The recombinant *E. coli* strain XL 1-Blue (pSYL107) harboring the PHA biosynthesis genes of *R. eutropha* and the *ftsZ* gene of *E. coli* on the high copy-number plasmid pSYL107 produced poly(3HB) to 77 g/liter, with a production rate of 2 g/liter · h, in a defined medium with glucose as the carbon source (Wang and Lee, 1998a). Overexpression of the cell-division protein FtsZ was crucial as it suppresses filamentation, which limits PHA production by *E. coli*. Further optimization of the fed-batch culture conditions increased the poly(3HB) concentration to 10^4 g/liter.

The recombinant *E. coli* strain XL1-Blue (pJC4) harboring the PHA biosynthesis genes of *A. latus* was used in pH-stat fed-batch cultures to produce poly(3HB-co-3HV) from glucose and propionic acid in a defined medium (Choi and Lee, 1999b). In the absence of an induction treatment with acetic acid to stimulate the uptake and utilization of propionic acid, the cells accumulated a relatively low level (42.5%) of poly(3HB-co-3HV). With the acetic acid induction treatment in the fed-batch culture, the recombinant *E. coli* produced a cell concentration of 141.9 g/liter, a poly(3HB-co-HV) concentration of 88.1 g/liter, a poly(3HB-co-3HV) content of 62.1%, and a 3HV fraction of 15.3 mol%. With the supplementation of oleic acid (to spare NADPH), the acetic acid induction, and an improved nutrient feeding strategy, the recombinant *E. coli* produced a cell concentration of 203.1 g/liter, a poly(3HB-co-3HV) concentration of 158.8 g/liter, a poly(3HB-co-3HV) content of 78.2%, and a 3HV fraction of 10.6 mol%, resulting in a high production rate of 2.88 g/liter · h.

The result of an economic analysis was reported for the production of the poly(3HB-co-3HV) copolymer by a recombinant *E. coli* strain (Choi and Lee, 2000). For this analysis, simple NaOH digestion was used for the release of PHA from the cell because *E. coli* cells accumulating large amounts of PHA become very fragile (Choi and Lee, 1999a). Because propionic acid is more expensive than glucose, the production cost for poly(3HB-co-3HV) increased linearly with the increase in the 3HV fraction in the copolymer. Not surprisingly, the production cost for the copolymer increased significantly when the 3HV content (increasing from 5 to 50 mol%) was high and the 3HV yield (g of 3HV produced from each g of propionic acid used) was low (decreasing from 0.5 to 0.2).

The recombinant *E. coli* strain CGSC 4401, harboring the PHA biosynthesis genes of *A. latus*, produced poly(3HB) from whey (concentrated to contain 280 g of lactose-equivalent per liter) in pH-stat fed-cultures and reached a final cell concentration of 119.5 g/liter and poly(3HB) concentration of 96.2 g/liter in 37.5 h, resulting in a poly(3HB) productivity of 2.57 g/liter · h (Ahn et al., 2000). This recombinant strain was then tested in a pH-stat cell-recycle membrane system to produce poly(3HB) from similarly concentrated whey as a feeding solution (Ahn et al., 2001). The cell-recycle system produced a final cell concentration of 194 g/liter, a poly(3HB) concentration of 168 g/liter, and a PHB content of 87% in 36.5 h, resulting in a poly(3HB) productivity of 4.6 g/liter · h. This level of PHA production is among the highest, other than the level produced by the methanol-grown bacteria (Table 23).

A recombinant strain of *E. coli* was used in the development of a quantitative spectroscopic method for the measurement of poly(3HB) content in the cell (Kansiz et al., 2000). Fourier transform infrared (FTIR) spectroscopy and multivariative statistical methods were performed to determine the cellular poly(3HB) content, and a correlation coefficient of 0.988, with a standard error of 1.49% poly(3HB), was obtained between the measured and the predicted values. The spectroscopic method circumvented the need to use solvents to extract the PHA before quantitative measurements.

Search for Inexpensive Carbon Substrates

Economic evaluation of the bacterial process for poly(3HB) production suggests that the cost of the carbon substrate accounts for up to 50% of the total cost of poly(3HB) production (Choi and Lee, 1997). A successful bacterial process for PHA production hence depends on the availability of a low-cost carbon substrate. Besides carbohydrates, organic acids and short-chain alcohols are also potential carbon substrates for the industrial production of PHAs. The cellular toxicity of the latter compounds, however, requires the isolation or identification of PHA-producers that are more tolerant to these compounds. Reported progress includes the production of PHAs from whey or acetic and butyric acids.

Whey is a major by-product in the manufacturing of cheese or casein from milk. Whey from bovine milk contains approximately 4.5% (wt/vol) lactose, 0.8% (wt/vol) protein, 0.1–0.8% (wt/vol) lactic acid, and 1% (wt/vol) salts (Wong and Lee, 1998). In the United States, only half of the whey is recycled into useful products such as food ingredients and animal feed (Ahn et al., 2000). Because of its high volume and high biological oxygen demand, the rest of the whey is regarded as a pollutant that is costly to manage. Using a concentrated whey solution (280 g of lactose equivalent per liter) and a recombinant *E. coli* strain harboring PHA biosynthesis genes, final cell and poly(3HB) concentration reached 119.5 and 96.2 g/liter, respectively, in 37.5 h, which resulted in a poly(3HB) productivity of 2.57 g/liter · h (Ahn et al., 2000). These investigators found that whey could actually be concentrated by evaporation to contain 280 g of lactose per liter, which exceeds the solubility of lactose in water (200–210 g/liter). By using the fed-batch culture with the highly concentrated whey solution and a stepwise decrease in the dissolved oxygen concentration from 40% to 15%, the highest poly(3HB) productivity was obtained. By using a cell-recycle membrane system, these investigators obtained cell concentration, poly(3HB) concentration, and poly(3HB) content of 194 g/liter, 168 g/liter and 87%, respectively (Ahn et al., 2001). In localities where the disposal of whey is a problem, the production of PHA from this carbon source should provide a higher economical return.

In an attempt to improve the economics of the anaerobic acetone-butanol (AB) fermentation, scientists in Vienna, Austria, are testing the by-products, acetate and butyrate, from the AB fermentation as substrates for PHA production (Parrer et al., 2000). A butanol-tolerant strain of *Alcaligenes* was isolated that could convert acetate (5 g/liter), butyrate (7 g/liter), and added valerate (3 g/liter) to poly(3HB-co-3HV) copolymers (37 mol% 3HV) that constituted 52% of the cellular dry matter (Parrer et al., 2000).

Production of PHAs by Transgenic Plants

The established commercial process for the production of BIOPOL used bacteria (see "Production of BIOPOL" in this Chapter). However, the high cost of the conventional carbon substrates has limited the usefulness of the bacterial process. Transgenic plants, which harbor the bacterial genes for the synthesis of PHAs, have been developed to couple directly the photosynthetic activity of the green plants to the production of PHAs (Poirier et al., 1992; Nawrath et al., 1994; John and Keller, 1996; Hahn et al., 1997; Slater et al., 1999).

Initially, the *R. eutropha* (*A. eutrophus*) genes for acetoacetyl-CoA reductase (*phbB*) and poly(3HB) polymerase (*phbC*) were introduced into *Arabidopsis thaliana* through Ti plasmid-mediated transformation and cross-pollination of homozygous transgenic lines harboring either the *phbB* or the *phbC* gene (Poirier et al., 1992). These two introduced genes are expressed in the cytoplasm of the transformed plant, where an endogenous 3-ketothiolase is present. Poly(3HB) is produced by the transgenic plant, but the expression of large amounts of acetoacetyl-CoA reductase in the cytoplasm of the transgenic plants caused a significant reduction in growth and seed production.

This problem was alleviated when the three *R. eutropha* genes (*phbA*, *phbB* and *phbC*) were properly fused to signal sequences to target the expression of these genes in plastids, where storage lipids are normally synthesized. These plants accumulated poly(3HB) up to 14% of the dry weight of leaves, as 0.2–0.7-μm granules within plastids (Nawrath et al., 1994). However, varying amounts of poly(3HB) were produced by different lines of the triple hybrids, and the variation appears to be related to the widely different levels of thiolase and acetoacetyl-CoA reductase activities that are expressed in the hybrid plants. Compared with starch synthesis, the average daily rate of poly(3HB) synthesis is relatively low, although poly(3HB) is not reutilized by the plant and hence acts as a terminal carbon sink.

The copolymer poly(3-hydroxybutyrate-co-3-hydroxyvalerate) or poly(3HB-co-3HV) was produced in transgenic *Arabidopsis thaliana* and in the seeds of transgenic *Brassica napus* (oilseed rape) by diverting metabolic pools of acetyl-CoA and threonine into PHA production through four introduced genes that are targeted for expression in the plastids (Slater et al., 1999). The four genes involved are:

1) the *E. coli ilvA* gene, which codes for the threonine deaminase, an enzyme converting

threonine to 2-ketobutyrate (the plant pyruvate dehydrogenase complex can convert 2-ketobutyrate to propionyl-CoA, which is the precursor for (*R*)-3-hydroxyvaleryl-CoA);

2) the *R. eutropha bktB* gene, which codes for the 3-ketothiolase that can produce both acetoacetyl-CoA (from acetyl-CoA) and 3-ketovaleryl-CoA (from acetyl-CoA and propionyl-CoA);

3) the *R. eutropha phbB* gene for acetoacetyl-CoA reductase; and

4) the *phbC* gene, for the poly(3HB) polymerase, from either *R. eutropha* or *Nocardia corallina*. This designed pathway allows the production of PHA copolymers by the transgenic plants, but the level of accumulated copolymer is low, less than 3% of plant tissue dry weight (*Arabidopsis*) or the seed weight (*Brassica*). These investigators expect that polymer concentrations in plants will need to reach at least 15% of dry weight for economical production to be feasible.

The *R. eutropha phbB* and *phbC* genes also have been introduced into cotton (*Gossypium hirsutum*) with the fiber cells as the target site of expression during early or late fiber development stages (John and Keller, 1996). The objective was to alter the characteristics of the cotton fibers. Although poly(3HB) was present at a low level in the fiber (3.4 mg/g of dry fiber), it already increased the heat capacity and hence improved the insulation properties of the purified cotton. Future goals for the effort are to improve cotton characteristics such as dyeability, warmth and wrinkle resistance.

Genes for poly(3HB) biosynthesis have been introduced into Black Mexican sweet corn (maize, *Zea mays*) and expressed in cultured cells (Hahn et al., 1997). During a two-year period in a bioreactor, the introduced *phbB* and *phbC* genes were unstable, whereas the thiolase activity was constant. Also, the transformed plant cells grew more slowly than the wild-type cells. The construction of suitable plant species for the production of PHAs in specific cellular locations and at the right time will depend on progress in knowledge and tools for genetic and metabolic engineering. The introduction of new characteristics into plant materials, such as the cotton fibers, by the incorporation of PHAs represents an excellent application for the biodegradable polymer.

Patent and Regulatory Issues

Many processes for the production and application of PHAs are under the protection of patents. Steinbüchel (1996) compiled 74 patents and patent applications in his review, and 16 of them were assigned to ICI. Among them, 33 patents or patent applications were for the production of PHA, encompassing the poly(3HB) homopolymer (e.g., EP 46344-A1, EP 144017-A1, JP 06251889-A2 and US 4910145), the poly(3HB-co-3HV) copolymer (e.g., EP 204442-A2, EP 288908-A2, EP 396289-A1, and EP 90304267.9), the poly(3HB-co-4HV) copolymer (EP466050-A1) and the poly(3HB-co-4HB) copolymer (e.g., JP 2234683-A2, JP 03216193-A2, and JP 03292889-A2), as well as the PHA biosynthesis genes (US 5229279, US 5245023, and US 5250430, all assigned to Metabolix); 23 were for the isolation of PHA, including those for the poly(3HB) homopolymer (e.g., EP 46335, EP 145233-A1, and JP 62205787-A2) and the poly(3HB-co-3HV) copolymer (EP 431883-A1 and WO 9118995-A1); 8 were for the processing or modification of PHA into films (US 3182036), 3HB monomer and oligomers (US 4365088-A1 and EP 320046-A1), and 3HB esters (EP 377260-A1 and US 5107016-A1); 10 were for the applications of PHA, which include microporous membranes (JP 60137402-A1), surgical devices for bone fractures (WO 8607250-A1), microcapsules for retard materials (DE 3428372-A1 and EP 315875-A1), cigarette filter tips (DE 4013293-C2 and DE 4013304-A1), toner and developer for photocopier (US 5004664-A1), flavor delivery systems (WO 9209210-A1), and cream substitute (WO 9209211-A1). The number of pertinent patents can be expected to increase when more recombinant organisms, novel production systems and applications are developed.

When the PHA-based consumer products or medical devices are proclaimed to be biodegradable, government regulations and standards become necessary to safeguard the quality of the environment and the welfare of patients. It is necessary to define biodegradability, standards, and the test methods. At the Third International Scientific Workshop on Biodegradable Plastics that was held in Osaka, Japan, in November 1993, a session was devoted to government policy, regulations and standards (Albertsson and Marchessault, 1994). Pertinent government policy and regulations of the United States (Narayan, 1994), Italy (Chiellini, 1994) and Korea (Chang et al., 1994) can be found in these publications.

Prospects

The commercialization of consumer goods manufactured from BIOPOL has confirmed the usefulness of PHAs as a substitute for petrochemical-derived thermoplastics. The discontinuation of the BIOPOL process, however, illustrates that the high cost of bacterial fermentation will limit the commercial potential of PHAs that are produced by fermentation-based

processes. The result of a case study casts doubt on the environmental benefits of producing PHAs from corn-derived glucose (Gerngross, 1999). Because a considerable amount of fossil fuels is needed to produce corn and then to convert corn starch into glucose for bacterial fermentation, a greater amount of fossil fuels (2.39 kg versus 2.26 kg) may actually be required to produce 1 kg of PHAs than to produce 1 kg of polystyrene from petrochemicals. To overcome this unfavorable situation, less expensive carbon substrates are being sought to replace glucose as the starting material. Whey has been identified as a promising alternative substrate (Ahn et al., 2001). In addition, phototrophic organisms are being tested as the primary producers of PHAs so that CO_2 can serve as the carbon substrate. Transgenic plants with introduced bacterial genes have been shown to produce PHAs, but the level of PHAs produced is so far lower than that in the bacteria. Another approach is to use unicellular phototrophic bacteria, which may be more efficient than the higher plants in the utilization of carbon and energy, to produce PHAs. The use of less expensive carbon substrates or phototrophic bacteria may allow the development of more economical and sustainable processes for the future commercial production of PHAs.

Besides uses as a commodity chemical for the manufacturing of consumer goods, PHAs also have other possible novel applications. For example, PHAs may be used in the delivery system for the long-term release of drugs, in open-heart surgery as non-woven patches for pericardium repair or in orthopedic medicine because the piezoelectric properties of PHAs stimulate bone growth (Steinbüchel, 1996). It has also been suggested that PHAs can serve as the source of a broad range of chiral hydroxy acids, which are valuable building blocks for the pharmaceutical industry (Lee et al., 1999c). These novel uses for PHAs will ensure a future for this class of biomaterial whether or not it will be produced by phototrophic or nonphototrophic organisms.

Organic Acid and Solvent Production
Part II: Propionic and Butyric Acids and Ethanol

PALMER ROGERS, JIANN-SHIN CHEN AND MARY JO ZIDWICK

Section 6: Propionic Acid and Butyric Acid

Introduction

Both propionic acid and butyric acid together with their acid salts are incorporated into a large number of commercial products (Boyaval and Corre, 1995; Zigova and Sturdik, 2000). These include food additives and flavors, preservatives, cellulose-based plastics, drug formulations, and fragrances. In the future, production of these short-chain organic acids by low-cost efficient fermentation processes also may make them attractive as feedstocks for conversion into various industrial chemicals. Numerous reaction pathways are already available for conversion of lactic acid and succinic acid into useful chemicals that are potentially competitive with petroleum-based routes (Varadarajan and Miller, 1999). As economic conditions favor the growth of a bio-based chemical industry in the twenty-first century, fermentation-derived organic acids will play an increasingly important role as chemical feedstocks.

At present, both propionic and butyric acids are manufactured by a number of chemical processes using petrochemical routes (Sauer, 1991). For example, butyric acid is usually prepared by oxidation of butyraldehyde, which is produced from propylene by oxosynthesis (Billig and Bryant, 1991). Chemical synthesis of these organic acids is favored because chemical processes are still less expensive to perform. In spite of this cost advantage, butyric and propionic acids obtained from natural sources are often required. Consumers prefer that food additives and pharmaceutical products contain ingredients of natural origin. Thus research and development of bacterial fermentation processes yielding propionic or butyric acid has emerged during the last century. Indeed, a small number of pilot plants were designed and tested for the production of these organic acids from inexpensive biomass materials (Playne, 1985). The history of these two fermentations is treated separately below.

The history of the bacterial propionic acid fermentation began from the investigations by Adolph Strecker (Strecker, 1854) in which he observed for the first time the formation of propionic acid from sugar. He showed that a calcium carbonate-sugar mixture, to which cheese and sour milk were added, first formed a thick, calcium-lactate slurry. Later a second fermentation occurred in the mixture that converted the lactic acid to mostly propionic acid, some acetic acid, and a gas (later identified as carbon dioxide [CO_2]).

Pasteur (Pasteur, 1861b; Pasteur, 1879) demonstrated that the phenomena of fermentation, including the butyric and propionic acid fermentations, were due to the activities of living microbes. The earliest investigations of the morphology and physiology of the propionic acid bacteria were reported by Albert Fitz (Fitz, 1878). From experiments using a variety of carbon sources, Fitz predicted a balanced equation for propionic acid production from organic acid and sugars:

$$3\ \text{Lactic acid} \leftrightarrow 2\ \text{propionic acid} + 1\ \text{acetic acid} + 1CO_2 + 1H_2O \qquad (12)$$

Studies by von Freudenreich and Jensen (1906) and Van Niel (1928) defined and differentiated eleven species of the *Propionibacterium* that have a role in propionic acid production during cheese making. Van Niel's thesis on the propionic acid bacteria contains extensive experimental data on growth and fermentations by these bacteria (Van Niel, 1928). He demonstrated a 90–100% yield (m/m) of propionic acid during growth of a number of strains of *Propionibacterium* on glycerol. The significance of this finding is discussed (see "Scientific Background" and "Areas of Research and Development" in this Chapter). Van Niel predicted that the *Propionibacterium* fermentation might form the basis for future industrial production of propionic acid.

Research on the factors affecting the growth and fermentation by the propionic acid bacteria was published in the 1920s and 1930s and is nicely reviewed by Prescott and Dunn (1949).

The early history of process development for the production of propionic acid began about the same time and has extended to the present. A detailed review of development of this process up to 1981 has been presented by Playne (1985). According to Playne (1985), Sherman and Shaw (1923) first promoted developing this fermentation into an industrial process. During the period 1920–1953, 17 patents were granted on propionic acid production by fermentation. Following this early work, three pilot-plant projects were reported which utilized sulfite waste liquors from wood pulp processing. The Wayman process (Wayman et al., 1962) was a continuous process with *Propionibacterium arabinosum* immobilized on calcium carbonate beads (>3 mm). The liquor was recycled, the pH was adjusted to above 5.7, and the operating temperature was 35–38°C. The acids were separated by steam distillation or by solvent extraction. The designed plant would use 4,000 liters/min of sulfite waste and produce 50 tons of acetic and propionic acid per day. Martin et al. (1961) designed a smaller plant based on the same process in which bacterial mass was pre-grown and then immobilized in columns. With nongrowing cells, a much lower amount of yeast extract was required to maintain production and the pH tolerated was lower than pH 5.7, resulting in a higher concentration of acids during production. Utilizing the same Wayman process, Nishikawa et al. (1970) employed immobilized *Propionibacterium freudenreichii* instead of *P. arabinosum* to investigate coproduction of vitamin B_{12} along with propionic and acetic acid after the addition of cobalt ion. Difficulties due to inhibition of growth of this strain with the sulfite liquor were reported.

The history of the butyric acid fermentation began with Pasteur's discovery that a living infusion both grew and produced butyric acid in the absence of air (Pasteur, 1861a). Further, he found that the activities of these rod-shaped bodies were inhibited by exposure to air, suggesting that his bacterium was most likely a butyric clostridium. A number of scientists studied the butyric-acid fermenting bacteria during the 1880s. Beijerinck proposed that the anaerobic spore-forming microbes that were butyric fermenting could be divided into two groups: those producing mostly butyric acid or those producing mostly butyl alcohol (Morris, 1993). The commercial exploitation of the acetone-butanol (AB) fermentation, which began during the First World War (1914–1918), had a great impact on the study of the anaerobic sporeforming bacteria and the history of their utilization for manufacture of chemical products (Morris, 1993). The AB fermentation dependent on strains of *Clostridium acetobutylicum* dominated the market for acetone during the war and then for butanol after the war up to the early 1940s. Even with massive fermentation plants and development of downstream processing, the lower costs of chemical synthesis from petroleum became more economically competitive during the 1950s and indeed up to the present time. There was a major attempt to produce calcium butyrate from a number of waste carbon sources including sawdust by a fermentation process developed by Lefranc and coworkers (Lefranc, 1923). Employing the "Lefranc Process," the calcium butyrate was converted downstream to dipropyl ketone by a pyrolytic process (Société Lefranc et Cie., 1925). The proposal was to use the ketones as a fuel or a fuel additive. Depasse (1945) reported a detailed description of a commercial process that would produce 5,000 liters/day of ketones from beet molasses through butyrate fermentation. There is no evidence that a factory was ever built to manufacture ketones by this process (Playne, 1985). Advances in strain development and in fermentation or downstream process technology for butyric acid production have been extremely slow. In a recent short review, Zigova and Sturdik (2000) outline some of the developments since 1985 referred to below (see "Areas of Research and Development" in this Chapter).

Scientific Background

Propionic Acid Process Table 24 lists the most prominent bacteria in the development of processes for propionic acid production. The propionibacteria *Propionibacterium acidopropionicum*, *P. freudenreichii* subsp. *freudenreichii*, and *P. freudenreichii* subs. *P. shermanii* are the organisms used in the most recent investigations for improvement of the propionic acid fermentation.

Even though these important dairy bacteria play successful roles in Swiss-type cheese production, they suffer three major drawbacks as biocatalysts effective for commercial production of propionic acid from biomass sources. Strains of the genus *Propionibacterium* are characterized by 1) very low growth rates and fermentation rates, so that a batch process would require 7–12 days to complete, 2) low tolerance to acid and to moderate concentrations of propionic or acetic acids resulting in low yields, and 3) simultaneous production of acetic acid and other products complicating downstream purification. In an attempt to allay the problem of acid sensitivity, three relatively acid-tolerant species of propionibacteria (*P. thoenii*, *P. jensenii* and *P. cyclohexanicum*) have been investigated (Table 24). Finally, the obligate anaerobic bacterium, *Clostridium propionicum*, is listed since it converts lactate to propionic acid, acetic acid and CO_2, as do the

Table 24. Bacteria used in developing processes for propionic acid and butyric acid production.

Organism	Properties
1. Propionic acid bacteria	
Propionibacterium acidipropionici	High yield of propionic acid
ATCC 25562, ATCC4875, P9, P68, P200910	Production strains
	Genetic development
P. freudenreichii subsp. *freudenreichii*	Used in Swiss-type cheese
P. freudenreichii subsp. *shermanii*	production
P. shermanii	New production strains
CDB10014, IF012426, TL162, P93, ATCC 6207^T	Genetic development
P. thoenii	Acid-tolerant strain
P20, P38, P54	Genetic studies
P. jensenii	Acid-tolerant strain
P114, P117	Genetic studies
P. cyclohexanicum	Acid-tolerant, cyclohexyl fatty
TA-12^T, IAM 14535^T	acid in membranes
	Acid tolerant
	High lactic acid produced
Clostridum propionicum	Obligate anaerobe
ATCC 25522	Acrylate pathway to propionate
2. Butyric acid bacteria	
Clostridium butyricum	Uses many C-sources
S21	
C. tyrobutyricum	Selective
CIP I-776, CNRZ 596	Uses few sugars: glucose and fructose
	Produces 90% butyrate
C. beijerinckii	Uses many C-sources
ATCC 25732	Will produce solvents: isopropanol, butanol and ethanol
C. acetobutylicum	Uses many C-sources
ATC 4259	Will produce solvents: acetone, butanol and ethanol
Butyribacterium methylotrophicum	Uses CO as a C-source

propionibacteria, according to the Fitz equation (12); see "Introduction" in this Chapter. In contrast to the propionibacteria, *C. propionicum* reduces lactate directly to propionic acid probably through an acrylate intermediate (Sinskey et al., 1981) rather than via succinate, as shown for the propionibacteria (Fig. 22). Even though acrylic acid is an important chemical feedstock presently produced by chemical synthesis, it is unlikely that the *C. propionicum* fermentation will develop as a bioprocess for production of this chemical (Rogers and Gottschalk, 1993).

Organic acid inhibition of the propionic acid fermentation and cell growth is the most serious problem facing the use of both the propionibacteria and *C. propionicum* for any bioconversion process. Rather belatedly, research focused in this area is emerging. Batch fermentations of lactose by *P. acidipropionici* were studied at a broad pH range (4.5–7.1; Hsu and Yang, 1991). As the growth rate fell from 0.23 h^{-1} at pH 6.0–7.1 to 0.08 h^{-1} at pH 4.5, the yield of propionic acid increased from 33% (w/w) to about 63% (w/w), while the yield of acetic acid was unchanged at about 9–12%. The authors also found that after growth ceased, propionic acid production continued for many hours apparently uncoupled from growth. These basic findings have led to development of improved fermentation processes; see "Areas of Research and Development." A propionic acid-tolerant strain of *P. acidipropionici* (strain P200910) was isolated that produced significantly more propionic acid than the parent strain, P9 (Woskow and Glatz, 1991). Strain P200910 contained an increase in the proportion of straight-chain fatty acids in cellular lipids. During batch and semicontinuous fermentations of whey permeate, strain P200910 showed uncoupling of propionic acid production from growth, produced a higher ratio of propionic acid to acetic acid, utilized lactose more efficiently, and produced more propionic acid per gram of cell mass than did the parent, P9, in all fermentations. Further research is needed to determine the biochemical and genetic nature of the changes responsible for the observed superiority

of acid-tolerant strains. Rehberger and Glatz (1998) tested 17 strains of propionibacteria for organic acid production after fermentation of glucose, maltose or fructose. In general, strains of *P. acidipropionici* produced more propionic acid and reached a lower final pH than strains of other species. Strains of *P. acidipropionici*, *P. jensenii* and *P. thoenii* were tested for ability to grow and/or survive at low pH with lactic, propionic (found to be the most inhibitory) or hydrochloric acid. The strains of *P. jensenii* and *P. thoenii* started growth and survived at a lower pH than did the *P. acidipropionici* strains. Apparently the ability to produce large amounts of propionic acid does not coincide with the ability to initiate growth or to survive at a low pH. A newly described acid tolerant propionibacterium, *P. cyclohexanicum*, strain TA-12, grows at pH range 3.2–7.5, whereas the closely related *P. freudenreichii* grows at pH 4.5–8.5 (Kusano et al., 1997). Strain TA-12 is also resistant to heating at 90°C for 10 min. although it is not a sporeformer. The major cellular fatty acid was *w*-cyclohexylundecanoic acid, which was 52.7% of the total fatty acids. It may be that the presence of this unusual lipid contributes to the acid and heat resistance of this organism. Unfortunately, following fermentation of glucose, TA-12 yielded a 5 : 4 : 2 ratio of lactic acid, propionic acid and acetic acid (Kusano et al., 1997). These results are important for design of future experiments to determine the biological basis for acid tolerance and its relationship to acid production; see "Areas of Research and Development" in this Chapter.

The relationship of the propionibacteria to oxygen with respect to both growth rate and fermentation products has been examined. *Propionibacterium shermanii* CDB 10014 was reported to grow well at high oxygen (O_2) transfer rates of 24 mmoles O_2 liter^{-1} h^{-1} (Quesada-Chanto et al., 1998b). Cell growth rate was reduced about one third during growth on glucose in the presence of O_2, compared with anaerobic growth; whereas growth yield in the presence of O_2 increased about 50% over growth yield in anaerobic conditions. Thus, growth of propionibacteria cannot be considered O_2 sensitive. However, in contrast, growth with O_2 completely inhibits propionic acid production and enhances both acetic acid and lactic acid production by *P. shermanii* and *P. acidipropionici* (Quesada-Chanto et al., 1994b; Quesada-Chanto et al., 1998b).

Both cell growth and propionic acid production by propionibacteria are dependent upon the vitamin-nitrogen sources as well as their concentrations in the fermentation broth. Comparative experiments using various sources of yeast extract and corn-steep liquor (CSL) showed slightly better growth and optimal production of propionic acid by either *P. shermanii* or *P. acidipropionici* using the less expensive CSL (Quesada-Chanto et al., 1998a).

The propionibacterium strains of the species listed in Table 24 are rather omnivorous with respect to carbon sources for growth and acid formation. Most strains grow on lactic acid, glycerol and erythritol, all strains grow on a panel of sugars, and *P. thoenii* and *P. acidipropionici* grow on starch (Cummins and Johnson, 1986; Kusano et al., 1997). The general fermentation pathway used by the majority of propionic acid-producing bacteria, including the propionibacteria, is the succinate-propionate pathway combined with the central pathway of carbon metabolism for conversion of glucose (sugars), lactic acid, and glycerol.

The pathway for propionic acid synthesis involves the following reactions, as first proposed by Swick and Wood (1960). Pyruvate is converted to oxaloacetate by a transcarboxylation of CO_2 from (S)-methymalonyl-CoA by a biotin-enzyme as a CO_2-carrier. Oxaloacetate is reduced and converted to fumarate by the enzymes malate dehydrogenase and fumarase. The reduction of fumarate to succinate by a membrane-bound fumarate reductase is coupled in anaerobically grown propionibacteria to an electrochemical proton gradient sufficient to synthesize one ATP. The high growth yields of propionibacteria during fermentation are consistent with ATP formation in this reaction (Gottschalk, 1986). Then succinyl-CoA is formed by transfer (catalyzed by a CoA transferase) of coenzyme A from propionyl-CoA. Rearrangement of succinyl-CoA to (R)-methylmalonyl-CoA is a coenzyme B_{12}-dependent reaction catalyzed by methylmalonyl-CoA mutase (Barker, 1972). Finally, the (R)-methylmalonyl-CoA is converted to (S)-methylmalonyl-CoA by a specific racemase. The S-enantiomer is the specific substrate for the transcarboxylase yielding propionyl-CoA. The CoA transferase recycles the coenzyme A back to another succinic acid, resulting in the release of propionic acid into the broth. Thus, with the interlocking of a "one-carbon" cycle and a CoA cycle, pyruvate is reduced to propionate with a minimum expenditure of energy.

Considering the pathways for the three carbon sources displayed in Fig. 22, under ideal conditions, the propionibacteria will produce the ratio of the three major products as well as smaller amounts of minor products such as succinic acid, lactic acid, etc., according to balance restrictions. For example, Fitz showed the usual product balance from the fermentation of lactate: 3 lactic acid = 2 propionic acid + 1 acetic acid + $1CO_2$ + $1H_2O$. Similarly, when glucose is fermented the same ratio of products is usually obtained:

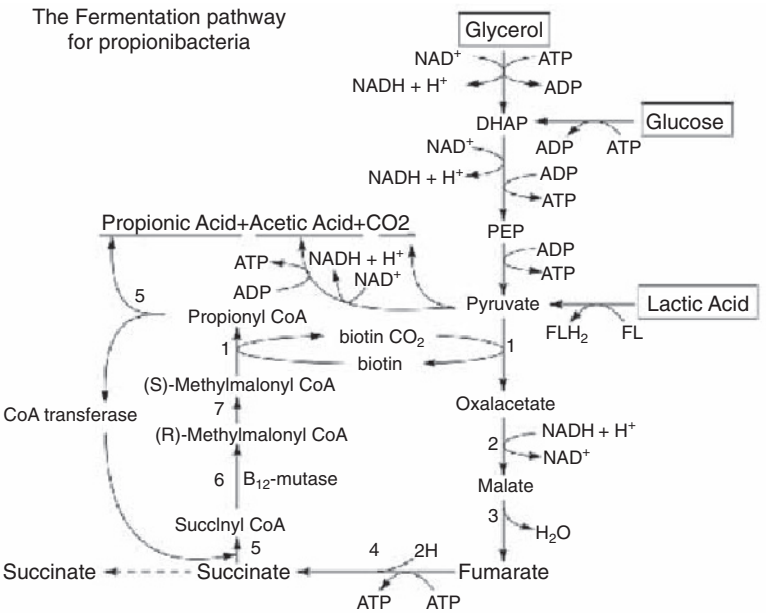

Fig. 22. Fermentation of glucose, glycerol, and lactic acid by propionibacteria utilizing the succinate-propionate pathway. 1, (S)-methylmalonyl-CoA-pyruvate transcarboxylase; 2, malate dehydrogenase; 3, fumarase; 4, fumarate reductase; 5, CoA transferase; 6, (R)-methylmalonyl-CoA mutase; and 7, methylmalonyl-CoA racemase.

$$1.5\ \text{glucose} \leftrightarrow 2\ \text{propionic acid} + 1\ \text{acetic acid} + 1CO_2 + 1H_2O \quad (13)$$

With respect to products produced, the same ratio is expected, and according to the pathways shown in Fig. 22, the major difference is that only 3 ATPs are produced during fermentation of 3 lactic acid molecules, while 6 ATPs are expected when 1.5 glucose molecules are fermented. The maximum theoretical weight yields for sugar from the balanced equation (13) are 54% (w/w) as propionic acid and 22.2% as acetic acid. The yield for the lactic acid fermentation (equation 12) is the same as for sugars. In a recent review, Piveteau (1999) lists a comparison of the relative amounts of propionate and acetate produced from sugars or lactate by 12 strains of propionibacteria grown under 26 different conditions. The molar ratios, P/A, varied between 0.9/1.0 and 3.8/1.0, clustering around 2.0/1.0, as predicted from equations (12) and (13). These ratios are in contrast to that predicted and realized from the fermentation of glycerol to propionic acid. The pathway in Fig. 22 predicts:

$$1\ \text{Glycerol} \leftrightarrow 1\ \text{propionic acid} + 1H_2O \quad (14)$$

In this case, the balance does not demand any formation of CO_2 or acetic acid. Further, 6 ATPs are predicted when 3 glycerol molecules are fermented. It is interesting that Van Niel reported in his thesis (Van Niel, 1928) that seven strains of propionic acid bacteria produced 90–100% propionic acid when grown with glycerol as major carbon source. Research efforts are focusing on production of propionic acid from glycerol; see "Areas of Research and Development" in this Chapter.

Butyric Acid Process Several bacterial species are known to produce significant amounts of butyric acid. They are members of the genera *Clostridium*, *Butyribacterium*, *Butyrivbrio*, *Eubacterium* and *Fusobacterium*. However, it is strains of the genus *Clostridium* (Hippe et al., 1991) that have been used for development of butyric acid or butanol production (Table 24). The productivity of these strains is high and they are relatively stable. In contrast to the *Propionibacterium*, they are strict anaerobes and form heat-resistant endospores. During the 1980s and 1990s, *C. butyricum* was the favored organism for the development of fermentation technologies and fermentations combined with simultaneous product recovery (Vandak et al., 1995a; Vandak et al., 1995b; Vandak et al., 1997). *Clostridium butyricum* can grow well on a large number of sugars including complex mixtures, such as molasses, potato starch, and cheese-whey permeate, producing only butyric acid, acetic acid, CO_2 and H_2 in most fermentations. *Clostridium tyrobutyricum* has been studied, since fermentation of glucose yields mostly butyric acid, CO_2 and H_2 with very little acetic acid or other products. Unfortunately, natural strains of *C. tyrobutyricum* grow and ferment on only a few sugars such as glucose and fructose (Table 24). Both *C. acetobutylicum* and *C. beijerinckii* are important butanol-producing strains, which also synthesize primarily butyric acid under specific growth conditions (Alam et al., 1988; Evans and Wang,

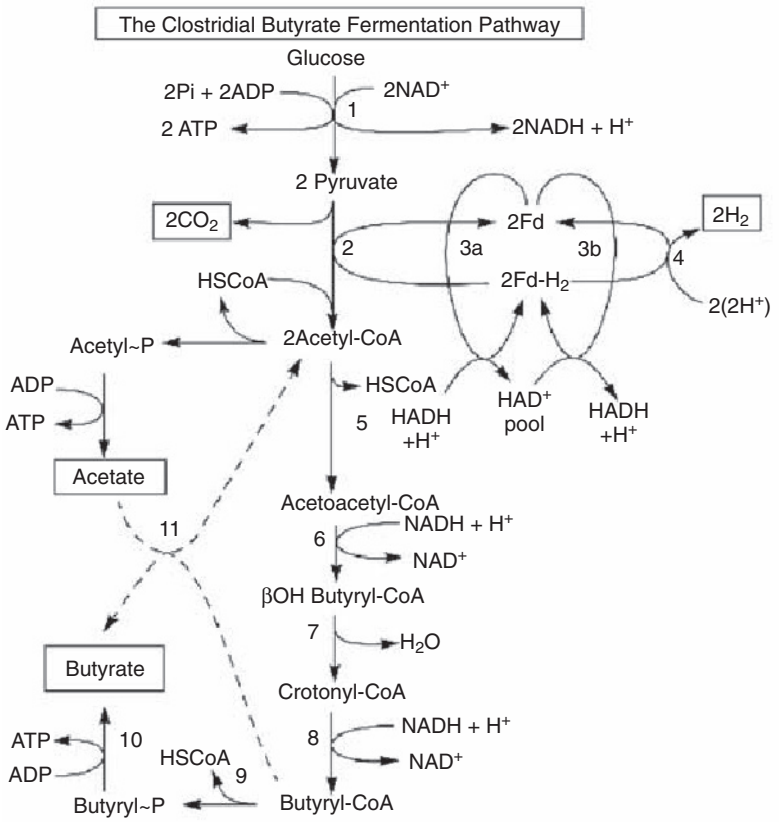

Fig. 23. The pathway of the clostridia for the formation of butyrate and acetate from glucose. 1, Embden-Myerhof-Parnas pathway and hexose phosphotransferase; 2, pyruvate-ferredoxin oxidoreductase; 3a, NAD(P)H-ferredoxin reductase; 3b, ferredoxin-$NAD(P)^+$ reductase; 4, hydrogenase; 5, acetyl CoA-acetyltransferase; 6, β-hydroxylbutyryl CoA dehydrogenase; 7, crotonase; 8, butyryl CoA dehydrogenase; 9, phosphotransbutyrylase; 10, butyrate kinase; and 11, proposed enzyme butyryl CoA-acetate transferase (for recycling of acetate).

1990). A great deal of research effort has been centered on these bacteria, aimed at development of the butanol-acetone process; see "Butanol, Acetone and Isopropanol" in this Volume and Rogers (1999). Because of the extensive knowledge of the regulatory system and the genetics of these organisms, they are excellent candidates for strains to be used in future development of the butyric acid process. Finally, *Butyribacterium methylotrophicum* is listed since it can grow on carbon monoxide (CO) as a sole carbon and energy source and produces primarily butyric acid under specific culture conditions (Worden et al., 1989; Shen et al., 1996). Since CO is produced by gasification of waste biomass, it is potentially a cheap feedstock for butyric acid and acetic acid production.

The pathway for the butyric acid fermentation in the clostridia (and in fact all of the anaerobic bacteria that produce butyric acid) is illustrated in Fig. 23.

It is clearly a branched pathway, yielding both acetic acid and butyric acid in the fermentation. As in the case of the propionic acid fermentation, this is a serious problem for downstream recovery of pure butyric acid. A second problem is that one-third of a carbon source, such as glucose, is removed as CO_2, leaving only two-thirds of the carbon for organic acid production. This loss is a consequence of the conversion of a major portion of the pyruvate produced from sugars to acetyl-CoA, CO_2 and reduced ferredoxin (FdH_2) by the enzyme pyruvate:ferredoxin oxidoreductase, which is ubiquitous in all butyrate-producing bacteria (Fig. 23). Reduced ferredoxin FdH_2 is reoxidized to Fd by hydrogenase which passes the two electrons to hydrogen ions yielding the H_2 gas typically produced by these organisms. The role of the butyrate branch leading from acetyl-CoA is the reoxidation of NADH to NAD^+ so that the pathway from glucose to pyruvate can continue uninterrupted. There is also an additional ATP formed from butyryl-phosphate, so that a net yield of 3ATPs for each butyrate is formed from glucose. In the alternate branch, formation of two acetic acid molecules instead of one butyric acid would not provide for reoxidation of NADH, but a net yield of 4 ATPs results from conversion of glucose to two acetic acids. Since a major characteristic of this fermentation is the simultaneous production of both butyric and acetic acids, the identification of specific control points in the bacterium that will allow selective butyric acid formation is crucial for the eventual development of a commercial process. *Clostridium*

butyricum and *C. tyrobutyricum* are purely acidogenic species and fermentation by them follows this approximate ratio of products:

$$1\ \text{glucose} \leftrightarrow 0.8\ \text{butyrate} + 0.4\ \text{acetate} + 2CO_2 + 2.4H_2 \quad (15)$$

Thauer et al. (1977) have interpreted the production ratio of acetate to butyrate in terms of supplying the energy requirements in the cell. Some work has demonstrated that at high growth rates, acetate production increases, whereas at low rates of growth, butyric acid increases and acetate production either decreases or almost stops (Andel et al., 1985; Michel-Savin et al., 1990a). These observations are consistent with the view that more acetate production results in more ATP synthesis, which would be necessary for rapid growth. Also, for every acetate molecule produced, the excess electrons are removed by the production of extra H_2 gas via hydrogenase, as shown in equation (15) above. The electron traffic is apparently regulated in these cells by allosteric modification of the NADH:ferredoxin oxidoreductase and reduced ferredoxin: NAD^+oxidoreductase (reactions 3a and 3b, Fig. 23). They are sensitive to the CoA/acetyl-CoA ratio and the NAD^+/NADH ratio, respectively (Petitdemange et al., 1976). Measurements of the intracellular concentrations of NADH and acetyl-CoA in *C. butyricum* at various growth rates in a glucose-limited chemostat confirm this view of the control of the butyrate-to-acetate ratio (Abbad-Andaloussi et al., 1996). In all cases, the amount of acetic acid production remains lower than that of butyric acid. This is probably due to the unfavorable potential difference between the Fd/FdH_2 couple and the NAD^+/NADH couple slowing transfer of electrons from NADH to Fd, which is essential when acetate is produced (reaction 3a, Fig. 23).

It was observed that fed-batch supply of glucose increased the productivity for butyrate by *C. tyrobutylicum*. The ratio of butyrate to acetate (selectivity) was influenced by growth rate. At high growth rates, both acetate and butyrate were produced, whereas in glucose-limited fed-batch cultures, acetate (which accumulated at high growth rates) was recycled and converted to butyrate (Michel-Savin et al., 1990a). This recycling process (probably involving a CoA transferase; Fig. 23 [dashed lines]) provides no direct energetic advantage for re-utilization of acetate. The purpose of recycling in the organism may be to detoxify the medium by reducing total hydrogen ion concentration, which occurs when one butyrate substitutes for two acetates. In nonlimited glucose fed-batch cultures, *C. tyrobutyricum* produced a butyrate concentration of 42.5 g/liter with a selectivity of 0.90 and a yield of 36.6 g/100 gm of glucose. (Michel-Savin et al., 1990b). This unusually high selectivity may be related to recycling of acetate by these bacteria.

Commercial Applications

Major Uses of Propionic and Butyric Acids

These organic acids serve important roles in a great variety of products and industrial processes. Propionic acid and its sodium, potassium and calcium salts are excellent antifungicides. They are used extensively in the food industry to suppress mold growth in breads, meats, fruits, and on the surfaces of cheeses and also as preservatives for grains, silage and tobacco during storage and transport. Dipping and spraying food containers, caps, and wrappers with solutions containing propionate salts are used for preservation. Solutions of propionic acid mixed with acetic and lactic acids have been shown to be effective in growth inhibition of *Listeria monocytogenes* in foods. The Food and Drug Administration (FDA) considers the sodium, potassium and calcium propionate salts as safe additives (GRAS), since they are found normally in a number of foods and are metabolized easily by all mammals. Propionic acid is used in the production of cellulose-based plastics (such as cellulose acetate propionate), which are used in textiles, filters, reverse osmosis membranes, sheeting, film products, lacquers, and molding plastics. Propionic acid esters and other derivatives are used as anti-arthritic and antibiotic drug preparations, as perfumes and flavors (e.g., citronellyl propionate and geranyl propionate), as plasticizers (e.g., phenyl propionate and glycerol tripropionate), and as specialized solvents.

A major use of butyric acid is in the manufacture of cellulose acetate butyrate plastics. They are used as textile fibers and in situations where resistance to heat and sunlight is essential. Calcium butyrate has been used in some leather tanning processes. Butyric acid esters are added as flavors in some soft drinks and chewing gums. Various derivatives of butyric acid are used as vasoconstrictor drugs, in anesthetics, and as antioxidants (Playne, 1985).

Market Size and Prices

The main producers of propionic acid in the United States are Eastman, Hoechst Celanese, and Union Carbide (Sauer, 1991). Eastman and Hoechst Celanese also manufacture butyric acid. The estimates of propionic acid production are 120×10^6 lbs/per yr in the United States and 80×10^6 lbs/per yr in Western Europe (Boyaval and Corre, 1995). The price for propionic acid is currently \$1.01–1.08 per kgm (Anonymous, 2001a). The production of butyric acid in the United States was

about 48×10^6 lbs/yr in 1991, and no estimate of world production is available (Sauer, 1991). The price for butyric acid is not available, but the price for synthetic butyraldehyde is \$1.19–1.28/per kgm (Anonymous, 2001b). Normally synthetic butyric acid is produced by air oxidation of butyraldehyde (Billig and Bryant, 1991). Thus, the price may be close to the price quoted for butyric acid, \$1.50/per kgm, in May 1982 (Playne, 1985).

Processes for Production of Propionic and Butyric Acids Chemical processes dominate the production of short chain organic acids. The primary route of synthesis employs the "Oxo" process (Billig and Bryant, 1991). Propionic acid is made by oxo synthesis of propionaldehyde from ethylene, CO and H_2 with a rhodium catalyst. Liquid-phase oxidation of the aldehyde yields propionic acid. Butyric acid is made by air oxidation of butyraldehyde, which is synthesized by the oxo process from propylene, CO and H_2. The triphenylphosphine-modified rhodium oxo process, termed the "LP Oxo" process, is the industry standard for the hydroformylation of ethylene and propylene (Billig and Bryant, 1991). Also pure propionic acid can be obtained from propionitrile or by oxidation of propane gas.

Three changing economic forces have combined to revive a search for alternative production routes for propionic and butyric acids. The decreasing supply of world crude oil reserves will eventually increase the cost of substrates for chemical synthesis. The increasing amounts of food industry by-products and unused agricultural biomass can serve as substrates for microbial conversion. The increasing consumer demand for organic natural products in food additives, pharmaceutical products, and preservatives has produced a favorable business climate for the emergence of the microbial fermentation route for production of these organic acids. For example, organic acids produced by fermentation are favored over chemically synthesized acids when the fermentation product can be labeled a "natural preservative" for foods or feeds. Several products produced by *Propionibacterium* fermentation of milk or whey after concentration and drying have been marketed as preservatives. These include: Upgrade, made by Microlife Techniques; CAPARVE, produced by PTX Food Corp.; and Microgard, made by Wesman Foods, Inc. (Lyon and Glatz, 1995). The United States Food and Drug Administration approved the use of Microgard in cottage cheese to prolong its shelf life and an estimated 30% of the cottage cheese made in the United States contains this preservative (Weber and Broich, 1986).

Significant improvements in the yield, productivity, and selectivity of the fermentations producing propionic acid or butyric acid would be required if these methods were to become competitive with chemical synthesis methods used for industrial applications of these acids as commodity chemicals.

Research and Development

Improvement of Bacterial Strains Modern genetic methods are being applied to the strains of propionibacteria that are listed in Table 24. Lyon and Glatz (1995) have reviewed the plasmid biology, the application of DNA transfer methods, and mutagenesis and selection techniques applied to these organisms. The cryptic plasmid pRG01 is present in a number of strains of *P. acidipropionici*, *P. freudenreichii*, *P. jensenii* and *P. thoenii*. Kiatpapan et al. (2000) sequenced this plasmid and constructed a shuttle vector, pPK705, using parts of pRG01, the *Escherichia coli* plasmid pUC18, and the hygromycin B-resistant gene as a drug marker. The pPK705 has been transferred into *P. freudenreichii* strains by electroporation at an efficiency of 8×10^6 CFU/microgram of DNA. This and other similar vectors will facilitate genetic analysis of strains of propionibacteria and allow transfer of genes for producing new industrial strains.

The solvent-forming clostridia have been the focus of a great deal of research effort over the past twenty years because of the potential to apply their ability to convert biomass into the important commodity chemicals butanol, acetone, and isopropanol. The metabolic pathways for solvent and acid production as well as the basic mechanisms of regulation of these pathways have been determined for *C. acetobutylicum* and related clostridia (see reviews by Rogers and Gottschalk, 1993, and Rogers, 1999). Genetic systems for gene manipulation of the clostridia have been developed including ones involving mutagenesis (Jones, 1993), conjugative gene transfer (Young, 1993), clostridial cloning vectors (Minton et al., 1993), and transformation and electroporative transformation (Reysset and Sebald, 1993). With these techniques, the cloning, structure and expression of acid and solvent pathway genes of *Clostridium acetobutylicum* have been examined in some detail (Papoutsakis and Bennett, 1993; Mermelstein et al., 1994; Dürre et al., 1995). The obvious application of these basic studies is to develop clostridial strains that will be useful in processes for commercial solvent production (Papoutsakis and Bennett, 1999). However, since these solventogenic organisms also produce butyric acid, strains can be developed for production of this acid as well (Alam et al., 1988; Evans and Wang, 1990). Fur-

thermore, the mechanisms of regulation of the fermentation pathways in the solvent-forming clostridia have been fairly well defined (Girbal et al., 1995; Rogers, 1999). Using these studies as a model, regulation of carbon and electron flow in *C. butyricum* is being examined under conditions for optimal production of butyric acid or of 1,3-propanediol (Saint-Amans et al., 2001).

The complete genome sequence of the bacterium *C. acetobutylicum* ATCC 824 was determined including a 192-kb megaplasmid that contains the majority of the genes necessary for solvent production (Nolling et al., 2001). With this information, it is now possible to effectively develop industrial strains that can be utilized for either butanol or butyric acid production from a variety of biomass sources.

A major barrier blocking commercialization of bacterial fermentation for production of propionic or butyric acid is that the available strains of propionibacteria and clostridia have low tolerance to organic acids and sensitivity to acid stress in general. The acid tolerance response (ATR) of *P. freudenreichii* was studied (Jan et al., 2000). Survival at pH 2 was conferred by preexposure of the bacteria in media at pH 4–5, so that adaptation was established within 3–10 min. Later, it was shown that new "stress" proteins are synthesized rapidly during adaptation. These proteins were identified as chaparonins GroEL and GroES. Also, specific DNA synthesis and repair enzymes were upregulated (Jan et al., 2001). However, in what way is sensitivity to accumulated organic acids related to production capacity? Rehberger and Glatz (1998) showed that *P. jensenii* and *P. thoenii* survive at a lower pH than *P. acidipropionici*, yet *P. acidipropionici* produces the highest yield (g/liter) of propionic and acetic acids during fermentation. The newly described propionibacterium, *P. cyclohexanicum* (Kusano et al., 1997), grows and ferments at a low pH optimum of pH 5.5–6.5, while the pH optimum of *P. freudenreichii* and other dairy propionibacteria is 6.5–7.0. *Propionibacterium cyclohexanicum*, strain TA-12, *w*-cyclohexyl undecanoic acid is the major cellular fatty acid (52.7% of the total fatty acids). Thus there appears to be a number of factors governing the tolerance of propionibacteria to organic acids as well as their sensitivity to acids. The low tolerance of the clostridia to organic acids and to solvents has been a major factor preventing their use in commercial production of acetic acid and of solvents such as butanol (see "Acetic Acid" in Organic Acid and Solvent Production, Part I in this Volume and "Butanol, Acetone and Isopropanol" in this Volume). Although numerous mutants and so-called "butanol tolerant strains" of *C. acetobutylicum* and *C. beijerinckii* have been selected, this research has had only a limited impact on our understanding of tolerance or on producing industrially useful strains (Rogers, 1999). On the other hand, important research has emerged on the basic elements of the general stress response and of the σ factors and the phosphorelay pathway essential for the initiation of endosporulation in *Clostridium* (Bahl et al., 1995; Sauer et al., 1995; Wilkinson et al., 1995). It was found that the transcription factor SpOA in *C. beijerinckii* not only controls entry into the sporulation cycle but also upregulates expression of genes for the solvent pathways and downregulates expression of the genes for organic acid production (Brown et al., 1994). As organic acid concentration increases and the pH drops, *C. acetobutylicum* rapidly accumulates a set of stress proteins, the chaperonins, required for proper folding of newly synthesized proteins in the bacterium; in addition, a series of ATP-dependent proteases (Lon, ClpP, and ClpX) is induced (Bahl et al., 1995). This research may be applied to the future development of organic acid-tolerant strains of the clostridia useful for commercial fermentations.

New Process Technologies: Propionic Acid Production Comparative fermentations with a variety of substrates confirmed the earlier finding reported by Van Niel (1928) that numerous species of the propionibacteria produce propionic acid selectively with very little acetic acid when fermenting glycerol (Boyaval et al., 1994; Barbirato et al., 1997; Himmi et al., 2000). Propionic acid/acetic acid molar ratios for *P. acidipropionici* and *P. freudenreichii* subs *P. shermanii* were 5.7 and 3.8, respectively, with glycerol, and 1.7 and 1.3, respectively, with glucose (Himmi et al., 2000). Barbirato et al. (1997) obtained an even better propionic acid to acetic acid ratio of 37 with *P. acidipropionici*. Since selective acid production simplifies downstream processing for recovery of propionic acid, the choice of glycerol for this process is suggested. The high proportion of acetic acid produced with glucose or lactic acid as substrate explains the lower yields of propionic acid compared to that reached when fermenting glycerol, as recorded in Table 25. Inexpensive industrial grades of glycerol are readily available as by-products of processing of natural fats and oils during production of fatty acids.

The two major weaknesses of the fermentation process for propionic acid production are the low final product concentration and the extremely low productivity due to the sensitivity of the bacterial cells to organic acids and their slow fermentation and growth rates. Two developments in fermentation technology that improve the process are the high cell-density reactor and improved ultrafiltration membranes

Table 25. Experimental fermentation processes for production of propionic acid.

for recovery of the product. The Laboratory of Dairy Technology Research of the Institut National de la Recherche (INRA) in Rennes, France, is investigating the application of these techniques for improved propionic acid production (Boyaval and Corre, 1995). Colomban et al. (1993) demonstrated the production of propionic acid from whey permeate by *P. acidipropionici* at high cell density combined with sequential cell recycling and ultrafiltration. Figure 24 is a diagram of the process employing a 5-m^3 industrial pilot plant bioreactor.

Initially the fermentation was run batchwise for about 100 h until the lactose concentration reached less than 5 g·liter^{-1} in the bioreactor. The culture was then pumped through an ultrafiltration (UF) module to produce a permeate fraction (fermented permeate) that contained propionic and acetic acids plus unfermented lactose (Fig. 24). The permeate was eventually concentrated to 36% (w/w) propionic acid and 11% acetic acid. The retentate from the UF module containing the cell biomass and about 25% of the culture volume was recycled back into the bioreactor together with a stream of fresh medium sufficient to replace the culture volume. Figure 25 presents the results of a typical run in the 5-m^3 pilot plant, showing the sequential cycles of usually 70 to 40 h.

In a typical pilot plant run, the biomass was maintained at about 40 g dry wt liter^{-1} by partial cell bleeding (B) at the times shown during the 15 cycles for a total time of 950 h (Fig. 25a). At this biomass density, the lactose is exhausted regularly after 50–70 h, leading to a new cycle of ultrafiltration and feeding (Fig. 25b). During this high cell density fermentation, the propionic acid and acetic acid concentrations reached were normally 35 and 9 g·liter^{-1}, respectively (Fig. 25c), which are 3 times greater than those observed in batch cultures (Table 25). The productivity of propionic acid was normalized at about 0.65 g·liter^{-1} h^{-1}, which is 3.8-fold better than in batch cultures (Table 25). Experimental fermentations by *P. acidipropionici* using sucrose or blackstrap molasses (cane sugar) as substrate were studied employing the same high cell density and continuous recycle process as described above (Table 25). In a 1.5-liter reactor, at a cell density of 125 g dry wt liter^{-1}, sucrose was converted to propionic acid at the high productivity of 3.0–8.0 g·liter^{-1}h^{-1} and at a concentration of 30–16.2 g·liter^{-1}, dependent on the dilution rate (Quesada-Chanto, 1994a). At a cell density of 75 g dry wt liter^{-1}, blackstrap molasses was fermented to propionic acid at a productivity of 4.4 g·liter^{-1}h^{-1}, and at a concentration of 17.7 g·liter^{-1}. Stable production was maintained at a constant product concentration "over many weeks" (Quesada-Chanto, 1994a). The most encouraging report was that of the experimental fermentation of glycerol to propionic acid by *P. thoenii* NCDO 1082 by the continuous high cell density cell recycle process (Boyaval et al., 1994). During stable operation with a cell density of only 20 g dry wt liter^{-1}, a propionic acid concentration of 10 g·liter^{-1} and a productivity of 1.0 g·liter^{-1}h^{-1} were maintained, while the acetic acid concentration was only 0.1 g·liter^{-1}. During the continuous ultrafiltration, the only nutrient added to the reactor was glycerol. At 140 h, a short 10-h regeneration period with yeast extract was inserted. The application of the high cell density reactor with ultrafiltration to the fermentation of glycerol as a substrate appears very promising for future development of a commercial propionic acid production process (Boyaval and Corre, 1995).

Experimental fermentation processes employing cell immobilization have been applied to propionic acid production by the propionibacteria. The objectives are to create a stable high-density cell module that will produce a high concentration of propionic acid in a relatively short time. *Propionibacterium acidipropionici* was immobilized in Ca alginate beads at about 10^{10} cells/g of

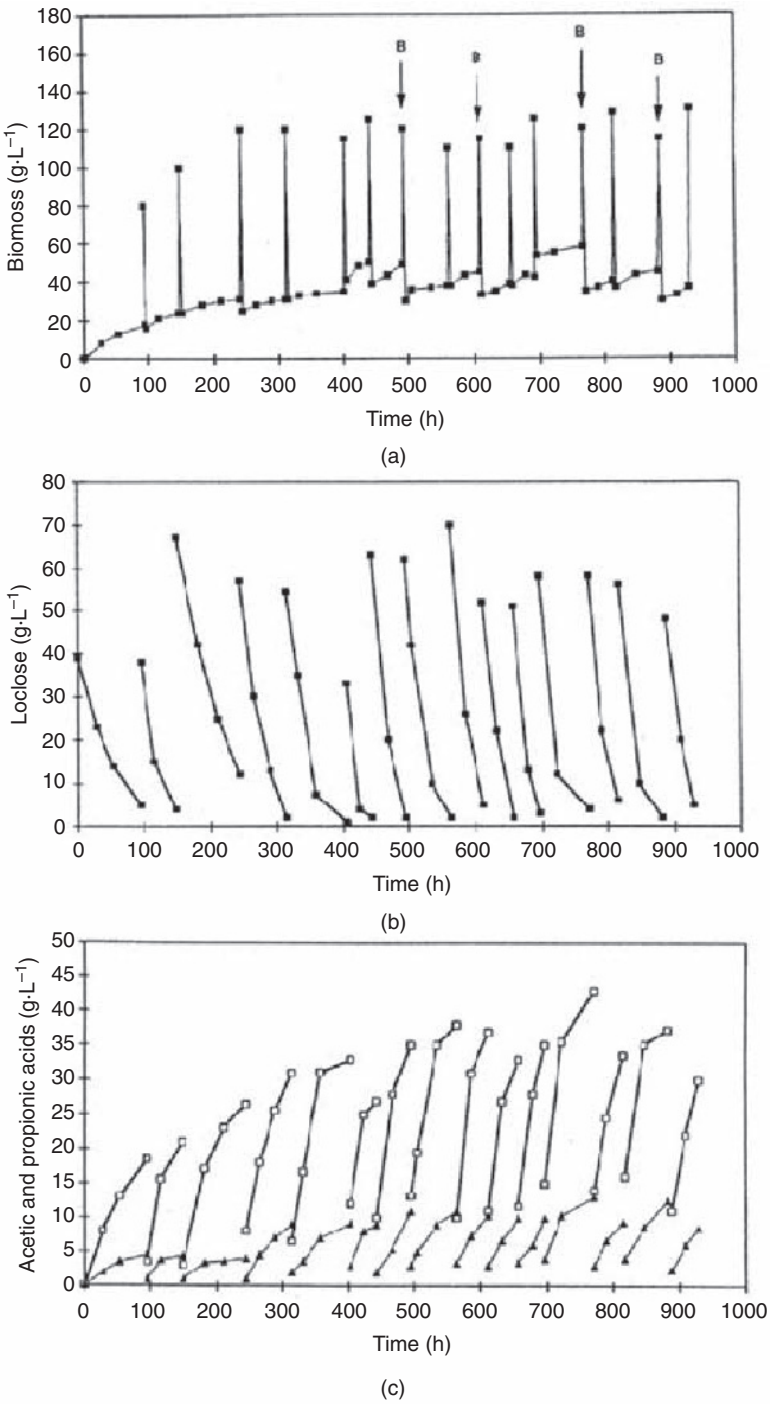

Fig. 25. (a) Biomass evolution during a typical run in a 5-m^3 bioreactor. Each peak results from the concentration of the cells by ultrafiltration. At the times indicated by the arrows, a cell bleed, B, was done. (b) Lactose concentration during the same run. (c) Propionic acid ("box") and acetic acid ("triangle") concentrations in the same run. From Colomban et al. (1993), with permission.

beads. Fed-batch fermentations with 80 g of beads in 290 ml medium were incubated 250 h with either glucose or corn steep liquor as substrate (Paik and Glatz, 1994). Unusually high concentrations of propionic acid were obtained: 45.6 g·liter^{-1} with corn steep liquor and 57 g·liter^{-1} with glucose (Table 25). Using Ca alginate immobilized *P. thoenii* P20 at 2×10^{11} cells per g of beads, Rickert et al. (1998) demonstrated complete conversion of high concentrations of glucose (65–115 g·liter^{-1}) to propionic acid during a short 12-h fermentation time. For example, 75 g·liter^{-1} glucose yielded 34 g·liter^{-1} of propionic acid (Table 25). A second type of immobilization technique, which appears promising, is the fibrous bed bioreactor (Lewis and Yang, 1992), which consists of a piece of cotton towel (15 × 45 cm) rolled up with a stainless steel mesh and placed in a 5

×15 cm glass column. *Propionibacterum acidipropionici* is added to the reactor with 290 ml of growth medium and incubated for 2–3 days until about 40–60 g dry wt liter^{-1} of immobilized cells is reached. Cells form a biofilm on the fiber surfaces and are entrapped in the fibrous matrix. Reactor performance was studied during continuous operation at a variety of retention times to determine the best conditions for converting the lactate or lactose in whey permeate to propionic and acetic acids (Lewis and Yang, 1992; Yang et al., 1994). These reactors are capable of complete conversion of high concentrations of whey permeate-lactose to 20–22 g·liter^{-1} propionic acid at a productivity of 0.38 g·liter^{-1} h^{-1} for 4–6 months of stable operation (Table 25). Co-immobilization of *P. acidipropionici* and *S. lactis* did not improve the productivity of the fermentation (Yang et al., 1994; see Table 25). The nature of this immobilization system allows constant cell renewal, and consequently, the bioreactor could operate continuously for 6 months without clogging, degeneration or contamination.

Extractive fermentation is a relatively new technology that combines the fermentation process with product separation from beer. This process has been applied to commercial production of both lactic acid and ethanol, and experimental results suggest application to the propionic acid process will overcome some of the barriers indicated above. Solichien et al. (1995) examined a series of microporous membranes and polymer films for performance in membrane-based extraction of propionic and acetic acids with a range of organic solvents and acid-complexing carriers. The hollow-fiber membrane extractors, Celgard X20-400 or X-30, were found to be most satisfactory for laboratory-scale fermentations. Each extractor consisted of 200–800 hydrophobic, microporous, polypropylene hollow fibers jacketed in an extractor shell such that the extraction solvent could flow through the hollow fibers while the fermentation broth with the cells circulated on the shell side of the extractor. Solvent leakage from the membrane pores was prevented by applying back pressure to the shell side of the extractor. The hydrophobic structure of the fibers prevented the broth from entering the solvent phase. This set-up allowed the extractive fermentation to operate continuously. The solvent selected for extractive fermentation of propionic acid was 40% Alamine 304-1 (trilaurylamine) in oleyl alcohol because it was nontoxic, provided good partitioning of propionic acid, and allowed free recovery of the acid by distillation (Gu et al., 1998; Gu et al., 1999). Jin and Yang (1998) used a similar extraction solvent: 4–15% Adogen 283 (a secondary amine, ditridecylamine; Sherex Chemical Co., Dublin, OH) in oleyl alcohol. Jin and Yang (1998) demonstrated a fed-batch extractive fermentation of lactose by *P. acidipropionici* for propionic acid production. Lactose was added up to 50 g·liter^{-1} every 20 h, while the culture was cycled through the extractor module for 120 h. The extracted propionic acid reached 75 g·liter^{-1}, at a productivity of 0.98 g·liter^{-1}h^{-1} and a yield of 0.66 g/g of lactose (Table 25). This was the first report of a successful demonstration of extractive fermentation of propionic acid. Further, the fed batch extractive fermentation produced a propionic to acetic acid ratio (P/A ratio) of 9.8, probably owing to the selectivity of the extraction step for propionic acid combined with the low pH (5.3) of the fermentation (Jin and Yang, 1998). Production of propionic acid by fermentation of glucose by immobilized cells of *P. thoenii* P20 was combined with concurrent liquid extraction employing a hollow-fiber membrane extractor (Gu et al., 1999). Cells immobilized in Ca alginate beads were suspended in 300 ml broth with glucose maintained at 75 g·liter^{-1} in a fed-batch operation. The culture was continuously cycled through the shell side of the extractor with concurrent circulation of the organic extraction solvent through the tube side for more than 200 h. A total of 71 g·liter^{-1} of propionic acid and 16 g·liter^{-1} of acetic acid was produced with a propionic acid productivity varying between 0.4 and 0.6 g·liter^{-1}h^{-1} during the fermentation (Table 25). Gu et al. (1999) also noted a partial selectivity of the extractive fermentation for propionic acid with a P/A ratio of 4.4.

New Process Technologies: Butyric Acid Production The development of processes for the production of butyric acid by fermentation has centered on two species of *Clostridium*, *C. butyricum* and *C. tyrobutyricum*. Experiments employing *C. tyrobutyricum* seem the most promising primarily because strains of this bacterium are highly selective for butyric acid over acetic acid, both of which are produced simultaneously during fermentation of carbohydrates. For example, in batch culture *C. butyricum* produces a butyric acid to acetic acid weight ratio (B/A) of 2.0–2.5, whereas the B/A for *C. tyrobutyricum* is 4.0–6.0. Thus, compared to *C. butyricum*, *C. tyrobutyricum* produces higher yields of butyrate per g of carbohydrate and higher product concentrations (see Table 26).

The most successful process reported for fermentation of glucose by *C. tyrobutyricum* was a continuous fermentation with cell recycle through a microfiltration membrane module for about 20 days (Michel-Savin, 1990c). With glucose fed to maintain 65 g·liter^{-1} and at a dilution rate D = 0.32 h^{-1}, an excellent butyric acid concentration of 29.7 g·liter^{-1} and a remarkable productivity of 9.5 g·liter^{-1}h^{-1} were obtained and

Table 26. Experimental fermentation processes for production of butyric acid.

Organism	Process	Substrate	Time of operation (h)	Product concentration ($g \cdot liter^{-1}$)	Product productivity ($g \cdot liter^{-1}\ h^{-1}$)	Yield for major product (g/g)	References

remained constant for more than 15 days (see Table 26). Importantly, the selectivity for butyric acid production improved to a B/A ratio of 16, or 0.94 g of butyric acid per g of total acid produced. Fayolle et al. (1990) demonstrated fed-batch fermentation of wheat flour hydrolysate (glucose) or corn steep liquor by *C. tyrobutyricum* compared to batch fermentation (see Table 26). Again productivity was greatly improved over batch fermentation and selectivity for butyric acid reported was a B/A ratio of 10–30. The reason for the high selectivity for butyric acid observed for the *C. tyrobutyricum* fermentation may be related to the reutilization of acetate discovered by Michel-Savin et al. (1990a); see "Scientific Background" in this Chapter. In a very preliminary investigation, butyric acid production by *C. butyricum* was demonstrated with simultaneous extraction or pertraction of butyric acid using as an organic phase, Hostarex A327 (*n*-octyl[*n*-decyl]amine; 20% w/w in oleylalcohol; Zigova et al., 1999). They reported an increase in butyric acid concentration compared to the control batch fermentation with either integrated extraction or pertraction during the fermentation (see Table 26).

Final recovery and purification of organic acids from the fermentation broth is the most energy-intensive and costly stage in any bulk manufacturing process. Experiments using the modern solvents for simultaneous extraction during the fermentations of propionic or butyric acid resulted in rather low concentrations of organic acids (50–70 g·liter^{-1}), as shown in Tables 25 and 26. Thus further separation steps would be necessary. Playne (1985) reviewed nine different approaches to the problem of separation of organic acids available at that time, with no real solution. Boyaval et al. (1993) demonstrated the application of electrodialysis with bipolar membranes and electro-electrodialysis for concentration of propionic acid up to 130 g·liter^{-1} from fermentation broth with 40 g·liter^{-1}. Boyaval and Corre (1995) propose that this technique considerably improves the recovery and purification step, but it had not been evaluated for an industrial process at that time.

Propionic and Butyric Acid Production by Fermentation

Today, chemical synthesis of propionic and butyric acids dominates the production of these and most other organic acids used in industry. However, since these organic acids are added to products for human consumption by both the food and pharmaceutical industries, consumer demand for "natural sources" of these acids is substantial. Thus fermentation can play a role in supplying these markets. The prospect of future challenge of the dominant chemical methods by fermentation technology will depend upon decreased availability and increasing cost of ethylene, propylene, or other chemical precursors.

Developments of the propionic acid fermentation catalyzed by propionibacteria are outlined above (see "Areas of Research and Development" in this Chapter). First, selectivity for propionic acid was improved to better than 95% of total organic acids by using glycerol as a carbon source. Low-cost industrial-grade glycerol is available and is used in production of 1,3-propanediol by *C. butyricum* (Papanikolaou, 2000). Secondly, the research laboratories at INRA, France, combined new production technologies to demonstrate an economical production of propionic acid from cheese whey with propionibacteria (Colomban et al., 1993). Downstream processing with electrodialysis membrane modules facilitated recovery and purification from the fermentation medium (Boyaval et al., 1993). A second approach is the simultaneous extractive fermentation, using a hollow fiber membrane module and an amine extractant to keep the organic acid concentration in the growth medium low and to recover the propionic acid in a separate solution (Jin and Yang, 1998; Gu et al., 1999). Although this experimental work appears promising, these new technologies have yet to reach a commercial production stage.

Work on fermentation processes yielding butyric acid is not as advanced as that for propionic acid. *Clostridium tyrobutyricum* was found superior to *C. butyricum* in that *C. tyrobutyricum* is more selective, yielding 90% of total organic acids as butyric acid. Some preliminary studies gave high productivities and product concentrations (Fayolle et al., 1990; Michel-Savin et al., 1990c). Unfortunately, this clostridium will grow and ferment only glucose and fructose as carbon sources. However, there is every reason to be optimistic about the future of this fermentation for two reasons. First, a great deal of genetic and physiologic work on the closely related butanol-producing strains such as *C. acetobutylicum* has been done (see "Areas of Research and Development" in this Chapter). Thus, the panel of carbon sources available to *C. tyrobutyricum* can be changed easily. Secondly, fermentation processes for the production of 1,3-propanediol have been greatly developed (see "1,3- and 1,2-propanediols" in Butanol, Acetone, and Isopropanol in this Volume). The methods developed for production of 1,3-propanediol, employing strains of *C. butyricum*, will certainly be applicable to developing processes for butyric acid production (Papanikolaou et al., 2000).

Section 7: Ethanol

Introduction

Among alcohols, ethanol is the best known because it is the intoxicating ingredient of alcoholic beverages, which mankind has consumed since ancient times. The use of fermentation to convert starchy or sugary material into ethanol-containing liquid is thus among the earliest practices of applied microbiology. It has been suggested that alcoholic fermentation played a role in making water potable where other methods for the treatment of water were not available. The commercial value of the alcoholic beverages alone would rank ethanolic fermentation (for the production of wine and spirits) as one of the most important applications of microbial activities.

Despite the long practice of ethanolic fermentation by mankind, the active agent for this process was not known until the mid-nineteenth century. In the 1830s, after the successful synthesis of urea from inorganic materials, chemists debated intensely the subject of whether ethanol is a product of biological action. That yeast is the agent responsible for ethanol production in sugary liquid was eventually established by Louis Pasteur (1822–1895). Since the discovery of anaerobic bacteria by Pasteur, the number of known mesophilic ethanol-producing bacteria has been rising continuously. During the past 20 years, many saccharolytic thermophilic anaerobic bacteria have been isolated, and some of them can produce ethanol from hexoses and pentoses with a high yield (see Ethanol-producing Microorganisms in this Chapter).

Among ethanol-producing bacteria, *Zymomonas mobilis* is unusual in having an ethanol productivity higher than that of the yeast *Saccharomyces cerevisiae* and an ethanol tolerance comparable to that of the yeast (Buchholz et al., 1987). However, the substrate range of *Z. mobilis* is as limited as the yeast's. The high ethanol productivity of *Z. mobilis* is partly attributable to the high levels of pyruvate decarboxylase and alcohol dehydrogenase in *Z. mobilis*. This property has been utilized in the engineering (see Metabolic Engineering in this Chapter) of *Z. mobilis*, *Escherichia coli*, *Klebsiella oxytoca*, and other bacteria to create strains that can produce high yields of ethanol from all sugars that are monomers of hemicellulose and cellulose.

Ethanol has many uses. Besides being the key ingredient of alcoholic beverages, ethanol is traditionally used as an industrial chemical and as a component of pharmaceuticals and other healthcare and consumer products. As a chemical, ethanol can be produced either through chemical synthesis or by fermentation. Owing to changes in the availability and cost of the raw materials and the needs of the market, the major route for ethanol production has changed back and forth between fermentation and chemical synthesis since the 1930s. In the United States, synthetic ethanol began to dominate the market in the 1950s, and the trend continued until the early 1980s when fermentation again became the major route (see Commercial Production in this Chapter). At present, the United States production of fermentation ethanol at over 1.6 billion gallons a year has greatly exceeded previous levels achieved by the synthetic route. In Brazil, over 3.6 billion gallons of fermentation ethanol were produced during the 1997–1998 harvest (Zanin et al., 2000). This dramatic increase in ethanol production is because of the use of ethanol as an automobile fuel, which results from the jump in oil prices in the early 1970s and from the uncertainty of an unobstructed supply of crude oil. Ethanol has been used as a fuel for various purposes, and its use as an automobile fuel also has a long history (Jackson and Moyer, 1991). However, the extensive use of ethanol (as an automobile fuel) did not start until the implementation of the Brazilian National Alcohol Program (the Pro-Alcohol Program) in 1975 (Jackson and Moyer, 1991; Zanin et al., 2000).

Fermentation ethanol has traditionally been produced by using yeasts with sugars from corn, sugar beet, and sugarcane juice as the raw material. During the past 20 years, great advances have been made in the development of a bacterial process for the production of ethanol from lignocellulosic biomass (Sheehan, 2000). A commercial plant is under construction to use an engineered strain of *E. coli* to produce 20 million gallons of ethanol per year from sugarcane residues and rice hull (see Commercial Production). Further improvement of bacteria for the commercial production of ethanol from lignocellulosic materials should increase the proportion of ethanol produced by bacteria.

Fermentation ethanol that is produced from the lignocellulosic biomass has been identified as bioethanol, to distinguish it from ethanol produced from feed grains. Lignocellulosic materials represent the bulk of plant biomass and are a desirable source of energy because they are less expensive to produce than grains and are not used for food or feed. When taking into consideration the use of fuel through all stages of production, producing ethanol from lignocellulosic biomass requires much less fossil fuel than producing ethanol from feed grains. Up to 7 gallons of oil may be needed to produce 8 gallons of ethanol from feed grains, whereas only about one gallon of oil is needed to produce 7 gallons of ethanol from cellulosic biomass (Lugar and Woolsey, 1999). Comprehensive reviews on the

technology, economics, and policy issues of bioethanol production by bacterial fermentation are available (Himmel et al., 1997; Sheehan, 2000; Wyman, 2001).

Scientific Background

PHYSICOCHEMICAL PROPERTIES Ethanol or ethyl alcohol (CH_3CH_2OH, mol. wt. 46.07) is a colorless, flammable liquid. Anhydrous ethanol has a boiling point of 78.5°C and is hygroscopic. It has a specific gravity of 0.7893 at 20°C (relative to water at 4°C), or a weight of 6.578 lb (20°C) per gallon. Ethanol and water form an azeotrope, which has an ethanol concentration of 95.57% (by weight), 94.9% (by volume), or 92.3% (by weight of ethanol at 15.56°C). The azeotropic mixture has a boiling point of 78.15°C. Therefore, distillation of a fermentation broth yields the "95%" ethanol, which must be further processed to yield the anhydrous ethanol. The 95% ethanol can be used directly as a fuel for automobiles equipped with a specially designed engine (Jackson and Moyer, 1991; Zanin et al., 2000). However, anhydrous ethanol must be used when it is blended with gasoline.

After 1975, a major use for ethanol was as a fuel or fuel additive for automobiles (see Commercial Applications in this Chapter). Ethanol has a number of desirable properties when used as a fuel in an internal combustion engine (Winston, 1981; Jackson and Moyer, 1991). These desirable properties include: 1) High heat of combustion relative to volume. Ethanol has a heating value of 11,500–12,800 British thermal units (Btu)/lb, which is about two-thirds that of gasoline (18,900–20,260 Btu/lb). 2) High rate of flame propagation. The rate of flame propagation of ethanol is roughly comparable to that of gasoline. A high rate of propagation is important because the fuel in the combustion chamber must burn completely during the combustion stroke or it is blown out in the exhaust stroke without doing useful work. 3) High octane rating. The octane rating measures the relative tendency of fuels to pre-ignite, which is an undesirable property, when a mixture of fuel and air is compressed on the second stroke in an automobile (Otto cycle) engine. *Iso*-octane was chosen as a standard and assigned an octane rating of 100. Fuels that burn less readily than *iso*-octane are assigned octane ratings higher than 100. Ethanol has a Research Octane Number (RON) of 106 and a Motor Octane Number (MON) of 92. In comparison, "straight run" gasolines have RON and MON ranging as low as 80s and 60s, respectively. Gasoline sold as an automobile fuel in the United States generally has an octane rating between 87 and 93, which is based on (RON + MON)/2. Ethanol is therefore an effective octane-rating enhancer for gasoline and is a substitute for MTBE (methyl *tert*-butyl ether), which replaces the lead-based octane-rating enhancer in gasoline; however, use of MTBE in the United States is now being phased out because of its threat to the environment (Houge, 2000).

Ethanol has an oxygen content of 35% (on a weight basis) and is hence also described as an oxygenate when used as a fuel additive. When blended with gasoline, ethanol can improve the combustion of fuel in the automobile engine to reduce the amount of carbon monoxide in the exhaust gas (Sheehan, 2000). Therefore, besides its usefulness as an octane-rating enhancer, ethanol has been blended with gasoline to be used in regions where carbon monoxide emission from automobiles is a problem, especially in cold climate.

ETHANOL-PRODUCING MICROORGANISMS Ethanol, a product of anaerobic metabolism, is produced by a wide range of eukaryotic and prokaryotic microorganisms when growth or redox metabolism takes place under oxygen-free or low-oxygen conditions (Wiegel, 1980). Because alcohol dehydrogenases (see Toxicity of Ethanol to Microbial Cells) catalyze a readily reversible reaction, it is natural for short-term ethanol production to occur when the intracellular condition favors the formation of ethanol. Thus, even obligate aerobic bacteria like *Pseudomonas* and *Alcaligenes* can produce ethanol if they are incubated under anaerobic conditions (Vollbrecht and El Nawawy, 1980). In general, however, ethanol is a product of obligate and facultative anaerobes, including *Bacillus subtilis* (Nakano et al., 1997), which may produce ethanol when grown under anaerobic conditions in the absence of external electron acceptors.

Among ethanol-producing microorganisms, the yeast *Saccharomyces cerevisiae* is the best known, and it is still the most widely used organism for the production of industrial ethanol from glucose (from corn) and sucrose (from sugarcane or sugar beet). *Saccharomyces cerevisiae* can metabolize glucose, fructose, galactose, maltose and sucrose, but not starch or other polysaccharides (Helbert, 1982). The lager beer yeast *Saccharomyces uvarum* is sometimes used because it is more flocculent and sediments faster than *S. cerevisiae* (Reed, 1982). In addition to *S. cerevisiae* and *S. uvarum*, other ethanol-producing yeasts are used to ferment raw materials containing sugars not efficiently used by *S. cerevisiae* (Reed, 1982). *Candida utilis* is used for the fermentation of the sulfite liquor (waste from the paper industry) because it also ferments pentoses. The fermentation of whey (waste from

cheese-making) requires the use of a "dairy" yeast, such as *Kluyveromyces fragilis* and *Kluyveromyces lactis*, because the dairy yeasts can ferment lactose at a rate comparable to that of glucose utilization by *S. cereviase*. Besides yeasts, several other fungi within the genera of *Aspergillus*, *Fusarium* and *Penicillium* can produce more than a mole of ethanol per mole of glucose consumed, but these fungi do not grow or metabolize sugars as fast as yeasts or bacteria do (Wiegel, 1980).

Many bacteria have the ability to produce ethanol, but relatively few taxa contain bacteria that produce ethanol as a major end product. Ethanol-producing species can be found among aerobic, anaerobic and facultative anaerobic bacteria within the family Enterobacteriaceae and the genera *Bacillus*, *Bacteroides*, *Bifidobacterium*, *Clostridium*, *Eubacterium*, *Lactobacillus* and many others (Wiegel, 1980). Examples of mesophilic (Table 27) and thermophilic (Table 28) bacteria that can produce one or more moles of ethanol per mole of glucose metabolized have been compiled by Wiegel (Wiegel, 1980; Wiegel, 1992).

Mesophilic Ethanol-Producing Bacteria Several mesophilic species are potentially useful for the production of industrial or fuel ethanol. Among them, the facultative anaerobes *Escherichia coli*

Table 27. Mesophilic bacterial species producing ethanol as a major end product.

Organism	Moles of ethanol produced per mole of glucose metabolized
Clostridium sporogenes	Up to 4.15[a]
Clostridium indolis (pathogenic)	1.96[a]
Clostridium sphenoides	1.8[a] (1.8)[b]
Clostridium sordelii (pathogenic)	1.7
Zymomonas mobilis (syn. *Z. anaerobica*)	1.9
Zymomonas mobilis subsp. *pomaceae*	1.7
Spirochaeta aurantia	1.5 (0.8)
Spirochaeta stenostrepia	0.84 (1.46)
Spirochaeta litoralis	1.1 (1.4)
Erwinia amylovora	1.2
Leuconostoc mesenteroides	1.1
Streptococcus lactis	1.0
Sarcina ventriculi (syn. *Zymosarcina*)	1.0

[a]In the presence of high amounts of yeast extract.
[b]Values in parentheses were obtained with resting cells.

and *Zymomonas mobilis* have been extensively investigated. The metabolic capabilities of *E. coli* (Ingram et al., 1998b; Ingram et al., 1999) and *Z. mobilis* (Zhang et al., 1995) have been expanded by genetic manipulations to enable these species to produce ethanol efficiently from sugars derived from hemicellulosic materials (see Metabolic Engineering in this Chapter). Besides the sugar-fermenting species, the CO-utilizing *Butyribacterium methylotrophicum* (Worden et al., 1991), *Clostridium ljungdhalii* (Tanner et al., 1993), and *Clostridium autoethanogenum* (Abrini et al., 1994) can produce ethanol from synthesis gas (CO plus H_2), which may be derived by gasification of biomass (Klasson et al., 1992; Philips et al., 1994; Clausen and Gaddy, 1996) or coal (Barik et al., 1988). Members of the genus *Acetobacterium*, including *Acetobacterium woodii*, *Acetobacterium carbinolicum* and *Acetobacterium wieringae*, which do not normally produce ethanol from glucose and CO_2, shift their metabolism to produce ethanol when the phosphate concentration of the growth medium is below a certain level (Buschhorn et al., 1989). The amount of ethanol produced by *A. woodii* is moderate (below 15 mM), but its production of ethanol in the stationary phase when there is an excess of glucose or fructose in the medium and when the phosphate concentration is low (below 8.4 mM) suggests an interesting regulatory mechanism. In addition, growth of *A. woodii* can tolerate an ethanol concentration up to 1 M (4.6%, w/v), which is unusual among bacteria (Buschhorn et al., 1989). Properties of extensively investigated mesophilic ethanol-producing bacteria are described below.

Zymomonas mobilis is a remarkable ethanol producer (Swings and De Ley, 1977; Rogers et al., 1982). It is one of the natural fermentative agents in the production of palm and cactus wines and the Mexican drink "pulque" and has been isolated from various fermenting, sugar-rich fluids (Rogers et al., 1982). About 20 different names have been used for this organism since its original naming as "*Termobacterium mobile*;" the names and the history have been reviewed (Swings and De Ley, 1977). *Zymomonas mobilis* is a facultative anaerobic rod (some strains are obligately anaerobic, whereas others can tolerate some O_2). It can produce almost 2 moles of ethanol and 2 moles of CO_2 from each mole of glucose or fructose metabolized. Some strains can also ferment sucrose, but no other carbon sources are used. *Zymomonas mobilis* is the only species in the genus (Swings and De Ley, 1984). It is excluded from the Enterobacteriaceae on the basis of its polar flagellation, its inability to reduce nitrates, its growth at pH 4, and its growth in the presence of 5% ethanol. Genetically, phenotypically, and ecologically, *Zymomonas* is related to the acetic acid bacteria, especially *Gluconobacter*: they both occur in acidic, sugary and alcoholic niches such as tropical plant juices and beer (Buchholz et al., 1987).

Zymomonas mobilis can produce ethanol to a concentration of 10–12%, which is comparable to the performance of the yeasts *S. cerevisiae* (Buchholz et al., 1987) and *S. uvarum* (Kosaric, 1996). Compared with the yeasts, the bacterium *Z. mobilis* has higher rates (two-fold or greater) of sugar uptake and ethanol production. It converts sugar to ethanol with a similar yield (above 90%) and tolerates high sugar concentrations (above 40%). *Zymomonas mobilis* ferments sugars exclusively via the Entner-Doudoroff pathway. The key intermediate of the Entner-Doudoroff pathway, 2-keto-3-deoxy-6-phosphogluconate (KDPG), is cleaved by KDPG aldolase to pyruvate and glyceraldehyde-3-phosphate, and the latter is further metabolized to pyruvate. Thus, two moles of pyruvate are produced per mole of glucose, but only one mole of ATP is obtained per mole of glucose consumed. *Zymomonas mobilis* uses pyruvate decarboxylase (PDC) to convert pyruvate directly to acetaldehyde and CO_2, whereas most other ethanol-producing organisms convert pyruvate to acetyl-CoA and CO_2 first and require an acetaldehyde dehydrogenase to convert acetyl-CoA to acetaldehyde, the substrate for alcohol dehydrogenase (ADH). The high ethanol productivity of *Z. mobilis* is correlated with the organism's high cellular level of PDC and ADH.

Under anaerobic growth conditions, *Escherichia*, *Klebsiella* and other enteric bacteria produce ethanol as a minor end product (Gottschalk, 1986). The native ethanol productivity of these bacteria is not useful for industrial applications. However, the enteric bacteria can ferment hexose as well as pentose sugars derived from hemicellulosic materials (Ingram and Doran, 1995a). To take advantage of their broad substrate range, the enteric bacteria have been recipients of the *Z. mobilis* PDC and ADH genes, and recombinant strains of *E. coli* will be used in the commercial production of fuel ethanol (see Metabolic Engineering in this Chapter).

In addition to the organisms that convert carbohydrates into ethanol, there are mesophilic anaerobic bacteria that can convert CO into ethanol. A strain of *Butyribacterium methylotrophicum* that was adapted to grow on 100% CO (with a doubling time of 12 h) produced small amounts of butanol and ethanol (Grethlein et al., 1990; Worden et al., 1991). Ethanol production in a continuous culture doubled (from 0.026 to 0.056 g/liter) when the pH decreased from 6.8 to 6.0 (Grethlein et al., 1990). *Clostridium autoethanogenum* is another anaerobe that can grow on 100% CO and pro-

duce ethanol besides acetate and CO_2 (Abrini et al., 1994). *Clostridium autoethanogenum* was isolated from rabbit feces, which is known to contain active CO-utilizing bacteria. Besides 100% CO, this organism can also grow on CO_2 plus H_2, pyruvate, arabinose, xylose, fructose, rhamnose and L-glutamate. From chicken yard waste, another CO-utilizing anaerobe, *Clostridium ljungdahlii*, was isolated (Barik et al., 1988; Vega et al., 1989; Tanner et al., 1993). *Clostridium ljungdahlii* can grow on CO, CO_2 plus H_2, ethanol, pyruvate, arabinose, xylose, fructose or glucose. The amount of ethanol produced by *C. ljungdahlii* was low initially (Klasson et al., 1992), but the productivity increased in response to changes in growth conditions (Philips et al., 1994). By maintaining the pH at 4–4.5 and using a nutrient-limited medium, the ethanol concentration was raised to 20 g/liter, whereas the acetate concentration was lowered to 2–3 g/liter (Clausen and Gaddy, 1996). Ethanol production from CO and H_2 (synthesis gas) has a low volumetric productivity, which is attributed to low cell densities, production of unwanted by-products, and slow transfer of the gases into the liquid phase (Worden et al., 1997). These engineering and biological problems will need to be resolved before synthesis gas, which may be generated through gasification of coal or cellulosic materials, can be biologically converted into ethanol on a commercial scale.

Thermophilic Ethanol-Producing Bacteria

Thermophilic bacteria have been proposed for the production of useful chemicals (Wiegel and Ljungdahl, 1986; Slapack et al., 1987; Lynd, 1989; Wiegel, 1992; Lowe et al., 1993). Wiegel (1980) listed seven advantages of using thermophilic anaerobic bacteria for ethanol fermentation. They include higher ethanol yields due to the utilization of a wide range of substrates as well as less biomass production (relative to aerobes), fast fermentation, little or no possibility for microbial contamination, no need for aeration or cooling, and a growth condition conducive to continuous distillation for the removal of ethanol and other volatile products. Commercial utilization of the thermophiles for ethanol production will be more attractive when genetic tools for engineering these organisms are further developed.

Ethanol-producing thermophiles are members of the genera *Clostridium*, *Thermoanaerobacterium* and *Thermoanaerobacter*. The latter two genera include several species that were at first identified as members of the genus *Clostridium* (Wiegel, 1992; Lee et al., 1993). The first thermophilic anaerobe that is still validly described (being included in the Approved Lists of Bacterial Names) is the cellulose-degrading, ethanol-producing *Clostridium thermocellum*; however, it took nearly 20 years after its first description before a pure culture was obtained (Wiegel, 1992). In early 2001, there are over 20 named species in the two genera *Thermoanaerobacterium* and *Thermoanaerobacter*. A taxonomic key was proposed for the preliminary identification of saccharolytic, ethanol-producing, thermophilic anaerobic bacteria (Lee et al., 1993). However, the description for the genus *Thermoanaerobacterium* has been emended concerning the location of sulfur droplets (Liu et al., 1996) or the lack of reduction of thiosulfate to sulfur (Cann et al., 2001). The lack of defining phenotypic characteristics for some species makes their assignment to a proper genus difficult. Therefore, the following taxonomic key may be revised when useful criteria for further differentiation emerge.

A. Does not reduce thiosulfate, ferments cellulose
   1. *Clostridium thermocellum* (Wiegel, 1992)
B. Does reduce thiosulfate, does not ferment cellulose
   1. May reduce thiosulfate to elemental sulfur
      Thermoanaerobacterium aotearoense (Liu et al., 1996)
      Thermoanaerobacterium polysaccharolyticum (Cann et al., 2001)
      Thermoanaerobacterium saccharolyticum (Lee et al., 1993)
      Thermoanaerobacterium thermosaccharolyticum (Cann et al., 2001)
      Thermoanaerobacterium thermosulfurigenes (Lee et al., 1993)
      Thermoanaerobacterium xylanolyticum (Lee et al., 1993)
      Thermoanaerobacterium zeae (Cann et al., 2001)
   2. Reduces thiosulfate to hydrogen sulfide (H_2S)
      Thermoanaerobacter brockii (Lee et al., 1993)
      Thermoanaerobacter ethanolicus (Lee et al., 1993)
      Thermoanaerobacter mathranii (Larsen et al., 1997)
      Thermoanaerobacter thermohydrosulfuricus (Lee et al., 1993)
      Thermoanaerobacter tengcongensis (Xue et al., 2001)
      Thermoanaerobacter wiegelii (Cook et al., 1996)

Among the ethanol-producing thermophiles, *C. thermocellum* was extensively studied for its ability to degrade cellulose and produce ethanol (Wiegel, 1980; Wiegel, 1992). Strains of *C. thermocellum* are readily isolated from nearly all

decaying organic material. They produce 0.3 to nearly 1 mole of ethanol per mole of glucose-equivalent contained in the cellulose utilized. It was possible to develop strains with an increased tolerance to ethanol (up to 8%; based on cellulose degradation) and an improved ratio of ethanol to acetate produced (from 1 : 1 to 10 : 1); however, growth of the mutants was still inhibited to 50% when 5% of ethanol was present in the growth medium (reviewed by Wiegel, 1980). Isolation of strains that tolerate 4–5% ethanol was reported (Rani and Seenayya, 1999). *Clostridium thermocellum* forms stable mixed cultures with saccharolytic organisms in a beneficial, syntrophic association. Cocultures of *C. thermocellum* and the saccharolytic ethanol-producing *Thermoanaerobacter ethanolicus* produced a significantly higher amount of ethanol from cellulose than the pure cultures produced (Wiegel, 1980), suggesting that the cellulolytic activity of *C. thermocellum* is in practice more important than its ethanol-producing activity for the production of ethanol from cellulose. Since the early 1980s, the cellulolytic enzymes of *C. thermocellum* have been subjects of active research, and the cellulosome, an extracellular supramolecular machine that can efficiently degrade crystalline cellulosic substrates, was identified through this research (Shoham et al., 1999).

The genera *Thermoanaerobacter* and *Thermoanaerobacterium* contain saccharolytic species with a high ethanol productivity. The thermophilic anaerobes that have T_{max} above 72°C and can produce more than 1.5 moles of ethanol per mole of glucose consumed are *Thermoanaerobacter ethanolicus* (including the former *Clostridium thermohydrosulfuricum* strain 39E), *Thermoanaerobacter brockii* subspecies *finii* (formerly *Thermoanaerobacter finii*), and *Thermoanaerobacter thermohydrosulfuricus*. Some of these thermophiles were isolated from hot springs, where the glucose concentration is not high. Therefore, the observed high ethanol productivity of the newly isolated strains, when provided with high glucose concentrations in the laboratory, may represent a lack of refined regulatory mechanisms for these organisms to respond to rich growth conditions. After repeated subculturing in a rich medium, these organisms may adapt to a metabolism producing more acetate and less ethanol (Wiegel, 1992).

Thermoanaerobacter ethanolicus has a broad pH optimum between 5.5 and 8.5 (growth occurs between pH 4.5 and 9.5), and it ferments glucose to ethanol (up to 1.8 moles ethanol per mole of glucose used) as efficiently as yeast and *Zymomonas* (Wiegel, 1992). In addition, *T. ethanolicus* has a broad substrate range: glucose, xylose, oligomers of xylose, xylan, mannose, ribose, arabinose, lactose, cellobiose, maltose, starch and pyruvate are used. These properties make *T. ethanolicus* an attractive candidate for the conversion of lignocellulosic material or whey into ethanol.

ENZYMOLOGY OF ETHANOL FORMATION Pyruvate is the central metabolic intermediate during sugar metabolism. The saccharolytic ethanol-producing bacteria can be divided into two groups based on how pyruvate is converted into the direct precursor for ethanol formation. One group, which encompasses the majority of fermentative bacteria, converts pyruvate into acetyl-CoA and CO_2, and acetyl-CoA is then reduced to acetaldehyde by aldehyde dehydrogenase. Like yeasts, the other group, including *Z. mobilis*, *Sarcina ventriculi*, *Erwinia amylovora*, and the acetic acid bacteria, converts pyruvate directly into acetaldehyde and CO_2 by pyruvate decarboxylase (Bringer-Meyer et al., 1986). Acetaldehyde is reduced to ethanol by alcohol dehydrogenase. The alcohol-producing organisms have multiple alcohol dehydrogenases (ADHs), and in many cases, the physiological importance of each ADH isozyme remains to be determined.

Pyruvate Decarboxylase The thiamine pyrophosphate- and Mg^{2+}-dependent pyruvate decarboxylase (EC 4.1.1.1) catalyzes the nonoxidative decarboxylation of pyruvate to form acetaldehyde and CO_2. Pyruvate decarboxylase (PDC) is widely present in plants and fungi, but its occurrence among the bacteria is limited. Constituting 4–6% of the total soluble protein of *Z. mobilis*, PDC is one of the most abundant proteins in this organism (Bringer-Meyer et al., 1986). Also, PDC has been purified from *Z. mobilis* (Hoppner and Doelle, 1983; Bringer-Meyer et al., 1986), and its structural gene has been cloned from two strains of *Z. mobilis* (Brau and Sahm, 1986; Conway et al., 1987; Neale et al., 1987; Reynen and Sahm, 1988). The *Z. mobilis* PDC is a tetrameric protein consisting of apparently identical subunits with a molecular weight of 56,500. The *pdc* gene of *Z. mobilis* ATCC 29191 encodes a polypeptide of 567 amino acids (Neale et al., 1987; Reynen and Sahm, 1988), whereas the *pdc* gene of *Z. mobilis* ATCC 31821 encodes a polypeptide of 559 amino acids (Conway et al., 1987). The difference involves two internal amino acids and seven at the C-terminus. The K_M of PDC for pyruvate was first reported at 4.4 mM (Hoppner and Doelle, 1983). But when the PDC activity was measured in the presence of Mg^{2+} (20 mM) and thiamine pyrophosphate (1.5 mM), a K_M of 0.4 mM was found (Bringer-Meyer et al., 1986). The lower K_M value of *Z. mobilis* PDC for pyruvate should allow the enzyme to compete favorably against the other pyruvate-utilizing

enzymes (e.g., pyruvate formate lyase [K_M = 2.05 mM] and D-lactate dehydrogenase [K_M = 4.4 mM]) in *E. coli* (Brau and Sahm, 1986). This difference in K_M values for pyruvate could explain the increase in ethanol production from 6.5 mM to 41.5 mM and the lack of acid production when a recombinant strain of *E. coli* harboring the *Z. mobilis pdc* gene was compared with the parent strain (Brau and Sahm, 1986). The apparent benefit of expressing *Z. mobilis* PDC in *E. coli* for ethanol production is confirmed by the successful engineering of *E. coli* for fuel ethanol production (see Metabolic Engineering in this Chapter). Antiserum raised against *Z. mobilis* PDC did not detect any hybridizing protein in cell extracts of *Sarcina ventriculi*, *Erwinia amylovora*, *Gluconobacter oxydans* or *Saccharomyces cerevisiae*, although the PDCs of *Z. mobilis* and *S. cerevisiae* have a similar molecular size and subunit structure (Bringer-Meyer et al., 1986).

In anaerobic bacteria, oxidation of pyruvate is generally catalyzed by a ferredoxin- or flavodoxin-linked pyruvate dehydrogenase (Chen, 1987; Chen, 1993) to form acetyl-CoA, CO_2, and reduced ferredoxin or flavodoxin. In CO-utilizing organisms, acetyl-CoA is synthesized by the nickel-containing CO dehydrogenase/acetyl-CoA synthase (Ragsdale and Riordan, 1996). Acetyl-CoA is reduced by acyl-CoA-dependent aldehyde dehydrogenases (ALDHs) to acetaldehyde.

CoA-Acylating Aldehyde Dehydrogenase The reduction of acetyl-CoA to acetaldehyde is catalyzed by CoA-acylating aldehyde dehydrogenase (EC 1.2.1.10), which catalyzes the reaction Acyl-CoA + NAD(P)H + H^+ ⇔ aldehyde + CoASH + $NAD(P)^+$. Although more than 150 full-length aldehyde dehydrogenase (ALDH) sequences are now compiled and aligned at the website (http://www.psc.edu/biomed/pages/researchCol_HBN_ALDH.html), relatively few ALDHs, especially CoA-acylating ALDHs, have been isolated and characterized from ethanol-producing organisms. Most organisms have several distinct ALDH genes, and 13 have been recognized in the *E. coli* genome (Perozich et al., 1999). Nevertheless, only the *adhE* gene has been shown to be responsible for the CoA-linked ALDH activity and is required for ethanol production in *E. coli* (Clark, 1989; Holland-Staley et al., 2000). The ADH-E protein of *E. coli* has been purified as a polymer, and it has a third function, the pyruvate-formate lyase (PFL) deactivase activity, besides the acetyl-CoA reducing activity and ADH activity (Kessler et al., 1991; Kessler et al., 1992). Based on its molecular size and its ADH and CoA-acylating ALDH activity, the ALDH purified from *E. coli* by Fromm and coworkers (Rudolph et al., 1968; Shone and Fromm, 1981) appears to be the *adhE* product. Results of steady-state measurements (in the direction of CoA-acylation) suggest that the enzyme uses a bi-uni-uni-uni ping-pong mechanism in which NAD^+ binds to the free enzyme followed by acetaldehyde; the product NADH is then released before CoASH can bind, and acetyl-CoA is the final product released (Shone and Fromm, 1981).

In the butanol- and ethanol-producing clostridia, two types of CoA-acylating ALDHs have been found (Toth et al., 1999). *Clostridium acetobutylicum* has an *adhE*- or *aad*-encoded enzyme very similar to the ADH-E of *E. coli* (Fischer et al., 1993; Nair et al., 1994), whereas *Clostridium* species NRRL B643 (Palosaari and Rogers, 1988) and *C. beijerinckii* (Yan and Chen, 1990; Toth et al., 1999) have a dimeric enzyme with a subunit of 55–56 kDa. The gene (*ald*) encoding the *C. beijerinckii* ALDH has been cloned and sequenced (Toth et al., 1999). Results of Southern analysis suggest that each species of the butanol- and ethanol-producing clostridia uses either an aldehyde-alcohol dehydrogenase or an aldehyde dehydrogenase, but not both, for the reduction of acyl-CoA to the respective aldehyde. The ALDH of *C. beijerinckii* is most similar to the *eutE*-encoded ALDH of *Salmonella typhimurium* and *E. coli*, which use the ALDH during growth on ethanolamine.

Alcohol Dehydrogenase Alcohol dehydrogenase (ADH; EC 1.1.1.1 for NAD^+-linked ADH; EC1.1.1.2 for $NADP^+$-linked ADH; EC 1.1.1.71 for $NAD(P)^+$-linked ADH) catalyzes the readily reversible reaction: aldehyde or ketone + NAD(P)H + H^+ ⇔ primary or secondary alcohol + $NAD(P)^+$. ADHs may be differentiated by their coenzyme and substrate specificities, metal requirement, and the number and size of their subunits (Reid and Fewson, 1994).

Multiple ADHs are often present in an organism (Chen, 1995). Two ADHs have been found in *Z. mobilis* (Wills et al., 1981; Kinoshita et al., 1985; Neale et al., 1986). Both ADHs use NADH to reduce acetaldehyde to ethanol and were reported to be dimeric or tetrameric. ADH-I is a zinc enzyme with a subunit molecular weight of 40,000 (Kinoshita et al., 1985; Neale et al., 1986), whereas ADH-II is activated by iron (Scopes, 1983; Neale et al., 1986) and has a subunit molecular weight of 37,000 (Neale et al., 1986) or 38,000 (Kinoshita et al., 1985). ADH-II accounts for 90% of ADH activity in cell extracts (Neale et al., 1986). It has been proposed that ADH-I forms a complex with glyceraldehyde-3-phosphate dehydrogenase and phosphoglycerate kinase (Aldrich et al., 1992). Mutants lacking ADH-II but not ADH-I have been obtained

(O'Mullan et al., 1995). These mutants were isolated by using allyl alcohol as the selecting agent. ADH-I mutants may not be detectable by this procedure because of the high activity of ADH-II, which would reduce allyl alcohol to toxic acrolein more rapidly than would ADH-I, and perhaps because of the presence of ADH-I in an enzyme complex. The level of ADH-I and ADH-II can be modulated by iron and zinc (Mackenzie et al., 1989). The structural gene for ADH-I, designated *adhA*, has been cloned and sequenced (Keshav et al., 1990), and it encodes a polypeptide of 337 amino acids with a molecular weight of 36,096. The structural gene for ADH-II, designated *adhB*, encodes a polypeptide of 383 amino acids with a molecular weight of 40,141 (Conway et al., 1987; Yoon and Pack, 1990). The *adhB* gene of *Z. mobilis* has been used in the engineering of *E. coli* for ethanol production from lignocellulosic material (see Metabolic Engineering in this Chapter).

ADHs have been purified from the ethanol-producing thermophiles *Thermoanaerobacter brockii* subsp. *brockii* (Lamed and Zeikus, 1981) and *Thermoanaerobacter ethanolicus* (Bryant et al., 1988; Burdette and Zeikus, 1994). Although these thermophiles do not produce secondary alcohols, an NADP(H)-dependent ADH purified from these organisms is active in reducing both aldehydes and ketones to the respective primary or secondary alcohols. In addition, the secondary ADH from *T. ethanolicus* 39E can produce ethanol from acetyl-CoA, indicating the presence of acetyl-CoA reductive thioesterase (CoA-acylating ALDH) activity in the enzyme (Burdette and Zeikus, 1994). The structural gene for the primary-secondary ADH has been cloned from *T. ethanolicus* 39E (Burdette et al., 1996) and *T. brockii* subsp. *brockii* (Peretz et al., 1997). X-ray crystallographic data (Korkhin et al., 1998) show that the primary-secondary ADH of *T. brockii* subsp. *brockii* is structurally related to the primary-secondary ADH of *Clostridium beijerinckii* NRRL B593, which produces isopropanol in addition to *n*-butanol and ethanol (Korkhin et al., 1998).

Fermentative growth of *E. coli* depends on the *adhE*-encoded protein, which is a polypeptide of 891 amino acids, with a molecular weight of 96,008, and has CoA-acylating ALDH activity in addition to ADH activity (Clark, 1989; Goodlove et al., 1989). Thus, ADH-E is responsible for the two reductive reactions in converting acetyl-CoA to ethanol and the regeneration of NAD^+. The *adhE* gene is expressed only under anaerobic growth conditions, and the ADH-E protein is inactive in air. Interestingly, mutations in the promoter region and in the coding region of *adhE* allowed production of active ADH-E under aerobic growth conditions, and the amino acid Glu568 alone determines the oxygen sensitivity of ADH-E (Holland-Staley et al., 2000). In addition to the aldehyde-alcohol dehydrogenase, *E. coli* has a 1,2-propanediol oxidoreductase (encoded by the *fucO* gene), which has 41.7% identity at the amino acid level with the iron-containing ADH-II of *Z. mobilis* (Conway and Ingram, 1989).

Toxicity of Ethanol to Microbial Cells

Short-chain alcohols (C_1 to C_5) elicit a number of cellular responses that are potentially cytotoxic, and this cytotoxicity is manifested in all cell types, although the threshhold level of alcohol cytotoxicity may vary from organism to organism (Baker and Kramer, 1999). Effects of alcohols on microorganisms have been reviewed (Ingram and Buttke, 1984; Ingram, 1986; Buchholz et al., 1987; Mishra and Kaur, 1991). Reviews are also available on ethanol tolerance in bacteria (Ingram, 1990), *E. coli* (Ingram and Dombek, 1989), *Z. mobilis* (Ingram and Dombek, 1989; Rogers et al., 1989) and clostridia (Linden and Kuhn, 1989). Cytotoxicity is the basis for the practical use of alcohols as a disinfectant or as a preservative, but it is also a major factor limiting the final ethanol concentration during commercial fermentation.

The cytotoxicity of short-chain alcohols ranges from reversible effects to cell death. Besides the toxicity to microbes, human exposure to ethanol and other short-chain alcohols in the environment is widespread because these alcohols are extensively used as industrial solvents and are increasingly used as a component of automobile fuels. In mammalian cells, aberrations in phospholipid and fatty acid metabolism, changes in the cellular redox state, disruptions of the energy state, and increased production of reactive oxygen metabolites have been implicated in cellular damage resulting from acute or chronic exposure to short-chain alcohols. Such cellular damage can result in disruptions of the intracellular signaling cascades and decreases in phosphorylation potential and lipid peroxidation, which are the suggested mechanisms by which alcohols can affect the rate of cell proliferation (Baker and Kramer, 1999). Nonoxidative metabolism of short-chain alcohols, including synthesis of alcohol phospholipids and fatty acid alcohol esters, is an additional mechanism by which alcohols can affect membrane structure and compromise cell function. The reasons for specific cell types to exhibit different sensitivities to individual short-chain alcohols have been attributed to unique membrane compositions (Buchholz et al., 1987; Ingram, 1990) and to unique metabolites produced in the affected cell and to perturbations of functions unique to the cell type (Baker and Kramer, 1999).

Concentrations of ethanol above 15% result in immediate inactivation of most vegetative organisms, with spores being considerably more resistant, whereas low concentrations of ethanol also render bacteria more sensitive to inactivation by ionizing radiation and by lipophilic acids (Ingram and Buttke, 1984). The toxicity of ethanol to yeasts and bacteria has a major impact on the cost of industrial ethanol fermentation. As ethanol accumulates in the growth medium, the rate of conversion of sugars into ethanol declines progressively and the fermentation terminates when an ample supply of substrates is still available in the medium. The limit of the achievable ethanol concentration in a reactor and the decreasing rate of ethanol accumulation during fermentation increase the cost of the process because the production facility cannot be used more efficiently. It is thus important to understand the mechanism of ethanol toxicity so that bacterial strains more tolerant to ethanol may be developed for industrial uses. However, when studying ethanol toxicity or tolerance, it is useful to consider that rather than the increasing ethanol concentration, other growth-stage related changes in the medium composition might inhibit growth. It has been reported that salt accumulation resulting from the addition of base for pH control, not ethanol, limits the growth of an ethanol-producing organism (Lynd et al., 2001).

The cell membrane has been identified as the prime target for the toxic effect of ethanol, but other cellular components can also be deleteriously affected by ethanol to contribute to the cytotoxicity of ethanol (Ingram, 1986; Ingram and Dombek, 1989; Mishra and Kaur, 1991). A primary action of ethanol in biological systems is to increase membrane leakage. The rates of leakage of hydrogen, magnesium, and potassium ions increased with added ethanol. Nucleotides are lost from cells at a surprising rate in the absence of ethanol, and this rate of loss is accelerated by the addition of ethanol (Ingram, 1990). Loss of magnesium ions and nucleotides can cause a decrease in glycolytic flux and hence lower fermentation activity. At higher ethanol concentrations, the integrity of the membrane is further disrupted, and large molecules like proteins are also lost and cell death will follow.

From a consideration of the possible structural and functional changes in the membrane as a result of a change in the fatty acyl composition of the membrane lipids, it is possible to infer the mechanism by which ethanol inhibits growth and survival through its actions on the plasma membrane (Ingram, 1986; Ingram, 1990). Ethanol exerts its effects on the membrane by affecting hydrophobic associations. Thus, the potency of alcohols as inhibitors of cellular functions is directly related to hydrophobicity, rather than involving specific steric interactions or receptors. Ethanol is less polar than water but more polar than the hydrophobic core of the membrane. High concentrations of ethanol in the culture fluid and cytoplasm alter the colligative properties of the culture fluid and cytoplasm. Ethanol increases the dielectric strength and the strength of ionic or coulombic interactions in the aqueous milieu, hence causing a decrease in the ability of the aqueous environment to accommodate charged species and a shift of the p*Ka* of all ionizable groups toward the conjugate neutral form. Such changes may alter the conformation of and interactions between macromolecules, the pH optima for enzymic reactions, or the pH of the environment itself (Ingram, 1990).

When situated within the hydrophobic core of the membrane, ethanol decreases the dielectric strength of the membrane, the primary barrier for the cell, which in turn increases the ability of the membrane core to accommodate charged or polar molecules. The passage of molecules across the membrane is restricted primarily by the energy barrier for their transfer from an aqueous to a hydrophobic environment. Ethanol decreases this energy barrier both by its effects on the aqueous milieu (decreasing polarity) and its effects on the hydrophobic core of the membrane (increasing polarity), thus increasing the permeability of the membrane to polar and charged molecules (Ingram, 1990).

Research conducted with *E. coli* and *S. cerevisiae* shows that in response to elevated levels of ethanol in the surrounding medium, the composition of the fatty acids in the cell membrane changes with an increase in the proportion of unsaturated long-chain fatty acids, especially the *cis*-18:1 (Δ11) fatty acid (vaccenic acid) for *E. coli* and the *cis*-18:1 (Δ) fatty acid (oleic acid) for *S. cerevisiae* (Ingram, 1986). These findings suggest that the changed fatty acid compositions of the membrane lipids and hence the properties of the cell membrane may afford the cells a greater tolerance toward ethanol. The fatty acid composition of the membrane lipids of naturally ethanol-tolerant organisms provides supporting evidence for this relationship.

Zymomonas mobilis, *Lactobacillus homohiochii* and *Lactobacillus heterohiochii* are among the most ethanol-tolerant organisms so far identified. (*Lactobacillus heterohiochii* is now considered a subjective synonym of *Lactobacillus fruitivorans* because of high DNA/DNA homology between the strains; Weiss et al., 1983.) *Zymomonas mobilis* is unusual among the ethanol-producing bacteria in that it can produce ethanol to a concentration of 12% (w/v), which is comparable to that of the yeast *S. cerevisiae*. In comparison, growth of *A. woodii* can tolerate an

ethanol concentration of 4.6% (w/v), which is considered high for bacteria (Buschhorn et al., 1989). The membrane of *Z. mobilis* maintains a stable and exceptionally high amount (70% of the fatty acids) of vaccenic acid and unusual hopanoids, which are evolutionary precursors of sterols (Buchholz et al., 1987). Ethanol-dependent changes in the membranes of *Z. mobilis* include a decrease in the phospholipid content, an increase in the proportion of cardiolipin and phosphatidylcholine, and an increase in the proportion of hopanoids. *Lactobacillus homohiochii* and *L. heterohiochii* are not ethanol-producing bacteria; they were originally isolated as spoilage organisms from Japanese rice wine (Kitahara et al., 1957; Demain et al., 1961). These two lactobacilli can grow in ethanol concentrations above 16% (w/v), and both organisms exhibit ethanol-inducible changes in fatty acid composition. During growth in the presence of high concentrations of ethanol, the membranes of *L. homohiochii* contain less than 3% of saturated fatty acids, with the balance being primarily the *cis*-18:1 (Δ11) vaccenic acid (Uchida, 1975b). *Lactobacillus heterohiochii* exhibits an ethanol-inducible increase in the proportion of long-chain, *cis*-mono-unsaturated fatty acids including 18:1, 20:1, 22:1, 24:1, 26:1, 28:1, and 30:1 fatty acids (Uchida, 1974; Uchida, 1975a). During growth in the presence of ethanol, over 30% of the fatty acyl chains in the membranes of *L. heterohiochii* are monounsaturated and have a chain length of 20 or more carbons, which is a property not yet observed in any other organism (Ingram, 1986).

The relationship between the fatty acid composition of the membrane lipids and an organism's ethanol tolerance also has been investigated using mutants of *E. coli*. The membrane fatty acyl composition of *E. coli* is easily manipulated using mutants defective in lipid biosynthesis and fatty acid supplements (Ingram and Buttke, 1984). Mutant strains of *E. coli*, which are unable to synthesize vaccenic acid (an 18:1 fatty acid), contain membranes composed of nearly equal proportions of palmityl and palmitoleyl residues. These mutants are hypersensitive to growth inhibition and death caused by exposure to ethanol in comparison to the wildtype cells. Exogenously added fatty acids are readily incorporated into *E. coli* cells, and addition of 18:1 fatty acids to the growth medium resulted in an increase in the growth rate of the mutant in the presence of ethanol and a restoration of the tolerance level to that of the wildtype strain. No other fatty acids were found beneficial. Similar enhancement in ethanol tolerance was observed in ethanol-producing yeasts when the fermentation medium was supplemented with unsaturated fatty acids or sterols (Ingram and Buttke, 1984; Mishra and Kaur, 1991). These studies have led to the conclusion that an elevated level of ethanol tolerance involves an increase in the fatty acyl chain length and in the proportion of *cis*-mono-unsaturated fatty acids in the membrane lipids, and with *E. coli* at least, the increase in chain-length appears to be more significant than the increase in *cis*-unsaturation. The adaptative changes in the fatty acyl composition of the membrane of the ethanol-tolerant cells indicate that the plasma membrane is a flexible system that may be manipulated by genetic engineering to increase the ethanol tolerance of the cell.

Metabolic Engineering Efforts to use genetic tools to improve bacteria for ethanol production have focused on the enteric bacteria (Ingram et al., 1998b; Ingram et al., 1999) and *Z. mobilis* (Himmel et al., 1997). The rationale for this endeavor resides in the fact that for subtropical or temperate regions the abundant and renewable lignocellulosic biomass is the only choice of carbon substrates for an expanded fermentation industry because the starchy grains will be increasingly needed as food and feed and hence cannot meet the growing need of the ethanol industry. The yeast *S. cerevisiae* is not chosen for several reasons: 1) it cannot efficiently use the pentose sugars that are the major component of hemicellulose, 2) it is less amenable to genetic manipulation than the prokaryotes, and 3) it has different requirements for O_2 during growth and during ethanol production, which practically limit the duration of the production period. On the other hand, enteric bacteria can ferment these pentose sugars, and *Z. mobilis* has superb ethanol tolerance and high specific rates of sugar uptake and ethanol production, both under anaerobic conditions. Therefore, efforts of metabolic engineering have been directed to either expanding the substrate range of *Z. mobilis* or increasing the ethanol productivity of enteric bacteria.

Z. mobilis Results of earlier genetic studies with *Z. mobilis* have been reviewed (Rogers et al., 1982), and mutants with better ethanol tolerance and better viability in liquid media were selected. The use of recombinant DNA techniques allowed the construction of a chimeric plasmid carrying a xylose assimilation operon (*xylA* and *xylB* genes under the promoter for glyceraldehyde-3-phosphate) and a pentose phosphate pathway operon (*tal* and *tktA* genes under the promoter for enolase) consisting of the *E. coli* genes or gene homolog encoding xylose isomerase (*xylA*), xylulokinase (*xylB*), transaldolase (*tal*) and transketolase (*tkt*) under the control of strong promoters from *Z. mobilis*

(Zhang et al., 1995). The recombinant *Z. mobilis* harboring the plasmid expresses the respective enzymes, can grow on xylose as the sole carbon source, and produces 1.43 moles ethanol per mole of xylose consumed (86% theoretical yield). In the presence of a mixture of glucose and xylose, the recombinant strain fermented both sugars to ethanol at 95% of theoretical yield within 30 hours. Glucose is used at a faster rate than xylose by the recombinant strain, although there is not an apparent diauxic effect. A recombinant strain of *Z. mobilis* capable of fermenting arabinose to ethanol has also been constructed (Himmel et al., 1997). These accomplishments provide a foundation for the further broadening of the substrate range of *Z. mobilis*.

Enteric Bacteria The metabolic engineering of enteric bacteria for the production of ethanol from hexose and pentose sugars, the major components of hemicellulose syrup, has been reviewed (Ingram and Doran, 1995a; Ingram et al., 1998b; Ingram et al., 1999). Initial efforts involved the introduction of recombinant plasmids carrying either the *pdc* gene or the *pdc* and *adhB* genes of *Z. mobilis* into enteric bacteria to obtain high ethanol production from pentose and hexose sugars. When the *pdc* gene alone was introduced into wildtype *Klebsiella planticola* (Tolan and Finn, 1987) or *K. planticola* mutant deficient in pyruvate formate lyase (Feldmann et al., 1989) or *E. coli* (Brau and Sahm, 1986), increased ethanol production from xylose or glucose was observed. However, the recombinant strains exhibited plasmid instability, decreased ethanol tolerance, decreased growth rate under fermentative conditions, decreased cell yield, incomplete conversion of substrate, and accumulation of acidic fermentation products. When recombinant plasmids carrying both *pdc* and *adhB* genes of *Z. mobilis* were introduced into *E. coli* (Ingram et al., 1987; Ingram and Conway, 1988; Neale et al., 1988) or *Klebsiella oxytoca* (Ohta et al., 1991b), the central metabolism was effectively redirected into ethanol production under both aerobic and anaerobic conditions, resulting in diminished acid production and dramatically increased final cell density. The ADH-II of *Z. mobilis* has a K_M of 12 μM for NADH, which is much lower than those of the competing dehydrogenases of *E. coli* (Ingram and Conway, 1988). A high level of ADH-II activity in the recombinant *E. coli* results in efficient removal of acetaldehyde to increase ethanol production, to facilitate the continued action of pyruvate decarboxylase, and to prevent the production of acids. The results indicate that the acids produced by enteric bacteria are more damaging than ethanol is to the cell (Ingram and Conway, 1988).

For an efficient transfer of both the *pdc* and the *adhB* genes of *Z. mobilis* into different recipient cells, an artificial operon, dubbed the "PET operon" for the production of ethanol, has been constructed as a portable ethanol production cassette (Ingram et al., 1987). The PET operon consists of the *Z. mobilis pdc* and *adhB* genes under the control of the *lac* promoter, and it was initially introduced into recipient enteric bacteria on a pUC18 plasmid. Use of a putative *Z. mobilis* promoter in place of the *E. coli lac* promoter for the PET operon gave optimal expression of PDC and ADH-II activities and much higher ethanol production in recombinant *E. coli* strains harboring the plasmid (Ingram and Conway, 1988).

To alleviate the problem of plasmid instability, *Z. mobilis pdc* and *adhB* genes were successfully inserted into the chromosome of *E. coli* at the *pfl* site under the control of the *pfl* promoter (Ohta et al., 1991a). The *pfl* site (encoding pyruvate formate lyase or PFL) was chosen because PFL represents a competing branch point (causing diversion of pyruvate to acid production) and because the *pfl* gene is expressed at very high levels during anaerobic growth. The latter is important for high-level expression of PDC and ADH-II from single-copy genes in *E. coli*. Additional genetic modifications, which include a selection for resistance to a high level of chloramphenicol, inactivation of succinate production and block of homologous recombination, were required to increase the level of expression, to decrease acid production, and to ensure genetic stability. The resulting *E. coli* strain was designated *E. coli* KO11 (Ohta et al., 1991a). Ethanol concentrations of 54.4 and 41.6 g/liter were obtained from 10% glucose and 8% xylose, respectively. Although the high yield was partly attributed to the utilization of fermentable complex nutrients in the medium, that *E. coli* can accumulate ethanol above 5% is significant. *Escherichia coli* KO11 has since been used widely to demonstrate the fermentation of hemicellulose hydrolysates from various lignocellulosic materials (Ingram et al., 1999). *Zymomonas mobilis pdc* and *adhB* genes have also been integrated into the *pfl* gene on the chromosome of *K. oxytoca* to enable the recombinant strain P2 to produce ethanol from cellulose and hemicellulose (Wood and Ingram, 1992). In 1991, the use of recombinant *E. coli* KO11 harboring the *Z. mobilis pdc* and *adhB* genes for ethanol production was awarded the United States patent no. 5,000,000 (Ingram et al., 1991).

When autoclaved crystalline cellulose is the substrate, commercial fungal (*Trichoderma*) cellulase is added to the growth medium to allow simultaneous saccharification and fermentation or SSF (Doran and Ingram, 1993; see "Polyhy-

droxyalkanoic Acids" in Organic Acid and Solvent Production, Part I in this Volume). When sugarcane bagasse is the substrate, a pretreatment is essential to render the cellulose accessible to enzymic digestion. Either ammonia freeze explosion (AFEX) or hydrolysis of hemicellulose with dilute sulfuric acid is an effective pretreatment to increase cellulose digestibility (Doran et al., 1994). At present, low sugar concentrations in hemicellulose hydrolysate rather than alcohol tolerance of the bacteria limit the final concentration of ethanol achieved during fermentation.

During the pretreatment of lignocellulose with acid, substances toxic to enteric bacteria are produced. At present, additional treatments of the acid hydrolysate are necessary, which include the separation of liquid (hemicellulose syrup) and solid (cellulose and lignin) followed by washing and detoxification steps. The hemicellulose syrup containing the monosaccharides of hemicellulose is fermented to ethanol by *E. coli* KO11. The fibrous solid containing cellulose and lignin is converted to ethanol by SSF using recombinant *K. oxytoca* and commercial fungal cellulase, with the lignin-rich residue after SSF burned to provide energy (Ingram et al., 1999).

Other Bacteria The *Z. mobilis pdc* gene was introduced into the soft-rot bacterium *Erwinia chrysanthemi* to produce ethanol from xylose and arabinose (Tolan and Finn, 1987). Plasmids carrying the PET operon have been introduced into the soft-rot bacteria *Erwinia carotovora* and *E. chrysanthemi* (Beall and Ingram, 1993). These plant pathogenic bacteria have the native ability to secrete a battery of hydrolases and lyases to aid in the solubilization of lignocellulose and to macerate and penetrate plant tissues. Strains harboring the PET operon produced ethanol efficiently from glucose, cellobiose, and xylose. The PET operon has also been introduced into *Bacillus subtilis* and *Bacillus polymyxa* (de F. S. Barbosa and Ingram, 1994). The *Z. mobilis* genes encoding PDC and ADH are expressed in these recombinant strains; however, the level of expression is not high enough for ethanol production. The presence of multiple proteinases in these Gram-positive bacteria may limit high-level expression. Although the glycohydrolases of Gram-positive organisms may prove advantageous for the production of ethanol from cellulosic material, further improvement in the expression level of the introduced ethanol-pathway enzymes will be needed to make the recombinant strains useful.

Commercial Applications

Commercial Production Ethanol has traditionally been produced by chemical synthesis (mostly via catalytic hydration of ethylene) or by fermentation using yeasts. The synthetic procedures for ethanol production can be found in Lowenheim and Moran (1975) or Logsdon (1994), and the ethanolic fermentation using yeasts can be found in Reed (1982). The bacterial fermentation to be used by BC International Corp. (McCoy, 1998) at its plant in Jennings, Louisiana, is based on United States patent no. 5,000,000 awarded to Dr. L. O. Ingram and coworkers (Ingram et al., 1991) for a recombinant *E. coli* that can ferment both pentose and hexose sugars to ethanol (see Metabolic Engineering in this Chapter).

The proportion of ethanol produced by the synthetic and the fermentation processes is largely determined by the production costs, the market condition, and the government policies at the time. In 1935, 90% of the United States supply of industrial ethanol came from fermentation plants; less than 10% was of synthetic origin. By 1954, 70% was synthetic, and by 1963, synthetic ethanol accounted for 91% of the production (Lowenheim and Moran, 1975). However, the trend has reversed since the early 1980s. During the past 25 years, the annual production of ethanol by the United States and Brazil, the two largest ethanol producers in the world, increased dramatically (Table 29), whereas the United States production of synthetic ethanol decreased from a peak of 360 million gallons in 1969 (Anonymous, 1979) to 100 million gallons or less in the early 1990s (Table 29). The United States ethanol production is about 1.7 billion gallons per year; roughly 350 million gallons (20%) are used in industry and beverage-making. The unprecedented increase in ethanol production in the United States after 1980 Renewable Fuels Association (http://www.ethanolrfa.org) and Brazil after 1975 (Zanin et al., 2000) is mainly because of the use of ethanol in the automobile fuel to reduce the consumption of gasoline. With properly modified gasoline engines, anhydrous ethanol can be blended with gasoline up to a concentration of 85% ethanol (E85) for automobile use, whereas hydrated ethanol (the azeotropic mixture with water, containing about 95% ethanol) can be used as straight motor fuel in alcohol-fueled automobiles (Jackson and Moyer, 1991; Zanin et al., 2000). Dehydration of ethanol can now be accomplished by using a molecular sieve dehydrator according to Commercial Alcohols, Inc. (http://www.comalc.com), which is the largest alcohol producer and distributor in Canada, or by the traditional procedure of adding benzene to form a ternary azeotrope containing 74% benzene, 18.5% ethanol, and 7.5% water, which has a boiling point of 68°C, much lower than that (78.15°C) of the ethanol-water azeotrope. Fuel ethanol and industrial ethanol can be

manufactured by the same fermentation process, but with different finishing steps.

Essentially all of the fermentation ethanol is produced from sugars derived from corn (Table 30) and sugarcane juice (Zanin et al., 2000) using yeasts as the fermentation agent. However, BC International is building a production facility in Louisiana, in the United States, that will use *E. coli* KO11 (see Metabolic Engineering in this Chapter) to convert sugars present in bagasse and rice hull to ethanol (McCoy, 1998; Table 30). The BC International facility has an annual production capacity of 20 million gallons, which is comparable to or larger than the capacity of over 35 United States companies that are producing fuel ethanol from grains or waste materials (http://www.ethanolrfa. org). Positive results at the BC International plant can lead to expanded commercial uses of recombinant bacteria for the conversion of lignocellulosic material to ethanol.

Non-fuel Uses Alcoholic beverages are perhaps the most important use for ethanol, other than its industrial uses and its use as a fuel. The use of pure ethanol in alcoholic beverages is likely limited, because besides neutral spirits such as Vodka, ethanol is but one of the many crucial ingredients of each distinctive beverage. Useful information on the processes for the manufacturing of alcoholic beverages can be found in the following references: wine (Benda, 1982), beer (Helbert, 1982) and distilled spirits (Brandt, 1982).

Ethanol is one of the most versatile oxygen-containing organic chemicals. It has important uses as a solvent and in the manufacturing of other organic chemicals, pharmaceuticals, perfumes, toiletries, detergents, flavors, disinfectants and other products (Logsdon, 1994). The consumption of ethanol in these non-fuel products can be expected to grow, especially because ethanol is easily degraded in the environment and can be produced from renewable raw materials.

Fuel Ethanol The dramatic increase in the production and use of ethanol as an automobile fuel started in 1975 when the Brazilian National Alcohol Program or Pro-Alcohol Program was implemented (Jackson and Moyer, 1991; Zanin et al., 2000). Between 1975 and 1986, annual Brazilian ethanol production (from sugarcane juice) increased from 0.5 billion liters (132 million gallons) to 13 billion liters (3,434 million gallons). However, ethanol production decreased in the early 1980s before it stabilized after 1986 because of policy changes which reduced incentives for sugarcane production, the manufacturing of alcohol-driven automobiles, and the guaranteed price for ethanol. The production level was maintained at 14.16 billion liters (3,741 million gallons) for the 1996–1997 harvest and 13.8 billion liters (3,646 million gallons) for the 1997–1998 harvest. The performance of the Pro-Alcohol Program and the evolution of alcohol-fueled automobiles in Brazil were reviewed (Zanin et al., 2000).

Several reviews examined the merit, the technology, and the economics of producing fuel ethanol from lignocellulosic biomass, also known as "bioethanol" or "cellulosic ethanol" (Lynd et al., 1991; Ballerini et al., 1994; Wyman, 1994; Wyman, 1996; Himmel et al., 1997; Lugar and Woolsey, 1999; Sheehan, 2000). One review summarized key events of the last 20 years of this effort (Wyman, 2001). It was stressed that the production and use of bioethanol cause very low net greenhouse gas emissions, as shown by full fuel-cycle analysis. Fuel properties of ethanol,

other additives of gasoline, and unleaded regular gasoline can be found in Jackson and Moyer (1991) and Wyman (1994). More information about the fuel properties of ethanol can be found in a book produced by the Solar Energy Information Data Bank and published by the United States Government Printing Office (Winston, 1981).

Research and Development of Bacterial Ethanol Production

The technology is now available to produce fuel ethanol from lignocellulosic material. The challenge is to assemble the various process options into a commercial venture and to begin the task of incremental improvements (Ingram et al., 1999). The task of incremental improvements is a continuing one so that an initially successful process can remain competitive. For example, *E. coli* KO11 (Ohta et al., 1991a) is remarkable in having the capacity to ferment the constituent pentoses and hexoses of hemicellulose into ethanol with a high yield. Nevertheless, its ability to ferment simultaneously all the sugars in a mixture may be limited due to catabolite repression. The high ethanol productivity of *E. coli* KO11 may also be an unstable trait under certain conditions, and the ethanol tolerance of *E. coli* KO11 is still lower than that of yeasts used for commercial ethanol production. These are some of the shortcomings of *E. coli* KO11 that will require continued attention to improve. Mutants of *E. coli* KO11 have been obtained that are unable to ferment glucose and other sugars transported by the phosphoenolpyruvate-dependent sugar transport system, but these mutants retain the ability to ferment arabinose and xylose not transported by this system. Such mutants can use xylose efficiently in the presence of high concentrations of glucose, and a second fermentation step or a coculture may be employed to utilize the remaining glucose. Additional mutants have been obtained that retain the ability to ferment all sugars and can produce 60 g/liter of ethanol from 120 g/liter of xylose in 60 hours (Lindsay et al., 1995). Using an enrichment method that selects alternatively for ethanol tolerance and for ethanol production, more ethanol-tolerant mutants of *E. coli* KO11 were isolated (Yomano et al., 1998). Conditions have been identified that cause *E. coli* KO11 to lose

its high ethanol productivity. For example, maintenance of *E. coli* KO11 on xylose in chemostat cultures leads to the irreversible loss of high ethanol productivity (Dumsday et al., 1999). Such knowledge is important to the further improvement of this organism.

Research on growth and ethanol production by *Z. mobilis* is also in progress at the United States National Renewable Energy Laboratory or NREL (Himmel et al., 1997) and elsewhere (Zakpaa et al., 1997; Joachimsthal et al., 1998; McLellan et al., 1999; Silveira et al., 2001). The topics of these studies range from the selection of a mutant capable of ethanol production from glucose in the presence of 20 g/liter of sodium acetate (Joachimsthal et al., 1998) to the mechanism that causes an oscillatory behavior in the continuous fermentation of *Z. mobilis* (McLellan et al., 1999). The development of acetate-tolerant ethanol-producers is important because during acid hydrolysis of hemicellulose, acetic acid (which inhibits fermentation) is produced at a high ratio relative to fermentable sugars.

The conversion of cellulose into fermentable glucose requires the use of expensive fungal cellulase, and it remains a limiting factor in the conversion of lignocellulosic material to ethanol. There is intense research on cellulase, with an aim of decreasing the cost of cellulase production (Himmel et al., 1997). There has also been success in adding the ability to produce and secrete high levels of endoglucanase to *K. oxytoca* P2 so that the requirement for fungal cellulase is reduced in the simultaneous saccharification and fermentation (SSF) process for cellulose (Ingram et al., 1999). An alternative approach is to convert lignocellulosic material into CO and H_2 (synthesis gas), which can be converted to ethanol by some anaerobic bacteria (Clausen and Gaddy, 1996). At present, the synthesis-gas fermentation has a low volumetric productivity owing to physical and biological limitations (Worden et al., 1997). Improvements in both bioreactor design and metabolic capacity of the organism will be needed to make the process commercially useful.

The thermophilic anaerobic bacteria in the genera *Thermoanaerobacter* and *Thermoanaerobacterium* may emerge as useful organisms for ethanol production from lignocellulosic material because of their high ethanol productivity and their natural ability to use a wide range of sugars, oligosaccharides and polysaccharide. New ethanol-producing species of *Thermoanaerobacter* and *Thermoanaerobacterium* are reported (Cook et al., 1996; Liu et al., 1996; Larsen et al., 1997; Cann et al., 2001; Xue et al., 2001). These organisms offer a growing pool of potentially useful traits for use in metabolic engineering. Besides metabolic engineering, the performance of these organisms may also be enhanced under special growth conditions. A coculture of *T. ethanolicus* and *C. thermocellum* can convert cellulose into ethanol more efficiently than pure cultures can, without the addition of fungal cellulase (Wiegel, 1980). To make the thermophilic bacteria useful for commercial ethanol production, genetic tools are needed to refine their properties both now and in future incremental improvement. Electrotransformation procedures (Klapatch et al., 1996; Mai et al., 1997) as well as shuttle vectors and homologous recombination for chromosomal integration (Mai and Wiegel, 2000) have been developed for *Thermoanaerobacterium saccharolyticum* or *Thermoanaerobacterium thermosaccharolyticum*. Genes for hydrolytic enzymes have been introduced into *T. saccharolyticum* and expressed (Mai and Wiegel, 2000). These genetic tools should facilitate research with thermophiles such as *T. ethanolicus* and *C. thermocellum*.

Patents and Regulatory Issues

There are patents that cover three critical areas of bacterial ethanol production: the use of genetically engineered bacteria for ethanol production, the commercial production of cellulase for the saccharification of cellulosic materials, and the development of the simultaneous saccharification and fermentation (SSF) process.

The issuance of the United States patent no. 5,000,000 (Ethanol production by *Escherichia coli* strains coexpressing *Zymomonas mobilis pdc* and *adh* genes; Ingram et al., 1991) is a landmark event attesting to the innovative nature of using rationally constructed bacteria (see Metabolic Engineering in this Chapter) for producing ethanol from lignocellulosic material. Further improvement and extension of this approach have led to additional patents, for example, United States patents 5,028,539 (Ethanol production using engineered mutant *Escherichia coli*; Ingram and Clark, 1992), 5,424,202 (Ethanol production by recombinant hosts; Ingram et al., 1995b), 5,482,846 (Ethanol production by Gram-positive microbes; Ingram and Barbosa-Alleyne, 1996), and 5,821,093 (Recombinant cells that highly express chromosomally integrated heterologous genes; Ingram and Ohta, 1998a).

The development of manufacturing processes for stable cellulytic enzymes has resulted in United States patents 3,990,945 (Enzymatic hydrolysis of cellulose; Huff and Yata, 1976), 5,275,944 (Thermostable purified endoglucanase from *Acidothermus cellulyticus*; Himmel et al., 1994), and 5,712,142 (Method for increasing thermostability in cellulase enzymes; Thomas et al., 1997).

The introduction of simultaneous saccharification and fermentation (SSF) has been considered the most important process improvement made

for the enzymatic hydrolysis of biomass for bioethanol production (Sheehan, 2000). United States patent 3,990,944 (Manufacturing alcohol from cellulosic materials using plural ferments; Gauss et al., 1976) describes the SSF process. In the SSF process, the hydrolysis of cellulosic materials to glucose by a separately prepared cellulase and the fermentation of glucose by an alcohol-producing organism occur simultaneously in a reactor under anaerobic conditions. The advantages of the SSF process include the reduction of the number of reactors required and the alleviation of product inhibition of the hydrolytic enzymes.

The construction of the 20-million gallons per year plant by BC International Corporation (see Commercial Production in this Chapter) to utilize these technologies is an endorsement to the commercial value of the bacterial process. Future growth of the fermentation industry for producing fuel ethanol will depend on the price and availability of crude oil, the environmental issues, public policy and legislative trends, and public opinion (Himmel et al., 1997). At present, the costs of producing fuel ethanol by fermentation are still high that without tax credits and other forms of subsidy (Sheehan, 2000), fermentation ethanol will not be able to compete against gasoline, especially during periods when the price of oil drops. As illustrated by what occurred in Brazil in the 1980s, the production of fermentation ethanol is vulnerable to changes in economic and political factors. The "Brazilian miracle" ended when oil prices dropped and stabilized, the government-guaranteed price for ethanol was lowered, the special credit line for the cultivation of sugarcane was cut, and the tax incentive for manufacturing alcohol-driven automobiles was reduced (Zanin et al., 2000). The continuous growth of the demand for hydrated ethanol, which cannot be used in gasoline, further constrained the production of anhydrous ethanol. Thus, the production of fermentation ethanol in Brazil leveled off after 1986. On the other hand, the production of fuel ethanol in the United States is still on the rise (Table 30), and there are laws and regulations in the United States that encourage an increase in use of ethanol in automobile fuels.

The 1990 amendments to the Clean Air Act, requiring the addition of oxygenates to gasoline to reduce the formation of carbon dioxide and ozone in urban areas where the climate conditions favor the production of these pollutants, have created demand for ethanol, which is an oxygenate. The use of methyl *tert*-butyl ether (MTBE) as an octane-rating enhancer in gasoline is being phased out because of its leakage into the groundwater, hence creating another need for ethanol, which has a high octane rating (see Physicochemical Properties in this Chapter). The Biomass R&D Act of 2000 helps to support biomass conversion projects, which can help lower the production costs for ethanol as less expensive enzymes may be developed for converting lignocellulosic material into fermentable substrates. Any legislation that would require all United States gasoline to contain a certain amount of renewable fuels will further expand the market for ethanol.

Prospects

Production of ethanol by microbial fermentation is an ancient art. The tool of molecular biology has made it possible to alter the metabolic pathways of enteric bacteria and to allow their use in commercial production of ethanol from lignocellulosic material. As illustrated by Ingram and Conway (1988), the relative activity levels of pyruvate decarboxylase and alcohol dehydrogenase in genetically engineered *E. coli* have a major influence on ethanol productivity. In *E. coli* KO11 (Ohta et al., 1991a) and *K. oxytoca* P2 (Wood and Ingram, 1992), expression of these two enzymes is under the control of one promoter, the *pfl* promoter. It is conceivable that further improvement in ethanol productivity by these bacteria may be realized when the expression of these two enzymes is further fine-tuned and the competing reactions or limitations further decreased. The thermophilic ethanol producer *T. ethanolicus* (Wiegel, 1992) is an attractive candidate for future commercial use because of its high ethanol productivity and its natural ability to use a wide range of substrates including pentose and hexose sugars, lactose, and oligosaccharides containing xylose. To use lignocellulosic material as the raw material for ethanol production, the polymer must be pretreated to convert it into fermentable substrates—a costly process. Future improvement in this area holds the greatest promise in making bacterial ethanolic fermentation a more successful commercial process.

Ethanol tolerance remains a potential limiting factor for ethanol production by bacteria. However, it has been shown that by suppressing acid production, the recombinant *E. coli* can produce ethanol to a much higher level than what is achievable by the acid-producing parent strain, suggesting that carboxylic acids are more detrimental than ethanol to the cell. Therefore, when ethanol is the predominant end product, it not only facilitates product recovery but also circumvents inhibition caused by other products. At present, the low sugar concentration in the hemicellulose hydrolysate, rather than ethanol toxicity, is limiting the final ethanol concentration obtained with hemicellulosic substrates. Use of bacterial strains that are more tolerant to ethanol will improve the productivity of a process

when ethanol toxicity becomes the limiting factor for the process.

The use of ethanol in automobile fuels is by far the largest use for this chemical. Inclusion of ethanol in diesel fuels will further increase its market size. The future growth of the fuel ethanol market, however, will not be determined solely by the fuel properties of ethanol, the technological capabilities for its production, and economic factors. Public policies and the attitude of the consumer will play an important role in determining whether ethanol will remain the most substantial commercial product of microbial action.

Organic Acid and Solvent Production Part III: Butanol, Acetone and Isopropanol; 1,3- and 1,2-Propanediol Production; and 2,3-Butanediol Production

PALMER ROGERS, JIANN-SHIN CHEN AND MARY JO ZIDWICK

Section 8: Butanol, Acetone, and Isopropanol

Introduction

Butanol (also known as *n*-butanol or 1-butanol), acetone and isopropanol (2-propanol) are major fermentation products of several species of clostridia. As microbial products, butanol, acetone and isopropanol are usually studied together because their production involves shared metabolic pathways. These three compounds are important industrial chemicals with a broad range of uses. They also have potential uses as additives in automobile fuels because of their oxygen content, octane rating, heating value, and capacity to increase water tolerance of ethanol-gasoline blends. At present, butanol and isopropanol are commercially produced by synthesis using petroleum-derived propylene as the starting material. Acetone is coproduced during the synthesis of phenol, and this route satisfies the bulk of the market need for acetone. Therefore, isopropanol is a useful by-product from a biomass-based process for the production of butanol, whereas acetone is not as desirable unless the manufacturing method for phenol or the relative market need for acetone and phenol changes.

Because acetone and butanol were traditionally used as solvents, the industrial fermentation for the production of acetone, butanol and isopropanol is known as the "solvent fermentation." Industrial solvent fermentation is unique: it was the first industrial fermentation utilizing pure cultures and aseptic techniques, its large scale was unprecedented, and it was the first method for the production of butanol as a commodity chemical. In addition, modern industrial microbiology is based on the serendipitous history behind the development of this industrial fermentation (Kelly, 1936), the pivotal role played by the scientist-turned-statesman Chaim Weizmann in this endeavor (Rose, 1986), and the intricate relationship between enterprising scientists and businessmen who turned this fermentation into a successful industry (Rose, 1986). With its preeminent past and the continued improvements through research, solvent fermentation may serve to demonstrate the practicality of changing a petroleum-based economy back to a biomass-based (or bio-based) economy, which will utilize biomass-derived feedstocks to produce liquid fuels, organic chemicals, and materials. For the United States, a bio-based economy has been advocated as the primary route toward a sustainable and secure future (Thayer, 2000).

Butanol-acetone fermentation was first developed to produce butanol for use in the manufacture of synthetic rubber. However, it was the need for acetone as a solvent during World War I that provided the impetus for developing this fermentation into a successful industrial process. After World War I, the established fermentation process was used commercially to produce butanol needed to make butyl acetate (a solvent for the rapidly growing lacquer industry; Gabriel, 1928). The industrial process went through significant changes in the ensuing fifteen years as both the organisms and the raw materials for the fermentation were changed as a result of continued efforts to improve this fermentation (Beesch, 1952; Beesch, 1953).

Although most known solvent-producing clostridia produce both acetone and butanol, the discovery of these chemicals as products of microbial fermentation was reported half a century apart and with different organisms. Pasteur in 1861–62 (McCoy et al., 1926; Dürre and Bahl, 1996) reported the production of butanol by butyric acid-producing microorganisms, whereas Schardinger in 1905 (Prescott and Dunn, 1959b) reported the production of acetone by *Bacillus macerans*, which is not a butanol or butyric acid-producing organism. It was Fernbach who observed the production of both acetone and butanol by a bacillus he isolated for the production of butanol, which was used in the production of butadiene for the manufacture of synthetic rubber (Fernbach and Strange, 1911). Industrial solvent fermentation began in 1913 as a process

for producing butanol from potatoes (Gabriel, 1928).

The outbreak of World War I in 1914 changed the course of industrial solvent fermentation. To make large amounts of acetone needed in Britain as a solvent for the production of the smokeless explosive cordite, the Fernbach and Strange process was used at first (Gabriel, 1928). However, when the Weizmann bacterium or BY (which was later named "*Clostridium acetobutylium*") was found to produce from corn more acetone and butanol than the Fernbach bacillus produced, it replaced the Fernbach bacillus for the production of acetone, first in Britain and then in North America, during World War I (Gabriel, 1928). After the Armistice in 1919, acetone was no longer in demand and the government-operated fermentation system was terminated. However, butanol was soon found to be extremely valuable for the manufacture of the fast drying lacquer used by the automobile industry. Thus, beginning in 1920, solvent fermentation (used to produce butanol and acetone or isopropanol and other products) was a major commercial operation for four decades. For about a decade, the industry used the patented Weizmann process exclusively, with strains of *C. acetobutylicum* developed against phage infections and with corn as the raw material. But by 1933, the raw material was switched to molasses, and *C. acetobutylicum* (which is not productive in a molasses-based medium) was replaced by an organism known as "No. 8" (Kelly, 1936). This switch in raw materials and organisms occurred before the expiration of the Weizmann patent in 1936.

When the raw material was switched from corn to molasses, many new patents were issued for the molasses-based fermentation processes, and many newly isolated bacteria for these processes were named in the patents (Beesch, 1952). Public culture collections have maintained some of these molasses-fermenting solvent-producing clostridia, most of which were referred to as strains of *C. acetobutylicum* either by the culture collections or by the investigators. When research on solvent fermentation became active again in the late 1970s, several strains of "*C. acetobutylicum*" from public and private culture collections were extensively studied, and these "*C. acetobutylicum*" strains displayed surprisingly different properties (Johnson and Chen, 1995; Keis et al., 1995).

A systematic study of these cultures revealed nine groups (Keis et al., 1995), whereas analysis of DNA-DNA reassociation identified these cultures as strains of four species (Johnson and Chen, 1995; Johnson et al., 1997). These four *Clostridium* species, *C. acetobutylicum*, *C. beijerinckii*, *C. saccharobutylicum* and *C. saccharoperbutylacetonicum* can now be differentiated by their genetic and phenotypic traits (Johnson et al., 1997; Keis et al., 2001a). Several other characterized species of *Clostridium* produce butanol but in lower concentrations than that produced by these four *Clostridium* species (see the subsection Solvent-Producing Bacteria in this Chapter).

In addition to the correct identification of the solvent-producing organisms, much progress has been made since the early 1980s in determining the properties of the solvent-producing enzymes (see the subsection Metabolic Pathways and Enzymology of Solvent Production in this Chapter) and their structural genes (see the subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter). Manipulation of the genes encoding the acid- and solvent-producing enzymes in *C. acetobutylicum* has demonstrated the feasibility of reaching a butanol concentration higher than any previously reported values (see the subsection Metabolic Engineering in this Chapter). The genome of *C. acetobutylicum* ATCC 824 has now been sequenced (Nolling et al., 2001), which should facilitate the characterization of the regulatory mechanisms for solvent production.

Since the mid-1980s, a number of reviews have been written on microbial production of butanol, acetone, and isopropanol (Jones and Woods, 1986; McNeil and Kristiansen, 1986; Dürre and Bahl, 1996; Dürre, 1998; Rogers, 1999). There are also reviews that cover all aspects of industrial solvent fermentation (Gabriel, 1928; McCutchan and Hickey, 1954; Ryden, 1958; Prescott and Dunn, 1959c; Ross, 1961; Hastings, 1978). The following reviews address in detail specific aspects of solvent fermentation or the solvent-producing clostridia: microbiology (Beesch, 1952; Beesch, 1953; Prescott and Dunn, 1959c; Johnson and Chen, 1995; Jones and Keis, 1995), biochemistry and physiology (Rogers, 1986; Chen, 1993; Chen, 1995; Bennett and Rudolph, 1995; Dürre et al., 1995; Girbal and Soucaille, 1998; Mitchell, 1998), genetics (Rogers, 1986; Minton and Oultram, 1988; Young et al., 1989; Woods, 1995; Dürre, 1998), the industrial processes (Killeffer, 1927; Gabriel, 1928; Beesch, 1952; Beesch, 1953; McCutchan and Hickey, 1954; Ryden, 1958; Spivey, 1978; Walton and Martin, 1979), and history (Gabriel, 1928; Gabriel and Crawford, 1930; Kelly, 1936; McCutchan and Hickey, 1954; Jones and Woods, 1986).

Scientific Background

PHYSICOCHEMICAL PROPERTIES The physicochemical properties of acetone, butanol, and isopropanol are listed in Table 31. Ethanol is included in the table because it is a product of all known

Table 31. Physical properties of the neutral products of the solvent-producing bacteria.

	Acetone	*n*-Butanol	Isopropanol	Ethanol
Formula	$(CH_3)_2CO$	$CH_3(CH_2)_3OH$	$(CH_3)_2CHOH$	C_2H_5OH
Mol. wt.	58.08	74.12	60.09	46.07
Boiling point (°C)	56.5	117.7	82.5	78.5
Specific gravity	0.791 (20°/20°)	0.811 (20°/4°)	0.785 (20°/4°)	0.789 (20°/4°)
Pounds/gallon	6.58	6.75	6.55	6.578
Heating value				
Btu/gallon	93,028	103,849	87,400	76,000
MJ/liter	26	29	24	21
Oxygen content	27.6	21.6	26.6	34.7
RON[a]		113	121[b]	106, 130[b]
MON[a]	93	94	96[b]	92, 96[b]

Abbreviations: Btu, British thermal units; MJ, megajoules; RON, research octane number, the number used in predicting antiknock performance during low-speed acceleration; and MON, motor octane number, the number used in predicting antiknock performance at high constant speed.

[a]In gasoline blends, these and other measurements of octane numbers are influenced by the composition of the base fuel and other factors, which makes it difficult to give absolute values for the octane quality of the various alcohols and oxygenates (Owen and Coley, 1990; Houben, 1995).

[b]Blending octane numbers (Houben, 1995).

solvent-producing bacteria and because these four compounds share properties which make them useful as oxygenates and as octane-rating enhancers in gasoline (see "Ethanol" in Organic Acid and Solvent Production, Part II in this Volume). These compounds, because of their similar fuel properties, can be used as a mixture in gasoline or diesel. Besides increasing the oxygen content and the octane rating, acetone and isopropanol can increase the water tolerance of the ethanol-gasoline mixture (see the subsection Uses in this Chapter).

Solvent-Producing Bacteria The early history (1861–1909) of the discovery of the butanol-, acetone-, and isopropanol-producing bacteria has been reviewed by Dürre and Bahl (1996), who listed 22 references (all in either German or French) documenting the contribution of Pasteur, Fitz, Beijerinck, Schardinger, and Pringsheim to the field. Pasteur, Schardinger and Pringsheim, respectively, were the first to observe or report the production of, respectively, butanol, acetone and isopropanol by anaerobic bacteria. Pasteur coined the term "anaerobic" to describe butyric acid- and butanol-producing bacteria that were killed in air.

All known butanol-producing and most acetone-producing organisms are Gram-positive, spore-forming bacteria, and all produce ethanol in addition to butanol and acetone or isopropanol. Processes using butanol-producing bacteria yield less ethanol than other neutral products, whereas processes using bacteria that do not produce butanol yield more ethanol than acetone, which can be explained by the fact that the latter organisms (such as *B. macerans*) dispose of excess reducing power mainly through ethanol production.

The correct identification of the butanol- and acetone-producing clostridia is difficult because they are phenotypically similar. In addition, some useful criteria for bacterial identification are not reliable when applied to this group of organisms. The fatty acid composition of the membrane lipids (Lepage et al., 1987) and the pattern of fermentation products change when cells switch from the acid-producing stage to the solvent-producing stage of growth or when solventogenesis occurs under slightly different conditions. Although the phylogeny of the genus *Clostridium* can be deduced from a comparison of 16S rRNA sequences (Collins et al., 1994), data of chromosomal DNA-DNA hybridization are necessary to establish the species status (Stackebrandt and Goebel, 1994). Most of the recognized species of solvent-producing clostridia have been examined by the DNA-DNA hybridization technique (Cummins and Johnson, 1971; George et al., 1983b; Johnson et al., 1997).

The solvent-producing bacteria may be divided into four groups (Table 32) according to their major end products: 1) Those producing acetone but not butanol or isopropanol, 2) those producing butanol and acetone, 3) those producing isopropanol in addition to acetone and butanol, and 4) those producing butanol but not acetone. The salient properties of species within each group are described below.

Acetone-Producing Bacteria Acetone as a product of bacterial fermentation was first reported by Schardinger in 1905 (Prescott and Dunn, 1959b) when the species *Bacillus macerans* was named. Ethanol, acetone, and acetic and formic acids are the major end products from the fermentation of potatoes or potato starch in media

Table 32. Four groups of solvent-producing bacteria[a] on the basis of their neutral end products.

Neutral end products			
Acetone	Butanol and acetone	Butanol, isopropanol and acetone	Butanol
Bacillus macerans *Methylosinus trichosporium*	*Clostridium acetobutylicum* *Clostridium beijerinckii* (some strains) *Clostridium saccharoperbutylacetonicum* *Clostridium saccharobutylicum* *Clostridium puniceum* *Clostridium pasteurianum*	*Clostridium aurantibutyricum* *Clostridium beijerinckii* (some strains) "*Clostridium toanum*"	*Clostridium tetanomorphum* *Clostridium thermosaccharolyticum*

[a]All produce ethanol.

also containing peptone and calcium carbonate. Subsequently, an organism named "*Bacillus acetoethylicum*" (later changed to "*Bacillus acetoethylicus*" and is now considered synonymous to *B. macerans*) was isolated (Northrop et al., 1919) and used in the study of factors influencing acetone formation (Arzberger et al., 1920). "*Bacillus acetoethylicum*" produced ethanol (12–26% of the weight of the carbon substrate) and acetone (4–10% of the weight of the carbon substrate) from mono-, di- and polysaccharides; however, it produced ethanol (40–43% of the weight of the carbon substrate) but no acetone when glycerol was the fermentation substrate (Northrop et al., 1919). The lack of acetone production has also been observed with *Clostridium acetobutylicum* when it is grown under the alcohologenic conditions (see the subsection Physiology of Solvent Production in this Chapter), which include the use of a mixture of glucose and glycerol in the growth medium (Girbal and Soucaille, 1994; Vasconcelos et al., 1994).

Acetone production by *B. macerans* occurs late in the fermentation and is enhanced by a low culture pH (Prescott and Dunn, 1959b). A significant increase in acetone (from 12 to 40 mM) and ethanol (from 44 to 154 mM) production by *B. macerans* ATCC 7068 was observed when $CaCO_3$ (100 mM) and sodium acetate (24 mM) were added to the CM5 medium containing 2% glucose and 0.2% yeast extract (Weimer, 1984a).

In addition to strains maintained at national culture collections, the culture collection of the United States Department of Agriculture (USDA) at the Midwest Area National Center for Agricultural Utilization Research in Peoria, Illinois, maintains many strains of *B. macerans*, which carry the designation "NRRL." These NRRL strains of *B. macerans* include the NRS strains originally maintained by N. R. Smith. The following NRRL strains of *B. macerans* produced 20–40 mM acetone and >150 mM ethanol at 35°C in the CM5 medium (see above) containing 2% glucose and 0.2% yeast extract without the addition of $CaCO_3$ or sodium acetate: B-392 (NRS-646), B-433 (NRS-1098), B-434 (NRS-1099), and B-3185 (NRS-649; P. Moldenhawer and J.-S. Chen, unpublished result).

Acetone is also produced from poly-3-hydroxybutyrate by the methylobacterium *Methylosinus trichosporium* OB3B (Thomson et al., 1976). It was proposed that poly-3-hydroxybutyrate is metabolized to 3-hydroxybutyrate and acetoacetate, whereas acetone is produced from acetoacetate via acetoacetate decarboxylase (reaction 17 in Fig. 26).

Butanol- and Acetone-Producing Bacteria

Clostridium acetobutylicum is the best known butanol- and acetone-producing organism, and some misconception about this species persists in the literature. Elizabeth McCoy and coworkers at the University of Wisconsin proposed the name "*Clostridium acetobutylicum*" in 1926 for "the acetone butyl alcohol organism" represented by the 11 strains they used in a cultural study (McCoy et al., 1926). Seven of the 11 strains were received from the Commercial Solvents Corporation of Terre Haute (Indiana, United States), and the other four (strains 6, 8, 10, and 11) were from the Department of Agricultural Bacteriology at the University of Wisconsin (McCoy et al., 1926; McCoy and McClung, 1935). Strain 1 of this study was believed to be a Weizmann culture although its history was not fully known (McCoy and McClung, 1935). In 1927, Weyer and Rettger (1927) reported the result of a comparative study of six cultures of the acetone butyl alcohol organism, one of which was isolated from Connecticut (United States) garden soil in October 1924 and was designated "strain *So*," which eventually became ATCC 824, the type strain for the species *C. acetobutylicum* (McCoy and McClung, 1935). Weyer and Rettger (1927) supported the use of the name *Clostridium acetobutylicum* for this group of organisms. In a study on "the serological agglutination of *Clostridum acetobutylicum*

and related species" (McCoy and McClung, 1935), 22 cultures were used and they included "Strain W_{17}" as well as "Strain 1" (believed to be a Weizmann culture) and "Strain W" (the Weyer and Rettger Strain *So*; now ATCC 824). Strain W_{17} was an original Weizmann culture, which was "preserved in a sealed spore stock for seventeen years by Weizmann, and received by us through one intermediate, the late Sir Frederick Andrews of London" (McCoy and McClung, 1935). Results of these cultural and serological studies support the conclusion that these strains are sufficiently similar among themselves and different from other known species to be considered *C. acetobutylicum*.

Some publications incorrectly credited Chaim Weizmann for proposing the name *Clostridium acetobutylicum*. McCoy and McClung (1935) clearly stated "discovery of the organism and certainly discovery of its usefulness in industrial fermentation is attributed to Weizmann, who, though he never fully described or named his organism, succeeded in differentiating it from formerly known butyl-alcohol-producing anaerobes." For several reasons, some investigators thought that Weizmann named the species *C. acetobutylicum*. McCoy and coworkers (McCoy et al., 1926) proposed the name "Clostridium acetobutylicum (Weizmann)" [*sic*] for the species, whereas Weyer and Rettger (1927) gave the name "*Clostridium acetobutylicum*, Weizmann" [*sic*] in the description chart for their Strain *So* (now ATCC 824). Statements such as "the butyl alcohol organism of Weizmann, *Clostridium acetobutylicum*" (McCoy and McClung, 1935) and "*Clostridium acetobutylicum Weizmann* [*sic*]" in the biography for Weizmann (Rose, 1986) probably also contributed to the misconception. That the strain *So* (now ATCC 824), which was isolated by Weyer and Rettger, was designated "strain W" by McCoy and McClung (1935) may also have misled some investigators to think that strain ATCC 824 was the Weizmann strain.

Weizmann did not fully describe the isolation of the organism that was successfully used in industrial production of acetone and butanol from corn, which may have prompted John J. H. Hastings to suggest "Weizmann obtained such an organism, though it is possible that he did not isolate it himself" (Hastings, 1971) and "there is some doubt whether he in fact isolated his own culture or obtained it from an existing source" (Hastings, 1978). However, in the Weizmann biography (p. 120; Rose, 1986), it is stated that "...Weizmann turned to a relatively new field: microbiology. From the spring of 1909 he began to spend his vacations at the Pasteur Institute in Paris." Weizmann studied microbiology under Professor Auguste Fernbach, the director of the Fermentation Laboratories of the Pasteur Institute, and was considered by contemporary microbiologists as "a student of Fernbach's" (Arzberger et al., 1920). It is thus conceivable that Weizmann was proficient in anaerobic bacteriological techniques and capable of isolating from corn the strain used in his industrial process awarded the 1915 British Letters patent no. 4845 (Weizmann, 1915). Fernbach isolated an organism (bacillus of the type of Fitz or BF) that produced acetone and butanol from potatoes but not corn, and the industrial performance of the Fernbach's patented process (Fernbach and Strange, 1911) was inferior to the Weizmann process using *C. acetobutylicum* and corn mash (see the subsection Industrial Solvent Fermentation in this Chapter). After the outbreak of World War I, the Fernbach process was replaced by the Weizmann process for better acetone production (Gabriel, 1928; Gabriel and Crawford, 1930).

As an obligate anaerobe, *C. acetobutylicum* is relatively insensitive to O_2, which was considered somewhat paradoxical because

"...it can be cultured in open tubes of fresh carbohydrate media.... Germination of spores in air is not possible as in the case of ordinary facultative organisms. And yet after a culture is well started in corn mash, oxygen may be bubbled through it intermittently without seriously disturbing its fermentation. Likewise, colonies developed in an anaerobic jar may on removal to air continue to grow by piling up of the bottom layers of growth." (McCoy et al., 1926).

The oxygen tolerance of *C. acetobutylicum* may have contributed to its commercial success and is a useful property.

In 1926, the name "*Clostridium acetonigenum*" was proposed by H. J. L. Donker, a Dutch microbiologist at Delft, for the species now known as "*C. acetobutylicum*." To circumvent the need to determine the priority of the names and to avoid confusion, the Dutch scientist later withdrew the name "*Clostridium acetonigenum*" (McCoy and McClung, 1935).

Clostridium acetobutylicum can use a wide range of carbohydrates ranging from pentoses to starch for growth and is strongly proteolytic. Production of acetone and butanol from sugars by *C. acetobutylicum*, however, requires close control of the pH of the medium. Corn mash, on the other hand, has the right buffering capacity so that this species can without pH control produce acetone and butanol in corn mash. An inability to produce high levels of solvents from molasses distinguishes *C. acetobutylicum* from the other solvent-producing clostridia. *Clostridium acetobutylicum* can now be clearly differentiated from the other solvent-producing species by measuring DNA-DNA reassociation (Johnson et al., 1997) or by comparing several genetic and phenotypic traits (Keis et al., 2001a).

Although acetone, butanol, and ethanol are the characteristic end products of *C. acetobutylicum* during the well known solventogenic mode of growth, there is another solventogenic mode of growth, dubbed alcohologenesis, during which *C. acetobutylicum* produces butanol and ethanol but little or no acetone. See the subsection Physiology of Solvent Production in this Chapter for growth conditions leading to alcohologenesis.

Clostridium beijerinckii (one of the molasses-fermenting butanol-producing clostridia) is less well known than *C. acetobutylicum* because many strains of this species were previously given different species names. *Clostridium beijerinckii* replaced *C. acetobutylicum* for commercial solvent production after the corn-based Weizmann process was phased out in the late 1930s (Johnson and Chen, 1995; Jones et al., 2000). Many extant strains of *C. beijerinckii* have been definitively identified by DNA-DNA reassociation or a combination of traits and are available from culture collections (Cummins and Johnson, 1971; Johnson et al., 1997; Keis et al., 2001a).

Clostridium acetobutylicum and *C. beijerinckii* are among the many species of butyric acid-producing clostridia that are difficult to differentiate on the basis of morphological and growth characteristics alone. The seventh edition of *Bergey's Manual of Determinative Bacteriology* listed 19 species of nonpathogenic, butyric acid-producing clostridia (Cummins and Johnson, 1971). Measurements of DNA-DNA reassociation and cell wall composition allowed the identification of a species (Homology group II) of butyric acid-producing clostridia (e.g., *C. beijerinckii*; Cummins and Johnson, 1971). This group initially consisted of 20 cultures previously designated as "*C. butyricum*," "*C. multifermentans*," "*C. amylolyticum*," "*C. rubrum*," "*C. lactoacetophilum*" and "*C. aurantibutyricumi*" (Cummins and Johnson, 1971). Notably, only some of the strains previously labeled as members of these species as well as "*Clostridium butylicum*" (George et al., 1983b), "*C. madisonii*" (Keis et al., 2001a), several strains of *C. acetobutylicum*, and others (Johnson et al., 1997) were found to belong to *C. beijerinckii*.

The species *C. beijerinckii* was named after the Dutch bacteriologist M. W. Beijerinck by Donker in his 1926 thesis (George et al., 1983b). At that time, *C. beijerinckii* was thought to be unable to ferment starch and hence differed from "*Clostridium butylicum*" (originally "*Granulobacter butylicum Beijerinck 1893*"). However, many strains of *C. beijerinckii* have since been found to ferment starch (George et al., 1983b; Nimcevic et al., 1998), and *C. beijerinckii* NRRL B592 has been used in pilot-plant studies to produce solvents from potatoes (Nimcevic and Gapes, 2000). Although the name "*C. butylicum*" would have priority over *C. beijerinckii*, an apparent oversight during the preparation of the *1980 Approved Lists of Bacterial Names* resulted in the use of *C. beijerinckii* as the name for this solvent-producing species (George et al., 1983b). *Clostridium beijerinckii* also contains strains that produce isopropanol, instead of acetone, as a major end product. When methyl viologen is added to the medium, *C. beijerinckii* NRRL B591 (formerly labeled as "*C. acetobutylicum*") produces either ethanol (pH 6.8) or butanol and ethanol (pH 5), but with little or no acetone (Rao and Mutharasan, 1986).

Clostridium aurantibutyricum is a species distinguishable from *C. beijerinckii* and *C. butyricum* on the basis of DNA-DNA reassociation (Cummins and Johnson, 1971). Two strains (including the type strain) of *C. aurantibutyricum* have been examined for solvent production, and both produce butanol, acetone and isopropanol from glucose (George et al., 1983b). It is not known whether isopropanol production is a general property of this species; however, many strains of *C. beijerinckii* produce acetone but not isopropanol, and some do not produce solvents under conditions that are solventogenic for the producing strains (Chen and Hiu, 1986).

Clostridium saccharoperbutylacetonicum was isolated from Japanese soil by Hongo and Nagata in 1959 (Hongo and Murata, 1965a). Derivatives of *C. saccharoperbutylacetonicum* strain N1 were used in industrial production of acetone and butanol from molasses in Japan between 1959 and 1960 (Ogata and Hongo, 1979). This species was chosen for industrial application because it produced a high proportion of butanol (Hongo and Murata, 1965a). During the period that *C. saccharoperbutylacetonicum* was used in industrial butanol production, a series of phage-resistant strains (such as *C. saccharoperbutylacetonicum* strains N1-120, N1-508, and N1-621) were selected to counter the frequent occurrence (12 times in a year) of phage contamination of the fermentation (Hongo and Murata, 1965a; Ogata and Hongo, 1979), and a record of their development is available.

"*Clostridium saccharobutylicum*" is the name proposed (Keis et al., 2001a) for the species represented by strains NCP 262 (also known as P262 or NCP P262) and NRRL B-643 (Johnson and Chen, 1995; Johnson et al., 1997). Strain NCP 262 was one of the production strains used at the National Chemical Products (NCP) plant in Germiston, South Africa (Keis et al., 1995), whereas strain NRRL B-643 was provided by Commercial Solvents Co. to Northern Regional Research Laboratory (now Midwest Area National Center for Agricultural Utilization Research) of the USDA (L. K. Nakamura, personal communica-

tion). The Commercial Solvents Co. utilized a number of molasses-fermenting clostridia for solvent production after the expiration of the Weizmann patent (see the subsection Industrial Solvent Fermentation in this Chapter).

Clostridium puniceum produces butanol and acetone from glucose or starch, and a molar ratio of butanol (179 mM) to acetone (16.8 mM) reached above 10 in a fed-batch fermentation with a total of 7.2% (w/v) of glucose (Holt et al., 1988). *Clostridium puniceum* is a pink-pigmented, pectinolytic bacterium (Lund et al., 1981), while *C. beijerinckii* NRRL B592 produces a pink-lavender pigment (J.-S. Chen, unpublished observation). On the basis of 16S rRNA sequences, *C. puniceum* is phylogenetically close to *C. beijerinckii* and three not validly published clostridial species "*C. corinoforum*," "*C. favososporum*" and "*C. caliptrosporum*" (Collins et al., 1994). *Clostridium puniceum* has not been examined by the DNA-DNA reassociation technique.

Clostridium pasteurianum ATCC 6013 produces acetone (90 mM), butanol (135 mM) and a low level of ethanol in a mineral salts medium with 12.5% (w/v) of glucose (Harris et al., 1986). In media containing 3.5% (w/v) or less of glucose, *C. pasteurianum* produced only low levels of butanol and little or no acetone (George et al., 1983b; Harris et al., 1986; Dabrock et al., 1992). A newly isolated strain of *C. pasteurianum* produced acetone and butanol from 3% dahlia inulin (Oiwa et al., 1987). *Clostridium pasteurianum* produces butanol, 1,3-propanediol, and ethanol from glycerol (Nakas et al., 1983; Heyndrickx et al., 1991; Dabrock et al., 1992).

Butanol- and Isopropanol-Producing Bacteria Some strains of *Clostridium aurantibutyricum* and *C. beijerinckii* have the capacity to reduce acetone to isopropanol, and in these organisms, isopropanol may supercede acetone as the second most abundant neutral end product after butanol (George et al., 1983b). The butanol- and isopropanol-producing organism "*Clostridium toanum* Baba" (Prescott and Dunn, 1959c) was used in large-scale production of butanol and isopropanol in Taiwan between 1942 and 1958 (see the subsection Industrial Solvent Fermentation in this Chapter), but this organism is not available from any major culture collection.

Butanol-Producing Bacteria When a viologen dye or one of the other additives is present in the growth medium and the pH is maintained above a certain value, *C. acetobutylicum* and *C. beijerinckii* produce butanol and ethanol but not acetone (see the subsection Physiology of Solvent Production in this Chapter). There are other species of clostridia that produce butanol but not acetone or isopropanol in growth media without these additives. They include *Clostridium tetanomorphum* (Gottwald et al., 1984) and *Clostridium thermosaccharolyticum* (Freier-Schroeder et al., 1989). The amount of butanol produced by these species is much less than that produced by the acetone- and butanol-producing species.

Taxonomic Studies For over 60 years, many strains of solvent-producing clostridia were used in large-scale commercial production. Other strains that were developed for patented processes and documented in the literature were not actually used in commercial production. Some of these strains are still available from culture collections, but many of them have been assigned incorrect species names. Historically, strains that are similar enough to qualify as members of the same species were often given different species or genus names when they were part of patented processes (Beesch, 1952). After the expiration of the patents, culture collections and individual laboratories may do the reverse, i.e., lump genuinely different organisms into a single species. The latter practice is especially problematic because seemingly contradictory properties would be reported for cultures labeled with the same name but actually belonging to different species (Johnson and Chen, 1995).

When the species *C. acetobutylicum* was proposed by McCoy and coworkers (McCoy et al., 1926) for the 11 strains of acetone- and butanol-producing clostridia that include a strain believed to have come from Weizmann (McCoy and McClung, 1935), the comprehensive cultural study provided a detailed description of the organism's growth characteristics. For many of the solvent-producing clostridia that were isolated later for the molasses (sucrose)-based fermentation, there are no published records of comparably comprehensive cultural studies, but some of these cultures were labeled as *C. acetobutylicum* after they were maintained in the culture collections (Johnson and Chen, 1995; Keis et al., 1995; Keis et al., 2001a; Johnson et al., 1997). The loose use of species names plagued the early investigators (McCoy and McClung, 1935), and it remains a problem now. Attention to the current definition for a bacterial species (Johnson, 1984) and the proper procedure for differentiating species (Stackebrandt and Goebel, 1994) should be helpful.

For phenotypically similar bacteria, provided they share a similar DNA base composition (mol% G+C), which is a characteristic of most solvent-producing clostridia, the DNA-DNA reassociation technique is required to separate them to the species level (Stackebrandt and Goebel, 1994). On the basis of percent DNA relatedness as measured by DNA-DNA reassociation, cultures of "*C. acetobutylicum*" from var-

ious collections can be clearly separated into four species (Johnson and Chen, 1995; Johnson et al., 1997): *C. acetobutylicum*, *C. beijerinckii*, *C. saccharoperbutylacetonicum* and *C. saccharobutylicum* (Keis et al., 2001a). On average, *C. acetobutylicum* strains have a 10% DNA sequence similarity with the other three species, whereas the other three species share a 20% sequence similarity. Within each species, the level of DNA sequence similarity among strains is between 70 and 100%, except for strain NCIMB 6444, which has a similarity level between 54 and 80% (average 69.6%) with 16 strains of *C. beijerinckii*. The cutoff value for strains to be considered as belonging to the same species is 70% (Johnson, 1984).

Using DNA fingerprinting and biotyping (susceptibility to rifampin, inhibition by bacteriocins, and cell lysis by bacteriophages), 55 cultures of solvent-producing clostridia (most of them having been labeled as "*C. acetobutylicum*") were separated into nine groups (Keis et al., 1995). Sequence analyses of the partial and almost complete 16S rRNA genes of strains representing the nine groups clearly separated *C. acetobutylicum* strain ATCC 824 from the others; however, these other strains of solvent-producing clostridia shared a 16S rRNA sequence similarity above 98% and could not be further divided into groups. In fact, some of these strains are more similar to each other (such as *C. saccharobutylicum* strain NCP 262 and *C. saccharoperbutylacetonicum*) than to *Clostridium puniceum* on the basis of 16S rRNA sequence (Keis et al., 1995). That bacterial species within a genus cannot generally be differentiated on the basis of the 16S rRNA sequence has been emphatically pointed out (Stackebrandt and Goebel, 1994).

Industrial Solvent Fermentation Solvent fermentation was a significant industrial process between the late 1910s and early 1960s, and it was used for commercial purposes for most of this period. After the early 1960s, use of this biomass-based fermentation process remained practical at only a few places. The continued operation of this fermentation in those localities as well as the operation before the fermentation was commercialized shows that the usefulness of solvent fermentation is not solely dictated by commercial or economic factors; the bacterial process enables a nation to use locally generated biomass, instead of imported or strategically more important raw materials, to produce needed chemicals. Examples of such strategic operations are the production of acetone for the British Navy during World War I (Jones and Woods, 1986), the production of butanol for Japanese armed forces during World War II (Anonymous, 1956), and the production of acetone and butanol in South Africa, until the early 1980s (Jones and Woods, 1986). The future usefulness of this fermentation will continue to be affected by national security needs.

All aspects of industrial solvent fermentation have been reviewed, both during the years of peak production (Killeffer, 1927; Gabriel, 1928; Gabriel and Crawford, 1930; Kelly, 1936; Prescott and Dunn, 1949; Beesch, 1952; Beesch, 1953; McCutchan and Hickey, 1954) and thereafter when industrial solvent fermentation was viewed from a different perspective (Ryden, 1958; Ross, 1961; Hastings, 1971; Hastings, 1978; Spivey, 1978; Walton and Martin, 1979; Jones and Woods, 1986; McNeil and Kristiansen, 1986). Therefore, only a brief history of industrial solvent fermentation is given here.

Industrial interests in butanol fermentation began during the first decade of the 20th century because of a drive to make synthetic rubber. Butadiene, a leading monomer being considered for polymerization into synthetic rubber, can be manufactured from butanol, but at that time, butanol had not been produced commercially. Auguste Fernbach, director of the Fermentation Laboratories at the Pasteur Institute (Paris), was then a principal investigator of fermentation studies, and since the spring of 1909, Chaim Weizmann began to spend his vacations with Fernbach to study fermentations (Rose, 1986). In 1910, E. Halford Strange of the English firm Strange and Graham, Ltd., contracted Sir William Perkin, professor of chemistry at Manchester University (who in turn contracted his assistant Chaim Weizmann) to conduct research on synthetic rubber. From his study with Fernbach, Weizmann gained the expertise in anaerobic microbiology that he applied to his investigation in Manchester on the fermentation processes related to synthetic rubber. Through Weizmann, Fernbach was also under contract with Strange by December 1910 to work on butanol fermentation (Rose, 1986).

Fernbach and Strange (1911) were issued the British patents 15,203–15,204 on "Acetone and high alcohols (amyl, butyl, or ethyl alcohols and butyric, propionic or acetic acid) from starches, sugars, and other carbohydrates." In 1913, the first plant for the production of butanol from potatoes began in Rainham, England, using the bacillus isolated by Fernbach (Gabriel and Crawford, 1930). In the meantime, Weizmann was conducting research on butanol fermentation on his own, after he had broken his association with Perkin, Strange and Fernbach in 1912 (Rose, 1986). It was during this period that Weizmann isolated the acetone- and butanol-producing anaerobic bacterium that was later named "*Clostridium acetobutylicum*" by McCoy and coworkers (McCoy et al., 1926). *Clostridium*

acetobutylicum produces useful quantities of butanol and acetone from corn, which is a property not possessed by the bacillus used in the patented process of Fernbach and Strange.

When World War I broke out in 1914, the British government recognized the usefulness of the fermentation process of Weizmann for the production of acetone, which was needed as a solvent for the production of the smokeless explosive cordite for the British Navy. The process was initially used in England to produce acetone, but a shortage of corn there forced the transfer of the operation to Canada (between August 1916 and November 1918), where 3,000 tons of acetone were produced for the British government. After the entry of the United States into World War I in 1917, two distilleries (the Commercial Distillery and the Majestic Distillery) in Terra Haute, Indiana, were purchased, respectively, by the British and United States governments to produce acetone, and they were in operation between May and November 1918 (Gabriel, 1928). These government-operated plants were closed after Armistice in November, 1918. However, commercial solvent fermentation began in the United States two years later, and by the end of 1927, a total of 148 fermentors were in operation to produce solvents.

The commercial success of solvent fermentation was driven by the fast-growing automobile industry, which needed a fast-drying, low-viscosity paint for finishing the automobile body. Butyl acetate, which is produced from butanol, has the desired properties for the manufacturing of the fast-drying nitrocellulose lacquer. This potential use of butanol resulted in the formation of the Commercial Solvents Corporation of Maryland, which purchased from the Allied War Board the two plants at Terre Haute in 1919. Operations at the Majestic Distillery started in 1920, which is the real beginning of the commercial use of the Weizmann process and the associated organism *C. acetobutylicum* (Gabriel, 1928).

The rapid growth in demand for butanol is illustrated by the rate at which the plant capacity was expanded between 1920 and 1927. The Terre Haute plant had 40 fermentors initially, and it was increased to 52 during 1923. When the plant in Peoria began operation at the end of 1923, it had 32 fermentors (50,000 gallons each). A year later, the Peoria plant had 48 fermentors, and toward the end of 1927, the number increased to 96 (50,000 gallons each), for a total of 148 fermentors for both plants (Gabriel, 1928). By 1927, the two plants together produced more than 100 tons of solvents per day (Killeffer, 1927). After the expiration of the Weizmann patent in 1936, industrial solvent fermentation was practiced around the world as other companies built plants in the United States, Puerto Rico, the United Kingdom, Japan, India, Australia, South Africa and elsewhere (Jones and Woods, 1986). Fermentors with a volume up to 15,000 barrels (472,500 gallons) were used for acetone-butanol fermentation (Beesch, 1953). Although molasses replaced corn as the predominant raw material in the United States, new processes utilizing starchy materials or admixtures of starchy and sugary materials were used where it is economical to do so (Beesch, 1953).

The Weizmann process is based on the fermentation of corn by *C. acetobutylicum*. The kernel is ground into a coarse meal (Prescott and Dunn, 1949) or a fine powder (Beesch, 1953; McCutchan and Hickey, 1954) and mixed with water and stillage (distillation slop), and the cooked corn mash does not require any other nutrients to be added for the fermentation. When it was economical, the germ of corn was removed for oil extraction, but the oil-cake meal may be returned to the mash to increase the feed value of the recovered solids at the end of the fermentation. Besides *C. acetobutylicum*, an unusual variant of "*Clostridium saccharo-butyl-acetonicum-liquefaciens*" (known as Code C-12) was also used for the corn-based fermentation, but it required the addition of ammonia to the corn mash because of its poor proteolytic power (Walton and Martin, 1979).

The concentration of corn in the mash is about 8.5% (based on the original dried corn), and this concentration was used to ensure that the final butanol concentration in the broth (beer) did not exceed 13 gm/liter (1.3% or 175 mM) and to ensure complete utilization of the starch by the end of the fermentation (Walton and Martin, 1979). The normal fermentation of starches gives a final total solvent concentration of about 2.2% (22 gm/liter), with an approximate 6 : 3 : 1 weight ratio of butanol:acetone:ethanol. This corresponds to a yield of 1 lb (0.4536 kg) of mixed solvents from 4.3 lb (1.95 kg) of corn or 2.9 lb (1.315 kg) of starch (Beesch, 1953). In addition, hydrogen, carbon dioxide, and the dried stillage (which contained proteins and vitamins B_2 and B_{12} and was used in animal feeds) were recovered and sold (Walton and Martin, 1979).

An interesting practice that was part of the corn- and the molasses-based fermentation is the reutilization of the distillation slop or stillage, i.e., the fermentation broth from which the solvents have been removed. This practice was known as "slop-back," and the volume of the spent medium reutilized amounted to 25–50% of the total mash (Walton and Martin, 1979). The advantages of slopback include an increase in yields of solvents, a decrease in the amount of nutrients required (for the molasses-based process), and savings in heat, cooling water, and steam for the various steps. Considering the

physiological effects of added acetate and butyrate on the solvent-producing bacteria (see the subsection Physiology of Solvent Production in this Chapter), slop-back could be an important aspect of the industrial process. A more detailed description of the industrial fermentation can be found in several reviews (Beesch, 1953; Walton and Martin, 1979).

Molasses was the most widely used raw material for solvent fermentation, and the use of corn or *C. acetobutylicum* was phased out by 1933 (Kelly, 1936; Walton and Martin, 1979). However, other starch-based processes were later developed and used for industrial production while the molasses-based processes were in use (Beesch, 1953), and some of the saccharolytic organisms are capable of fermenting starch directly under suitable conditions and producing almost full yields of solvents (Beesch, 1952). Two types of molasses, the blackstrap molasses and the high-test or invert molasses, were predominantly used in industrial solvent fermentation (McCutchan and Hickey, 1954; Walton and Martin, 1979), although other types of molasses and sugary materials were also used (Beesch, 1952).

Blackstrap molasses is the concentrated mother liquor remaining after the crystallization of sucrose from sugar cane juice and contains on average 52% total sugars, consisting of about 30% sucrose and 22% invert sugar (glucose plus fructose). It contains salts that are added to aid in the recovery of crystalline sucrose. Batch-to-batch variations in the composition of blackstrap molasses caused wide variation in yields and nutrient requirements for fermentation based on this raw material (McCutchan and Hickey, 1954).

High-test molasses contains about 50% invert sugar and 25% sucrose and is a better raw material than blackstrap molasses because it contains less nonfermentable solids, including salts, and has a more consistent composition. High-test molasses is produced from excess sugar cane. The juice is concentrated to about 70–75% sugar in the presence of a small amount of mineral acid, which hydrolyzes (inverts) about two-thirds of the sucrose to glucose and fructose to avoid crystallization on standing (McCutchan and Hickey, 1954). As in the corn fermentation, the concentration of molasses in the fermentor medium was calibrated so that it was not more than what was needed to give a final butanol concentration of 13 gm/liter. The sugar concentration used in the fermentor medium varied from 5.5 to 7.5% depending upon the solvent ratio produced by the culture selected (Walton and Martin, 1979).

Although the patent literature contains the names of many organisms for the molasses-based processes (Beesch, 1952), information is scarce as to the strains actually used by the industry. It is now known that the "*C. madisonii*" strain used in Puerto Rico in the 1940s (Jones et al., 2000) and the two strains (P265 and P270) used at National Chemical Products in South Africa in the late 1970s (Spivey, 1978) are *C. beijerinckii* (Keis et al., 2001a). Before solvent fermentation was terminated in Japan in the early 1960s, the organisms used were strains of *C. saccharoperbutylacetonicum* (Hongo and Murata, 1965a; Hongo and Murata, 1965b), a species now recognizable by molecular methods (Johnson et al., 1997; Keis et al., 2001a).

Molasses-based media are generally deficient in available nitrogen and phosphate, which may be responsible for poor solvent production when *C. acetobutylicum* was tested in unfortified media in early studies, although the low buffering capacity of molasses may also be a factor. Good growth and solvent production in molasses-based media require the addition of a pH-control agent, vitamins, and mineral nutrients in addition to nitrogen and phosphorus compounds. In practice, ammonia (1.2–1.3% NH_3 based on sugar concentration) was added both as a pH-control agent (when used in the form of ammonium hydroxide) and as a nitrogen source. Although ammonia alone gave satisfactory results, the use of ammonia plus a source of complex nitrogen (such as yeast water, corn-steep liquor or stillage) was usually preferred in the fermentor medium to ensure a maximum yield of solvents (Beesch, 1952). Superphosphate (depending on the manufacturing process, different preparations of superphosphate contain different amounts of the key ingredient, monobasic calcium phosphate, and other phosphorus compounds; the available amount of phosphorus in superphosphate is measured as P_2O_5) was used to give 0.05–0.2% of P_2O_5 based on sugar (Walton and Martin, 1979). Table 33 shows the result of the molasses-based industrial fermentation used in South Africa in the 1970s.

Fermentable Substrates Corn and molasses (sugar cane) were the principal raw materials for industrial solvent fermentation. Corn was primarily used during the era of the Weizmann process, which was based on *C. acetobutylicum*, whereas molasses was used when other bacteria replaced *C. acetobutylicum* in the industrial fermentation (see the subsection Industrial Solvent Fermentation in this Chapter). Besides corn and molasses, other starchy substrates were also used in industrial solvent fermentation outside North America. For example, the raw materials for solvent production by "*Clostridium toanum* Baba" in Taiwan (Formosa) between 1947 and 1957 included sweet potato, casava, and wheat starch (a by-product of gluten production; Yeh, 1955; Anonymous, 1956; Anonymous, 1958). In addi-

Table 33. Production of acetone, butanol, and ethanol from molasses in 90,000-liter batch fermentation in South Africa.[a,b]

Product	Amount (kg)	Percent (wt/wt) of sugar fermented
Butanol	1,053	18
Acetone	526	9
Ethanol	175	3
Carbon dioxide	2,900	50
Hydrogen	117	2

[a]The 90,000-liter batch contains 5,850 (approx.) kgm of fermentable sugars from molasses.
[b]*Clostridium beijerinckii* strains NCP265 and NCP270 were used (Spivey, 1978; Keis et al., 2001a). The fermentation medium was supplemented with corn steep liquor, in addition to liquid ammonia, as a source of nitrogen and other growth stimulants to enhance solvent production. The starting pH was adjusted to 5.8–6.0 with ammonia, and calcium carbonate was added for its pH regulatory effect. The total cycle of cleaning, sterilization, filling, fermentation, and emptying the fermentor took 48 hours, of which 30–34 hours was fermentation time.
Data from Spivey (1978).

tion, a diverse range of raw materials has been tested as alternative substrates for solvent production (McCutchan and Hickey, 1954; Prescott and Dunn, 1959a; Jones and Woods, 1986; Dürre and Bahl, 1996).

The succession of the corn- and the molasses-based fermentations implies that the molasses (sugar)-fermenting clostridia are not suitable for fermenting starchy substrates. In fact, starch is a fermentable substrate for strains of *C. aurantybutyricum*, *C. beijerinckii*, *C. saccharobutylicum*, and *C. saccharoperbutylacetonicum*, besides *C. acetobutylicum* (Cato et al., 1986; Keis et al., 2001a). Potatoes have been used successfully as a substrate for solvent production by *C. beijerinckii* NRRL B592 (Nimcevic et al., 1998), although partially hydrolyzed (liquefied) starch is preferred for operational reasons (Nimcevic and Gapes, 2000). It is economically attractive to produce solvents from alternative substrates that are considered waste and normally present disposal problems. Besides potato waste (which includes industrial residues, low-grade potatoes, and spoiled potatoes; Nimcevic et al., 1998), other waste materials including cheese whey (Maddox, 1980; Schoutens et al., 1984; Schoutens et al., 1985b; Ennis and Maddox, 1985; Stevens et al., 1988), hydrolyzed lignocellulosic and hemicellulosic materials (Compere and Griffith, 1979; Compere et al., 1985; Fond et al., 1986a; Fond et al., 1986b; Lemmel et al., 1986), palm oil mill effluent (Somrutai et al., 1996), apple pomace (Voget et al., 1985), and soy molasses (Qureshi et al., 2001b) can be substrates for solvent production. The range of fermentable substrates for the solvent-producing clostridia is thus much broader than starch, sucrose, and their component sugars. A comprehensive review of the physiology of carbohydrate utilization by the solvent-producing clostridia is available (Mitchell, 1998). A brief review of the properties of the polymers starch, cellulose and xylan is given below, as these polymers represent potential substrates for future industrial solvent fermentation.

Starch is composed of amylose (a linear polymer of α-1,4-linked D-glucose residues) and amylopectin, which has α-1,6 linkages to connect branching linear chains. Endo-acting α-amylase randomly hydrolyzes α-1,4-D-glucosidic linkages in a chain containing three or more glucose units, with the reducing groups liberated in the α-configuration, whereas β-amylase hydrolyzes α-1,4-D-glucosidic linkages to remove successive β-maltose units from the nonreducing end. Glucoamylase hydrolyzes the terminal 1,4-linked α-D-glucose residues successively from the nonreducing ends, releasing β-D-glucose. The α-1,6 linkages at the branch points are hydrolyzed by pullulanase. Although starch was a major substrate for industrial solvent production, little is known about the amylolytic system in *C. acetobutylicum* or *C. beijerinckii*, and a consistent picture of the regulation of starch hydrolysis and metabolism is yet to emerge (Dürre and Bahl, 1996; Mitchell, 1998). An 84-kDa α-amylase has been purified from *C. acetobutylicum* ATCC 824 (Paquet et al., 1991), yet a cloned amylase gene from the organism encodes a 53.9-kDa polypeptide (Verhasselt et al., 1989), indicating that *C. acetobutylicum* ATCC 824 produces different amylases for the utilization of starch. Two α-amylase genes (CAP0098 and CAP0168) have been identified on the plasmid pSOL1 (Nolling et al., 2001), and they encode polypeptides of about 60 and 80 kDa, respectively.

Solvent-producing clostridia have not been reported to grow on cellulose, but the disaccharide cellobiose is metabolized by *C. acetobutylicum*, *C. aurantibutyricum*, *C. beijerinckii*, *C. saccharobutylicum* and *C. saccharoperbutylacetonicum* (Cato et al., 1986; Keis et al., 2001a). Cellobiose is an excellent substrate for solvent production by *C. beijerinckii* NRRL B592 but not by *C. acetobutylicum* NRRL B527 (= ATCC 824) or *C. beijerinckii* NRRL B593 (Compere and Griffith, 1979). Efficient degradation of crystalline cellulose requires cellulosomes (extracellular supramolecular structures composed of scaffold-bound endo- and exoglucosidases and cellulose-binding proteins; Mitchell, 1998). Genes encoding at least 11 cellulosome component proteins have been identified in the genome of *C. acetobutylicum* ATCC 824 (Nolling et al., 2001). Inducible activities of endoglucanase (endoglucanase is endo-1,4-β-glucanase or

1,4-[1,3; 1,4]-β-D-glucan 4-glucanohydrolase) and cellobiase were in *C. acetobutylicum* NRRL B527 and ATCC 824 (Lee et al., 1985) and *C. beijerinckii* NCP270 (Allcock and Woods, 1981a). The endoglucanase hydrolyzes carboxymethyl cellulose, acid-swollen cellulose, and microcrystalline cellulose (Avicel) but not crytalline cellulose. Genes encoding an endoglucanase and a cellobiase have been cloned from *C. saccharobutylicum* NCP 262 (Zappe et al., 1986; Zappe et al., 1988).

The solvent-producing clostridia can grow on xylan and pentoses (Cato et al., 1986; Mitchell, 1998; Keis et al., 2001a) and produce moderate levels of solvents (Compere and Griffith, 1979). Arabinose is an excellent substrate for solvent production by *C. beijerinckii* NRRL B592, but not for *C. acetobutylicum* NRRL B527 (= ATCC 824) or *C. beijerinckii* NRRL B593 (Compere and Griffith, 1979). Pentoses are broken down by the transaldolase-transketolase pathway to produce fructose 6-phosphate and glyceraldehyde 3-phosphate, which are further metabolized via glycolysis to pyruvate before entering the acid- and solvent-producing pathways. A predicted operon (genes CAP0114 to CAP0120) consisting mostly of genes for xylan degradation has been identified on the pSOL1 plasmid of *C. acetobutylicum* ATCC 824 (Nolling et al., 2001). The gene encoding a xylanase has been cloned from *C. saccharobutylicum* NCP262 (Zappe et al., 1987).

For both hexoses and pentoses, the mono-, di- and oligosaccharides and their derivatives are taken up via specific membrane-bound transport proteins. Few detailed studies of sugar uptake by the clostridia have been reported, but observations made to date indicate that the transport mechanisms are similar to those found in a wide variety of other bacteria (Mitchell, 1998). A large number of genes for different types of transporters has been found in the genome of *C. acetobutylicum* ATCC 824 (Nolling et al., 2001).

Bacteriophage Infections, Autolysins, and Cell Lysis Infections by bacteriophages were a recurrent problem for industrial solvent fermentation. The first phage contamination incident on record occurred in 1923 (Ogata and Hongo, 1979), in the Terre Haute (Indiana, United States) plant, and resulted in the halving of fermentation yields for about a year (Gabriel, 1928). Many cases of such "sluggish fermentation" experienced in the ensuing years were presumed to be caused by phage infections. However, no proven case of phage contamination occurred until 1943 when McCoy and Sylvester reported the isolation of phages from fermentation broth from a plant in Puerto Rico that used "*Clostridium madisonii*," a strain now recognized as *C. beijerinckii* (Ogata and Hongo, 1979; Jones et al., 2000). A specific abnormal fermentation, called "sleeping sickness of acetone-butanol fermentation," occurred at several factories in Japan around 1943, and incidences of such sleeping sickness or sluggish fermentation continued to occur for years. The review by Ogata and Hongo (1979) describes the isolation and characterization of phages from the abnormal fermentation broth as well as the selection of phage-resistant strains of clostridia for industrial uses.

By examining previously unreleased company reports and records, a review (Jones et al., 2000) provided information about phage infections at the National Chemical Products (NCP) factory, which produced solvents by fermentation from 1936 until 1982 in Germiston, South Africa. Confirmed or presumed phage infections of 1943, 1947, 1960, 1976 and 1980 at the NCP factory were described in this review, and the properties of the phage CA1 that caused the relatively mild 1980 phage infection were reported.

The characteristics of phage infections in solvent fermentation may be summarized as follows (Jones et al., 2000): Regardless of the bacterial strains or substrates used, the typical symptoms of phage-infected batches are slow or sluggish fermentations with extended fermentation times and reduced solvent yields. Because of a decrease in the metabolic and growth rates, the infected cultures produce less gas and leave more substrates unused. There are changes in the cell population and morphology that include a marked reduction in cell numbers, a loss of motility, and the presence of etched cells. In some cases, elongated cells or protoplasts may be observed. Lysis of infected cells can be observed in the laboratory but may not occur at the factory. Virulent, lysogenic, and pseudo-lysogenic phages have been identified, and they are quite strain-specific. Of the seven phages that were tested against the strains of *C. acetobutylicum*, *C. beijerinckii*, *C. saccharobutylicum* and *C. saccharoperbutylacetonicum*, all have restricted host ranges (Keis et al., 1995). At present, the selection of phage-resistant variants and the maintenance of good plant practice and hygiene remain the effective measures against phage infections. The selection and isolation of phage-resistant mutants or variants that retain solvent-producing capabilities are referred to as "phage immunization." One danger of producing resistant strains is the possibility of generating lysogenic cultures, which may later release phage particles and continue to cause phage infections (Ryden, 1958). It has been suggested that no matter how good the plant practice and hygiene, phage infections are bound to occur from time to time. It is therefore important that companies operating this fermen-

tation process develop strategies to minimize the impact of such infections (Jones et al., 2000).

Solvent-producing clostridia are also known to undergo autolysis as a result of lytic enzyme activity or bacteriocins with lytic activity (Barber et al., 1979; Allcock et al., 1981b; Webster et al., 1981; van der Westhuizen et al., 1982; Roos et al., 1985; Croux et al., 1992b). Lysis of *C. acetobutylicum* ATCC 824 is stimulated by environmental conditions (e.g., pH 6.3, 55°C and the presence of monovalent cations; Croux et al., 1992b) and can be reduced by treatment with chloramphenical (Zhou and Traxler, 1992). The *lyc* gene (CAC0554) of *C. acetobutylicum* ATCC 824, which encodes an autolytic lysozyme (a muramidase acting on non-*n*-acetylated peptidoglycan; Croux et al., 1992c), has been cloned and characterized (Croux and Garcia, 1991; Croux and Garcia, 1992a). When expressed in a recombinant strain of *Escherichia coli* under the control of the *lac* promoter, the autolytic lysozyme was secreted although it does not contain a cleavable signal peptide, suggesting that like other autolysins this lytic enzyme is also secreted through a specific mechanism (Croux and Garcia, 1992a). The use of autolytic deficient mutants of solvent-producing clostridia may be a useful improvement for the industrial fermentation.

Physiology of Solvent Production Butyric acid is a characteristic fermentation product of many anaerobic bacteria. In the carbohydrate-fermenting clostridia, the key metabolic intermediate pyruvate is cleaved by the pyruvate : ferredoxin oxidoreductase to acetyl-CoA and CO_2, with ferredoxin serving as the electron acceptor (Chen, 1993). Two molecules of acetyl-CoA are combined by thiolase to form acetoacetyl-CoA, which is metabolized through the reactions catalyzed by enzymes 4 through 9 (Fig. 26) to form a molecule of butyric acid, with the concomitant consumption of two molecules of reduced nicotinamide adenine dinucleotide (NADH) or reduced nicotinamide adenine dinucleotide phosphate (NADPH) and the production of an ATP. During the exponential phase of growth, acetic acid is produced in addition to butyric acid, and the acetate-producing pathway could be viewed as a branch of the butyrate-producing pathway (Fig. 26). Acetyl-CoA is thus the branch-point between the acetate- and the butyrate-producing pathways. The production of butanol and acetone/isopropanol, on the other

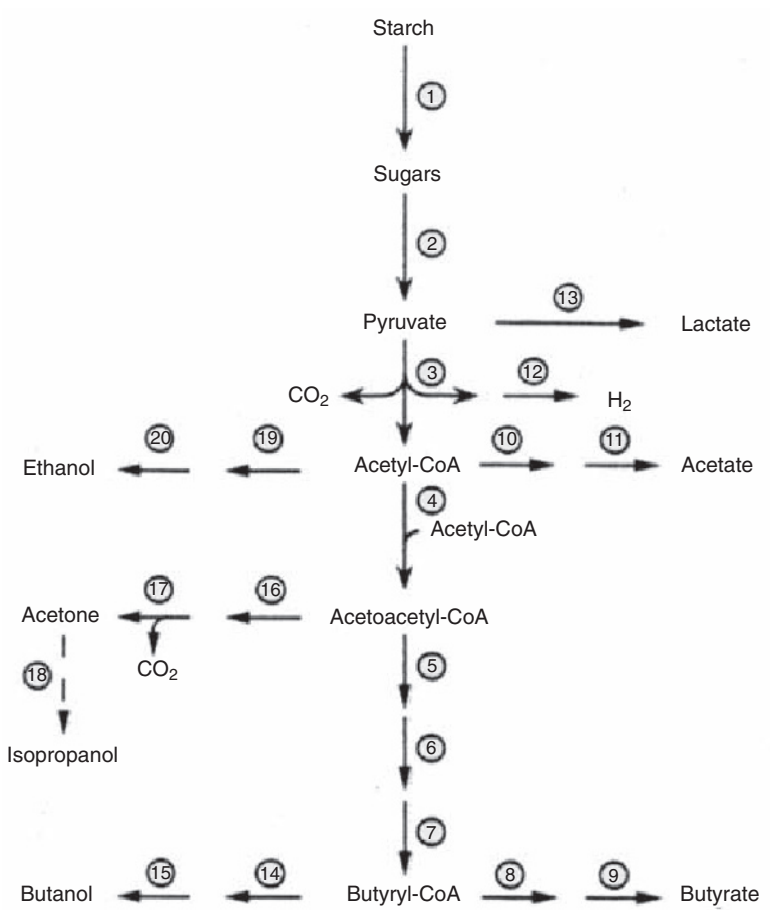

Fig. 26. Metabolic pathways for the fermentation of starch and sugars to acids, solvents, hydrogen and carbon dioxide in the clostridia. Arrows indicate the direction of carbon or electron flow as well as the major steps of the pathways. The enzyme(s) catalyzing the reaction(s) represented by an arrow is numbered: 1) amylase; 2) phosphoenolpyruvate phosphotransferase systems and glycolytic enzymes of the Embden-Meyerhof-Parnas pathway; 3) pyruvate:ferredoxin oxidoreductase; 4) thiolase; 5) 3-hydroxybutyryl-CoA dehydrogenase; 6) crotonase; 7) butyryl-CoA dehydrogenase; 8) phosphotransbutyrylase; 9) butyrate kinase; 10) phosphotransacetylase; 11) acetate kinase; 12) hydrogenase; 13) lactate dehydrogenase; 14) aldehyde (butyraldehyde) dehydrogenase and aldehyde/alcohol dehydrogenase; 15) alcohol (butanol) dehydrogenase and aldehyde/alcohol dehydrogenase; 16) acetoacetate: acetate/butyrate CoA-transferase; 17) acetoacetate decarboxylase; 18) primary/secondary alcohol dehydrogenase; 19) aldehyde (acetaldehyde) dehydrogenase, and 20) alcohol (ethanol) dehydrogenase. The dashed line to isopropanol indicates that only some strains of a species are able to perform this reaction. From Dürre (1998).

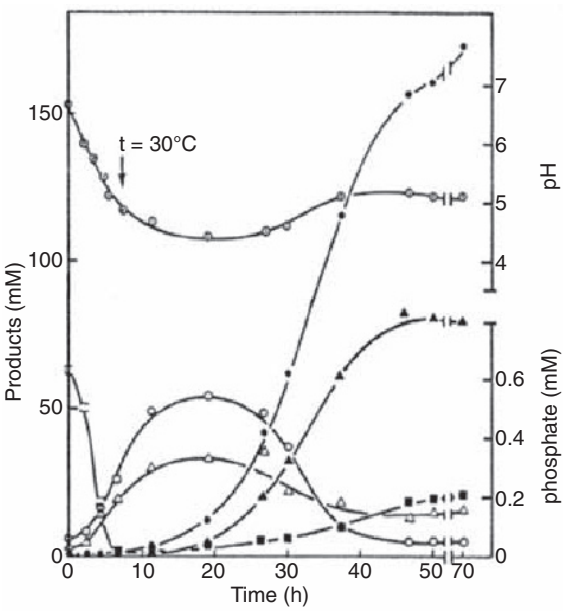

Fig. 27. Time course of acid production and subsequent solvent accumulation with concurrent acid reutilization in a batch culture of *C. acetobutylicum* DSM 1731. The mineral medium contained 60 gm/liter of glucose and a low concentration (0.62 mM) of phosphate. The temperature was 37°C during the exponential phase of growth, and the pH was regulated to allow it to decrease linearly from 6.6 to 5.0. When phosphate was exhausted in the medium and the pH was below 5.0, the temperature was lowered to 30°C and the pH regulation was switched off. The final concentrations (mM) after three days were: butanol, 175; acetone, 77; ethanol, 22; butyrate, 9; acetate, 18; acetoin, 9; glucose, 0; and phosphate, 0. Symbols: butanol, ●; acetone, ▲; ethanol, ■; butyrate, ○; acetate, △; phosphate, □; and pH, ○. From Bahl et al. (1982a).

hand, involves regulated metabolic pathways that branch off the butyrate-producing pathways at the C_4-intermediates butyryl-CoA and acetoacetyl-CoA, respectively (Fig. 26). The accumulation of solvents in the culture medium occurs late during growth of *C. acetobutylicum* as shown in Fig. 27. Other solvent-producing species exhibit a similar time course (Rogers, 1986; Yan et al., 1988), suggesting that solvent production is a programmed response to either specific environmental conditions or growth-stage related signals.

Initiation of Solvent Production In batch cultures, the start of solvent production by wildtype cells requires a variety of environmental conditions, including a high concentration of butyric acid, a low culture pH, and a growth-limiting concentration of phosphate or sulfate. These conditions are associated with changes in carbon and electron flux and in concentrations of high-energy intermediates in the cell, and the growth rate decreases under such environmental conditions. One or several of the environmental conditions determine the accompanying cellular conditions present shortly before the start of active solvent production, and the extracellular and intracellular conditions directly or indirectly serve as signals for activating the transcription of the solvent-production genes and result in a metabolic switch from acid to solvent production. Although the solventogenic switch clearly involves events at the transcriptional level (Dürre et al., 2002), the molecular mechanism for activating the transcription of solvent-production genes remains to be elucidated. It has been suggested that because the environmental conditions required for solvent production can affect DNA topology directly, a relaxation of the degree of negative DNA supercoiling might be the trigger for solvent-production gene activation (Dürre et al., 1995; Dürre, 1998). However, specific regulatory (effector) proteins apparently play important roles in the transcriptional activation of solvent-production genes inasmuch as conserved motifs have been identified in the promoter region of solvent-production operons (Ravagnani et al., 2000; Thormann et al., 2002). In addition, different carboxylic acids affect the initiation of transcription of the solvent-production genes differently, suggesting a specificity of the sensor proteins toward the solventogenic signals.

In a glucose-limited continuous culture maintained at pH 4.3 and with an excess of phosphate, the presence of butyric acid at 20 mM or above allowed *C. acetobutylicum* DSM 1731 to produce solvents (Bahl et al., 1982a). In batch cultures (Husemann and Papoutsakis, 1986) or with washed logarithmic growth-phase cells (Ballongue et al., 1985), addition of butyrate (6–20 mM), acetoacetate (12–20 mM), acetate (8–33 mM), and several other C_1 to C_4 straight-chain acids can induce the solventogenic transition in *C. acetobutylicum* ATCC 824. When the culture pH was maintained at 6 and the starting glucose concentration was about 275 mM (about 5%, w/v), solvent production by *C. acetobutylicum* ATCC 824 was observed when 65 mM of butyrate was added early during growth, but it ceased immediately upon glucose depletion (Husemann and Papoutsakis, 1988). The addition of butyrate plus acetate accelerated *C. beijerinckii* strain NRRL B592 (George and Chen, 1983a) and strain NCIMB 8052 (Holt et al., 1984) into the solventogenic transition at neutral pH, but the addition of butyrate or acetate alone was not effective (George and Chen, 1983a). Among the carboxylic acids tested, citric acid (Husemann and Papoutsakis, 1986) and straight-chain carboxylic acids with 5–7 carbon

atoms and branched-chain acids (Ballongue et al., 1985) could not induce the solventogenic transition. The specificity towards the straight-chain C_1 to C_4 carboxylic acids indicates that it is not the acid-base properties of the carboxylic acids that are responsible for their solventogenic triggering effect. Furthermore, specific enzymes or sensors must be involved in transducing the external signal to the transcriptional apparatus.

The concentration of total or undissociated butyric or acetic acid at the onset of solvent production has been the subject of a number of investigations as this parameter is likely a quantitative triggering signal for solventogenesis. Depending on the medium composition and other growth conditions used, the concentration of undissociated butyric acid at the onset of solvent production by *C. acetobutylicum* ranged from about 5 to 20 mM when the culture pH was below 5.5 (Monot et al., 1984; Terracciano and Kashket, 1986; Husemann and Papoutsakis, 1988) and below 5 mM when the culture pH was controlled at 6 (Husemann and Papoutsakis, 1988). A correlation was not found between the onset of solvent production and the external pH, the intracellular pH, the pH difference across the cytoplasmic membrane, and the external and intracellular butyrate and acetate concentrations (Husemann and Papoutsakis, 1988). The correlation between the concentration of undissociated butyric acid and the onset of solvent production is not absolute, and it may reflect a combined effect of the pH and the dissociated butyric acid concentration on solventogenesis (Husemann and Papoutsakis, 1988), as the undissociated butyric acid is a biochemically inert species (Gottwald and Gottschalk, 1985).

Although the time-course of fermentation is similar among different species of solvent-producing clostridia, suggesting a common regulatory mechanism for solventogenesis, there are qualitative or quantitative differences in the response exhibited by different solvent-producing species to the same set of environmental signals. A prominent example is the different pH-dependence for the onset or progress of solvent-production (Johnson and Chen, 1995). In laboratory media, a pH of 5.5 or below is usually considered necessary for *C. acetobutylicum* to show sustained solvent production, and an optimal pH of 4.3 was reported for *C. acetobutylicum* strains DSM 792 and 1731. *C. acetobutylicum* ATCC 824 produced 48 mM butanol and 27 mM acetone when the culture pH was controlled at 6 and the initial glucose concentration was about 550 mM (about 10%, w/v), whereas it produced little butanol or acetone at pH 6 when the initial glucose concentration was about 275 mM (Husemann and Papoutsakis, 1988). In contrast, *C. beijerinckii* NRRL B592 produced these solvents at pH 6.8 with an initial sucrose concentration of 6% (w/v) and without butyrate supplementation (George and Chen, 1983a). *Clostridium saccharobutylicum* NCP262 (formerly *C. acetobutylicum* P262) produced these solvents at pH 5.5–6.5, but not when the pH of the culture was allowed to drop below 4.5 during the early part of the fermentation (Jones and Woods, 1986).

In batch or continuous cultures of *C. acetobutylicum* DSM 1731, phosphate limitation (initial phosphate concentrations between 0.62 and 0.74 mM) has a profound effect on enhancing the consumption of glucose and production of solvents (Bahl et al., 1982b). The onset of solvent production coincided with the exhaustion of phosphate in the medium and with the culture pH falling below 5.

Among the conditions conducive to the onset of solvent production, a high concentration of acids is effective with different species of clostridia. It is interesting to note that the practice of "slopback" (the reuse of the hot stillage [i.e., the fermentation broth after the removal of cells and solvents] to substitute for 10–100% of the volume of water in the fermentor medium) during industrial solvent production resulted in a slightly faster fermentation (McCutchan and Hickey, 1954) and also an increase in yield of solvents (Beesch, 1952; Beesch, 1953; Walton and Martin, 1979). Slopback was practiced to lower water usage, the cost of heating, and the cost of waste disposal. However, it could also be a source of butyric and acetic acids in each batch of fermentor medium. The actual concentrations of butyrate and acetate in the stillage are not clear but could be estimated. When batch cultures of *C. acetobutylicum* DSM 1731 were grown for three days in a medium containing 60 gm/liter of glucose and either a low (0.62 mM) or a high (12.25 mM) concentration of phosphate, the final butyrate and acetate concentrations were 9 and 18 mM, respectively, for the low-phosphate culture, and 68 and 42 mM, respectively, for the high-phosphate culture, whereas the final butanol concentrations were 175 and 47 mM, respectively, for the two cultures (Bahl et al., 1982b). The concentrations of butyrate and acetate in stillage might be within this range.

The onset of solvent production by PJC4BK strains of *C. acetobutylicum* ATCC 824 (these mutant strains have the butyrate kinase, *buk*, gene in the *ptb-buk* locus inactivated) occurs during the exponential phase of growth (Green et al., 1996b; Harris et al., 2000). The total external butyric acid concentration was 1 mM, and the undissociated butyric acid concentration was estimated at 0.4 mM when butanol (about 2 mM) was first detected (Harris et al., 2000). These observations suggest that a high concentration of

butyrate (or its transport) is not involved in triggering the onset of solvent production. Because these mutant strains have a lowered level of butyrate kinase (*C. acetobutylicum* ATCC 824 has a second butyrate kinase gene; see the subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter), it is postulated that the accumulation of butyryl-phosphate or butyryl-CoA might be responsible for triggering solvent production, as previously suggested (Gottwald and Gottschalk, 1985). When the butyrate kinase level was lowered by the antisense RNA technique (see subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter), the peak and final butyrate concentrations were actually higher than that of the control culture (Desai and Papoutsakis, 1999). Because of the high butyrate concentration produced in the presence of anti-*buk*-RNA, it is unclear what triggers the earlier onset of solvent production in the presence of anti-*buk*-RNA.

Relationship to Sporulation Although solvent production can be observed in exponentially growing cells, significant solvent accumulation occurs in cells beyond the logarithmic phase of growth. The duration of solvent production indeed has a close temporal relationship to growth stages, especially sporulation. Weizmann is credited with the discovery of a correlation between a strain's ability to sporulate and its ability to produce solvents as he used repeated pasteurization (100–150 cycles) to select heat-resistant spores for selecting and preserving a productive strain (Prescott and Dunn, 1959a). McCoy and Fred (1941) reported the result of a serial transfer experiment that lasted over two years. When three pure cultures were subjected to 150 cycles of the Weizmann procedure (pasteurization at 100°C for 1–2 min at intervals of 4–5 days to allow spore formation), the initial solvent yield was 26.2% and the final solvent yield was 24.7%, and the ratio of solvents was unchanged. On the other hand, when a strain was subjected to 200–300 transfers using vegetative cells (transfers were made at 12- and 24-h intervals), degeneration was observed by the 10–20th transfer. The solvent yield usually dropped to 0.5–2% before the 50th transfer, and spore formation was almost completely lost.

It is now established that an early step(s) of the switch for solvent production and sporulation is activated by a shared regulatory element. The Spo0A protein has been found to control the switch from acid to solvent production in *C. acetobutylicum* and *C. beijerinckii* (Ravagnani et al., 2000; Harris et al., 2002; Thormann et al., 2002). In *Bacillus subtilis*, the phosphorylated Spo0A protein plays a crucial role both as a negative and as a positive effector of gene expression at early times in the sporulation gene activation program (Baldus et al., 1994). Sequences resembling the Spo0A-binding motif (the 0A box) 5′-TGTCGAA are present in either orientation in the promoter region of the solvent-production operons and are required for transcriptional activation. However, additional upstream sequences are also required for the transcription of the *adhE* gene of *C. acetobutylicum* DSM 792, indicating the involvement of additional transcription effectors for solvent production (Thormann et al., 2002).

Because solvent production and sporulation share a key regulatory element for an early part of the two processes, mature spores are a good source of cells competent for solvent production. However, some asporogenous mutants are able to produce solvents (Meinecke et al., 1984). This is consistent with the interpretation that only an early step(s) of sporulation and solvent production depends on the common regulatory element Spo0A for transcriptional activation, and mutations disabling reactions specific for the late stages of sporulation should not affect solvent production. In fact, even the mutant strain of *C. acetobutylicum* ATCC 824, whose *spo0A* gene was inactivated, expressed the solvent-production genes to a limited extent and produced low levels of acetone and butanol (Harris et al., 2002), indicating that the transcription of the solvent-production genes is greatly enhanced by but not absolutely dependent on Spo0A. Because of the shared regulatory element, cells entering the solvent-producing stage are also entering sporulation, resulting in the formation of resting cells. Therefore, the shared regulatory circuit between solvent production and sporulation effectively sets a practical limit on the duration of active solvent production, regardless of the toxicity of the fermentation products. Because some asporogenous mutants of *C. acetobutylicum* are solvent-producers (see the subsection Strain Degeneration in this Chapter), it may be useful to identify factors that limit the duration of solvent production in these asporogenous mutants. The observation that solvent production by *C. beijerinckii* NRRL B592 is enhanced by high glucose but low yeast extract concentrations (conditions that appear to slow down growth and acid production) and that acid and solvent production can proceed simultaneously (Maddox et al., 2000) suggests that a combination of genetic manipulation and process engineering may significantly prolong solvent production in batch cultures.

Product Pattern As might be predicted from the metabolic pathways shown in Fig. 26, the ratio of

butanol to acetone (or isopropanol) produced by a culture can be expected to vary under different growth conditions. The determining factors could include the level of specific enzymes present, the availability of specific substrates, the supply of reducing power, and the activity of regulatory molecules. The production of acetone depends on the activity of acetoacetate : butyrate/acetate CoA-transferase (see the subsection Metabolic Pathways and Enzymology of Solvent Production in this Chapter) and is hence directly linked to the uptake of butyrate and acetate via CoA-transferase. The uptake of one butyrate or acetate molecule via CoA-transferase results in the production of one acetoacetate molecule, which leads to the production of one acetone molecule. Butyrate taken up via butyrate kinase does not contribute to the production of acetone because it generates butyryl-CoA, whereas acetate taken up via acetate kinase might contribute to acetone production if the resulting acetoacetyl-CoA is metabolized by CoA-transferase with the consumption of additional acids. Addition of acetate, or the practice of slop-back, is thus known to boost acetone production. The production of butanol and isopropanol requires reducing power and is limited to the period when cells metabolize (oxidize) carbohydrates actively.

In industrial solvent fermentation using *C. acetobutylicum*, the product ratio (based on weight) is usually reported as butanol : acetone : ethanol (6 : 3 : 1; Gabriel, 1928; McCutchan and Hickey, 1954). However, the butanol : acetone : ethanol ratio can range from 76.1 : 17.9 : 6.0 or 75.6 : 22.4 : 2.0 to 60 : 38 : 2 with different organisms grown under different conditions (McCutchan and Hickey, 1954). On the basis of sugar consumed, the solvent yield is about 30% (w/w), and it can be nearly quantitative on the mol/mol basis. With slop-back, solvent yields are generally about 34% (w/w; McCutchan and Hickey, 1954). Although butanol is toxic to the solvent-producing clostridia (Moreira et al., 1981; Bowles and Ellefson, 1985; for a discussion of cellular toxicity of alcohols, see "Ethanol" in Organic Acid and Solvent Production, Part II in this Volume), the final concentration of butanol in an industrial fermentation broth is not the highest that could be reached. Instead, it is purposely controlled by the use of a limited amount of carbon substrate so that a batch of fermentation is completed within a desirable period of time and little unused carbon substrate remains in the medium at the end. Whether butanol toxicity affects the progression of sporulation remains to be determined.

Alcohologenic Mode of Growth The production of both acetone and butanol by *C. acetobutylicum* is a characteristic of this species, and the two products are responsible for the organism's continued usefulness during and after World War I. Interestingly, under certain growth conditions, a different mode of fermentation (i.e., production of only butanol and ethanol) by this organism was discovered. Butanol but not acetone is produced when the culture pH is at or above 5.5 (Peguin et al., 1994; Girbal et al., 1995a). The term "alcohologenic" applies to the mode of fermentation that produces only the alcohols butanol and ethanol (Girbal and Soucaille, 1994). Growth conditions leading to alcohologenesis include the addition of methyl or benzyl viologen to the medium (Rao and Mutharasan, 1987; Rao and Mutharasan, 1988; Grupe and Gottschalk, 1992; Peguin et al., 1994; Dürre et al., 1995; Sauer and Dü, 1995), the addition of neutral red to the medium at neutral pH (Girbal et al., 1995b), and the addition of glycerol or glycerol plus pyruvate to a glucose-containing medium (Girbal and Soucaille, 1994; Vasconcelos et al., 1994). During alcohologenesis, the two acetone-producing enzymes, CoA-transferase and acetoacetate decarboxylase, are not detected (Dürre et al., 1995). It is now known that *C. acetobutylicum* has a second aldehyde-alcohol dehydrogenase that is encoded by the *adhE2* gene (CAP0035; see the subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter), and during the alcohologenic mode of growth, butanol and ethanol production is catalyzed by AdhE2 (Fontaine et al., 2002).

Strain Degeneration The solvent-producing clostridia gradually lose their productivity when cells are kept in the vegetative stage for a prolonged period of time (i.e., through serial transfers using growing cells as the inoculum), and this phenomenon is known as "degeneration" (McCoy and Fred, 1941; Kutzenok and Aschner, 1952). Strain degeneration is the result of genetic alterations, and it can be distinguished from the occasional failure of a culture to produce solvents because the growth conditions are unfavorable for sustained solvent production (Maddox et al., 2000). To clearly separate temporary, environmentally caused poor productivity from genetically based strain degeneration, the terms "acid crash" and "acidogenic fermentation" have been proposed (Maddox et al., 2000). Acid crash describes the early cessation of sugar uptake and solvent production when a culture is under a condition (pH below 5 for *C. beijerinckii* NRRL B592) that allows the concentration of undissociated acetic and butyric acids to exceed a threshold level, whereas acidogenic fermentation describes fast growth, sugar utilization, and acid production but slow solvent production when the pH of the culture is kept near neutrality and when yeast extract is present in ample amounts.

To circumvent deterioration of the strains for industrial fermentation, spores were preserved as the stock and repeated pasteurization was performed to select cells competent for solvent production (McCoy and Fred, 1941). The fact that a selection for mature spores also selects cells competent for solvent production indicates that a major mechanism for degeneration is sporulation-related (see the subsection Relationship to Sporulation in this Chapter).

Degeneration occurs more readily in *C. beijerinckii* than in *C. acetobutylicum* (Woolley and Morris, 1990). In continuous cultures, asporogenous mutants of *C. acetobutylicum* DSM 1731 are readily selected (Meinecke et al., 1984). Some asporogenous mutants from the continuous culture reverted to become sporeformers; however, after prolonged growth (35 days) in a continuous culture, a stable asporogenous mutant of *C. acetobutylicum* DSM 1731 became established, but it produced butanol and acetone as the major products. When asporogenous mutants of *C. beijerinckii* NCIMB 8052 were selected in continuous cultures, they degenerated into solvent nonproducing strains (Woolley and Morris, 1990). These mutants spontaneously reverted at a low frequency to the parental phenotype (positive for sporulation, granulose synthesis, and solvent production), indicating that the multiple loss of capacities is the pleiotrophic consequence of a lesion in some global regulatory gene. The discovery of the involvement of the Spo0A protein in the initiation of solvent production could explain the pleiotrophic effect of a single mutation on both solvent production and sporulation (see the subsection Relationship to Sporulation in this Chapter). However, because the molecular change(s) causing degeneration has not been characterized, it is still not known precisely how strain degeneration occurs.

Maintenance of cells in the vegetative state for a prolonged period, either by serial transfers or by continuous cultures, results in cultures of predominantly degenerated cells. During the transition into a culture of degenerated cells, the cell density and the rate of sugar metabolism decrease (Stephens et al., 1985). Interestingly, by maintaining a high cell density in a continuous culture (Stephens et al., 1985) or during serial transfers (Chen and Blaschek, 1999b), the rate of degeneration decreased. The turbidometric technique (Stephens et al., 1985) or the addition of acetate (Chen and Blaschek, 1999b) was used to maintain a high cell density. A mutant strain of *C. beijerinckii* NCIMB 8052 with a truncated peptide deformylase has a slower growth rate and a decreased tendency to undergo degeneration (Evans et al., 1998). The procedures for reducing the rate of degeneration, together with the identification of Spo0A as a key regulator for the initiation of solvent production, should help efforts to elucidate the mechanisms of degeneration and the solventogenic switch.

When compared with the parental strains, the degenerated cells exhibited several different physical and morphological characteristics that may facilitate the detection of degeneration during the preparation of seed cultures for an industrial fermentation. The degenerated cells of *C. beijerinckii* and *C. saccharobutylicum* tend to give larger and translucent colonies with an irregular shape (Adler and Crow, 1987; Woolley and Morris, 1990; Schuster et al., 2001), a longer but thinner cell shape (Adler and Crow, 1987), and a characteristic infrared spectrum (Fourier transform IR) that is distinguishable from the spectra of parental cells at different stages of growth (Schuster et al., 2001).

Metabolic Pathways and Enzymology of Solvent Production The general features of the metabolic pathways (Fig. 26) for solvent production have been known for some time (Rogers, 1986; Jones and Woods, 1986). The enzymology of solvent production was studied mostly with *C. acetobutylicum* and *C. beijerinckii* (Chen, 1993; Bennett and Rudolph, 1995; Dürre and Bahl, 1996), but because of the multiplicity of alcohol and aldehyde dehydrogenases in the solvent-producing clostridia (Chen, 1995), the specific role for each alcohol or aldehyde dehydrogenase in the formation of butanol or ethanol is still a subject of research. The genes encoding the specific solvent-forming enzymes (14–20 in Fig. 26) and the enzymes for the conversion of acetyl-CoA to butyryl-CoA (4–7 in Fig. 26), which are required for both acid and solvent production, have been cloned and sequenced (see below and the subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter). The specific acid-forming reactions (8–11 in Fig. 26) are also important to solvent production because the accumulation of acetate and butyrate during the exponential phase of growth plays a regulatory role in the solventogenic switch (see the subsection Physiology of Solvent Production in this Chapter) and the accumulated acetate and butyrate are reutilized through the activity of the CoA-transferase (16 in Fig. 26) essential to acetone/isopropanol formation.

In the acid- and solvent-producing pathways, three CoA-derivatives (acetyl-CoA, acetoacetyl-CoA, and butyryl-CoA) occupy branch points, and enzymes acting on these branch-point intermediates likely play a pivotal role in regulating the flux of carbon into each specific branch and end product. Three enzymes (thiolase, enzyme 4 in Fig. 26; phosphotransacetylase, enzyme 10; and aldehyde (acetaldehyde) dehydrogenase,

enzyme 19) react with acetyl-CoA, and their relative activities control the amount of acetyl-CoA that is available for the C_2 products (ethanol and acetate) or the C_4 intermediate acetoacetyl-CoA, which is the precursor for acetone/isopropanol, butanol and butyrate. Two enzymes (3-hydroxybutyryl-CoA dehydrogenase, enzyme 5; and acetoacetate:acetate/butyrate CoA-transferase, enzyme 16) react with acetoacetyl-CoA and control the amounts of C_3 (acetone/isopropanol) and C_4 (butanol and butyrate) products formed. Two enzymes (phosphotransbutyrylase, enzyme 8; and aldehyde [butyraldehyde] dehydrogenase, enzyme 14) react with butyryl-CoA and control the amounts of butanol and butyrate produced. The acid- and solvent-producing reactions are linked to ATP formation and $NAD(P)^+$ regeneration. Therefore, the substrate and product concentrations, the energy and redox states, and other cellular conditions can all affect the activities of the branch-point enzymes. Knowledge about the regulatory properties of these enzymes is useful in attempts to control the product ratio of solvent fermentation. The results of in vitro kinetic measurements predict that the activities of these enzymes are subject to regulation by pertinent metabolic intermediates, but in vivo data are difficult to obtain (Chen, 1993; Bennett and Rudolph, 1995; Dürre and Bahl, 1996). The following is a summary of the properties of these enzymes and their structural genes.

Thiolase The condensation of two acetyl-CoA molecules into acetoacetyl-CoA by thiolase (acetyl-CoA:acetyl-CoA *C*-acetyltransferase; enzyme 4 in Fig. 26) is an essential step for the formation of the C_4 precursor for acetone/isopropanol, butanol and butyrate. The reaction is therefore required for both the acid- and the solvent-producing stages of growth. Thiolase has been purified to different degrees of purity from several *Clostridium* species (Chen, 1993; Bennett and Rudolph, 1995). From *C. acetobutylicum* ATCC 824, thiolase has been purified 70-fold to homogeneity, and it has a subunit mol. wt. (MW) of 44 kDa and a native MW indicative of a homotetrameric structure (Wiesenborn et al., 1988). The purified thiolase is sensitive to inhibition by micromolar levels of CoASH in the direction of acetyl-CoA condensation, and it is also inhibited by ATP and butyryl-CoA. The *C. acetobutylicum* thiolase shows a high activity in the pH range of 5.5 to 7.0. It has been suggested that the relative amounts of CoASH and acetyl-CoA regulate the activity of thiolase (Wiesenborn et al., 1988).

The structural gene for the purified thiolase of *C. acetobutylicum* ATCC 824 has been cloned and sequenced (Stim-Herndon et al., 1995), and it encodes a polypeptide of 392 amino acids (calculated MW 41,237). The genome of *C. acetobutylicum* ATCC 824 contains two thiolase genes, with *thlA* located on the chromosome (CAC2873, denoting the gene number on the annotated chromosome sequence) and *thlB* located on the plasmid pSOL1 (CAP0078, denoting the gene number on the annotated plasmid sequence). The *thlA* gene encodes the purified thiolase, and its level of transcription reached a transient minimum 3–7 h after a continuous culture of *C. acetobutylicum* DSM 792 was induced for solvent production (Winzer et al., 2000). The *thlB* gene had a very low level of expression in both acid- and solvent-producing cells, and its physiological function is unknown. The transient decrease in the level of transcription of the *thlA* gene between the acid- and solvent-producing stages of growth may explain the observed variation in the level of thiolase activity in acid- and solvent-producing cells (Chen, 1993).

3-Hydroxybutyryl-CoA Dehydrogenase In the solvent-producing clostridia, 3-hydroxybutyryl-CoA dehydrogenase (β-hydroxybutyryl-CoA dehdyrogenase; enzyme 5) catalyzes the reduction of acetoacetyl-CoA to 3-hydroxybutyryl-CoA. The enzyme has been purified from *C. beijerinckii* NRRL B593, and it has subunit and native MWs of 30.8 and 213 kDa, respectively (Colby and Chen, 1992). The enzyme can use either reduced nicotinamide adenine dinucleotide (NADH) or NADPH as a cosubstrate, but NADH gives a 60-fold higher catalytic efficiency and is likely the physiological cosubstrate. The structural gene (*hbd*) for the enzyme of three solvent-producing clostridia has been sequenced. The length (number of amino acid residues) of the deduced polypeptide and its calculated MW are: *C. acetobutylicum* {ATCC824}, 282 and 30,500 (Boynton et al., 1996a); *C. beijerinckii* NRRL B593, 281 and 30,167 (J. Toth and J.-S. Chen, GenBank accession number {AF494018}); and *C. saccharobutylicum* NCP262 (formerly *C. acetobutylicum* P262), 282 and 31,435 (Youngleson et al., 1989). The *C. acetobutylicum hbd* gene is designated CAC2708 on the annotated genome sequence. The amino acid sequence of 3-hydroxybutyryl-CoA dehydrogenase among these three species is highly conserved throughout the length of the polypeptide, with the *C. beijerinckii* enzyme shortened by one amino acid at the C-terminus (J.-S. Chen and J. Toth, unpublished results). The *hbd* gene is part of the BCS (butyryl-CoA synthesis) operon (see the subsection Genes and Operons for Solvent Production and the Genome for Solvent-Producing Bacteria in this Chapter).

Crotonase In the solvent-producing clostridia, crotonase (enoyl-CoA hydratase; enzyme 6 in

Fig. 26) catalyzes the dehydration of 3-hydroxybutyryl-CoA to form crotonyl-CoA. Crotonase has been purified 131-fold (67% yield) to homogeneity from *C. acetobutylicum* (probably strain NRRL B528, as spores were provided by I. Fridovich whose laboratory used this strain; Waterson et al., 1972). The purified enzyme is active only toward C_4 and C_6 substrates, and it has a native MW of 158 kDa and a subunit MW of 40 kDa. The predicted structural gene (*crt*; CAC2712) for *C. acetobutylicum* ATCC824 encodes a polypeptide of 261 amino acids, with a predicted MW of 28.2 kDa (Boynton et al., 1996a). The predicted *crt* gene of *C. beijerinckii* NRRL B593 also encodes a polypeptide of 261 amino acids (predicted MW 28,180; J. Toth and J.-S. Chen, GenBank accession number {AF494018}). The *crt* genes of *C. acetobutylicum* {ATCC824} and *C. beijerinckii* NRRL B593 occupy a similar location in the BCS operon, which consists of five genes for the synthesis of butyryl-CoA (see the subsection Genes and Operons for Solvent Production and the Genome for Solvent-Producing Bacteria in this Chapter).

Butyryl-CoA Dehydrogenase In the solvent-producing clostridia, butyryl-CoA dehydrogenase (enzyme 7 in Fig. 26) catalyzes the reduction of crotonyl-CoA to butyryl-CoA. Butyryl-CoA dehydrogenase has not been purified from the solvent-producing clostridia, and results from studies using cell-free extracts of the clostridia suggest that the immediate electron donor for the enzyme is not NADH or NADPH (Chen, 1993; Boynton et al., 1996a). The structural gene (*bcd*) for the butyryl-CoA dehydrogenase of *C. acetobutylicum* and *C. beijerinckii* has been identified from its conserved amino acid sequence and location in the BCS operon (see the subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter). The predicted *bcd* gene (CAC2711) of *C. acetobutylicum* ATCC824 encodes a polypeptide of 379 amino acids (predicted MW 41,386; Boynton et al., 1996a). The predicted *bcd* gene of *C. beijerinckii* NRRL B593 also encodes a polypeptide of 379 amino acids (predicted MW 41,045; J. Toth and J.-S. Chen, GenBank accession number {AF494018}).

Two open-reading frames (CAC2709 and CAC2710) are present between the *bcd* and *hbd* genes of the BCS operon of *C. acetobutylicum* {ATCC824}, and they were identified as the *etfA* (syn. *fixB*) and *etfB* (syn. *fixA*) genes that code for the subunits of an electron-transferring flavoprotein (ETF; Boynton et al., 1996a). Two corresponding ORFs occur between the *bcd* and *hbd* genes of the BCS operon of *C. beijerinckii* NRRL B593 (J. Toth and J.-S. Chen, GenBank accession number {AF494018}) or preceding the *hbd* gene in *C. saccharobutylicum* NCP262 (formerly *C. acetobutylicum* P262; Youngleson et al., 1995). The ETF of the butyric acid-producing anaerobic bacterium *Megasphaera elsdenii* has been purified and characterized (Whitfield and Mayhew, 1974), and it mediates electron-transfer between NADH and butyryl-CoA dehydrogenase. The *M. elsdenii* ETF is a heterodimer, with the *etfA* and *etfB* genes encoding, respectively, the α- (338 amino acids; MW 36,101) and β- (270 amino acids; MW 29,081) subunits (O'Neill et al., 1998). The *etfA*- and *etfB*-encoded polypeptides of the solvent-producing clostridia are similar in size and amino acid sequence to, respectively, EtfA and EtfB of *M. elsdenii*. It may be postulated that in the solvent-producing clostridia, the *etfA*- and *etfB* genes encode an ETF that is the electron donor for the butyryl-CoA dehydrogenase.

Aldehyde Dehydrogenase Aldehyde dehydrogenase (ALDH; enzymes 14 and 19 in Fig. 26) is responsible for the formation of butyraldehyde from butyryl-CoA and acetaldehyde from acetyl-CoA for the production of, respectively, butanol and ethanol. Different ALDH activities can be measured in a strain of solvent-producing clostridia (Bertram et al., 1990), and the ALDH activity can reside in distinct proteins in different species of solvent-producing clostridia (Toth et al., 1999). A biochemically similar ALDH has been purified from *C. saccharobutylicum* NRRL B643 (formerly *C. acetobutylicum* NRRL B643; Palosaari and Rogers, 1988) and *C. beijerinckii* strains NRRL B592 (Yan and Chen, 1990) and NRRL B593 (Toth et al., 1999). The ALDH from these two species has a native MW of 100–115 kDa and a subunit MW of 55–56 kDa. NADH is a more efficient cosubstrate than NADPH, and butyryl-CoA is a better substrate than acetyl-CoA for these ALDHs. The gene (*ald*) encoding the ALDH has been cloned from two strains of *C. beijerinckii* and sequenced (Toth et al., 1999; Hong, 1999). The *ald* gene of both *C. beijerinckii* strain NRRL B592 and strain NRRL B593 encodes a polypeptide of 468 amino acids, with a predicted mol. wt. of 51,312 (strain NRRL B592) or 51,353 (strain NRRL B593). A probe derived from the *C. beijerinckii ald* gene hybridized to restriction fragments of the genomic DNA of all tested strains of *C. beijerinckii*, *C. saccharobutylicum*, and *C. saccharoperbutylacetonicum* but not of *C. acetobutylicum* (Toth et al., 1999). The *ald* gene is part of the solvent production operon of *C. beijerinckii* (see the subsection Genes and Operons for Solvent Production and the

Genome of Solvent-Producing Bacteria in this Chapter).

Cloning and sequencing of the solvent-production genes of *C. acetobutylicum* strains ATCC 824 and DSM 792 led to the discovery of the *aad*/*adhE* gene (CAP0162) in the solvent-production operon (Fischer et al., 1993; Nair et al., 1994). The *aad*/*adhE* gene is located on the naturally occurring plasmid pSOL1 (see the subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter for the genome structure) and encodes a polypeptide of 862 amino acids (predicted MW 95.2 kDa). The *aad*/*adhE*-encoded polypeptide is related to the AdhE protein of *E. coli* (see "Ethanol" in Organic Acid and Solvent Production, Part II in this Volume) and was therefore proposed as a fused aldehyde-alcohol dehydrogenase (Fischer et al., 1993; Nair et al., 1994), with residue 400 roughly the end of the aldehyde dehydrogenase domain and residue 450 roughly the start of the alcohol dehydrogenase domain. The Aad protein of *C. acetobutylicum* ATCC 824 has been purified to homogeneity (Ismaiel and Chen, 1998), and it has a native MW of 1.5 MDa or above and an observed subunit MW of 97.4 kDa. With NADH as a coenzyme, the purified Aad protein has a 400 times higher aldehyde dehydrogenase activity (with butyryl-CoA) than alcohol dehydrogenase activity (with butyraldehyde) on the basis of the catalytic efficiency or the V_{max}/K_m value (A. I. Ismaiel and J.-S. Chen, unpublished data). A DNA probe encompassing amino acid residues 278 to 556 of the *aad*-encoded polypeptide hybridized to restriction fragments of *C. acetobutylicum* genomic DNA but not to those of three other solvent-producing species of clostridia, suggesting that the Aad/AdhE protein is a source of ALDH activity in *C. acetobutylicum* (Toth et al., 1999).

Clostridium acetobutylicum ATCC 824 contains a second *adhE*-like gene (*adhE*2; CAP0035) on the pSOL1 plasmid, and the *adhE2* gene encodes a polypeptide of 858 amino acids (MW 94.4 kDa), which has a 66.1% identity with the AdhE of *C. acetobutylicum* ATCC 824 (Fontaine et al., 2002). The *adhE*2-encoded protein (AdhE2) is a NADH-dependent aldehyde-alcohol dehydrogenase responsible for butanol production under the alcohologenic condition (see the subsection Physiology of Solvent Production in this Chapter). The AdhE2 protein has been fused with *Strep*-tag II, overexpressed in *E. coli* and purified (Fontaine et al., 2002). Like the purified AdhE, the purified *Strep*-tag II-AdhE2 protein also exhibited higher NADH-dependent butyraldehyde dehydrogenase (0.74 units/mg) than NADH-dependent butanol dehydrogenase (0.18 units/mg) activities.

Alcohol Dehydrogenase Alcohol dehydrogenase (ADH; enzymes 15, 18 and 20 in Fig. 26) is a ubiquitous enzyme, and multiple forms of ADHs, with different molecular structures and physiological roles, are usually found in an organism. Although most ADHs accommodate substrates with different carbon-chain lengths, they generally display a specificity for either primary alcohols (and aldehydes) or secondary alcohols (and ketones), and they show a higher catalytic efficiency (based on the ratio $[k_{cat}]/K_m$) with NAD, NADH, NADP or NADPH as the coenzyme. For the production of butanol, isopropanol and ethanol by the solvent-producing clostridia, ADH catalyzes the final reaction of the respective pathways, and the presence of multiple ADHs may be expected.

The multiplicity of ADH and the relatedness of the ADHs in the solvent-producing clostridia have been reviewed (Chen, 1995). Besides the different primary ADHs, a novel primary-secondary ADH has been purified from two strains of *C. beijerinckii* that produce both butanol and isopropanol (Ismaiel et al., 1993). The primary-secondary ADH of *C. beijerinckii* NRRL B593 is a tetramer of identical subunits (351 amino acids), NADPH-dependent, and equally active in reducing aldehydes and ketones to, respectively, primary and secondary alcohols. Therefore, the primary-secondary ADH is sufficient for the production of both butanol and isopropanol. The gene for the primary-secondary ADH of *C. beijerinckii* NRRL B593 has been cloned and sequenced (Peretz et al., 1997), and the X-ray crystallographic structure of the ADH has been solved (Korkhin et al., 1998).

The solvent-producing clostridia have both NADH-dependent and NADPH-dependent primary ADHs (Dürre et al., 1987; Hiu et al., 1987; Youngleson et al., 1988; Welch, 1991; Yan, 1991). Although NADPH-dependent primary ADHs have been separated from NADH-dependent primary ADHs (Welch, 1991; Yan, 1991), only the NADH-dependent primary ADHs have been purified from *C. acetobutylicum* ATCC 824 and *C. beijerinckii* NRRL B592. From *C. acetobutylicum* ATCC 824, four enzymes with primary ADH activities have been purified: the butanol dehydrogenases I and II (BDH I and BDH II), with a native MW slightly higher than 80 kDa and a subunit MW of 42 kDa (Welch et al., 1989; Petersen et al., 1991), and the much larger aldehyde-alcohol dehydrogenases (Aad or AdhE and AdhE2; see the subsection Aldehyde Dehydrogenase for properties of Aad/AdhE and AdhE2 in this Chapter).

BDH I and BDH II of *C. acetobutylicum* ATCC824 are encoded, respectively, by *bdhA* (CAC3299) and *bdhB* (CAC3298), which are contiguous genes but are transcribed separately

(Petersen et al., 1991; Walter et al., 1992). It should be noted that, on the basis of the N-terminal amino acid sequence, the BDH I (NH_2-Met-Leu-Ser-Phe-) described in Walter et al. (1992) and in the annotation of the *C. acetobutylicum* genome sequence was designated "BDH II" (which binds to Blue-Sepharose) by Welch (1991). The *bdhA* and *bdhB* genes code for polypeptides of 389 (MW 43,039) and 390 (MW 43,227) amino acid residues, respectively (Walter et al., 1992). The amino acid sequences of BDH I and BDH II have a 72.9% positional identity. BDH II of Welch (Welch et al., 1989; Welch, 1991) has a 46-fold greater activity with butyraldehyde than acetaldehyde, whereas BDH I (which does not bind to Blue Sepharose) has only a twofold greater activity with the C_4 substrate than with the C_2 substrate.

Clostridium beijerinckii NRRL B592, a strain not producing isopropanol, has three NADH-dependent primary ADHs (Chen, 1995). These three ADHs, designated "ADH-1," "ADH-2" and "ADH-3," are homo- and heterodimers of subunits encoded by the *adhA* gene (388 amino acids; MW 42,617; J. Toth, A. Ismaiel, and J.-S. Chen, GenBank accession number {AF497741}) and the *adhB* gene (388 amino acids; MW 42,715; J. Toth and J.-S. Chen, GenBank accession number {AF497742}). The *adhA*- and *adhB*-encoded polypeptides differ by only 13 amino acids (3%), and except for the C-terminal 40 residues, the *C. beijerinckii* AdhA and AdhB sequences are highly similar to that of Adh-1 of *C. saccharobutylicum* NCP 262 (J. Toth et al., unpublished data). The *adhA*- and *adhB* genes of *C. beijerinckii* NRRL B592 are not contiguous, and they have unrelated flanking sequences. Thus, although the NADH-dependent primary ADHs of the solvent-producing clostridia are structurally related (Chen, 1995), their positions in the respective genomes are different.

Acetoacetate : Acetate/Butyrate CoA-transferase The enzyme (16 in Fig. 26) catalyzes the reversible transfer of the CoA moiety between an acyl-CoA and a carboxylic acid. The physiological reaction of the CoA-transferase, which is synthesized when cells enter the solventogenic phase, is to convert acetoacetyl-CoA into acetoacetate, with acetate or butyrate as the CoA acceptor. Therefore, the activity of the CoA-transferase results in the reutilization of preformed acetate and butyrate, and the CoA-derivatives of the two acids enter the acid- or solvent-producing pathways. When butyrate is the CoA-acceptor, reaction 16 leads to the production of one acetone (or isopropanol) and one butanol or butyrate. When acetate is the CoA-acceptor, the resulting acetyl-CoA will enter the solventogenic or butyrate-forming pathway through the condensation reaction catalyzed by thiolase (enzyme 4 in Fig. 26), and the acetoacetyl-CoA so produced can be used for the production of either acetone/isopropanol (via CoA-transferase) or butanol/butyrate (via 3-hydroxybutyryl-CoA dehydrogenase).

CoA-transferase has been purified from *C. acetobutylicum* ATCC 824 (Wiesenborn et al., 1989a) and *C. beijerinckii* NRRL B593 (Colby, 1993). During purification, the CoA-transferase of these two species requires high concentrations of ammonium sulfate (0.5–0.75 M) and glycerol (15–20%, vol/vol) at pH 7 to preserve activity. The CoA-transferase of *C. acetobutylicum* ATCC 824 has unusually high K_m values for acetate (1.2 M) and butyrate (0.66 M); whereas the enzyme from *C. beijerinckii* NRRL B593 has K_m values of 0.5 M for acetate and 10 mM for butyrate. The K_m values for acetoacetyl-CoA range between 21 and 56 μM with acetate or butyrate as the cosubstrate for the CoA-transferases from both species (Chen, 1993).

The CoA-transferase of *C. acetobutylicum* and *C. beijerinckii* has a native MW of 85–93 kDa and appears to be a tetramer composed of two types of subunits. The structural genes (*ctfA* and *ctfB*) for the subunits of CoA-transferase have been cloned from *C. acetobutylicum* strains ATCC 824 (Petersen et al., 1993) and DSM 792 (Fischer et al., 1993) and from *C. beijerinckii* strains NRRL B592 (Hong, 1999) and NRRL B593 (J. Toth et al., GenBank accession number {AF157306}). The *ctfA* and *ctfB* genes are conserved in the two species, and they are flanked by similar solvent-production genes in the two species. However, the actual flanking gene or the orientation of the flanking gene differs in the two species (see the subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter). The *C. acetobutylicum* ATCC 824 *ctfA* gene (CAP 0163) encodes a polypeptide of 218 amino acids (MW 23,643), and the *ctfB* gene (CAP 0164) encodes a polypeptide of 221 amino acids (MW 23,626). The *ctfA* and *ctfB* genes of *C. beijerinckii* strain NRRL B593 encode polypeptides of, respectively, 217 amino acids (MW 23,231) and 221 amino acids (MW 23,710). The *ctfA* and *ctfB* genes of *C. beijerinckii* strains NRRL B592 are very similar to the respective genes of *C. beijerinckii* strain NRRL B593 (Hong, 1999).

Acetoacetate Decarboxylase Acetoacetate decarboxylase (AADC; enzyme 17 in Fig. 26) catalyzes the irreversible conversion of acetoacetate to acetone and CO_2. AADC is thus a crucial enzyme for solvent production because of its consumption of acetoacetate to allow the CoA-transferase to continue to channel preformed

butyrate and acetate into solvent production. AADC of *C. acetobutylicum* strains BY (the Weizmann strain) and NRRL B528 is a stable protein and has been extensively studied, and the literature has been briefly reviewed (Chen, 1993).

AADC of *C. acetobutylicum* is an oligomeric protein (native MW about 300–330 kDa; Hamilton and Westheimer, 1959; Gerischer and Dü, 1990). Its structural gene (*adc*; CAP 0165) encodes a polypeptide of 244 amino acids (calculated MW 27,519; Gerischer and Dü, 1990; Petersen et al., 1993). The *adc* gene of *C. beijerinckii* strains NRRL B592 and NRRL B593 encodes a polypeptide of 246 amino acids (calculated MWs 27,392 and 27,353, respectively) for the two strains (Hong, 1999; J. Toth and J.-S. Chen, GenBank accession number {AF157305}).

Phosphotransbutyrylase and Butyrate Kinase

Phosphotransbutyrylase (PTB; enzyme 8 in Fig. 26) catalyzes the conversion between butyryl-CoA and butyryl phosphate, whereas butyrate kinase (BK; enzyme 9 in Fig. 26) catalyzes the conversion between butyryl phosphate and butyrate and ATP (Chen, 1993). PTB and BK are thus key enzymes for the formation of butyric acid. Theoretically, PTB and BK can catalyze the ATP-dependent reutilization of preformed butyrate for solvent production (Husemann and Papoutsakis, 1989), but direct evidence for any significant role played by PTB and BK in this respect is still lacking.

PTB has been purified from *C. acetobutylicum* ATCC 824 (Wiesenborn et al., 1989b) and *C. beijerinckii* NRRL B593 (Thompson and Chen, 1990), and the two purified PTBs are similar in native MW (264 versus 205 kDa), subunit MW (31 versus 33 kDa), and in the K_m for butyryl-CoA (0.11 versus 0.04 mM) and phosphate (14 versus 6.5 mM). The PTB of *C. beijerinckii* NRRL B593 also reacts with acetoacetyl-CoA (with a K_m of 1.1 mM) in the presence of phosphate, and coenzyme A-SH (CoASH) is a product of the reaction (Thompson and Chen, 1990).

PTB is encoded by the *ptb* gene. The *ptb* gene of *C. acetobutylicum* ATCC 824 (CAC 3076) encodes a polypeptide of 296 amino acids (calculated MW 31,546; Walter et al., 1993), whereas the *ptb* gene of *C. beijerinckii* NCIMB 8052 encodes a polypeptide of 302 amino acids (calculated MW 32,445; Oultram et al., 1993). PTB appears to be a hexamer or an octamer of identical subunits. The *ptb* gene follows a *buk* gene (for BK) to form an operon in these two organisms. In *C. acetobutylicum* ATCC 824, a second *buk* gene (CAC 1860) is present (Huang et al., 2000); the gene is expressed but its physiological significance is unknown.

Both butyrate kinases of *C. acetobutylicum* ATCC 824 have been purified. The first butyrate kinase (BK-I) was purified from *C. acetobutylicum* ATCC 824 (Hartmanis, 1987), whereas the second was purified from a recombinant *E. coli* expressing BK-II (Huang et al., 2000). The kinetic properties of BK-I (native MW 85 kDa) were measured in the acyl phosphate-forming or reverse direction. The *buk* gene for BK-I (CAC 3075) of *C. acetobutylicum* ATCC 824 encodes a polypeptide of 355 amino acids (calculated MW 39,002; Walter et al., 1993). The *buk* gene of *C. beijerinckii* NCIMB 8052 also encodes a polypeptide of 355 amino acids (calculated MW 38,438; Oultram et al., 1993).

It has been speculated that a decrease in the flux of butyryl-CoA going into butyrate formation may favor the production of butanol. Use of the antisense RNA technique to decrease the expression of either the BK or the PTB gene in *C. acetobutylicum* caused a lowering of both PTB and BK activities (but to a different degree), yet it did not have any significant impact on butyrate formation, suggesting that butyrate formation is not controlled by the levels of PTB and BK (Desai and Papoutsakis, 1999). However, the antisense RNA against the PTB gene caused an increase in solvent production, whereas the antisense RNA against the BK gene caused a decrease in solvent production, although both caused decreases in PTB and BK activities. A *C. acetobutylicum* mutant (PJC4BK) with the gene for BK inactivated showed superior solvent productivity between pH 5.0 and 5.5 (Harris et al., 2000), whereas it exhibited good solvent productivity at pH greater than or equal to 5.5 (Green et al., 1996b). Therefore, a decrease in the BK activity by any of these three manipulations had very different effects on the solvent productivity, which perhaps illustrates the complexity of the mechanisms regulating solvent production.

Phosphotransacetylase and Acetate Kinase

Phosphotransacetylase (PTA; enzyme 10 in Fig. 26) and acetate kinase (AK; enzyme 11 in Fig. 26) catalyze consecutive reactions analogous to those catalyzed, respectively, by phosphotransbutyrylase (PTB) and butyrate kinase (BK). Thus, PTA catalyzes the conversion between acetyl-CoA and acetyl phosphate, and AK catalyzes the conversion between acetyl phosphate and acetate and ATP (Chen, 1993). The two enzymes PTA and AK are potentially involved in ATP-dependent reutilization of preformed acetate during solvent production; however, like the situation involving PTB and BK, direct evidence in support of such a role is lacking.

PTA and AK activities have been measured in cell-free extracts of solvent-producing clostridia, and these activities can be separated from those

attributable to PTB and BK, respectively (Chen, 1993). PTA has only been partially purified from *C. beijerinckii* (Chen, 1993), whereas AK has been purified from *C. acetobutylicum* DSM 1731 (Winzer et al., 1997). AK of *C. acetobutylicum* DSM 1731 has a native MW of 87–94 kDa and a measured subunit MW of 43 kDa. The K_m values for acetyl phosphate, Mg-ADP, acetate, and Mg-ATP are, respectively, 0.58, 0.71, 73, and 0.37 mM. Results of Northern blot analysis show that there is no significant difference in the transcription of the acetate kinase gene (*ack*) in cells of *C. acetobutylicum* DSM 1731 under acid- and solvent-producing conditions (Winzer et al., 1997).

The *C. acetobutylicum* ATCC824 genes for PTA (*pta*; CAC 1742) and AK (*ack*; CAC 1743) have been cloned and sequenced, and the *pta* gene precedes the *ack* gene in forming an operon (Boynton et al., 1996b). The *pta* gene encodes a polypeptide of 333 amino acids (calculated MW 36.2 kDa), whereas the *ack* gene encodes a polypeptide of 401 amino acids (calculated MW 44.3 kDa).

Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria As shown in Fig. 26, the enzymes catalyzing reactions 16–18 (between acetoacetyl-CoA and acetone or isopropanol) and the enzymes catalyzing reactions 14 and 15 (between butyryl-CoA and butanol) are specifically required for solvent production. The genes encoding these enzymes (*ctfA* and *ctfB* for acetoacetate:butyrate/acetate CoA-transferase, *adc* for acetoacetate decarboxylase, and *ald* or *aad*/*adhE* for aldehyde and alcohol dehydrogenase) form monocistronic or polycistronic operons. All characterized strains of solvent-producing clostridia have a gene cluster, which contains the acetone-forming genes and most of the butanol-forming genes.

In *C. acetobutylicum* strains ATCC 824 and DSM 792, the main gene cluster for solvent production consists of two converging operons (Dürre et al., 2002) of the following organization (arrowheads indicating the direction of translation):

aad/*adhE* ►-R *ctfA* ►-R *ctfB* ►-R ◄-l *adc*

The solvent-production or "*sol*" operon contains the *aad*/*adhE* and the *ctf* genes, whereas the *adc* operon is monocistronic. The *aad*/*adhE* gene and the separately transcribed *adc* operon are characteristics of this species (Hong, 1999; Toth et al., 1999). Transcriptional regulation of the solvent-production genes of *C. acetobutylicum* has been reviewed (Dürre et al., 2002), and the Spo0A protein is a significant component of the regulatory networks for solventogenesis (Harris et al., 2002; Thormann et al., 2002).

In *C. beijerinckii* strains NRRL B592 and NRRL B593, the *ald* gene which encodes an aldehyde dehydrogenase precedes the *ctfA* gene to give a solvent-production operon of the following organization (Hong, 1999; Toth et al., 1999; Toth, J. and J.-S. Chen, GenBank accession numbers {AF157305} and {AF157306}):

ald ►-R *ctfA* ►-R *ctfB* ►-R *adc* ►-R

Both *C. acetobutylicum* and *C. beijerinckii* have genes located elsewhere for the multiple alcohol dehydrogenases. Whereas the *sol* and *adc* operons of *C. acetobutylicum* are located on the pSOL1 plasmid, the contiguous but monocistronic *bdhA* and *bdhB* genes are located on the chromosome (see subsection Metabolic Pathways and Enzymology of Solvent Production in this Chapter). *Clostridium beijerinckii* NRRL B592 has *adhA* and *adhB* genes, which encode the subunits of three dimeric isozymes of primary alcohol dehydrogenases, and the *adhA* and *adhB* genes are not contiguous genes (GenBank accession numbers {AF497741} and {AF497742}). The isopropanol-producing *C. beijerinckii* NRRL B593 has an *adh* gene encoding the primary-secondary alcohol dehydrogenase (Peretz et al., 1997). Although the *adhA* gene of *C. beijerinckii* NRRL B592 and the *adh* gene of *C. beijerinckii* NRRL B593 are structurally unrelated, both of them are preceded by an *stc* gene (Peretz et al., 1997; Hong, 1999; GenBank accession numbers {AF157307} and {AF497741}), which could encode an enhancer-binding protein belonging to the NtrC family (Osuna et al., 1997), and are followed by a *hydG* gene (Pedroni et al., 1995; Rakhley et al., 1999), which could encode an electron-transfer subunit of a redox enzyme. The conserved location of the *stc* gene relative to the *adh* or *adhA* gene in the two strains of *C. beijerinckii* suggests a regulatory role for the *stc* gene in the expression of the *adh* or *adhA* gene, but this relationship remains to be established.

The enzymes catalyzing reactions 5–7 (between acetoacetyl-CoA and butyryl-CoA) are required for the formation of both butyric acid and butanol (Chen, 1993). The five genes encoding these enzymes (*hbd* for 3-hydroxybutyryl-CoA dehydrogenase, *crt* for crotonase, and *bcd* for butyryl-CoA dehydrogenase) and an electron-transfer protein (*etfA* and *etfB*) form the "*bcs*" operon (Boynton et al., 1996a; Toth, J. and J.-S. Chen, GenBank accession number {AF494018}). The genes of the *bcs* operon are conserved in *C. acetobutylicum* and *C. beijerinckii* and have the following organization:

crt ►-R *bcd* ►-R *etfB* ►-R *etfA* ►-R *hbd* ►-R

Because the proteins encoded by these genes are needed for both primary and secondary metabolism, the promoter region of the *bcs* operon must differ from that for the *sol* operon.

In *C. saccharobutylicum* NCP 262, the following arrangement of solvent production-related genes has been described (Youngleson et al., 1995):

etfB ►-R *etfA* ►-R *hbd* ►-R *adh-1* ►-R

The *adh-1* gene encodes an NADPH-linked alcohol dehydrogenase, and its transcription peaks shortly before the onset of solvent production, suggesting the functioning of other *adh* genes later in the growth cycle (Youngleson et al., 1995). The *etfA* and *hbd* genes (the DNA sequence preceding the *etfB* gene has not been reported) are transcribed during both acid- and solvent-producing phases of growth.

Among the alcohol dehydrogenases of the solvent-producing clostridia, the enzymes encoded by the *bdhA* and *bdhB* genes of *C. acetobutylicum* ATCC 824, the *adhA* and *adhB* genes of *C. beijerinckii* NRRL B592, and the *adh-1* gene of *C. saccharobutylicum* NCP 262 are related (Walter et al., 1992; Chen, 1995; Toth, J. et al., unpublished results; GenBank accession numbers {AF497741} and AF497742}). The roles of these *adh* genes in butanol formation will need further clarification.

The Genome of Clostridium acetobutylicum *ATCC824* The genome of *C. acetobutylicum* consists of a chromosome of about 4 Mb and a megaplasmid of about 200 kb (Cornillot and Soucaille, 1996; Cornillot et al., 1997a; Cornillot et al., 1997b). The genome sequence of *C. acetobutylicum* ATCC 824 has been determined (Nolling et al., 2001). The chromosome is 3,940,880 bp in length (GenBank accession number {AE001437}), with a total of 3,740 polypeptide-encoding ORFs and 107 stable RNA genes having been identified and accounting for 88% of the chromosomal DNA. The average length of the intergenic regions is about 121 bp. The megaplasmid, pSOL1, is 192,000 bp in length (GenBank accession number {AE001438}) and appears to encode 178 polypeptides. There appear to be two unrelated cryptic prophages in the chromosome. The first spans about 90 kb and includes about 85 genes (CAC1113 to CAC1197), whereas the second spans about 60 kb and includes about 79 genes (CAC1878 to CAC1957). Genes for three distinct insertion sequence-related proteins are present on the chromosome, but only one of these is intact. It is believed that no active insertion sequence elements are present in the *C. acetobutylicum* genome.

Four genes (*aad*/*adhE*, *ctfA*, *ctfB* and *adc*; CAP0162 to CAP0165), which are required for butanol- and acetone-production under acidic growth conditions, occur as two converging operons on the pSOL1 plasmid. The pSOL1 plasmid also contains the second copy of the aldehyde-alcohol dehydrogenase gene (*adhE2*; CAP0035), which is required for butanol production under the neutral or alcohologenic growth conditions (Fontaine et al., 2002). In addition, the pSOL1 plasmid contains genes for a pyruvate decarboxylase (CAP0025) and an alcohol dehydrogenase (CAP0059), whose physiological roles have not been determined. The genes for two characterized alcohol dehydrogenases (CAC3298 and CAC3299) are present on the chromosome, and one or both of them may function during butanol production (Dürre et al., 2002).

On the basis of the genome sequence, the number of recognizable sporulation genes is smaller in *C. acetobutylicum* than in *Bacillus subtilus*. Some of the Spo0 and SpoV genes have not been detected in *C. acetobutylicum*, but the gene encoding an apparent ortholog of the Spo0A protein (CAC2071) has been identified. The number of identified genes for spore coat biosynthesis, spore germination, and septum formation is also smaller in *C. acetobutylicum* than in *B. subtilis* (Nolling et al., 2001), but it is not known how much of the difference can be attributed to mechanistic differences in the sporulation-germination processes between the two organisms.

A large number of genes, some of which are organized in apparent operons, have been identified for substrate utilization and transport, and they occur on both the chromosome and the megaplasmid (Nolling et al., 2001). For example, putative genes for cellulose degradation are found on the chromosome (CAC0910–CAC0919, CAC0561, and CAC3469), whereas putative genes for xylan degradation are found on both the chromosome (CAC0617 and CAC0706) and the megaplasmid (CAP0071, CAP0114, CAP0115, and CAP0117–CAP0120). Knowledge of genes for substrate utilization and their regulation could be useful in attempts to expand the substrate range of *C. acetobutylicum* or other solvent-producing species.

The Genome of C. beijerinckii *NCIMB 8052 Clostridium beijerinckii* NCIMB 8052 has a circular, 6.7-Mb chromosome (Wilkinson and Young, 1995). A combined physical and genetic map shows that the genes for acetoacetate decarboxylase (*adc*) and CoA-transferase (*ctfA* and *ctfB*) are located at some distance from either an alcohol dehydrogenase gene (*bdh*) or the genes for butyrate kinase (*buk*) and phosphotransbutyrylase (*ptb*). The "*deg*" gene, whose integrity is related to the strain's tendency to lose solvent productivity (degeneration), was later identified as the fms gene encoding the peptide deformylase (Evans et al., 1998).

The Genome of C. saccharobutylicum *NCP 262 Clostridium saccharobutylicum* NCP 262 has a circular, 5.3-Mb chromosome (Keis et al., 2001b).

The positions of genes required for the formation of butyric acid as well as of two genes for alcohol dehydrogenases have been located on the map. The position of the genes for acetone formation (*ctfA*, *ctfB* and *adc*) has not been reported.

Tools for the Genetic Manipulation of Solvent-Producing Clostridia Since the 1980s, much progress has been made in the development of tools for the genetic manipulation of solvent-producing clostridia (Young et al., 1989; Mitchell, 1998). The basic tools are now available for carrying out a variety of genetic and molecular biological experiments with the solvent-producing clostridia.

Mutagenesis experiments with solvent-producing clostridia have been performed in a number of laboratories. Irradiation with ultraviolet (UV) light is not effective (Bowring and Morris, 1985), whereas several alkylating agents have been used successfully (Allcock et al., 1981b; Bowring and Morris, 1985; Hermann et al., 1985; Lemmel, 1985; Junelles et al., 1987; Rogers and Palosaari, 1987; Clark et al., 1989; Cueto and Mendez, 1990; Annous and Blaschek, 1991; Gutierrez and Maddox, 1992). Mutagenesis with transposons has been used with good results (Woolley et al., 1989; Bertram et al., 1990; Babb et al., 1993; Sass et al., 1993; Mattsson and Rogers, 1994; Kashket and Cao, 1995). Homologous recombination for directed mutagenesis has been demonstrated in *C. acetobutylicum* (Green and Bennett, 1996a) and in *C. beijerinckii* (Wilkinson and Young, 1994) using nonreplicative plasmids and in *C. acetobutylicum* using a replicative plasmid (Harris et al., 2002). The antisense RNA technique (Desai and Papoutsakis, 1999) provides a strategy for altering the phenotype without modifying the targeted gene itself.

A dominant selective marker is an essential element of a gene-transfer system. The erythromycin resistance gene of the streptococcal plasmid pAMβ1 has been widely used (Young et al., 1989). When selection for erythromycin resistance needs to be performed under acidic culture conditions over an extended period of time, the more acid-stable clarithromycin is used in place of erythromycin (Mermelstein and Papoutsakis, 1993a). The *Bacillus* plasmid pIM13 has provided the replicon for several shuttle vectors that can be maintained in *E. coli* and *C. acetobutylicum* (Lee et al., 1992), *C. beijerinckii* (Li, 1998), *C. saccharobutylicum* (Azeddoug et al., 1992), and *C. saccharoperbutylacetonicum* (Truffaut et al., 1989). Plasmids isolated from clostridia also provided replicons for the construction of shuttle vectors (Yoshino et al., 1990; Yoon et al., 1991; Lee et al., 1992). *Clostridium acetobutylicum* ATCC 824 contains a restriction endonuclease *Cac*824I whose recognition sequence 5′-GCNGC occurs frequently in *E. coli* plasmids. To protect the *E. coli-Clostridium* shuttle vector from restriction by *Cac*824I, in vivo methylation of the plasmid in *E. coli* by the *Bacillus subtilis* phage ϕ 3T I methyltransferase has been successfully used (Mermelstein and Papoutsakis, 1993b).

Different methods, including conjugative and protoplast-mediated transfers, have been developed for the introduction of vectors carrying specific genes into the solvent-producing clostridia (Mitchell, 1998). Much effort was put into the development of conjugative transfer systems (Oultram and Young, 1985; Reysset and Sebald, 1985; Yu and Pearce, 1986; Oultram et al., 1987; Bertram and Dü, 1989; Woolley et al., 1989; Williams et al., 1990) and the protoplast-mediated transfers (Reid et al., 1983; Lin and Blaschek, 1984; Jones et al., 1985). However, it is the electroporation technique that has made it easier to transform different strains of solvent-producing clostridia. Conditions of electroporation for the following strains are available: *C. acetobutylicum* ATCC 824 (Mermelstein et al., 1992), *C. acetobutylicum* DSM 792 (Nakotte et al., 1998), *C. beijerinckii* NCIMB 8052 (Oultram et al., 1988), *C. beijerinckii* NRRL B592 (Birrer et al., 1994; Li, 1998), and *C. beijerinckii* NRRL B593 (Li, 1998).

A good reporter gene is required for the study of promoters. The commonly used reporter systems, such as the *E. coli* β-galactosidase or the green fluorescent protein (GFP), are not suitable for the solvent-producing clostridia because of the biased codon usage pattern (AT-rich), an acidic environment, and the absence of molecular oxygen (O_2) in the clostridia. A β-galactosidase encoded by the *lacZ* gene of *Thermoanaerobacterium thermosulfurogenes* EM1 has been used as a reporter in *C. acetobutylicum* ATCC 824 (Tummala et al., 1999). However, a β-galactosidase is present in *C. acetobutylicum* NCIMB 2951 (Hancock et al., 1991). The use of β-galactosidase as a reporter in the solvent-producing clostridia may be limited if other strains also contain this enzyme. The *gusA*-encoded β-glucuronidase activity was successfully used as a reporter in *C. beijerinckii* NCIMB 8052 (Ravagnani et al., 2000). The secondary alcohol dehydrogenase activity (reduction of acetone to isopropanol) of the primary-secondary ADH of *C. beijerinckii* NRRL B593 has been used as a reporter in non-isopropanol-producing strains, such as *C. acetobutylicum* ATCC 824 and *C. beijerinckii* NRRL B592 (Li, 1998). Further development of efficient reporter systems for the solvent-producing clostridia should facilitate the characterization of the promoters for solvent-production operons.

Commercial Applications

COMMERCIAL PRODUCTION Acetone, butanol and isopropanol are now produced by synthetic processes using petrochemicals as the starting material. However, the fermentation process is in operation in China (Jones and Keis, 1995; R.-X. Shen, personal communication). Use of the fermentation process in other countries has been reported (Billig, 1992), but the scale of the operation and other details have not. In Austria, *C. beijerinckii* NRRL B592 is being tested on the pilot-plant scale (50 liters for the first stage and approximately 150 liters for the second stage) to convert low-grade potatoes into acetone and butanol, and on a demonstration scale, tests are planned (Gapes, 2000b). commercial production of acetone, butanol, and isopropanol is briefly described below.

Acetone Most of the world's acetone is now obtained as a coproduct of phenol production by the cumene process. In the cumene-to-phenol process, benzene is alkylated to cumene, which is oxidized to cumene hydroperoxide, and the latter is cleaved to acetone and phenol. Dehydrogenation of isopropanol accounts for most of the acetone that is produced to meet the demand in excess of that supplied by the phenol process. The economics of acetone production are unusual in that the supply depends on the production of phenol, whereas the demand is controlled by the uses of acetone. When the consumption of acetone grows at a slower rate than the growth of demand for phenol, an excess in the supply of acetone occurs. More than 75% of the world's and about 95% of the United States' acetone production now comes from the cumene-to-phenol process. World production of acetone in 1990 was about three million metric tons per year, of which about one third was made in the United States. It has been predicted that acetone as a coproduct from the cumene-to-phenol process will continue to dominate supply, and production of "on-purpose" acetone will probably decline as supplies of by-product acetone increase (Howard, 1991), which effectively eliminates the need to use a fermentation process to produce acetone, except where the local economic situations may favor the fermentation process.

Butanol The principal commercial source of *n*-butanol is through hydrogenation of *n*-butyraldehyde, which is obtained from the Oxo reaction of propylene. The Oxo process produces *n*-butyraldehyde and isobutyraldehyde. The mixture may be separated before hydrogenation of *n*-butyraldehyde to *n*-butanol, or the mixture is hydrogenated and the products, *n*-butanol and isobutanol, are separated afterwards (Billig, 1992). As of January 1, 1990, the total United States capacity to produce *n*-butanol (591,000 tons or 1,182 million lbs per year) was roughly equal to the combined capacity of Western Europe and Southeast Asia (Billig, 1992). Between 1985 and 1995, the United States production of *n*-butanol increased from 716 to 1,493 million lbs (Anonymous, 1996b).

Isopropanol Isopropanol is generally known as the first petrochemical (Logsdon and Loke, 1999). It is manufactured from propylene by either an indirect hydration process (the sulfuric acid process) or direct hydration. Isopropanol is also produced by the hydrogenation of acetone, which is a coproduct of the cumene-to-phenol process (Logsdon and Loke, 1996). In addition, isopropanol is produced from crude acetone, which is generated as a by-product of propylene oxide manufacture (Anonymous, 2001b). Between 1986 and 1996, the United States annual production of isopropanol remained in the range 1,272–1,474 million lbs (Anonymous, 1997). The demand for 1999 and 2000 was, respectively, 1,180 and 1,200 million lbs, whereas the production capacity of the United States plants was 1,875 million lbs per year (Anonymous, 2001b).

USES *Acetone* Acetone is an excellent solvent for a wide range of industrial materials including gums, waxes, resins, fats, greases, oils, dyestuffs and cellulosics. Thus, solvent applications remain the largest uses for acetone worldwide, where both acetone and chemicals derived from acetone (the aldol chemicals) are used as solvents. However, because acetone is classified as a volatile organic compound, little or no growth in the solvents market is expected, although acetone is a normal constituent of the environment and is readily biodegradable (Howard, 1991).

Acetone is used as a carrier for acetylene, in the manufacturing of a variety of coatings and plastics, and as a raw material for the synthesis of a wide range of products including ketene, methyl methacrylate, and bisphenol A. Following solvent applications, the second largest use for acetone is for the manufacturing of acetone cyanohydrin, which is converted to methacrylates, and this use for acetone has been growing steadily. However, the fastest growing outlet for acetone is for the manufacturing of bisphenol A, which is used in the manufacturing of polycarbonate. It is interesting to note that although a mole of acetone is consumed in the production of a mole of bisphenol A, the process actually causes the net production of a mole of acetone because two moles of acetone are formed for every two moles of phenol formed (Howard, 1991).

Acetone is potentially useful in blends with gasoline as it can increase the oxygen content, the octane rating, and the water tolerance of the fuel (Bolt, 1980; Noon, 1982). Acetone can also be blended with butanol, ethanol and water to serve as an automobile fuel (see the next subsection Butanol in this Chapter).

Butanol *n*-Butanol is used as a direct solvent in paints and other surface coatings. Other direct solvent applications are in the formulation of pharmaceuticals, waxes and resins. Additional commercial markets for *n*-butanol include plasticizer esters, butylated melamine-formaldehyde resins, and mono-, di- and tributylamines. Butyl acetate is one of the more important derivatives of *n*-butanol and is employed as a solvent in rapid drying paints and coatings. *n*-Butanol and butyl acetate act synergistically to serve as a latent solvent system for nitrocellulose lacquers and thinners to give a solvent system stronger than either solvent alone.

Butyl glycol ethers such as 2-butoxyethanol are the largest-volume derivatives of *n*-butanol used in solvent applications. They are used in vinyl and acrylic paints, lacquers, varnishes, and aqueous cleaners to solubilize organic surfactants.

The largest-volume commercial derivatives of *n*-butanol, however, are *n*-butyl acrylate and methacrylate. These are used principally in emulsion polymers for latex paints, in textile applications, and in impact modifiers for polyvinyl chloride (Billig, 1992).

n-Butanol has been proposed as a blending agent with gasoline for the internal combustion engines (Noon, 1982; Bata et al., 1991; Ladisch, 1991) and with diesel (Ladisch, 1991). Besides being a component in the alcohol-gasoline blends, *n*-butanol can be blended with acetone, ethanol and water in a ratio of 51 : 25 : 6 : 18 (by weight) and the blend performed well in a spark-ignited, internal combustion engine (Noon, 1982).

n-Butanol can increase the water tolerance of gasoline-ethanol blends (Bolt, 1980; Noon, 1982). The water tolerance of the gasoline-ethanol blends increases with the ethanol concentration and temperature. At room temperature, a 25% ethanol blend with gasoline can tolerate about 1% of water. If 2% of water is present in the blend, most of the ethanol will separate from gasoline in a few seconds and settle to the bottom, which is known as phase separation. Phase separation renders the ethanol-gasoline blend unfit as an automobile fuel (Bolt, 1980). Addition of butanol to the blend increases the water tolerance to prevent phase separation (Bolt, 1980; Noon, 1982).

Isopropanol Isopropanol is used as chemical intermediates, solvents, and a component of many medical products. Estimated United States uses in 1993 were as chemical intermediates, 34%; personal care and household products, 24%; coating and ink solvent, 15%; processing solvent, 12%; pharmaceuticals, 10%; and miscellaneous uses, 5% (Logsdon and Loke, 1996). A more recent report (Anonymous, 2001b) gave the following breakdown: direct solvent uses, 46%; chemical derivatives, 36%; household and personal care products, 12%; pharmaceuticals, 4%; and acetone, 2%.

Isopropanol is used in the production of other chemicals such as derivative ketones, isopropylamines, and isopropyl esters. The use of isopropanol in the production of monoisopropylamine for herbicides (primarily glyphosate) continues to be the fastest growing segment (Anonymous, 2001b). A minor use for isopropanol is to serve as a feedstock for the production of acetone to meet the demand in excess of the coproduct acetone from phenol production. However, isopropanol is also produced from crude acetone, which is generated as a by-product of propylene oxide manufacture (Anonymous, 2001b).

Because of its balance between alcohol, water, and hydrocarbon-like characteristics, isopropanol is an excellent, low cost solvent free from government regulations and taxes that apply to ethanol. The lower toxicity of isopropanol favors its use over methanol. Consequently, isopropanol is used as a solvent in many consumer products and industrial products. It is used widely as a solvent for cosmetics, and many aerosol products contain isopropanol as a solvent. Because it is a good solvent for a variety of oils, gums, waxes, resins and alkaloids, isopropanol is used for preparing cements, primers, varnishes, paints, and printing inks (Logsdon and Loke, 1996).

Isopropanol is used as an antiseptic and disinfectant for home, hospital and industry. Rubbing alcohol, an aqueous solution of 70% (vol/vol) isopropanol, exemplifies the use of isopropanol in healthcare products. Other examples include 30% (vol/vol) isopropanol solutions for medicinal liniments, tinctures of green soap, scalp tonics, and tincture of mercurophen. It is also contained in pharmaceuticals such as local anesthetics, tincture of iodine, and bathing solutions for surgical sutures and dressings. Over 200 medical uses of isopropanol have been tabulated (Logsdon and Loke, 1996).

The use of diisopropyl ether as a fuel additive may become a significant outlet for isopropanol (Logsdon and Loke, 1996). Isopropanol itself is a useful blending component for gasoline because of its heating value, oxygen content, and octane rating (Wagner et al., 1980; Schoutens

and Groot, 1985a; Owen and Coley, 1990; Houben, 1995).

Areas of Research and Development

MICROBIOLOGY OF SOLVENT PRODUCTION The patents issued between the 1910s and 1940s contained many names of solvent-producing bacteria. Studies of industrial strains that are available from culture collections identified four species of *Clostridium* (Johnson et al., 1997; Keis et al., 2001a). Among these four species, *C. beijerinckii* is represented by many characterized strains, whereas the other three have few available strains. Considering the success of earlier investigators in isolating solvent-producing bacteria from nature, it is reasonable to expect that more solvent-producing organisms are yet to be isolated. There are new efforts in this area, such as the isolation of new solvent-producing clostridia from Columbian soil (Montoya et al., 2001). The new microbiological study may help provide novel solvent-producing organisms, from which more genetic determinants and phenotypic traits may be evaluated for the further development of industrial solvent fermentation.

ENZYMOLOGY, GENETICS, AND REGULATION OF SOLVENT PRODUCTION Efforts to define the enzymology of solvent production by the clostridia continue. Although the enzymes for most of the solvent-forming reactions have been purified from at least one strain of clostridia and characterized, the specific roles of the multiple aldehyde and alcohol dehydrogenases (Chen, 1993; Chen, 1995) are yet to be defined. The enzyme butyryl-CoA dehydrogenase also has not been characterized. Therefore, the enzymology for the three consecutive reactions leading to the formation of butanol is a subject of research. The characterization of the second aldehyde-alcohol dehydrogenase (AdhE2) from *C. acetobutylicum* ATCC 824 (Fontaine et al., 2002) and the cloning of the two genes (*adhA* and *adhB*) encoding the three primary ADH isozymes of *C. beijerinckii* NRRL B592 (GenBank accession numbers {AF497741} and {AF497742}) represent efforts in this area.

The regulation of the expression of the solvent-production operons is yet to be understood. The promoters for the solvent-production operons and the transcriptional factors for these promoters are the subjects of research. The completion of the genome sequence of *C. acetobutylicum* ATCC 824 and the sequence of the solvent-production operons from different species will facilitate the study of the components of the regulatory circuit. The identification of the Spo0A-binding sequence in the promoter region of solvent-production operons of *C. acetobutylicum* (Thormann et al., 2002) and *C. beijerinckii* (Ravagnani et al., 2000) as well as the role of Spo0A in solvent production by *C. acetobutylicum* (Harris et al., 2002) should accelerate the pace of research in this area. The development of better reporter systems for the study of promoter function in different solvent-producing species will be crucial to progress in this area.

Among the properties of solvent-producing clostridia, strain degeneration can have a serious impact on a commercial operation. Strain degeneration is the result of genetic alterations, but besides a decrease in solvent production, it is accompanied by other phenotypic changes (e.g., change in colony morphology or cell size [Adler and Crow, 1987] and Fourier transform infrared [FT-IR] spectra of cells [Schuster et al., 2001]), which may be useful indicators for the early detection of strain degeneration.

It has been observed that a truncated but functional peptide deformylase, which reduces the growth rate of the mutant (Evans et al., 1998), or an elevated acetate concentration in the growth medium (Chen and Blaschek, 1999a) will lower the frequency of degeneration of *C. beijerinckii* NCIMB 8052. At present, it is not known how many different classes of genetic changes may result in strain degeneration and how the proportion of degenerated cells in a population may change under different culture conditions. Research in this area will help define the molecular basis for strain degeneration and lead to procedures for the prevention and early detection of degeneration.

METABOLIC ENGINEERING With the genes for the acid- and solvent-forming pathways cloned from *C. acetobutylicum* ATCC 824, it becomes possible to manipulate the metabolic pathways in this and other species for the purpose of improving solvent production. Both gene inactivation and gene overexpression have been used. Nonreplicative integrational plasmids containing internal *buk* or *pta* gene fragments were used to inactivate genes encoding butyrate kinase (*buk*) or phosphotransacetylase (*pta*), respectively (Green et al., 1996b). Inactivation of the *buk* gene reduced butyrate kinase activity and increased butanol production (Green et al., 1996b; Harris et al., 2000). Interestingly, the onset of solvent production occurred earlier (in the exponential phase of growth) in the BK^- mutant (PJC4BK) and the final solvent concentration was significantly higher when the growth pH was lowered from 5.5 to 5.0 (Harris et al., 2000). When anti-*buk*-RNA was used to lower the level of butyrate kinase (Desai and Papoutsakis, 1999), the onset of solvent production also occurred earlier than in the control

culture. An earlier onset of solvent production allows a longer production period. The levels of butanol, acetone, and ethanol reached 225 mM (16.7 gm/liter), 76 mM (4.4 gm/liter), and 57 mM (2.6 gm/liter), respectively, when the BK^- mutant (PJC4BK) was grown at pH 5.0, indicating that the benchmark butanol concentration of 180 mM in the industrial fermentation broth is not due to butanol toxicity.

When a plasmid carrying the *aad* gene (encoding the aldehyde-alcohol dehydrogenase) was introduced into the butyrate kinase mutant (BK^-) to increase the level of the aldehyde-alcohol dehydrogenase, the resultant strain PJC4BK (pTAAD) produced similar amounts of butanol and acetone as PJC4BK, but 98 mM (4.5 gm/liter) of ethanol. Work with PJC4BK (pTAAD) indicated that the *aad*-encoded aldehyde-alcohol dehydrogenase did not limit butanol production under the fermentation conditions used. The level of ethanol produced by PJC4BK (pTAAD) approached the level (5 gm/liter) produced by several species of ethanol-producing clostridia (Rogers and Gottschalk, 1993).

A synthetic operon (the *ace* operon) for acetone production was constructed by placing the *C. acetobutylicum adc*, *ctfA* and *ctfB* genes (see subsection Genes and Operons for Solvent Production and the Genome of Solvent-Producing Bacteria in this Chapter) under the control of the *adc* promoter. Plasmid pFNK6 carrying the *ace* operon was introduced into *C. acetobutylicum* ATCC 824, and the resultant strain ATCC 824 (pFNK6) had an earlier onset of solvent production at pH 5.5 and 6.5 and produced higher levels of acetone and butanol than the parent strain (Mermelstein et al., 1993). Interestingly, a plasmid-control strain containing a vector without the *ace* operon also produced higher levels of solvents, but levels were lower than that produced by ATCC 824 (pFNK6).

A synthetic operon (the *ace4* operon) composed of four *C. acetobutylicum* ATCC 824 genes (*adc*, *ctfA*, *ctfB* and *thl*) under the control of the *thl* promoter was constructed to allow *E. coli* to produce acetone (Bermejo et al., 1998). The thiolase gene (*thl*) is included for the conversion of acetyl-CoA to acetoacetyl-CoA (see the subsection Metabolic Pathways and Enzymology of Solvent Production in this Chapter). One of the transformed *E. coli* strains, ATCC 11303 (pACT), produced 125–154 mM of acetone when sodium acetate was added to glucose-fed cultures. Besides their potential usefulness for acetone production, it was suggested that the recombinant strains may be useful hosts for recombinant protein production in that detrimental acetate accumulation can be avoided (Bermejo et al., 1998).

Because isopropanol is potentially a more desirable by-product than acetone for industrial butanol fermentation, a secondary alcohol dehydrogenase can be introduced into acetone- and butanol-producing strains that possess other superior properties, such as a broad substrate range or an early onset of solvent production. The *adh* gene encoding a primary-secondary alcohol dehydrogenase from *C. beijerinckii* NRRL B593 has been successfully expressed in *C. acetobutylicum* ATCC 824 and *C. beijerinckii* NRRL B592 and has enabled the transformants to produce isopropanol (instead of acetone) and butanol as major products (Li, 1998). Expression of the *C. beijerinckii* NRRL B593 primary-secondary alcohol dehydrogenase in *E. coli* allows the transformant to produce isopropanol from added acetone (Peretz et al., 1997).

Continuous Solvent Production A continuous fermentation is superior to a batch process because of more effective uses of the fermentation facility. Since the early 1980s, much effort has been devoted to the characterization of the parameters and the development of a continuous culture system for solvent production (see also patents listed in Table 34). On the basis of the results of these studies, it was concluded that no single growth-limiting factor specifically induces solvent production in a chemostat. In glucose-, nitrogen-, or magnesium-limited chemostats, steady-state solvent production was low or difficult to maintain, and an application of these kinds of limitations to an industrial process seems unlikely (Dürre and Bahl, 1996). However, phosphate- or sulfate-limitation promoted solvent production (Bahl et al., 1982b; Dürre and Bahl, 1996).

A two-stage phosphate-limited culture system allowed *C. acetobutylicum* DSM 1731 to produce solvents continuously (Bahl et al., 1982b). At the first stage, the cells are growing under conditions that induce the onset of solvent production. At the second stage, growth is not possible because the limiting nutrient is exhausted, and this stage is thus devoted to the conversion of remaining sugar to solvents. The dilution rate and temperature were 0.125 h^{-1} and 37°C for the first stage and 0.04 h^{-1} and 33°C for the second stage. In a one-stage continuous culture, butanol and acetone concentrations as well as the rate of glucose consumption increased when the dilution rate was decreased from 0.13 to 0.025 h^{-1}. Although a low dilution rate favors a high product concentration, the productivity (gm of butanol $\cdot$ liter^{-1} $\cdot$ h^{-1}) decreased with decreasing dilution rate, and at dilution rates below 0.025 h^{-1}, stable culture conditions could no longer be obtained. A two-stage continuous culture of *C. acetobutylicum* ATCC 824 was operated at dilution rates of

0.08 and 0.04 h^{-1} for the first and second stages and yielded similar results (Godin and Engasser, 1990).

A two-stage continuous culture, with on-line solvent removal by membrane evaporation, was carried out with *C. beijerinckii* NRRL B592 (Gapes et al., 1996). In this study, porous LECA (Lightweight Expanded Clay Aggregates) particles (particle size 5–10 mm) were included at both stages. The internal (accessible to cells) volume of the LECA particles represented 12 and 15% of the total volume (consisting of the working volume of the fermentor, the internal volume of the LECA particles, and the volume of the recirculation loop) of the first and second stages, respectively. The use of the LECA particles at both stages resulted in a significant increase in the final solvent concentration and solvent productivity at the second stage. The true dilution rate for each stage of the culture is difficult to determine because the medium inside the LECA particles must have a lower dilution rate than the medium outside the particles. Accordingly, the cells inside and outside of the LECA particles are likely at different physiological states. Continuous cultures of solvent-producing clostridia show periodic fluctuations of metabolic activities (known as metabolic oscillation). The inclusion of a membrane evaporation module in the recirculation loop of the second cultivation stage seems to reduce the magnitude of metabolic oscillations (Gapes et al., 1996). It should be informative to compare cells collected at different oscillatory cycles to see whether they represent different genotypic populations of cells, which differ in their capacity for substrate utilization, solvent production, and sporulation.

Active solvent production by *C. acetobutylicum* or *C. beijerinckii* at the second stage of a two-stage continuous culture may be analogous to solvent production in the batch culture, where solvent-producing cells are growing very slowly or not growing as they proceed to complete sporulation. Results suggest that the Spo0A regulatory protein is involved in the initiation of solvent production, besides its role in the initiation of sporulation (see the subsection Physiology of Solvent Production in this Chapter). If active solvent production by the wildtype cell is limited to a period during which the cell does not commence new division (although the optical density of the culture continues to increase owing to an increase in cell mass), it becomes apparent that a true chemostat or continuous culture of the wildtype solvent-producing cells should be difficult to maintain. For the same reason, cell immobilization or recycling will not be practical for continuous solvent production by the wildtype cells. However, appropriate asporogenous mutants (Meinecke et al., 1984; Lemme and Frankiewicz, 1985), whose lesion is at a step beyond the onset of solvent production and sporulation, could allow the use of immobilized cells for continuous solvent production (Largier et al., 1985). New research in this area will probably use asporogenous or sporulation-deficient mutants that are selected for prolonged active solvent production.

Product Recovery Solvent fermentation produces a dilute solution of butanol, acetone or isopropanol. The recovery of these products by distillation is an energy-intensive process. Unless the final product concentrations are elevated, the development of alternative methods for product recovery may improve the economics of this fermentation. Techniques for the alternative methods could include the use of membranes (reverse osmosis, perstraction, pervaporation and membrane evaporation), adsorbents, liquid-liquid extraction, gas striping, and chemical recovery methods (Dürre and Bahl, 1996; Dürre, 1998). Each of these techniques has its advantages and shortcomings, but all of them can be designed to allow on-line product recovery, which is desirable for a continuous solvent-production system (Gapes et al., 1996; Dürre, 1998).

Pilot Plant Studies Since the 1980s, two studies of solvent fermentation at the pilot-plant scale have been reported. A pilot project was started in Soustons, France, to evaluate the commercial potential of producing solvents for gasoline-substitute fuels. It was designed to use mainly hydrolysates of cereal straw and corn stover as the substrates. The raw materials were pretreated by steam explosion and then hydrolyzed by *Trichoderma* cellulase complex to yield fermentable substrates, and the aim was to produce one ton of solvents from 6–7 tons of raw materials (Nativel et al., 1992; Nimcevic and Gapes, 2000). Batch fermentations using strains of *C. acetobutylicum* were performed at 2 m^3 and 50 m^3 scales. Yields of one ton of solvents from 7.7 tons of corn cobs were reported. Economic evaluation of the process revealed that the costs of acetone-butanol fermentation from lignocellulosic materials are strongly dependent on the market value of the by-product lignin (Marchal et al., 1992).

Another pilot-plant study was performed in Austria, using potatoes as the raw materials (Nimcevic and Gapes, 2000). The pilot plant was designed for different modes of operation, including batch, fed-batch, and continuous. For continuous fermentation, potatoes were mashed and then liquified with a relatively small amount of amylase to prevent blockage of the equipment. The study used *C. beijerinckii* NRRL 592 and a two-stage setup (Gapes et al., 1996), with

the longest continuous fermentation lasting about four weeks. The first-stage fermentor was a gas-lift bioreactor with a working volume of 50 liters, and the second stage fermentor had a working volume up to 300 liters and was equipped with an on-line gas-stripping unit. For product removal and recovery, different on-line and off-line techniques were tested, and they included distillation, vacuum distillation, rectification, gas-stripping, and reverse osmosis. Membrane systems were not tested for product recovery at the pilot plant because it was assumed that the relatively low solvent flux through the membrane would require too large a membrane area for commercial operation. The results of the pilot-plant study have not been published yet. However, the solvent fermentation is attractive to certain localities because it provides an alternative to ethanolic fermentation: when there is a glut of ethanol, those regions which traditionally produce ethanol from surplus and waste starchy materials can now produce butanol and acetone or isopropanol instead (Gapes, 2000b).

Economic Evaluation Following the oil embargo in 1973 and the drastic rise in the price of crude oil, a renewed interest in the butanol-acetone fermentation has required periodic evaluation of the economic feasibility of this fermentation utilizing different substrates, engineering designs, and financing (Solomons, 1976; Lenz and Moreira, 1980; Gibbs, 1983; Schoutens and Groot, 1985a). These studies considered molasses, milk whey, and lignocellulosic materials as the source of the carbohydrates for the fermentation, as the cost of the carbon substrate is invariably the largest single cost item. The question "where is the sugar to come from" (Solomons, 1976) remains valid today. Evaluations utilizing corn or low-grade potatoes as the raw material yielded encouraging results (Gapes, 2000a; Qureshi and Blaschek, 2001a).

The analysis by Gapes (2000a) shows that the process can be run economically in niche markets on a relatively small industrial scale, processing low-grade agricultural products. The niche market is usually a rural region where cheap, low-grade substrates are available and the conversion of the raw material into bulk chemicals meets the specific needs of the locality, as exemplified by the many small ethanol distilleries that have been operated around Europe for many decades. On the basis of the average world market price of butanol (0.61 EUR/kg) and acetone (0.45 EUR/kg) for the five years preceding 2000, it was calculated that the break-even price of substrate lies between 0.05 and 0.09 EUR/kg for a grass-root plant or between 0.09 and 0.13 EUR/kg if an existing plant can be modified at low cost. The price of agricultural products, such as grains (primarily produced for food and feed), is thus too high under the conditions assumed in this analysis. Utilization of low-grade substrates, such as frozen potatoes, mycotoxin-contaminated corn, and surplus sugar beet, makes the fermentation economical. As suggested by several authors, butanol-acetone production by a fermentative process probably has higher capital costs but lower production costs than production by the petrochemical industry process. Gapes also suggests that from the viewpoint of investment costs alone, it is unlikely that a continuous operation is of great advantage because of the increased equipment cost for maintaining sterility during the fermentation.

The evaluation of a process using corn and the hyper-butanol-producing strain of *C. beijerinckii* BA101 in batch reactors at a plant with a capacity of 153,000 metric tons per year of butanol, acetone and ethanol gave the following results. At a corn price of US$79.23 per ton (US$2.01 per bushel) and a solvent yield of 0.42 gm per gm of glucose, the price for butanol is projected to be US$0.34 per kg. If the price of corn is at US$197.10 per ton, the price of butanol rises to US$0.47 per kg. Production from a grass-root plant would result in a butanol price of US$0.73 per kg, when the price of corn is US$79.23 per ton, or US$0.88 per kg, when the price of corn is US$197.10 per ton, or US$1.07 per kg, when the price of corn is US$197.10 per ton and no credit for gases is taken. In this evaluation, acetone and ethanol are treated as by-products, and a by-product credit is included in the calculation of the price of butanol. The price of petrochemical-derived butanol was US$1.21 per kg as reported in the Oct. 16, 2000, issue of *Chemical Market Reporter* (Qureshi and Blaschek, 2001a).

Patents and Regulatory Issues

There are two periods during which the majority of patents for bacterial solvent production were issued. The first period is between 1910 and 1950, and the second period started in 1982. The first period is characterized by the use of newly isolated bacteria (Beesch, 1952; Prescott and Dunn, 1959a), whereas the second period is characterized by the use of mutant strains derived from organisms in the culture collections (Table 34). Many of these patents have expired, but they continue to provide useful information for the correct identification and classification of industrial strains preserved in the culture collections (Jones and Keis, 1995; Keis et al., 1995).

Table 34. United States patents issued after 1981 for butanol production by fermentation.

Patent no.	Date	Inventors	Title
4,326,032	1982	Grove, L. H.	Process for the production of organic fuel
4,368,056	1983	Pierce, S. M., Wayman, M.	Diesel fuel by fermentation of wastes
4,424,275	1984	Levy, S.	Continuous process for producing *n*-butanol employing anaerobic fermentation
4,443,542	1984	Hayashida, S., Ogata, S., Yoshino, S.	Process for the production of butanol and novel microorganism composition used therein
4,520,104	1985	Heady, R. E., Frankiewicz, J. R.	Production of butanol by a contiuous fermentation process
4,521,516	1985	Lemme, C. J., Frankiewicz, J. R.	Strain of *Clostridium acetobutylicum* and process for its preparation
4,539,293	1985	Bergstrom, S. L., Foutch, G. L.	Production of butanol by fermentation in the presence of cocultures of *Clostridium*
4,560,658	1985	Datta, R., Zeikus, J. G.	Production of butanol by fermentation in the presence of carbon monoxide
4,568,643	1986	Levy, S.	Continuous process for producing *n*-butanol employing anaerobic fermentation
4,628,116	1986	Cenedella, R. J.	Vinyl bromide extraction of butyric acid and butanol from microbial fermentation broth
4,690,897	1987	Squires, C. H., Heefner, D. L., Evans, R. J., Kopp, B. J., Yarus, M. J.	Method for transformation of anaerobic microorganisms
4,757,010	1988	Hermann, M., Fayolle, F., Marchal, R.	Production of *Clostridium acetobutylicum* mutants of high butanol and acetone productivity, the resultant mutants, and the use of these mutants in the joint production of butanol and acetone
4,777,135	1988	Husted, G. R., Santangelo, J. D., Bostwick, D. W.	Method for producing butanol by fermentation
4,905,761	1990	Bryant, R. S.	Microbial enhanced oil recovery and compositions
5,063,156	1991	Glassner, D. A., Jain, M. K., Datta, R.	Process for the fermentative production of acetone, butanol and ethanol
5,192,673	1993	Jain, M. K., Beacom, D., Datta, R.	Mutant strain of *C. acetobutylicum* and process for making butanol
5,210,032	1993	Kashket, E. R.	Degeneration-resistant solventogenic clostridia
6,358,717	2002	Blaschek, H., Annous, B., Formanek, J., Chen, C.-K.	Method of producing butanol using a mutant strain of *Clostridium beijerinckii*

The new wave of patent applications coincided with the rise in interest in using fermentation as an alternative to the petrochemical-dependent synthetic routes for the production of butanol and acetone. For reasons of economics and environment protection, the use of industrial waste or lignocellulosic residues, instead of primary food products, as the substrates for the fermentation is desired (Pierce and Wayman, 1983). There are propositions to use butanol, acetone or isopropanol as components of fuels (Grove, 1982; Pierce and Wayman, 1983) or to use solvents produced in situ for enhanced oil recovery (Bryant, 1990). Another reason for making solvent fermentation important pertains to the desired use of fermentation-derived butanol as an extractant in the preparation of foods, flavors and pharmaceuticals to reduce the potential of carcinogen carryover from the petroleum-based synthetic butanol (Blaschek et al., 2002).

Prospects

The demise of solvent fermentation in North America and East Asia between the late 1950s and the early 1960s resulted from both the competitive uses for molasses, which drove up the cost of raw materials, and the rise of the petrochemical industry, which drove down the price of the chemically synthesized butanol and acetone. However, this industrial fermentation did not totally disappear after the 1960s. The continued operation of the fermentation in South Africa between 1936 and 1982 illustrates the importance of the local conditions in determining the cost effectiveness and the necessity of the fermentation. The use of butanol as an extractant by the food and pharmaceutical industries may also create a demand for the fermentation product as it does not contain the carcinogens that may be present in butanol produced from petrochemicals. The continued use of the fermentation

process to produce butanol in China may partly be due to this consideration.

With an increasing world population and an increased pressure to preserve the productivity of the land and the aquatic system, the use of petrochemicals and the further deterioration of the environment by pollution must be curtailed. Therefore, in addition to conserving the petroleum reserve, the production of valuable chemicals such as butanol, acetone and isopropanol from fermentable wastes or low-grade agricultural products can also help to improve the quality of the environment as well as the economy of localities where such raw materials are generated. Results of economic evaluations indicate that butanol production by fermentation can be profitable in niche markets where the cost of raw material is kept low (Gapes, 2000a; Qureshi and Blaschek, 2001a). The cost for raw material will probably remain the most significant item in the economics of solvent fermentation. The genome of *C. acetobutylicum* contains several sets of genes for the utilization of abundant and inexpensive polysaccharides. If solvents can be produced from lignocellulosic substrates, the fermentation will be even more attractive.

The economics of solvent fermentation can be further improved by increasing the final concentration of solvents in the fermentation broth so that the cost for product recovery is lowered. Although butanol is toxic to the cell, results of genetic manipulations show that significantly higher concentrations of butanol and acetone can be achieved when the metabolic machinery is altered, indicating that butanol toxicity is not the limiting factor for the final solvent concentration. Our understanding of the enzymology and regulation of solvent fermentation suggests that because of the shared regulatory element (Spo0A) for the onset of both solvent production and sporulation and because of the cell's progression toward sporulation, active solvent production has a limited duration and hence productivity within the life cycle of a *Clostridium* cell. It is thus tempting to postulate that if the regulation for the onset of solvent production can be disconnected from the regulation for the onset of sporulation (or if the sporulation process can be delayed or interrupted), the period of active solvent production may be significantly prolonged to increase the final concentration of solvents. At present, it appears that isopropanol is a more desirable by-product than acetone for butanol fermentation, because an adequate supply of acetone is available through phenol production. If there should be an additional demand for acetone or the route for acetone production changes, the product pattern can be adjusted through metabolic engineering so that the best combination is obtained.

Section 9: 1,3- and 1,2-Propanediol Production

Introduction

Three-carbon diols (1,3- and 1,2-propanediol) are of significant commercial interest. The first (1,3 propanediol; PDO; also known as "trimethylene glycol") can be produced by glycerol fermentation by several different microorganisms, including *Clostridium*, *Enterobacter*, *Klebsiella* and *Lactobacillus* (Rayner, 1926; Mickelson and Werkman, 1940). The fermentative production was first described in 1881 (Biebl et al., 1999). The reader is referred to several reviews on microbial production of 1,3-propanediol (Deckwer, 1995; Zeng et al., 1997; Cameron et al., 1998; Biebl et al., 1999). The second (1,2 propanediol; 1,2-PD; also known as "propylene glycol") is produced naturally by a few organisms such as *Thermoanaerobacterium thermosaccharolyticum* and various *Clostridium* spp. (Tran-Din and Gottschalk, 1985; Cameron and Cooney, 1986; Sanchez-Riera et al., 1987). *Escherichia coli* has been engineered to produce 1,2-propanediol, and this development may provide a competitive biotechnological route of production (Altaras and Cameron, 2000). The microbial production of 1,2-propanediol has been summarized in reviews (Cameron et al., 1998; Bennett and San, 2001).

Large quantities of 1,2-propanediol are made by a chemical process using propylene oxide as raw material. Consumption in the United States is estimated to be in the range of 850 million pounds per year (Ouellette, 2000). Propylene glycol is a viscous liquid that is used primarily in unsaturated polyester resins. Pricing of propylene glycol, as listed in the January 1, 2001, issue of *Chemical Marketing Reporter*, is about US$0.59 per pound. The relatively low cost of chemically produced propylene glycol makes it difficult for a biological process to compete economically.

On the other hand, 1,3-propanediol has been more difficult to produce via chemical synthesis, and for many years its high price limited its application. Sold as a specialty chemical, 1,3-propanediol was priced in the range of US$30/kg (Biebl et al., 1999). This high cost sparked interest in exploring the economics of a biological route, especially as PDO is a desirable monomer for polymer synthesis. Deckwer (1995) estimated that the cost of 1,3-propanediol produced by fermentation was highly dependent on glycerol, the primary raw material. He estimated that more than 2/3 of the production cost of 1,3-propanediol was due to glycerol, which sells for about US$0.65–0.80 per pound (Anonymous, 2001a).

The prospects for 1,3-propanediol changed significantly when Shell Chemical announced the commercialization of a new polyester in 1995 called "Corterra." This new polyester is a combination of terephthalic acid and 1,3-propanediol. The potential for widespread use of this polyester (polytrimethylene terephthalate [PTT]) lies in fiber applications, as it has excellent properties (Welling, 1998). Shell developed a lower cost chemical route to the monomer, but industrial interest in biotechnological routes remained.

As mentioned earlier, only a few microorganisms possess the ability to ferment glycerol anaerobically to 1,3-propanediol. Glycerol is converted to pyruvate through dihydroxyacetone phosphate. In *Klebsiella*, the pyruvate is cleaved to acetyl-CoA and formate, with ethanol, acetate, CO_2, and H_2 being generated. A balance of reducing equivalents is required, resulting in the conversion of glycerol to 3-hydroxypropionaldehyde via a vitamin B12-dependent glycerol dehydratase, and then subsequent reduction to 1,3-propanediol (Streekstra et al., 1987). DuPont and Genencor undertook a new biotechnological approach (adding genes to propanediol-producing hosts that allowed for the usage of dextrose as the substrate; Chotani et al., 2000). With the number of tools in molecular biology increasing and the potential benefits of constructing new pathways, the metabolic engineering approach towards production of 1,3-propanediol has become an important one (Cameron et al., 1998).

The anaerobe *Thermoanaerobacterium thermosaccharolyticum* can produce 1,2-propanediol from dextrose, whereas other microorganisms use costly 6-deoxysugars. Propylene glycol produced by chemical means is a mixture of R and S isomers. The pure R enantiomer, which may have added value as a chiral molecule, is produced by microbial processes. This organism can produce 1,2-propanediol from a variety of sugars, which may help lower the cost of production (Altaras et al., 2001). The naturally occurring strains do not produce 1,2-propanediol at high amounts, so an alternate approach involving metabolically engineered *E. coli* was followed. *Escherichia coli* typically makes 1,2-propanediol from costly 6-deoxyhexose sugars; however, expression of either glycerol dehydrogenase or methylglyoxal synthase resulted in anaerobic production from glucose (Altaras and Cameron, 1999). Many challenges still remain in the development of a bioprocess that can be competitive with the chemical route in the production of 1,2-propanediol.

To become competitive with a chemical process, one that is microbially based must overcome hurdles: 1) the cost of agricultural raw material versus the relative low cost of petrochemical feedstocks, and 2) purification, including both water removal and separation from a complex mixture. The approaches described in subsequent sections focus on using lower cost raw material and achieving gains in yield and titer.

Scientific Background

1,3-Propanediol The study of microbial production of 1,3-propanediol has an interesting history (reviewed by Biebl et al., 1999). It is one of the oldest fermentation products known and has been studied for over 100 years. For a number of years, interest in the fermentation was due to its potential as an outlet for surplus glycerol. Glycerol can be made via a chemical process, or it can be derived from various agricultural fats during the production of fatty acids and soaps. Increased availability of low-cost glycerol might be expected in the future, as it is a by-product of such processes as transesterification of fats for biodiesel production as well as the process for ethanol production by yeast.

Glycerol can be used aerobically for growth by a large number of microorganisms. Very few organisms are able to form PDO, which is typically formed as an anaerobic product of glycerol. Only bacteria in the genera *Klebsiella*, *Enterobacter*, *Citrobacter*, *Lactobacillus*, *Clostridium* (Biebl et al., 1999) and *Ilyobacter* (Stieb and Schink, 1984) have been shown to make PDO. Most of the work has been done utilizing *Klebsiella*, *Enterobacter* and *Clostridium* (Heyndrickx et al., 1991; Bouvet et al., 1994; Barbirato et al., 1995; Petitdemange et al., 1995; Solomon et al., 1995; Barbirato et al., 1996a; Zeng, 1996; Ahrens et al., 1998; Biebl et al., 1998).

Glycerol is converted via two pathways: an oxidative one to pyruvate and a reductive pathway to PDO. The oxidative pathway involves a NAD^+-linked enzyme, glycerol dehydrogenase, which converts glycerol to dihydroxyacetone. Interestingly, dihydroxyacetone has uses in the cosmetics industry (Barbirato et al., 1998). Dihydroxyacetone is then phosphorylated by DHA kinase and is then further metabolized to pyruvate through glycolytic reactions. From pyruvate, a mixture of end products is formed that varies among the different anaerobic glycerol utilizers (Forage and Lin, 1982b). The oxidative and reductive pathways are shown in Fig. 28.

In the reductive pathway, 3-hydroxypropionaldehyde is formed by the action of a vitamin B12-dependent glycerol dehydratase. The 3-hydroxypropionaldehyde is then reduced by the enzyme 1,3-PD dehydrogenase. The oxidative and reductive pathways of glycerol dissimilation form a balance, as the role of the PDO pathway is to regenerate reducing equivalents in the form

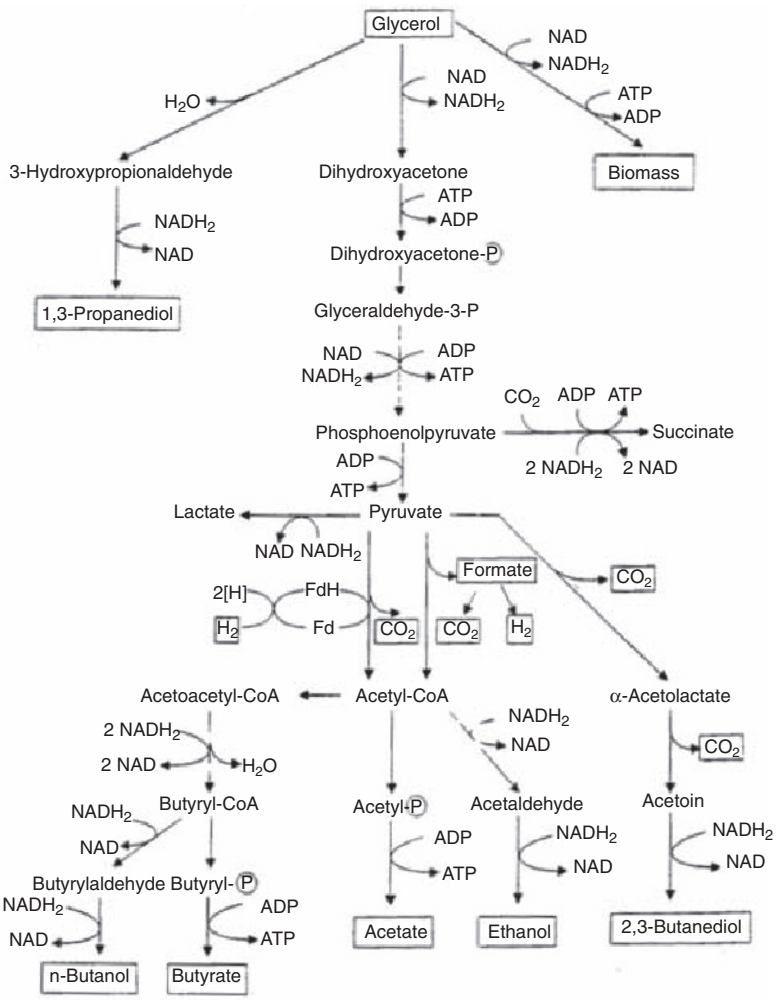

Fig. 28. Biochemical pathways of glycerol fermentation of representative microorganisms. From Biebl et al. (1999), with permission.

of reduced nicotinamide dinucleotide ($NADH_2$) produced from the dihydroxyacetone pathway (Deckwer, 1995; Zeng et al., 1997; Cameron et al., 1998).

The genes for the anaerobic dissimilation of glycerol are termed "the *dha* system." Dihydroxyacetone and glycerol are inducers of glycerol dehydrogenase, dihydroxyacetone kinase, glycerol dehydratase and 1,3-PD dehydrogenase (Forage and Foster, 1982a). Each of these genes and the resulting gene products have been studied in some detail and will be discussed below.

The first gene of the oxidative pathway is a NAD^+-linked glycerol dehydrogenase. The enzyme differs from other glycerol dehydrogenases such as the one found in *E. coli*. *Escherichia coli* does not contain the *dha* genes, but rather uses glycerol aerobically via an ATP-dependent kinase and an *sn*-glycerol 3-phosphate dehydrogenase (St. Martin et al., 1977). However, a NAD^+-glycerol dehydrogenase was isolated from a mutant *E. coli* strain with defects in two genes for aerobic glycerol dissimilation, which provided a forced selection for growth on glycerol. This glycerol dehydrogenase was purified and studied and was found to have a broad substrate specificity, including glycerol as well as a number of substituted diols (Tang et al., 1979). This *E. coli* enzyme was studied and found to be immunochemically similar to a glycerol dehydrogenase in *Klebsiella pneumoniae*, but not to the glycerol dehydrogenase of the *dha* system (Tang et al., 1982). This gene was later identified as *gldA* and is identical to D-1-amino-2-propanol oxidoreductase of *E. coli*. It maps near the *glpFKX* operon, and hydroxyacetone was shown to induce its expression (Trunger and Boos, 1994).

Glycerol dehydrogenase (E.C. 1.1.1.6) and dihydroxyacetone kinase (EC 2.7.1.29) were cloned and purified from *Citrobacter freundii*. Glycerol dehydrogenase is a hexamer of a polypeptide of 43 kDa. Like the *E. coli* glycerol dehydrogenase, the *Citrobacter* enzyme also has a broad substrate specificity. The DHA kinase is a dimer of a 57-kDa polypeptide. This enzyme is

very specific for its substrates dihydroxyacetone and ATP. DHA kinase shows some structural similarities to the glycerol kinase of *E. coli*. The glycerol dehydrogenase gene and the DHA kinase gene were denoted "*dhaD*" and "*dhaK*," respectively (Daniel et al., 1995b).

The *Citrobacter freundii* gene for 1,3-propanediol dehydrogenase (*dhaT*) has been cloned and overexpressed in *E. coli*. The enzyme is made up of eight identical subunits of 43.4 kDa and is able to catalyze a number of oxidation and reduction reactions. The enzyme oxidized a number of alcohols and was most active with diols containing two primary alcohol groups separated by one or two carbon atoms. This dehydrogenase reduced several aldehydes, with its greatest activity toward 3-hydroxypropionaldehyde. The authors compared the sequence of the *C. freundii* enzyme with alcohol dehydrogenases and concluded that it belonged to a novel family of type III alcohol dehydrogenases (Daniel et al., 1995a). The *dhaT* gene was also cloned from *C. pasteurianum*, and it showed an 89.8% similarity to the *C. freundii* gene (Luers et al., 1997).

The enzyme 1,3-propanediol dehydrogenase has also been purified from *E. agglomerans* and showed a pH optimum of 7.8. The enzyme was inhibited by NAD^+ and PDO, which may help to explain the finding that *E. agglomerans* accumulates 3-hydroxypropionaldehyde (Barbirato et al., 1997b).

Glycerol dehydratase is a key enzyme in the production of PDO from glycerol. It has been proposed that it is the rate-limiting step in PDO formation for *C. butyricum* (Abbad-Andaloussi et al., 1996), *K. pneumoniae* (Ahrens et al., 1998), and *C. freundii* (Boenigk et al., 1993). The enzyme has been purified and it requires coenzyme B12 (adenosylcobalamin) for activity (Schneider, et al., 1970). The genes from *Citrobacter freundii* (Daniel and Gottschalk, 1992; Seyfried et al., 1996), *Clostridium pasteurianum* (Macis et al., 1998), *Klebsiella pneumoniae* (Tobimatsu et al., 1996), and *Klebsiella oxytoca* (Tobimatsu et al., 1995) have been cloned and studied. The enzymes have sequence homology and similar substrate specificities and catalyze the conversion of 1,2-diols to deoxy aldehydes. The enzymes are similar in molecular weight and are made up of three subunits. In *Citrobacter freundii* the enzyme is $\alpha 2\beta 2\gamma 2$ and has a molecular weight of approximately 196 kDa (Seyfried et al., 1996).

The *dha* genes from *Klebsiella pneumoniae* were imported by conjugation into *E. coli*. The *E. coli* was then able to grow anaerobically on glycerol, but it did not produce PDO. All enzymes of the *dha* regulon were detected except for glycerol dehydratase. The growth yield of the *E. coli* was reduced and may be explained by the lack of glycerol dehydratase and difficulties in achieving redox balance (Sprenger et al., 1989). The presence of adenosylcobalamin was shown to be important for functioning of glycerol dehydratase. Addition of this cofactor and reduction of growth temperature from 37 to 28°C restored glycerol dehydratase activity and allowed *E. coli* to produce PDO from introduced *C. freundii dha* genes (Daniel and Gottschalk, 1992).

In a different study, PDO production from glycerol was seen using *E. coli* containing cosmid vector-introduced *K. pneumoniae* genes. The yield of PDO from glycerol in complex media was much higher than in defined media. The yield of 0.46 moles/mole was comparable to that reported for the *Klebsiella*, which was the source of the *dha* genes. In this case, apparently the glycerol dehydratase functioned in *E. coli*, and the authors speculate that this could be due to the large size of the DNA insert (Tong et al., 1991).

Glycerol dehydratase is inactivated by its substrate, glycerol. In *Citrobacter freundii*, *dhaF* and *dhaG* were identified as being responsible for reactivation of glycerol dehydratase. Coenzyme B12, ATP, and Mg^{+2} were necessary for this reactivation. By transcriptional analysis these two genes were shown to be expressed in glycerol but not glucose grown cells. The *dhaF* and *dhaG* subunits were purified and shown to form a tightly bound complex with a molecular mass of 150 kDa. The purified complex was tested for its ability to reactivate glycerol dehydratases of *C. freundii*, *K. pneumoniae*, *C. pasteurianum*, and the diol dehydratases of *K. oxytoca*, *Salmonella typhimurium* and *Propionibacterium freudenreichii*. The *C. freundii* and *K. pneumoniae* dehydratases were the only enzymes reactivated, which indicated that the *dhaF-dhaG* complex is specific for glycerol dehydratases of closely related organisms and does not function to reactivate diol dehydratases (Seifert et al., 2001). Similar reactivation gene products were found in *Klebsiella oxytoca* and were named "*ddrA*" and "*ddrB*" (Tobimatsu et al., 1999).

The genes encoding for glycerol dehydratase in *C. freundii* are the *dhaBCE* genes, which form part of the *dha* regulon. As mentioned earlier, the other key enzymes (*dhaD*, *dhaK* and *dhaT*) form part of the pathway. There is also a transcriptional activator protein *dhaR* (Daniel et al., 1999). The genes encoding for glycerol dehydratase in *Klebsiella oxytoca* are termed "*pddA*," "*pddB*," and "*pddC*" (Tobimatsu et al., 1995).

The mix of products derived from the dihydroxyacetone to pyruvate pathway varies depending on the microorganism. *Klebsiella* can produce ethanol, formate, acetic acid, and 2,3-

butanediol, while *Clostridium* can also produce butyric acid. Some strains of *C. pasteurianum* also form butanol (Heyndrickx et al., 1991). The pathways of glycerol fermentation and subsequent pyruvate use as drawn by Biebl et al. (1999) are shown in Fig. 28. The mix of products varies depending on the organism and the growth conditions, including pH and glycerol concentration.

Effort in calculating the theoretical yields of PDO and the mix of products formed has been considerable. To achieve economic production and maximize PDO yield, it is desirable to understand and eventually optimize by-product formation. The story is a complex one, as many different growth conditions have been examined and a variety of responses from different microorganisms can be seen.

The formation of PDO and its by-products under different conditions has been measured for *Klebsiella* and *Clostridium*, and some examples are given in the following paragraph. Using *Klebsiella aerogenes* NCTC 418, various growth-limited conditions were measured in an anaerobic chemostat. Under glycerol-limited conditions, energy generation was lower than expected owing to PDO formation. Under other growth limiting conditions such as phosphate, ammonia, or sulfate limitation, it was found that the products acetate, ethanol, succinate and PDO were formed but in differing amounts depending on the limitation. When glycerol was given in a pulse to glycerol-limited cultures, the glycerol was consumed quickly with most of the glycerol being converted to PDO and acetate (Streekstra et al., 1987).

A calculation of theoretical yield was done for *Klebsiella pneumoniae*. Two separate cases for ATP generation were assumed, one for acetic acid production and the other for ethanol. The acetic acid pathway was calculated to have a five times higher PDO yield than the ethanol pathway, while the ethanol pathway gave higher biomass and ATP yields. The theoretical maximum yield when acetate and not ethanol is produced is 0.64 moles of PDO/mole of glycerol (Zeng et al., 1993).

The theoretical yields for various conditions were calculated for *C. butyricum* and tested in chemostat culture. The products butyrate and/or acetate are necessary for generating ATP for biosynthesis. Butyrate production is more efficient for biomass synthesis as it yields a higher amount of ATP. The maximum PDO production occurs when butyrate and hydrogen are not produced. The theoretical maximum PDO yield is 0.72 moles of PDO/mole of glycerol in the case of no butyrate and no hydrogen formation.

The theoretical results were compared with experimental data of *C. butyricum* grown under glycerol limitation and excess in continuous culture. Significant differences were seen with the highest yield value of PDO seen under conditions of glycerol excess. The effects of dilution rate in continuous culture were also measured on *K. pneumoniae* and *C. butyricum*. Both reached about 80% of the theoretical maximum under high dilution rate, while *Klebsiella* reached a much higher yield and productivity under low dilution rate (Zeng, 1996).

Zeng et al. (1997) summarized this work and wrote equations for the biomass yield and the formation of various products by *C. butyricum*. The equation for biomass formation is

$$C_3H_8O_3 + 3NH_3 + 35ATP \rightarrow 3C_4H_7O_2N + 4NADH_2 + 6H_2O \quad (16)$$

For acetate formation:

$$C_3H_8O_3 \rightarrow C_2H_4O_2 + 2NADH_2 + 2ATP + CO_2 + H_2 + H_2O \quad (17)$$

For butyrate formation:

$$2C_3H_8O_3 \rightarrow C_4H_8O_2 + 2NADH_2 + 3ATP + 2CO_2 + 2H_2 \quad (18)$$

For 1,3-propanediol formation:

$$C_3H_8O_3 + NADH_2 \rightarrow C_3H_8O_2 + 2H_2O \quad (19)$$

The equations represent reactions in the glycerol fermentation that the cell needs to regulate to achieve an overall balance in energy generation, reducing equivalents, and biomass. The various reactants are balanced in the overall cell metabolism. The authors calculated cases where either one or the other pathway is the only one used for energy generation and with maximum or no H_2 formation. The acetic acid pathway gave a PDO yield about 30% higher than butyric acid formation, with a theoretical maximum PDO yield of 0.65 moles of PDO/mole of glycerol with H_2 formation. Thus, the acetate pathway is more attractive for PDO production (Zeng et al., 1997).

When *Enterobacter agglomerans* is grown anaerobically in a chemostat with glycerol, PDO is the major product, and acetate, ethanol, and formate are also produced in significant amounts, while lactate and succinate are minor products. When *E. agglomerans* is grown on glucose, PDO is not made and the enzymes of the *dha* regulon are decreased by 30- to 120-fold. The effects of different growth rates were also measured. When the dilution rate increased from

0.05–0.31 h^{-1}, the activities of the enzymes of the oxidative pathway (glycerol dehydrogenase and DHA kinase) decreased 2.5-fold. With the higher dilution rate, glycerol dehydratase increased 34-fold and the 1,3-propanediol dehydrogenase level remained stable. Enzymes of central metabolism, glyceraldehyde-3-phosphate dehydrogenase, pyruvate kinase, and pyruvate formate lyase all increased slightly, except for pyruvate dehydrogenase, which was reduced slightly. Pyruvate dehydrogenase, which is normally expressed aerobically, does appear to be responsible for a portion of the carbon flow in *E. agglomerans* under anaerobic glycerol-utilizing conditions. The flow of pyruvate through pyruvate formate lyase was reduced at higher dilution rate (Barbirato et al., 1997a).

Hydrogen is generated during glycerol fermentation and it should not be considered as merely a waste product. When anaerobic growth under low residual glycerol was compared for *C. butyricum* and *K. pneumoniae*, it was *K. pneumoniae* that was able to incorporate more of the glycerol electrons into hydrogen. When various media components such as phosphate, ammonia, and sulfate are limited, hydrogen but not PDO formation is also limited (Solomon et al., 1994).

The balance and recovery of reducing equivalents in glycerol fermentations are important to the final yield. Data from various authors were compared for *K. pneumoniae* fermentations run under different glycerol concentrations. Under glycerol limitation, a portion of the $NADH_2$ released from the dehydrogenases is oxidized through pathways other than those leading to PDO, ethanol, lactate, and 2,3-butanediol. These reducing equivalents are discharged by the cell as molecular hydrogen. In cultures with glycerol excess, the majority of reducing equivalents appear in PDO and only a small part is released as hydrogen. The authors suggest that the interconversion of $NADH_2$ and H_2 is mediated by pyruvate : ferredoxin reductase and hydrogenase (Zeng et al., 1993). This mechanism is also likely operating in *Clostridium*, as with some strains of *Clostridium* the theoretical yield of PDO was exceeded and it was attributed to some portion of ferredoxin-bound molecular hydrogen transferring reducing equivalents to NAD, which was used to reduce additional glycerol to PDO (Biebl et al., 1992).

Much of the work on PDO production has been done with only a few strains. Various laboratories have gone to various environments to isolate new PDO producers to look for microorganisms with potentially superior properties. For example, several strains were isolated from sewage sludge, and the PDO yield and mix of products were compared. These isolates were identified as *Klebsiella* and *Citrobacter*. The *Citrobacter* strains yielded primarily PDO and acetic acid, with only small quantities of lactic acid and ethanol formed, while the *Klebsiella* strains produced more ethanol and lactic acid. *Citrobacter* had a higher product yield than *Klebsiella*, yielding 0.65 moles/mole of glycerol compared to the *Klebsiella* yield of 0.53 moles/mole of glycerol. *Citrobacter* had an overall productivity lower than that of one of the *Klebsiella* strains, as *K. pneumoniae* DSM 2026 had the highest titer and the best productivity (Homann et al., 1990).

The ability to use glycerol is not widely distributed among the *Clostridium*. A number of clostridal strains from culture collections were tested which did not grow on glycerol. Using a selection of growth on glycerol, four strains were isolated from soil and mud samples. All were identified to be *C. butyricum*. The most active strain, designated "SH1" and deposited as DSM 5431, was able to produce 56 g/liter of PDO in 29 hours from 110 g/liter of glycerol in a batch fermentation (Biebl et al., 1992).

Additional PDO-producing *Clostridia* have been isolated and their by-products have been characterized. Strains of *C. butyricum* and *C. pasteurianum* were examined for both solvent and hydrogen production from glycerol. In batch fermentations, *C. butyricum* LMG 1212t3 converted glycerol to PDO, and the addition of acetate increased glycerol utilization fourfold with more hydrogen and butyrate and less PDO formed. The other strain examined, *C. pasteurianum* LMG 3285, used most of the glycerol in the presence or absence of acetate and produced mainly butanol and hydrogen, along with butyrate, ethanol, acetate, formate and PDO (Heyndrickx et al., 1991).

Several enterobacteria were compared for their ability to produce PDO. *Escherichia coli* lacks the *dha* regulon and is able to grow on glycerol using only the genes of the *glp* regulon, which require the presence of molecular oxygen or nitrate as an exogenous electron acceptor. *Klebsiella pneumoniae* is known to utilize glycerol and produce PDO whereas *Klebsiella oxytoca* made much less PDO from glycerol. *Klebsiella planticola*, *Klebsiella ozaenae*, *Klebsiella rhinoscleromatis* and *Hafnia alvei* did not produce PDO from glycerol. Some of the *Klebsiella* did not possess a *dha* regulon, while others demonstrated activity of some of the enzymes in the pathway. *Klebsiella oxytoca* had 1,3-propanediol dehydrogenase activity and no glycerol dehydratase activity. *Klebsiella ozaenae* has only glycerol dehydrogenase activity (Bouvet et al., 1994). Like among the clostridia, the ability to grow anaerobically on glycerol and form PDO does not appear to be widespread among species of *Klebsiella*.

A microorganism isolated from the anoxic mud of a distillery wastewater digestor, *Enterobacter agglomerans*, was also shown to ferment glycerol to PDO. Acetate is the primary by-product, but formate, ethanol, succinate and lactate are also formed. The initial concentration of glycerol affects the fermentation profile of products. At the high glycerol concentration of 100 g/liter, the PDO yield is higher, lactate concentration is reduced, and ethanol is not produced. Acetate was the primary by-product formed that generated ATP. At high glycerol concentrations, the substrate was not completely consumed, which suggested the accumulation of an inhibitory factor (Barbirato et al., 1995).

The inhibitory compound (3-hydroxypropionaldehyde) accumulates when glycerol is added at high initial concentrations. The highest levels are seen in *E. agglomerans*, but 3-hydroxypropionaldehyde is also observed in cultures of *C. freundii* and *K. pneumoniae* grown in high glycerol concentrations. Both natural and synthesized 3-hydroxypropionaldehyde were shown to have a bacteriostatic effect (Barbirato et al., 1996a). Culture pH affected 3-hydroxypropionaldehyde formation, as it accumulated much earlier at pH 6 compared to pH 8. As 3-hydroxypropionaldehyde accumulated, the NAD/NADH ratio increased. The authors propose that the PDO dehydrogenase is inhibited by NAD, and this increased nucleotide ratio could be responsible for the accumulation of 3-hydroxypropionaldehyde. The effects of 3-hydroxypropionaldehyde were measured on the activity of the enzymes involved in the anaerobic dissimilation of glycerol, and the enzyme glycerol dehydrogenase demonstrated the greatest sensitivity (Barbirato et al., 1996b).

The fermentation of glycerol to PDO is also sensitive to the various products produced. By use of a pH auxostat, growth of *Clostridium butyricum* was shown to be inhibited by concentrations of 60 g/liter of PDO, 27 g/liter of acetic acid, and 19 g/liter of butyric acid. Since acetic and butyric acid would be produced at lower levels in a typical fermentation, the inhibition by PDO is expected to be the most important consideration. Butyric acid appears to be more toxic than acetic acid. The undissociated forms of the acids are responsible for the inhibitory effects in fermentation (Biebl, 1991).

Externally added acids appear to have a two to three-fold lower inhibition than those produced by the microorganism, which could be attributed to transport through membrane lipids (Zeng et al., 1994b). The time of addition of PDO also affects its inhibition, as an initial PDO concentration of 65 g/liter stops glycerol fermentation, whereas with an initial concentration of PDO (50 g/liter) and glycerol (70 g/liter), the final PDO concentration reaches 83.7 g/liter with complete consumption of glycerol (Colin et al., 2000). This suggests that high PDO concentrations inhibit growth, but not the actual PDO formation.

1,2-Propanediol The chemical synthesis of 1,2-propanediol (1,2-PD) results in the mixture of the R and S isomer. Direct fermentation processes yield either the R or the S isomer, which may provide an advantage as a chiral synthon. Two main biochemical processes for the synthesis of 1,2-PD are known. The first pathway involves the metabolism of deoxyhexoses through the intermediate lactaldehyde. In the second pathway, methylglyoxal (Inoue and Kumura, 1995) is derived from dihydroxyacetone phosphate, and methylglyoxal is reduced to 1,2-propanediol. The microbial formation is covered in reviews (Cameron et al., 1998; Bennett and San, 2001).

The formation of 1,2-propanediol by catabolism of 6-deoxyhexose sugars such as fucose and rhamnose by bacteria and yeast has been known for many years (Suzuki and Onishi, 1968; Ghazvinizadeh et al., 1972; Cocks et al., 1974; Turner and Robertson, 1979; Weimer, 1984b). This pathway forms S-1,2-propanediol through cleavage of the sugar into dihydroxyacetone phosphate and S-lactaldehyde, which are then reduced to S-1,2-propanediol. A low cost source of these 6-deoxysugars is not readily available, making this fermentation route impractical. A diagram of the pathway as it is understood is below and taken from the review by Bennett and San (Bennett and San, 2001; Fig. 29).

Clostridium sphenoides DSM 614 was shown to form both D(–)-1,2-PD and D(–)-lactate from glucose but only under phosphate limiting conditions. Ethanol and acetate were the major products at a phosphate concentration of 0.4 mM and above. The 1,2-PD formation began at phosphate concentrations below 80 μM. Lactate also increased under low phosphate conditions. Besides glucose, 1,2-PD was formed from D-fructose, cellobiose, L-rhamnose and L-fucose. The activities of the enzymes methylglyoxal synthase, methylglyoxal reductase, and 1,2-PD dehydrogenase were all detected in the cell. Methylglyoxal synthase, the first enzyme of the methylglyoxal bypass, is strongly inhibited by phosphate (Tran-Din and Gottschalk, 1985). The possible routes to 1,2-propanediol are summarized by Bennett and San (Bennett and San, 2001; Fig. 30).

Besides *Clostridium sphenoides*, the organism *Clostridium thermosaccharolyticum* (now called "*Thermoanaerobacterium thermosaccharolyticum*") also produces R-1,2-PD and acetol from

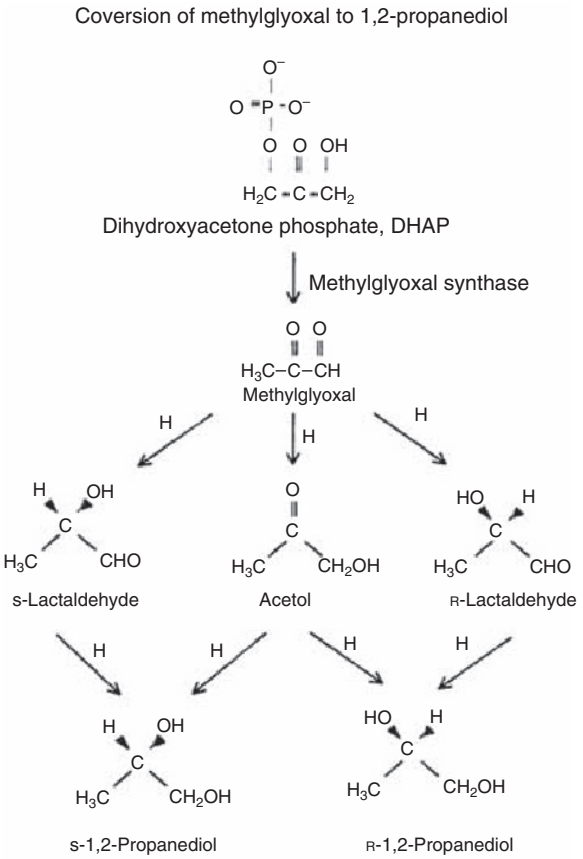

Fig. 29. Conversion of deoxy sugars to 1,2-propanediol. From Bennett and San (2001), with permission.

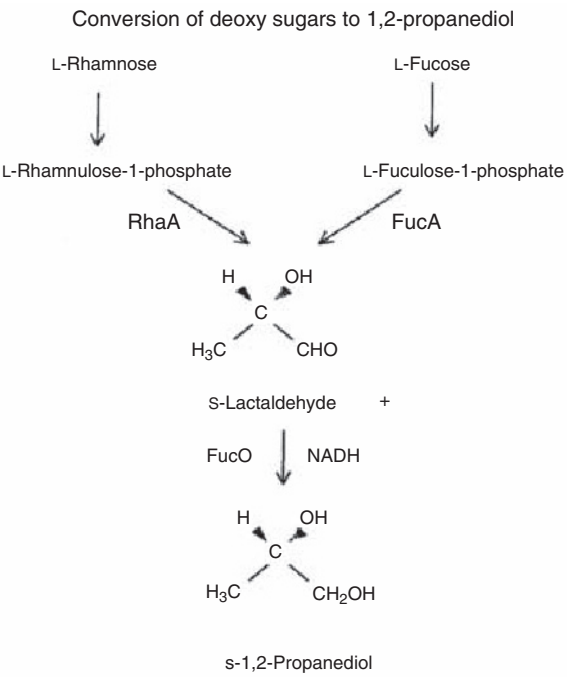

Fig. 30. Routes to 1,2-propanediol synthesis through methyglyoxal. From Bennett and San (Bennett and San, 2001), with permission.

glucose. Other products made include acetate, ethanol, and lactate. In a fed-batch fermentation, the yield of 1,2-PD on glucose was 0.27g/g at 30.7 hours. The maximum titer reached was 7.9 g/liter. In contrast to *C. sphenoides*, the *C. thermosaccharolyticum* production of 1,2-PD was not enhanced by phosphate limitation. A maximum theoretical yield of 0.42 grams of 1,2-PD per gram of glucose was calculated (Cameron and Cooney, 1986).

A novel route to 1,2-PD by the anaerobic conversion of lactic acid by *Lactobacillus buchneri* was described. Lactic acid had been shown to disappear in silage inoculated with *L. buchneri*. This organism anoxically converts 2 moles of lactic acid to 1 mole of acetic acid and 1 mole of 1,2-propanediol. This conversion does not occur unless the organism is at a pH below 5.8. In the proposed pathway, 1 mole of lactic acid is converted to 1,2-PD through lactaldehyde, while the other mole of lactic acid is converted through pyruvate to acetate (Oude Elferink et al., 2001).

The enzyme methylglyoxal synthase, which catalyzes the conversion of dihydroxyacetone phosphate to methylglyoxal, has been cloned from *Clostridium acetobutylicum* and expressed in *E. coli*. This enzyme has been found in number of bacteria. The clostridial enzyme has a pH optimum of 7.5, and when dihydroxyacetone phosphate, glyceraldehyde, and glyceraldehyde-3-phosphate were examined as substrates, only dihydroxyacetone phosphate could be converted to methylglyoxal (Huang et al., 1999). Other work with this pathway has included improvement of the *Thermoanaerobacterium thermosaccharolyticum* fermentation as well as the metabolic engineering of *E. coli* to produce 1,2-PD. This work will be discussed in the subsection Research and Development in this Chapter.

Commercial Applications

The product 1,3-propanediol and the properties of polytrimethylene terephthalate (PTT) were discovered in the early 1940s, but the high cost of PDO manufacture inhibited widespread commercial use (Anonymous, 1999). In the mid-1990s, Shell Chemical Company announced that it had developed a new chemical route to the production of PDO. It called its new PTT-based fiber "Corterra." Shell's process uses a hydroformylation of ethylene oxide and recovers the intermediate 3-hydroxypropionaldehyde which is then hydrogenated to PDO. Water and impurities are removed to produce a fiber grade PDO

(Shelley and D'Aquino, 1999). Shell first constructed a small development plant that had a nameplate capacity of 3,200 metric tons per year. It has constructed a world-scale PDO plant at Geismar, Lousiana, with a capacity of 75,000 metric tons per year that was scheduled to be online in late 1999. This is enough PDO to make just under 300,000 metric tons of PTT. The true potential of this new polymer may be in replacing large parts or all of the polyethylene terephthalate market (PET), which worldwide is around 20 million metric tons (Greenberg, 1999).

Degussa developed a chemical synthesis process for PDO in which propylene is catalytically converted to acrolein, which is then hydrated to 3-hydroxypropionaldehyde. PDO is formed by hydrogenation, and fiber-grade material is produced by distillation. This technology was licensed by DuPont, and Degussa and DuPont have been working together to produce PDO at a 20-million-lb/yr facility in Germany that came online in 1998. DuPont has named their polyester "Sonora." The polypropylene route is not believed to be as economical as the ethylene oxide route, primarily owing to the cost of the process plant (Shelley and D'Aquino, 1999).

DuPont is pursuing a third route to PDO, with a bioprocess that uses glucose as a starting material. This work has been done in collaboration with Genencor (Potera, 1997). The anaerobic conversion of glycerol to 1,3-propanediol was well known and has been documented in the scientific literature over many years. The DuPont and Genencor team of scientists created a microorganism that was able to convert carbohydrate to PDO, or "3G" as it is referred to by DuPont (Shelley and D'Aquino, 1999). With this new technology, low-cost renewable resources can be used as a raw material source. A glycerol dehydratase or diol dehydratase enzyme is expressed in a microorganism such as *E. coli*, which is able to utilize sugars such as glucose. Initial results showed that the level of PDO produced by recombinant microorganisms was very low (Laffend et al., 1997).

DuPont and Genencor have reported a 500-fold improvement in productivity (Moore, 1999). They announced that they would extend their research and development (R&D) collaboration through the end of 2001. DuPont is scaling up the bioprocess by an announced joint venture with Tate and Lyle. At their Decatur, Illinois, corn-wet mill, A.E. Staley, a subsidiary of Tate and Lyle, produces raw materials from renewable resources such as corn. PDO production is being tested by DuPont at a 200,000-lb/yr pilot plant there, and DuPont has said that it expects commercialization of the bio-based PDO in 2003 (Wood, 2001). Though the product can in part be called a "green" chemical since the PDO is derived from renewable resources, the terephthalate part of the polymer is derived from petrochemicals.

In large, commodity scale fermentations such as this one, the price of raw materials is significant and can account for 70% or more of total cost (Wilke, 1999). The variability in supply and raw material cost can affect the cost of production. Since most of the scientific effort on PDO in the past was conversion of glycerol, the DuPont/Genencor process should represent a potential cost advantage since it is based on glucose. Glycerol prices range between US$1 and $2/kg. At the yield of around 50% on glycerol, the cost of PDO would be high compared to production on glucose, which sells for below US$0.20 per pound (Wilke, 1999).

The long-term prospects for PDO appear excellent, as the fibers made from PTT are expected to compete with nylon and spandex and are touted to have superior properties. According to Shell, PTT fibers are chemical and stain resistant but have elasticity and good colorfastness. The fibers also dye easily and will be priced in the range of $US0.90–1 per pound. The Shell Corterra fiber won the R&D magazine award as one of the most technologically significant new products in 1998 (Welling, 1998). Besides apparel, the fibers can be used in carpet, engineering thermoplastics, and non-wovens. Other potential commercial applications include paints, adhesives, laminates and coatings (Anonymous, 1999).

While PDO use is just beginning to grow and become a large volume commodity chemical, propylene glycol is already made in vast quantities. Total production in the United States is estimated at over one billion pounds, with unsaturated polyester resins accounting for about 25% of the demand (Ouellette, 2000). One of the major uses of unsaturated polyester resins (UPR) is in construction, and demand for UPRs and hence propylene glycol is driven by the strength of the economy. As propylene glycol is safer than ethylene glycol, its use in antifreeze has climbed so that almost one fifth of the demand for propylene glycol goes to antifreeze. Other uses for propylene glycol include liquid laundry detergent, pharmaceuticals and cosmetics, and other miscellaneous uses (Anonymous, 1996a). The fact that it is clear and also has good emollient properties makes it desirable for these uses. Propylene glycol is "generally regarded as safe" (GRAS) by the United States Food and Drug Administration and has use in human foods and certain animal foods.

The demand for propylene glycol is expected to grow about 3% per year in the United States. The manufacture is by a chemical process using

hydration of propylene oxide. Propylene oxide is made from propylene, and prices of propylene have increased, tied to oil price increases. Propylene oxide also enjoys a high demand due to the growth of its biggest end use, polyurethanes (Ouellette, 2000). With propylene oxide costs being between $US0.20 and 0.30 per pound, it is difficult to envision a biological route to propylene glycol that can compete economically. However, as mentioned previously, the chemical route makes a mixture of isomers whereas the biological route makes a pure isomer. If chirality turns out to be important in an end use, then a bio-based process becomes much more attractive. Although there has been work on bio-based processes in academic labs, in contrast to PDO, no commercial activity is evident for a fermentation process for propylene glycol.

Research and Development

1,3-Propanediol With the increasing potential of use of PDO in polymers, there has been an impetus to improve the yield and rates of the various PDO producing strains. Various types of reactors and feeding strategies, the use of cosubstrates, and isolation of new organisms have all been approaches towards improvement of this fermentation based on glycerol. Also, metabolic engineering approaches have been used to widen the substrate range and to combine pathways of various microorganisms. The different approaches will be discussed in greater detail below.

A great deal of the focus has been on *Clostridium butyricum*, and the production of PDO from glycerol has been demonstrated at a scale of 2 m^3 using the strain *C. butyricum* DSM 5431. In this work, air-lift and stirred tank reactors were compared, and no difference in product formation was seen. The effect of pH and temperature was also studied and a temperature of 35°C and a pH of 7.0 were selected as optimal. PDO (46–58 g/liter) and productivities (2.3–2.9 g/liter/h) were seen at both small and large volume (Gunzel et al., 1991).

A fed-batch strategy was used to avoid substrate inhibition. This system measured CO_2 produced, and the glycerol feed volume was calculated on the basis of a constant stoichiometry. Using strain VPI 3266 of *Clostridium butyricum*, batch and fed-batch fermentation processes were compared. Generally, the fed-batch results were about twofold better, with 65 g/liter of PDO produced at a rate of 1.2 g/liter/h and a PDO yield of 0.57. The fed-batch approach helps circumvent the organism's sensitivity to high initial concentrations of glycerol (Saint-Amans et al., 1994). Another important process feature is the composition of the medium. A low nutrient, or minimal, medium was devised for *C. butyricum*. Biotin was shown to be the sole growth factor required by this organism, and when biotin was present, the organism was able to produce 67 g/liter PDO from 129 g/liter of glycerol, with a mixture of acetate and butyrate as by-products. Use of this media also provided evidence that nitrogen could be a limiting factor, especially when the carbon-to-nitrogen ratio was less than 81 : 1 (Himmi et al., 1999).

Continuous fermentations have also been used to improve PDO productivity. In a continuous *Klebsiella pneumoniae* fermentation, when glycerol was added in excess at an inlet substrate feed of approximately 74 g/liter, PDO and various by-product acids were the major products. Under glycerol limitation (an inlet concentration of approximately 15 g/liter), ethanol and hydrogen were the major products. The effect could be monitored by the evolution rates of hydrogen and CO_2. In glycerol excess, CO_2 evolution becomes higher than H_2 evolution, while it is the reverse in glycerol limitation (Solomon et al., 1994). Understanding the effects of various dilution rates on product distribution will help maximize the output of a PDO fermentation process.

Dilution rate was also shown to have an effect on PDO production by *K. pneumoniae*, with the highest PDO concentration achieved with a low dilution rate. This result differs from others mentioned below, and the authors state that in previous studies, the continuous cultures were run in a different fashion, with the substrate concentration in the feed constant, while the dilution rate was varied. In this study, the maximum experimental values seen were a PDO concentration of 35–48 g/liter and a productivity of 4.9–8.8 g/liter/h (Menzel et al., 1997).

In contrast, in a *Citrobacter freundii* fermentation, the highest PDO productivity was obtained under conditions of glycerol limitation at a high dilution rate. The highest values reported were 41.5 g/liter of PDO produced from 80.5 g/liter of glycerol, with an overall productivity of 1.38 g/liter/h (Boenigk et al., 1993). Streekstra et al. (1987) also showed that a higher dilution rate improved productivity with *Klebsiella*.

There has also been some work on new reactor types in the production of PDO. Pflugmacher and Gottschalk (1994) used cells of *Citrobacter freundii* DSM 30040 immobilized on polyurethane carrier particles. In this case, the productivity increased with the dilution rate, and the maximum productivity was very high, at 8.2 g/liter/h. A cell recycling system was tried with *Clostridium butyricum* using hollow fiber modules made from polysulfone. In this system, a productivity increase was seen; however, it could

be achieved only in a narrow section of the theoretical range (Reimann et al., 1998b). The potential of new types of reactors and fermentation configurations still needs additional exploration before an optimal system is found for PDO production from glycerol.

Identifying new microorganisms with various desirable features for PDO production is another avenue that has been explored. Some desirable features for PDO production that would help to reduce fermentation operating costs include the ability to grow at higher temperature, the ability to grow on crude glycerol stocks, tolerance to high substrate and product concentrations, and the ability to produce PDO at a higher rate.

Various mud and soil samples were examined and several glycerol-fermenting clostridia were isolated. The most active strain was able to convert up to 110 g/liter of glycerol to 5 g/liter of PDO in 29 h. In this strain, H_2 production was lower than expected, and reducing potential was transferred from ferredoxin to NAD, which increased PDO yields (Biebl et al., 1992). This strain, SH1, was renamed "DSM 5431" and was the parent strain used in further work to isolate more mutants with even more desirable characteristics.

Product tolerant mutants of *C. butyricum* DSM 5431 were isolated by Abbad-Andaloussi et al. (1995). Besides showing product tolerance, these mutants also yielded a higher biomass in fermentation. To further explore the use of these mutants, a fed-batch strategy was used which coupled the feeding of glycerol and ammonium to alkali consumption. A mixture of glycerol, ammonium chloride, and sodium phosphate was fed when initial glycerol was nearly three quarters depleted. Using this feeding strategy, one of the mutants was able to reach a concentration of 70 g/liter of PDO. The greatest increase, however, appeared to be in volumetric productivity, which more than doubled from 0.62–0.83 g/liter/h to 1.4–2.4 g/liter/h (Reimann and Biebl, 1996).

The mutants of DSM 5431 showed other interesting properties. Under conditions of glycerol excess, the parent strain showed a significant decrease in substrate conversion, while the product tolerant mutants continued to consume glycerol and form product at a constant level. The key enzymes of PDO formation are higher in the mutant strains. With increased carbon flow, the wildtype, but not the mutants, showed increased levels of NADH and NAD^+ and acetyl-CoA. The wildtype generated more reducing equivalents by producing more acetate and less butyrate (Reimann et al., 1998a).

One way by which cost can be addressed is by the use of lower cost, cruder raw materials in fermentation. Ten new environmental *Clostridium* strains were isolated and identified as *C. butyricum*. Of these ten, four were able to ferment industrial glycerol, which was derived from transesterification of rapeseed oil, while *Clostridium* sp. obtained from culture collections could not. The best new isolate, named "E5," was also more resistant to high levels of PDO. The new isolate was able to attain PDO yields on crude glycerol comparable to those of DSM 5431 on purified glycerol, reaching 58 g/liter of PDO from 109 g/liter of glycerol (Petitdemange et al., 1995). Another *Clostridium butyricum* isolate was also tested on industrial glycerol under a variety of conditions, including single-stage and two-stage fermentation. The maximum volumetric productivity was shown to be 5.5 g/liter/h. The strain was also shown to be very tolerant of high PDO concentration, up to 80 g/liter (Papanikolaou et al., 2000).

Another means of achieving process efficiency is by the use of thermophilic bacteria. With bacteria able to withstand high temperatures, hot effluents from fat cleavage plants can be used without cooling. It may also be possible to easily remove volatile by-products such as ethanol from the broth. A number of thermophilic producers of PDO from glycerol were isolated and the most active strain, called "AT1," was investigated further. Its pH optimum was 5.8–6.0 and temperature optimum was 58°C. In batch fermentations, its productivity was much lower than that of mesophilic *Clostridium* and it appeared to be inhibited strongly by PDO and various by-products. This initial work showed promise, but further work needs to be done in improving this new strain or continuing to screen additional thermophilic strains (Wittlich et al., 2001).

The work described above has focused on the use of glycerol as the fermentation substrate. Several laboratories have also examined the use of cosubstrates by adding another hydrogen donor substrate to glycerol. Tong and Cameron (1992) used an *E. coli* with the *K. pneumoniae dha* genes and glycerol co-fermented with either glucose or xylose. The best cell and PDO yield were obtained on glucose and glycerol. With glycerol alone, the PDO yield was 0.46 moles/mole compared to 0.63 moles/mole with glucose and glycerol. Lactate, formate and acetate were the primary by-products observed in most of the *E. coli* fermentations.

Three fermentable cosubstrates (glucose, 1,2-ethanediol and 1,2-propanediol) were used in *C. butyricum* and *C. freundii* fermentations. Glucose was shown to enhance PDO yield in *C. butyricum* but not in *C. freundii*. On 1,3-ethanediol, the products were acetate and ethanol, and on 1,2-propanediol, the primary product was 2-propanol. The diols used electrons from

glycerol that were oxidized to acids for an even hydrogen balance. Because approximately two times more glucose than glycerol is required to enhance yields, addition of glucose as a cosubstrate does not appear promising as an economic advantage in *C. butyricum* (Biebl and Martin, 1995).

In yet another approach, cofermentations were carried out using mixed cultures of glycerol producers such as *Saccharomyces cerevisiae* grown together with glycerol utilizers such *C. freundii*, *K. pneumoniae* and recombinant *E. coli*. PDO levels varied depending on the organisms used and the ratio of the organisms. PDO production was observed when various fermentable sugars were used, as well as during fed-batch production (Haynie and Wagner, 1997).

Another very promising approach for improvement of biological PDO production is the use of metabolic engineering to create organisms with new capabilities. A number of different approaches have been tried with varying degrees of success. The genes of the *Klebsiella dha* regulon were introduced into *E. coli* by conjugation. *Escherichia coli* was able to then grow anaerobically on glycerol, but it did not produce PDO. This was most likely due to the lack of glycerol dehydratase (Sprenger et al., 1989). When the appropriate cofactor for glycerol dehydratase was supplied to *E. coli* containing the *Citrobacter freundii dha* regulon, it was able to produce PDO at relatively high amounts (Daniel and Gottschalk, 1992).

Tong et al. (1991) detected production of PDO after transfer of the *dha* genes of *K. pneumoniae* into *E. coli*. The introduction of a new pathway into a microorganism is termed "metabolic engineering." Taking this concept further, Skraly et al. (1998) constructed an operon of PDO genes that could be used in a number of hosts and where the regulation could be manipulated. The *dhaB* gene and the *dhaT* gene, which code for glycerol dehydratase and 1,3-propanediol oxidoreductase, respectively, were put under the control of a single promoter. The constructed operon also contained certain restriction sites that allow new promoters to be easily inserted. With the artificial operon, *E. coli* did produce PDO; however, the mix of products was different than previously reported.

The use of metabolic pathway engineering in *E. coli* may provide advantages over the natural producers. The tools to modify *E. coli* are readily available, the substrate range may be broadened, and genes can be added and subtracted to obtain optimal genes for the pathway (Cameron et al., 1993). This approach was also demonstrated in industrial laboratories and descriptions appear in the patent literature.

Raw materials, especially the carbon source, are a large portion of the cost of the PDO fermentation. As mentioned previously, the cost of glycerol can be fairly high and a lower cost substrate such as glucose or even biomass-derived sugar is more attractive. This is the approach taken by DuPont and Genencor as evidenced by several patents. Glycerol or diol dehydratase was placed into microorganisms able to use various sugars, and the production of PDO from one microorganism using a sugar such as glucose was demonstrated (Laffend et al., 1997; Laffend et al., 2000). The diol dehydratase enzyme that is responsible for the degradation of 1,2-propanediol and is part of the *K. pneumoniae pdu* operon was isolated and used. *Escherichia coli* transformants were able to use this enzyme to produce PDO from glycerol (Nagarajan and Nakamura, 1998). A further improvement cited is to use a "protein X" gene, which consists of an open reading frame (ORF) coding for a protein responsible for in vivo activation of dehydratase activity. "Protein X" codes for a 51 KD polypeptide that was originally thought to be a subunit of the diol dehydratase activity. Host cells with this "protein X" and with the three known genes which encode subunits of diol dehydratase show increased PDO production (Diaz-Torres et al., 2000).

Another aspect of the DuPont and Genencor development was to transfer genes responsible for glycerol production into a host that did not naturally produce glycerol. The genes coding for the enzymes glycerol-3-phosphate dehydrogenase and glycerol-3-phosphatase were transformed into *E. coli*, and glycerol production was seen (Bulthuis et al., 1998).

The various approaches were combined into recombinant organisms that contained all the following genes: glycerol-3-phosphate dehydrogenase, glycerol-3-phosphatase, glycerol dehydratase, and 1,3-propanediol oxidoreductase. Microorganisms including *E. coli*, various *Klebsiella* species, and *Saccharomyces* were shown to produce PDO from glucose (Nakamura et al., 2000). The DuPont and Genencor effort has focused on *E. coli* because of the number of genetic tools available and since *E. coli* does not naturally produce PDO, no natural regulation needs to be overcome. The constructed *E. coli* strain equals or exceeds glycerol based natural organisms, with approximately 140 g/liter of PDO produced from glucose in 45 hours (Chotani et al., 2000).

1,2-Propanediol The industrial focus on 1,3-propanediol has sparked interest in the microbial production of 1,2-propanediol. Some work has focused on the fermentation process of 1,2-propanediol as well as the metabolic engineering

of pathways for its production. In early work with *C. thermosaccharolyticum*, various process conditions were examined such as temperature, pH, gas phase composition, and substrate concentration. This work was conducted in a volume of 2 liters. The maximum cell concentration achieved was in the range of 1.0 to 1.3 g/liter. The temperature range examined was 50–65°C and the optimal temperature for production was 60°C. At higher temperatures, lactate decreased and ethanol increased. The pH range studied was from 6.0 to 7.2. At the optimal pH of 6.0, a concentration of 5.6 g/liter of 1,2-PD was obtained. Other fermentation conditions were examined such as the use of H_2 in the headspace as well as the use of yeast extract, which was shown to have an important effect on 1,2-PD production. The optimal fermentation conditions were defined as 45 g/liter of glucose, 4.5 g/liter of yeast extract, a pH of 6.0, a temperature of 60°C, and the use of N_2 gas. Under these conditions, the final 1,2-PD concentration achieved was 9.05 g/liter with a yield of 0.20 g/g of glucose (Sanchez-Riera et al., 1987).

The cost of production of 1,2-PD could be lowered by the use of low cost, renewable sugars. D-Glucose, L-arabinose, and D-xylose are the major sugars from cellulosic biomass. Their use for 1,2-PD production was examined using *T. thermosaccharolyticum*. Also tested were L-galactose and lactose; lactose is of interest because it can be obtained at low cost from cheese whey (Altaras et al., 2001).

In earlier work, *T. thermosaccharolyticum* did not grow on lactose and D-galactose (Cameron and Cooney, 1986). This organism was selected to grow on these sugars by multiple serial transfers. When tested in fermentations, these adapted organisms produced primarily ethanol and lactate, and no 1,2-PD was detected. The five-carbon sugars arabinose and xylose showed more promise, and both yielded 1,2-PD during fermentation. Arabinose was fermented at a rate and yield similar to glucose, while xylose fermentation was slower and the yield was approximately half. Whey permeate was shown to be a useful substrate for 1,2-PD production but only after hydrolysis of the lactose and supplementation with yeast extract (Altaras et al., 2001).

Another approach towards the improvement of 1,2-PD production is the use of metabolic engineering. *Escherichia coli* was chosen as the host organism because many tools are available for genetic modification. Although it does not produce 1,2-PD from glucose, it is able to produce the intermediate methylglyoxal (Cameron et al., 1998). *Escherichia coli* strains expressing rat lens aldolase produced 1,2-PD and acetol from glucose (Altaras and Cameron, 1999).

Instead of rat lens aldolase, glycerol dehydrogenase from either *E. coli* or *K. pneumoniae* was overexpressed in *E. coli*. In this case *E. coli* produced R-1,2-PD from glucose. The metabolic pathway probably involves the reduction of methylglyoxal to R-lactaldehyde by the glycerol dehydrogenase, and the R-1,2-PD is produced by reduction of R-lactaldehyde. The overexpression of *E. coli* methylygloxal synthase alone causes *E. coli* to produce about the same amount of 1,2-PD as produced by the strains with overexpressed glycerol dehydrogenase. When both genes are overexpressed, the improvement in 1,2-PD production is even greater. Although the metabolic engineering of *E. coli* is promising, the maximum titer of 0.7 g/liter of 1,2-PD is low (Altaras and Cameron, 1999).

Further improvements were made by a series of metabolic engineering strategies. Activities of enzymes leading to the production of the byproduct, lactate, were abolished. A complete 1,2-PD pathway comprising glycerol dehydrogenase (*gldA*), methylglyoxal synthase (*mgs*), and 1,2-PD oxidoreductase (*fucO*) was put in the lactate minus background. The use of alcohol dehydrogenase in place of 1,2-PD oxidoreductase was also evaluated, but the use of 1,2-PD oxidoreductase ultimately gave better results. Using a fed-batch fermentation, *E. coli* lacking lactate dehydrogenase and containing *gldA*, *mgs*, and *fucO* genes gave the highest titers of 4.5 g/liter with a yield of 0.19 g of 1,2-PD per gram of glucose consumed (Altaras and Cameron, 2000). As *E. coli* is tolerant to over 100 g/liter of 1,2-PD (Cameron et al., 2000) and can be improved significantly by metabolic engineering, the potential for improving a process employing recombinant *E. coli* strains is significant.

Patents and Regulatory Issues

In the production of monomers such as PDO and 1,2-PD, there are many patents that cover the chemistry and process of synthesizing these chemicals. The separation of these chemicals from the synthetic mix is another important area of technology (Malinowski, 1999; Malinowski, 2000). There is patent activity, especially on the various new technologies for the chemical synthesis of PDO that have lowered the cost of the monomer and opened it for more widespread application. There are also undoubtedly numerous patents on the formulation of the various polymers that contain PDO and 1,2-PD and the applications and end use of these chemicals. It is beyond the scope of this review to cover the chemical process and application patents for PDO and 1,2-PD, inasmuch as a search of the United States Patent Database using the key

Table 35. Patents/patent applications for 1,3-propanediol and 1,2-propanediol production in the bioprocess area.

Assignee	Patent number	Year	Technology
Unilever	U.S. patent 5,164,309	1992	Production of PDO from glycerol by *Citrobacter*
Henkel Kommanditgesellschaft auf Aktien, Gesellschaft für Biotechnologische Forschung mbH	U.S. patent 5,254,467	1993	Production of PDO from glycerol
DuPont	U.S. patent 5,686276	1997	Production of PDO from a fermentable carbon source using a single microorganism
DuPont	U.S. patent 5,599,689	1997	Use of mixed microbial cultures to produce PDO
DuPont	U.S. Patent 5,821,092	1998	Production of PDO from glycerol with a recombinant bacteria expressing diol dehydratase
DuPont and Genencor	U.S. Patent 6,025,184	2000	Production of PDO from a fermentable carbon source by a microorganism containing a glycerol or diol dehydratase
DuPont and Genencor	U.S. patent 6,013,494	2000	Recombinant organisms for PDO production containing a variety of genes
Genencor	U.S. patent 6,136,576	2000	Use of recombinant microorganisms for PDO production
Genencor	PCT WO 00/70057	2000	Mutant 1,3-propanediol dehydrogenase
DuPont	PCT WO 01/12833	2001	Production of PDO from a fermentable carbon source in a single organism
Institut National de la Recherche Agronomique, Institut National des Sciences Appliquees de Toulouse, Centre National de la Recherche Scientifique	PCT WO 01/04324	2001	Production of PDO in the absence of coenzyme B12 or its precursors
DuPont	PCT WO 01/11070	2001	Isotopic fingerprinting of PDO produced from a fermentable carbon source
Wisconsin Alumni Research Foundation	U.S. patent 6,087,140	2000	Microbial production of 1,2-propanediol from sugar

Abbreviations: U.S., United States; PDO, 1,3 propanediol; PCT, Patent Cooperation Treaty; and PCT WO, international patent.

word "propylene glycol" turns up more than one thousand patents!

In PDO production by biological processes, the number of patents is fairly small, with the greatest patent activity occurring in the past five years. The patent activity for biological production of 1,2-PD is even less and will be summarized with the PDO patents. Although patents have been referenced where appropriate in the text, a summary of some of the patents on biological production is listed (Table 35).

Prospects for Production of 1,3-Propanediol and 1,2-Propanediol by a Bioprocess

There are many issues to be addressed in the production of any intermediate for the chemical industry with the use of a microbial process. Often the raw material is a chief cost component, so the microorganism must be able to use low cost substrates such as glucose derived from corn processing or other sugars that may be derived from the processing of low cost biomass. The yield of the product on the substrate as well as the ability to reach a fairly high product concentration is also important. Also, the by-products produced by the microorganism are important as they both impact yield as well as the design of the separation process.

Activity in designing new PDO processes using both a chemical route and a biological one has been considerable. Quite often, large volume chemicals are made by more than one chemical process, so it is possible that in the future, PDO may be made by more than one process, with one being a competitive, economic biological one. The advances in recombinant DNA technology

and the ability to create microorganisms with new pathways will help drive the production of industrial chemicals by biological means.

The possibility of future production of PDO by a biological process appears bright. By combining pathways of more than one organism into *E. coli*, DuPont and Genencor report a microorganism that can produce around 140 g/liter of PDO from glucose in less than 50 hours (Chotani et al., 2000). The availability of tools for genetically manipulating *E. coli* suggests that further improvements are likely to be made. Other challenges that remain will be the separation of PDO from broth and the purification of PDO such that it can be used in fiber production.

The near-term prospects for production of 1,2-PD via a biological process do not seem likely. A biological process must compete with well-known large-scale chemical processes using low-cost raw materials. The titers of 1,2-PD are still low; however, the use of host organisms such as *E. coli* may provide some opportunity to increase levels. An interest in bioprocess development may be sparked if a market or product opportunity can be identified for the racemically pure product produced by microorganisms (Cameron et al., 1998).

In the future, the economics of production of chemicals by biological processes may become more attractive with dwindling supplies and higher prices of oil. A bioprocess can also provide opportunities for the agricultural sector in the use of renewable resources such as corn. At some point, public interest in the use of renewable resources may also drive further development of these diols as well as other chemical products.

Section 10: 2,3-Butanediol Production

Introduction

A colorless odorless liquid, 2,3-butanediol (2,3-BD) is also called "2,3-butylene glycol," "dimethylethylene glycol," or "2,3-dihydroxybutane." It can be produced by a number of microorganisms in the genera *Serratia*, *Pseudomonas*, *Bacillus* and *Klebsiella*, but most investigators have focused on *Klebsiella pneumoniae* (also known as "*Klebsiella oxytoca*") and *Bacillus polymyxa*, which is now known as "*Paenibacillus polymyxa*" (Nakashimada et al., 2000). Reviews have covered the history, uses, and technical developments in this field (Afschar et al., 1993; Garg and Jain, 1995; Syu, 2001). The fermentation was described in the early part of the 20th century, but the height of interest came during wartime, as 2,3-BD can be converted to 1,3-butadiene, which is used in synthetic rubber (Syu, 2001).

Production of 2,3-BD is via a mixed acid fermentation pathway that also leads to a mix of acetate, lactate, formate, succinate and ethanol. Juni and Heym (1956) proposed that 2,3-BD is produced in bacteria from pyruvate through the intermediates α-acetolactate and acetoin. Also, microorganisms can degrade 2,3-BD (i.e., it is biodegradable), a feature that may add to its attractiveness as an industrial chemical.

2,3-BD has three stereoisomers: *dextro-* and *levo-* forms that are optically active and an optically inactive *meso-* form. Different microorganisms produce different stereoisomers, but generally a mixture of two is formed (Syu, 2001). Although stereoisomer formation has been studied and a new mechanism proposed (Ui et al., 1998), in much of the 2,3-BD-related work, stereoisomer formation is not measured.

Much of the focus of 2,3-BD work has been on the fermentation, and high productivities and high 2,3-BD concentration in fermentors have been achieved. Concentrations of 102.9 g/liter of butanediol and acetoin were achieved in 32 hours with *Enterobacter aerogenes* (Zeng et al., 1994a) and 113 g/liter of these combined products were achieved from *Klebsiella pneumoniae* (Yu and Saddler, 1983). Bioconversion yields of 0.45 g/g of glucose were also observed (Sablayrolles and Goma, 1984). The application of molecular biology and strain improvement may help to improve the fermentation process, although surprisingly little has been reported. The genes of the 2,3-BD operons were cloned from *Klebsiella terrigana* and *Enterobacter aerogenes* and characterized (Blomqvist et al., 1993). Reports describe the cloning of the gene responsible for the formation of *meso*-2,3-BD, which opens up the avenue of a strain producing a pure isomer (Ui et al., 1996; Ui et al., 1998).

The economics of the fermentation may be helped by the fact that the best 2,3-BD producers are able to grow and make product on a variety of sugars. The use of various low cost materials such as whey and hydrolyzed biomass has been investigated and shows promise for future use and will be discussed in more detail later (Yu et al., 1982b; Laube et al., 1984; Lee and Maddox, 1986; Champluvier et al., 1989).

The primary economic barrier to commercialization may not be the fermentation, but rather the separation of 2,3-BD from the media. It does not separate well by distillation, and chemical conversion of 2,3-BD in the broth and subsequent distillation are costly (Afschar et al., 1993). Other separation techniques that have been examined include salting out (Afschar et al., 1993) and countercurrent steam stripping (Garg and Jain, 1995). Continued fermentation and downstream improvements and a change in the economics of petrochemicals may at some future

date make 2,3-BD production from a bioprocess economically attractive.

Scientific Background

2,3-Butanediol is produced via a mixed acid pathway with a variety of end products. By this pathway the organism can make a less inhibitory neutral compound such as 2,3-BD in place of acid production (Johansen et al., 1975). *Bacillus polymyxa* catalyzes a number of biosynthetic reactions which the cell balances for energy and growth. The following reactions as described by de Mas et al. (1988) are included to illustrate the variety of end-products in parallel pathways:

$$\text{Glucose} \rightarrow 6CO_2 + 4ATP + 10NADH \quad (20)$$

$$\text{Glucose} \rightarrow 2\ \text{acetate} + 2CO_2 + 4ATP + 4NADH \quad (21)$$

$$\text{Glucose} \rightarrow \text{acetoin} + 2CO_2 + 2ATP + 2NADH \quad (22)$$

$$\text{Glucose} \rightarrow \text{butanediol} + 2CO_2 + 2ATP + NADH \quad (23)$$

$$\text{Glucose} \rightarrow 2\ \text{ethanol} + 2CO_2 + 2ATP \quad (24)$$

$$\text{Glucose} \rightarrow 2\ \text{lactate} + 2ATP \quad (25)$$

Reduced nicotinamide adenine dinucleotide (NADH) can be used to generate ATP through the electron transport system. The balance of the reactions and end products in the cell is affected by the oxygen availability and the oxygen uptake rate (deMas et al., 1988). Considerable effort has been spent on oxygen transfer and oxygen uptake in improving the fermentation. This topic will be discussed in more detail in the subsection "Research and Development" in this Chapter.

Juni and Heym (1956) described a cyclic pathway for the dissimilation of 2,3-butanediol. A number of microorganisms oxidize 2,3-BD to acetic acid. The pathway from Juni and Heym is shown in the following figure modified by Syu (2001). The three stereoisomeric forms of 2,3-BD are: 1) D(–) or R,R, 2) L(+) or S,S, and 3) *meso* or R,S.

Three enzymes are involved in the synthesis of 2,3-BD: α-acetolactate synthase (EC 4.1.3.18), α-acetolactate decarboxylase (EC 4.1.1.5) and butanediol dehydrogenase (also known as diacetyl [acetoin] reductase; Larsen and Stormer, 1973; Johansen et al., 1975; Stormer, 1975). Two different enzymes form acetolactate from pyruvate. The first, termed "catabolic α–acetolactate synthase," has a pH optimum of 5.8 in acetate and is part of the butanediol pathway. The other enzyme, termed "anabolic α–acetolactate synthase" or "acetohydroxyacid synthetase," has been well studied and characterized and will not be discussed here. This enzyme is part of the biosynthetic pathway for isoleucine, leucine, and valine and is coded for by the *ilvBN*, *ilvGM*, and *ilvH* genes in *E. coli* and *Salmonella typhimurium* (Bryn and Stormer, 1976).

The second enzyme in the butanediol pathway is acetolactate decarboxylase, which has a pH optimum of about 6.3 and which catalyzes the decarboxylation of acetolactate to acetoin. The third enzyme, diacetyl (acetoin) reductase, catalyzes a reversible reduction of acetoin to 2,3-BD and an irreversible reduction of diacetyl to acetoin. It is a tetrameric enzyme and requires NADH (Larsen and Stormer, 1973).

In *Klebsiella terrigena* and *Bacillus subtilis*, this enzyme is found within the acetoin cluster of genes. Interestingly, in *Lactobacillus lactis*, this gene is found within the gene cluster that encodes the enzymes of branched chain amino acid synthesis. This enzyme has different kinetic properties than the enzymes of *K. terrigena* and *B. subtilis* and may play a key role in acetolactate flux in *L. lactis* (Goupil-Feuillerat et al., 1997).

Acetate induces the three enzymes and activates acetolactate synthase. In a study comparing wildtype *Enterobacter aerogenes* and mutants deficient in 2,3-BD and acetoin production, during the highest phase of 2,3-BD production, the three enzymes of the pathway constituted approximately 2.5% of the protein in the cell. Butanediol production also appears to play a role in regulating the NADH/NAD ratio (Johansen et al., 1975).

Different mechanisms have been proposed for the formation of the various stereoisomers of 2,3-BD. Some of the initial difficulty was in obtaining a pure stereoisomer for study. A fermentation route to synthesis of pure *meso*-isomer was demonstrated in *Serratia*. *Bacillus polymyxa* was used to prepare the D(–)-isomer, and *Bacillus cereus* was used to make L(+)-isomer. Conditions such as pH, temperature, and shaking were modified to optimize production of the various isomers (Ui et al., 1983).

One of initial models for stereoisomer formation was postulated by Taylor and Juni (1960) for *K. pneumoniae*. They proposed the existence of an acetoin racemase, L(+) 2,3-BD dehydrogenase and D(–) 2,3-BD dehydrogenase. The L(+) 2,3-BD dehydrogenase would convert L(+) acetoin to L(+) 2,3-BD and *meso* 2,3-BD, whereas the D(–) 2,3-BD dehydrogenase would reduce D(–) acetoin to D(–) 2,3-BD and *meso*-2,3-BD.

A newer model for *K. pneumoniae* was similar to the earlier one in that it included an acetoin racemase. However, in this newer model, D(–) acetoin is converted to *meso*-2,3-BD, and L(+) acetoin is converted to L(+) 2,3-BD. This model

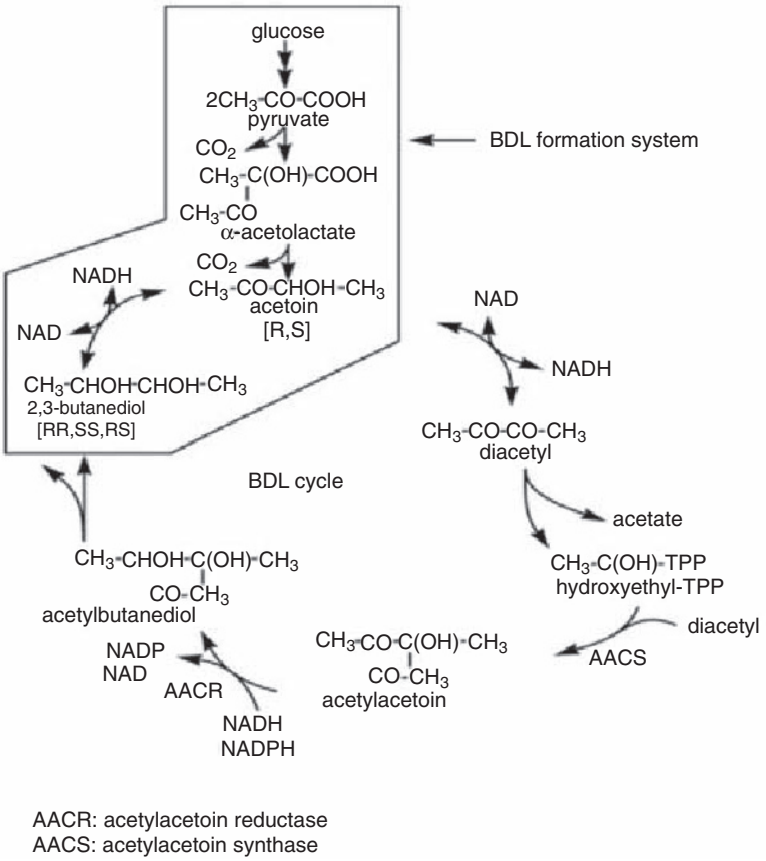

Fig. 31. The 2,3-butanediol cycle in bacteria, as proposed by Juni and Heym (1956). The boxed area represents 2,3-BD formation in bacteria. BDL, butanediol; TPP, thiamine pyrophosphate; AACS, acetylacetoin synthase; AACR, acetylacetoin reductase; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate. Redrawn from Syu (2001), with permission.

is based on the purification and separation of the two acetoin reductases and the determination of their stereospecificity (Voloch et al., 1983).

A novel mechanism for stereoisomer formation was described for *Bacillus polymyxa*. The RR-acetoin formed from pyruvate is converted into RR-butanediol by diacetyl (acetoin) reductase. The same enzyme reduces diacetyl to RR-acetoin. An S-acetoin-forming diacetyl reductase converts diacetyl to SS-acetoin. The racemic acetoin molecules are acted upon by a butanediol dehydrogenase, which generates either RR-butanediol or *meso*-butanediol (Ui et al., 1986).

Bacillus cereus was shown to have the enzymes of the butanediol cycle. Acetylacetoin was reduced to two new stereoisomers of acetylbutanediol by two separate acetylacetoin reductase enzymes. These isomers were subsequently converted by acetylbutanediol hydrolase to RR- and *meso*-2,3-BD (Ui et al., 1998). Clearly the production of the various stereoisomers is a complex issue that will require additional study and the purification of the various enzymes.

The production of 2,3-BD by microorganisms requires the balancing of a number of fermentation reactions in the cell. Mathematical models can be very useful to explain the interrelation of equations, and these models need to be verified by experimental data. Various models have been described and the reader is referred to Papoutsakis and Meyer (1985).

The acid end products of fermentation can inhibit growth and butanediol formation. Large quantities of butanediol, up to 130 g/liter, were not strongly inhibitory, while 0.45 g/liter of acetic acid can completely inhibit growth of *K. oxytoca*. Butanediol inhibition is believed to be due to the reduction of water activity, while acetic acid and not its salt is the inhibitory metabolite (Fond et al., 1985). In *Enterobacter aerogenes*, ethanol was also shown to be an inhibitory metabolite for growth (Zeng and Deckwer, 1991).

Klebsiella pneumoniae and other 2,3-BD producing microorganisms are able to use a variety of five and six carbon sugars to produce 2,3-BD. Pentoses are metabolized through a common intermediate, D-xylulose-5-phosphate. In *K. pneumoniae*, 3 moles of pentose are converted to 5 moles of D-glyceraldehyde-3-phosphate, which is an equivalent yield of D-glucose through glycolysis (Jansen and Tsao, 1983). The conversion

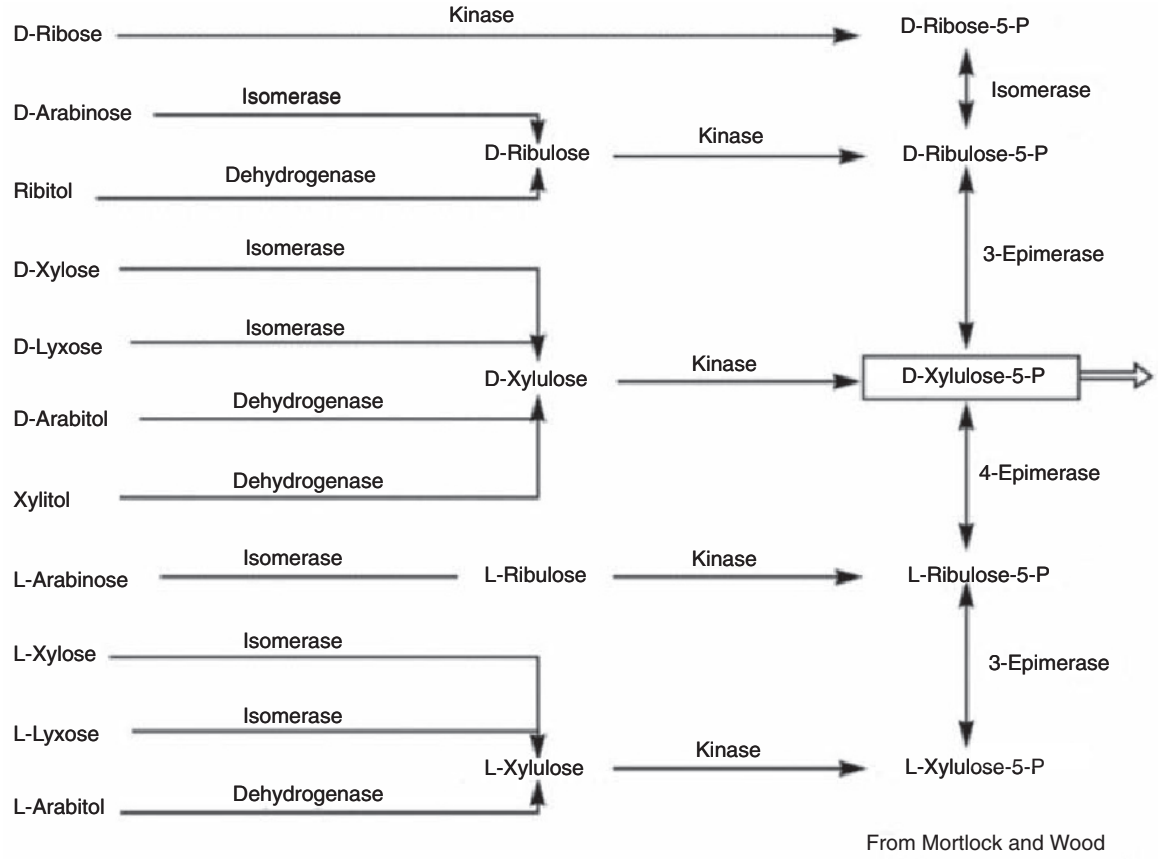

Fig. 32. Conversion of pentoses and pentitols. From Jansen and Tsao (1983), with permission.

of pentoses and pentitols is shown in Fig. 32, as described by Jansen and Tsao (1983).

There have been a number of fermentation studies on 2,3-BD formation. One of the most crucial factors identified is the amount and timing of oxygen supplied. A higher oxygen transfer coefficient favors the production of biomass while inhibiting butanediol production in *Aerobacter aerogenes*. Oxygen suppresses the production of ethanol, but some butanediol can be produced in the presence of oxygen. The maximum oxygen transfer coefficient (Kla) was found to be in the range of 50–100 h^{-1} (Sablayrolles and Goma, 1984).

Various control strategies for oxygen have been tried to maximize butanediol production. In one study, oxygen transfer rate (OTR) was used to maintain growth rate and specific oxygen uptake rate. When a set oxygen transfer rate was maintained that kept the culture at a constant level of oxygen limitation, the final butanediol concentration was similar to an experiment where OTR was uncontrolled. The improvement in the OTR-controlled fermentation was in the rate of 2,3-BD formation, as the productivity or rate of formation of 2,3-BD was 18% higher (Beronio and Tsao, 1993).

Control of microaerobic fermentations by oxygen transfer rate has limitations, as the distribution of oxygen may differ in various types and sizes of reactors. In a somewhat different approach, control by respiratory quotient was attempted. Optimum 2,3-BD production was seen at a respiratory quotient between 4.0 and 4.5, and product concentration (butanediol and acetoin) greater than 100 g/liter was measured. This was compared to a control fermentation where an oxygen transfer rate of 35 mmol/liter/h was maintained. In this case, the respiratory quotient eventually decreased to about 1.5 and product formation was only about 85 g/liter. Biomass in the fermentation with respiratory quotient control was higher than in the OTR-controlled fermentation (Zeng et al., 1994a).

Continuous culture can also be used to determine the optimum oxygen supply. In one system using *K. pneumoniae*, with an inlet feed glucose concentration of 100 g/liter, the optimum

oxygen transfer rate (defined as when maximum product was formed) was determined to be 25.0–35.0 mmol/liter/h. Increasing the oxygen input and thus the OTR reduced the product yield (Ramachandran and Goma, 1988).

In another continuous culture study, maximum oxygen uptake rates (OUR) were determined and they differed depending on the dilution rate. By varying the speed of the impeller with constant aeration, different OURs could be obtained. As dilution rate increased, the yield and product concentration decreased. Product formation was not dependent on growth rate, and even at low or no growth rates, higher specific productivity can be expected. At low OURs, the cells use fermentation for growth and maintenance and continue to convert substrate to 2,3-BD. The authors suggest that a cell recycling or cell immobilization system is a strategy used to take advantage of the potential productivity of nongrowing cells (Zeng et al., 1990).

There is some evidence that the availability of oxygen can also affect the optical purity of 2,3-BD isomers produced. In a continuous culture system with *Paenibacillus polymyxa*, when airflow was increased, the optical purity of 2,3-BD decreased (Nakashimada et al., 1998). Certainly control of oxygen is a critical parameter in the 2,3-BD fermentation process.

Commercial Applications

At present, 2,3-BD is sold as a commercial chemical intermediate. Interest in its production by fermentation peaked during World War II because 1,3-butanediene needed for synthetic rubber production could be made from 2,3-BD. With the rise of the petroleum industry and increase in the availability of cheap raw materials, industrial fermentations for 2,3-BD were no longer of commercial interest (Rosenberg, 1980).

In one method of production via petrochemical means, *n*-butenes can be separated by distillation from hydrocarbons. Treatment with hydrogen peroxide converts butanes such as 1-butene or 2-butene to their epoxide. A glycol such as 2,3-BD is then derived from the epoxide of 2-butene (Szmant, 1989).

The boiling and freezing points of 2,3-BD are 180–184°C and –60°C, respectively. It is either a colorless liquid or in crystalline form. It can be dehydrogenated to diacetyl, a highly valued flavoring agent in food products (Syu, 2001). It can also be dehydrated to methyl ethyl ketone, which has uses as a liquid fuel additive and a solvent. The levo-form of 2,3-BD has potential use in antifreeze. Butanediol can be esterified and in this form could be used as a precursor for drugs and cosmetics. Other potential industrial applications include inks, plasticizers and moistening agents (Garg and Jain, 1995). One of the attractive features of butanediol is its biodegradability. Numerous microorganisms are able to consume it at high rates. This makes it an environmentally friendly product (Afschar et al., 1993).

Butadiene appears to be the key intermediate for further conversion and other potential new uses of 2,3-BD. Butadiene can be dimerized to styrene, a large volume chemical intermediate for the polymer industry (Jansen and Tsao, 1983). Styrene is an eight-carbon molecule with an aromatic ring. Conversion of 2,3-BD to butadiene is not economically attractive. The butadiene market demand has dropped significantly, as its major styrene polymer end markets, automobile parts and construction, are also down sharply. Although the price of butadiene is presently in the range of $US0.20 per pound, future improvement in the economy is expected to increase demand for butadiene and possibly the price (Hoffman, 2001).

At the low selling price of butadiene, it is difficult to see how biologically produced material could be made cost competitive. Perhaps the greatest potential for 2,3-BD may lie in higher-value specialty product uses in such industries as chemical, pharmaceutical, and personal care. Better understanding of the market opportunity is necessary as well as further development of the various 2,3-BD chemical conversion processes.

Research and Development

There have been a number of fermentation studies for the production of 2,3-butanediol. From a process standpoint, it is not easy to make a direct comparison between the various studies because, often, types of fermentors and combinations of process conditions were different. One major focus has been the use of biomass and biomass-derived sugars for the production of 2,3-BD. There is good indication that with the proper conditions, large quantities of 2,3-BD can be made from low-cost or waste sugars.

It is possible to use high concentrations of glucose in *E. aerogenes* NRRL B199 fermentations and achieve good yields. At a glucose concentration of 195 g/liter, the yield of 2,3-BD was 0.45 g/g. However, there was some growth inhibition with such initial high substrate concentrations. At the high substrate concentration, only 2.4 g/liter of ethanol was produced. The productivity was over 1 g/liter/h, making this an attractive process (Sablayrolles and Goma, 1984). When a fed-batch approach was used with *K. pneumoniae* to overcome initial inhibitory sugar concentrations, up to 88 and 113 g of butanediol and acetyl methyl carbinol could be produced

from 190 g of xylose and 226 g of glucose, respectively (Yu and Saddler, 1983).

It is not surprising that various process conditions such as pH will also have an effect on fermentation. Biomass concentrations of *E. aerogenes* were shown to increase between pH of 5–7, while 2,3-BD production was optimum between pH 5.5 and 6.5 and dropped off at a higher pH (Zeng et al., 1990). *Paenibacillus polymxya* also showed a pH optimum for production of 2,3-BD between 5.7 and 6.3 in a chemostat system (Nakashimada et al., 1998).

The effect of added acetic acid also changed with pH. At pH of 5.5, less than 1 g/liter of acetic acid inhibited product formation, whereas at a culture pH of 6.7, it took roughly ten times more acetic acid to show the same effect. This inhibitory effect is due to the undissociated form of acetic acid (Zeng et al., 1990).

With *K. pneumoniae*, acetic acid was shown to stimulate 2.3-BD production up to two- to threefold when added at concentrations less than 1%. This media was at a pH of 6.5 and contained glucose, xylose and various nutrients. The stimulation by acetic acid may be due to activation of the 2,3-BD pathway enzymes. Yeast extract, urea, ammonium sulfate and trace elements were also shown to improve yields in this system (Yu and Saddler, 1982a). A variety of acids were found to enhance 2,3-BD production in *P. polymyxa*: acetate, propionate, pyruvate and succinate showed an effect, while *n*- and *iso*-valerate, *n*- and *iso*-butyrate, formate, malate and lactate had no effect. Acetic acid was the best and also did not reduce the optical purity of the 2,3-BD; thus a feeding strategy with acetic acid may show promise for this organism (Nakashimada et al., 2000).

The use of low cost biomass sources as a substrate for 2,3-BD production has received considerable attention as a way to improve the economics of the process. The main components of woody biomass are lignin, cellulose and hemicellulose. Cellulose is a polymer of D-glucose, while hemicellulose is a polymer containing mostly the five carbon sugars, D-xylose, L-arabinose and D-ribose (Rosenberg, 1980).

Klebsiella is a versatile organism and is able to utilize many sugars for growth and 2,3-BD production. In one study where xylose was evaluated, maximum cell growth occurred at a sugar concentration of 20 g/liter (Jansen and Tsao, 1983). The stoichiometry of the conversion of pentoses is equivalent to that of the conversion of hexoses. As seen with glucose fermentations, there is a growth phase in fermentors with xylose, and when oxygen becomes limiting, then 2,3-BD production is seen. In media with 100 g/liter of xylose, the pH optimum for growth is 5.2, but growth drops off sharply at pH lower than 5.2. A xylose concentration of 20 g/liter is optimum for growth, as higher sugar concentrations lower the water activity. Oxygen supply is critical and variations in oxygen supply can change the yields of the various products produced by *Klebsiella*. The best 2,3-BD production rate was shown to occur at an oxygen transfer rate of 0.027 moles/liter/h. With an initial xylose concentration of 100 g/liter, the average butanediol production rate was 1.35 g/liter/h (Jansen et al., 1984). Added succinate at 10 g/liter was shown to improve 2,3-BD productivity from xylose, while higher concentrations of succinate were inhibitory (Eiteman and Miller, 1995).

Pre-treated cellulosic materials have been tested with *Klebsiella* for butanediol production with some success. *Klebsiella* was grown on acid-hydrolyzed wood hemicellulose, and 2,3-BD yields of 0.4–0.5 g/g were obtained. The authors proposed that such high yields were partially due to the ability of *Klebsiella* to simultaneously ferment uronic acids, such as D-glucuronic and D-galacturonic acid, present in the wood samples. Other compounds in wood (such as furfural and lignin derivatives) are inhibitory to the bacteria if the wood hydrolysate is added at too high a concentration (Yu et al., 1982b). A study comparing the effects of a number of inhibitors on *Klebsiella* was reported. Sulfate and furfural up to concentrations of 0.2% w/v reduced 2,3-BD yield, and phenolic compounds inhibited bacterial growth (Frazer and McCaskey, 1991).

A more efficient approach to use of woody biomass was simultaneous saccharification and fermentation (SSF) for 2,3-BD production. Culture filtrates of *Trichoderma harzianum* were added as a source of hydrolytic enzymes. SSF can shorten overall process times and relieve end product inhibition. The mixture of sugars derived from both cellulose and hemicellulose can be used for 2,3-BD production, thus eliminating the costs of separating the sugars (Yu and Saddler, 1985a).

Klebsiella was grown on woody biomass in coculture with *T. harzianum*. The fungal growth medium was found to inhibit the growth of *Klebsiella*, therefore, resting cells of *Klebsiella* were used. Both the hemicellulose and cellulose sugar streams were used for 2,3-BD production, and yields of approximately 30% of theoretical were obtained (Yu et al., 1985b).

Another potential low cost substrate is cheese whey. Using *K. pneumoniae* cells immobilized in calcium alginate, a productivity of 2.3 g/liter/h on whey permeate was demonstrated. The system was stable during seven weeks of continuous operation (Lee and Maddox, 1986). In another study, *K. oxytoca* was shown to grow poorly on lactose, but it grew very well on the component sugars, glucose and galactose. The aeration rates

affected growth on lactose; low aeration results in a lower cell growth rate. One possible factor for the lower growth rate on lactose may have been inefficient transport into the cell (Champluvier et al., 1989).

Molasses appears to have potential value as a substrate for 2,3-BD production. *Klebsiella oxytoca* can ferment molasses at high concentrations. In one batch experiment, as much as 280 g/liter of molasses was converted to 118 g/liter of 2,3-BD and 2.3 g/liter of acetoin. These high concentrations are needed inasmuch as molasses is a relatively expensive substrate, and the separation costs of the final product may be difficult from such a complex carbohydrate source (Afschar et al., 1991).

Various new process concepts have been proposed for 2,3-BD production. The prospect of making both 1,3-propanediol and 2,3-BD in the same fermentation was proposed using *K. pneumoniae* and glycerol as a substrate. In continuous culture, if the pH was lowered stepwise, 2,3-BD formation started at pH 6.6. This fermentation has the potential to be economically attractive as few by-products are formed (Biebl et al., 1998).

New process methods have been investigated for 2,3-BD production. An improvement of productivity over a continuous or batch system was observed in a cell recycle system using *Klebsiella*. One drawback occurred when biomass built up past a certain level; at this point, the coefficient of mass transfer for oxygen decreased and the viscosity increased owing to microbial polysaccharide production (Ramachandran and Goma, 1988). A novel process technology that improved the use of lactose was employed using coimmobilized cells of *Kluyveromyces lactis* with *Klebsiella oxytoca*. The yeast cells were permeabilized with solvent and used as a source of lactase. The rate of production on lactose was similar to that of immobilized cells on glucose (Champluvier et al., 1989).

Other microorganisms have been studied for their potential in 2,3-BD production. Certain strains of *B. polymyxa* were shown to be 2,3-BD producers from xylose. Yeast extract improved yields, which reached 16 g/liter (Laube et al., 1984). In the process of searching for an organism that could produce ethanol from arabinose, an *Enterobacter cloaceae* was isolated that could produce 2,3-BD from arabinose, with yields as high as 0.4 g/g of arabinose. Besides the pure sugar, the organism could use sugars from acid and enzyme hydrolyzed corn fiber. The organism prefers arabinose but will also use glucose and xylose. This organism opens up the opportunity to produce 2,3-BD from a corn fiber feedstock (Saha and Bothast, 1999).

Various *Bacillus* have been studied for 2,3-BD production. Much of the focus has been on *Bacillus polymyxa*, as besides *Klebsiella*, it is considered to have industrial potential. It produces primarily pure L-isomer. A number of isolates of *B. polymyxa* were checked on media that contained xylan. One strain especially, *B. polymyxa* NRCC 9035, produced a considerable amount of diol on xylose. Yeast extract appeared to have a beneficial effect on the xylose fermentation, and diol concentrations of 4.2 g/liter were seen. *Bacillus polymyxa* also fermented other sugars in hemicellulose, including mannose, galactose and L-arabinose (Laube et al., 1984).

Bacillus amyloliquefaciens may be a promising organism for 2,3-BD production as its major products of fermentation are 2,3-BD and some minor acids. It is able to use a variety of sugars, but the best productivity and yield are on glucose. As observed in other 2,3-BD fermentations, aeration plays a critical role, with high aeration favoring biomass formation and lower aeration favoring 2,3-BD production. With this organism, approximately 33 g of diol were formed from 100 g of sugar (Alam et al., 1990).

One of the highest 2,3-BD yields was reported from *Bacillus licheniformis*. The theoretical yield of 2,3-BD from glucose is 0.5 g/g of glucose. *Bacillus licheniformis* was able to reach 94% of the theoretical yield in 72 h. The best yields were obtained when peptone and beef extract were added to the medium. This productivity was similar to that of *Klebsiella* and *Bacillus polymyxa* (Nilegaonkar et al., 1992). Additional work to characterize *B. licheniformis* strains was done by using profiles of the fermentation products formed. A number of *B. licheniformis* strains were compared with *B. polymxya* strains. The product profiles for the *B. licheniformis* strains were similar to each other; however, they differed from the *B. polymyxa* strains. Protein electrophoretic patterns were also used to classify the strains. Again, with protein electrophoretic patterns, *B. licheniformis* was mapped in a different cluster than *B. polymyxa*. In fermentation tests, some of the *B. licheniformis* strains were shown to be as promising as *B. polymyxa* for 2,3-BD production (Raspoet et al., 1991).

Very little appears in the literature on any genetic engineering of the 2,3-BD pathway. The 2,3-BD operon from *Klebsiella terrigena* and *Enterobacter aerogenes* was cloned and characterized. The genes coding for α-acetolactate decarboxylase, α-acetolactate synthase, and acetoin (diacetyl) reductase were shown to be clustered in one operon. The genes were sequenced and called "*budABC*." The *budABC* operon appears to be regulated at the transcriptional level, as the highest amount of transcript was seen under conditions that favored 2,3-BD production. A putative fumarate nitrate reduction regulatory protein (FNR) site was found at posi-

tion –6. The FNR protein can activate genes at the level of transcription that are involved in anaerobic processes. The cloning of the *budABC* operon will facilitate the study of gene regulation and improvement of the 2,3-BD process (Blomqvist et al., 1993).

A gene fragment from *K. pneumoniae* IAM1063 that contains the *meso*-2,3-butanediol dehydrogenase was cloned and transformed into *E. coli*. This transformed *E. coli* produced only *meso*-2,3-BD from racemic acetoin (Ui et al., 1996). Using sequence homology from the *Klebsiella terrigena* operon, the *meso*-2,3-butanediol dehydrogenase and the remainder of the 2,3-BD-forming operon were cloned into *E. coli*. *Escherichia coli* was shown to produce *meso*-2,3-BD from glucose with no contamination of the L-form. The *E. coli* was tested in shake flasks, and the highest productivity was with a starting glucose concentration of 100 g/liter, which yielded 17.7 g/liter of *meso*-2,3-BD (Ui et al., 1997). Clearly, this work is promising and applying techniques of molecular biology and metabolic engineering may further improve the productivity of the 2,3-BD fermentation.

Patents and Regulatory Issues

Few patents in the United States patent literature can be found that deal with 2,3-BD production via a microbial process. With commercialization efforts, one would expect to find patents that cover the microorganisms involved, genetic manipulations, fermentation process improvements, and downstream separation of the product from broth. This may indicate that a bioprocess has not yet attracted the interest of industry.

Prospects

The study of the formation of 2,3-butanediol by bacteria has spanned quite a number of years. Early work included the elucidation of the pathway and some of the basic biochemistry of the enzymes. More recently, much of the research has focused on the fermentation process and understanding the parameters that would lead to a fermentation of high yield and productivity.

As raw materials are likely a large part of the fermentation production cost of 2,3-BD, the variety of work with biomass shows promise in helping to reduce the costs of the fermentation. The cloning of the 2,3-BD genes will help open up opportunities for improving the host organism using techniques of metabolic engineering. One of the major challenges to the economics of this process will be the development of an efficient and cheap downstream process for separation of the material from fermentation broth.

As with any chemical intermediate that can be made by a biological process, several key challenges will remain. First, there must be a sufficient market demand to drive the research and development costs. Secondly, the cost of competing petrochemicals must be taken into account, as it will be difficult for a bio-based material to compete with very cheap petrochemical-derived products. Thirdly, it must be determined whether the unique properties of the bio-based material open up new end uses and markets. Examples of this would be the use of chiral molecules in special end uses. This prospect may exist for 2,3-BD with its three racemic forms. Another example would be whether the public finds the features of biodegradability, or use of renewable materials, attractive enough to possibly pay more for a product.

It appears that 2,3-BD achieved its peak of commercial interest around World War II due to the shortage of natural rubber. It remains to be seen whether evolving industrial needs will cause renewed interest in a bioprocess for production of 2,3-butanediol.

CHAPTER 3.2

Amino Acid Production

HIDEHIKO KUMAGAI

Introduction

The water extract of a marine algae "kelp" (*Laminaria japonica*) has been used in a number of Japanese recipes as a kind of soup to flavor cooking. The tasty ("Umami" in Japanese) factor in the marine algae was identified as monosodium glutamate by Prof. Kikunae Ikeda in 1908. Soon thereafter, Ajinomoto Co. Ltd. started to produce monosodium glutamate by extraction from wheat protein after hydrolysis with hydrochloric acid.

In 1956, Kyowa Hakko Kogyo Co. Ltd. succeeded in producing sodium glutamate by using a bacterium (*Corynebacter glutamicum*). Then, production using microbial methods of various amino acids (including of L-alanine, L-aspartic acid, L-arginine, L-citrulline, L-cysteine, L-DOPA [3,4-dihydroxyphenylalanine], L-glutamic acid, L-glutamine, glutathione, L-histidine, D-hydroxyphenylglycine, L-hydroxyproline, L-isoleucine, L-lysine, L-ornithine, L-phenylalanine, D-phenylglycine, L-polylysine, L-proline, L-serine, L-threonine, L-tryptophan, and L-tyrosine) was investigated and successfully manufactured on an industrial scale. Glycine is produced by chemical methods because the molecule has no chiral center, and methionine is also produced by chemical methods in its racemic form because the main use of the amino acid is as feedstuff. D-Methionine is metabolized in animals by the action of D-amino acid oxidase. These amino acids were useful as sources of medicines, food additives, feedstuffs, and starting materials for chemical synthesis.

The microbial methods for the production of amino acids are either fermentative or enzymatic. Fermentation methods use cheap carbon and nitrogen sources as the starting materials to produce rather large amounts of amino acids. These starting materials are metabolized by a number of enzymatic reaction steps and the product accumulates in the culture medium during cell growth. Enzymatic methods require substrates that are generally expensive because they usually are produced by chemical synthesis. So this method is suitable for rather expensive, small-scale production. Figure 1 shows the difference between fermentative and enzymatic methods.

This chapter describes the microbial production of some amino acids including the producing strains, production method, product usage, and industrial production.

L-Alanine

The annual world production of L-alanine is about 500 tons. This amino acid is useful as an enteral and parenteral nutrient and as a food additive, which has a sweet taste and bacteriostatic properties.

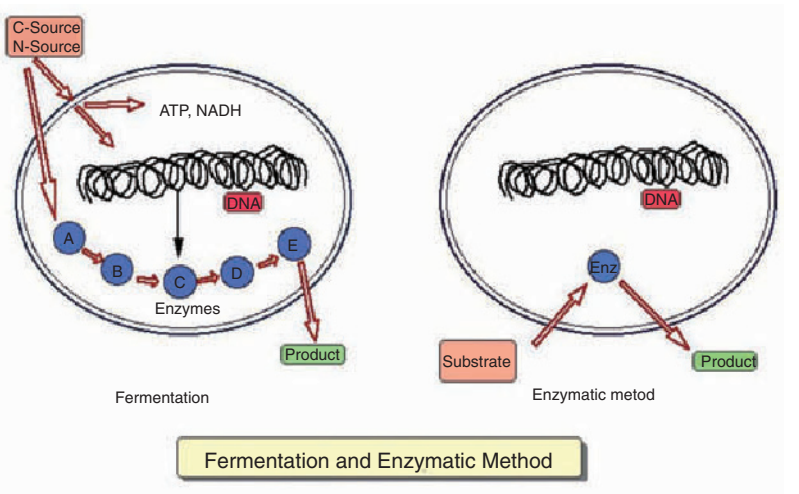
L-Alanine is produced from L-aspartate by a one-step enzymatic method using aspartate β-decarboxylase (Chibata et al., 1986).

L-Alanine production by fermentation is difficult because bacteria usually have an alanine racemase to racemize the product. Fermentative production of L-alanine with racemase-deficient strains of *Corynebacterium glutamicum*, *Brevibacterium flavum* and *Arthrobacter oxydans* (Hashimoto and Katsumata, 1999) has been investigated and good yields have been reported, although the method is not yet industrially applicable.

Tanabe Seiyaku Co. in Japan applied on an industrial scale the enzymatic method described above, using aspartic acid produced by immobilized enzymes as the starting material. A bacterial strain selected for its strong aspartate β-decarboxylase activity was identified as *Pseudomonas dacunhae* (Chibata et al., 1965). The bacterial cells with high activity were immobilized on κ-carageenan, a polysaccharide obtained from seaweed, and packed in a column. The L-alanine was produced by this column system continuously. To prevent the evolution of carbon dioxide gas, a closed column reactor was designed and used for the production. In this column the enzyme reaction proceeds under high pressure (Chibata et al., 1986).

The substrate, L-aspartate, is produced from fumarate by an enzyme system involving aspartase, as described in the section on L-aspartate.

Fig. 1. Fermentation and enzymatic methods.



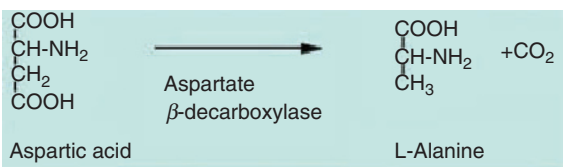


Fig. 2. Enzymatic synthesis of L-alanine.

To produce L-alanine directly from fumarate, the L-alanine-producing column was connected in tandem to an L-aspartate-producing column. In this tandem column system, side reactions caused by fumarase in *Escherichia coli* and alanine racemase in *P. dacunhae* reduced the yield. Then, both bacterial cells were separately treated with high temperature and low pH, respectively, and the enzymes responsible for the side reactions were inactivated. Immobilization of these two kind of bacterial cells with κ-carrageenan resulted in the production of L-alanine in a single reactor without the production of the side products, malate and D-alanine (Takamatsu et al., 1982; Chibata et al., 1986).

L-Aspartate

The annual world production of L-aspartate is estimated to be 7000 tons. L-Aspartate is used as an enteral and parenteral nutrient, a food additive, and a starting material for the low-calorie sweetener aspartame (aspartylphenylalanine methyl ester). It is also used as a raw material to synthesize detergent and for chelating or water treatment agents.

L-Aspartate is produced by the reaction of fumarate and ammonia catalyzed by aspartase.

L-Aspartate production began in 1960 using a batchwise process involving *E. coli* cells containing high aspartase activity. In 1973, Chibata and collaborators at the Tanabe Seiyaku Co. started producing L-aspartate using a continuous reaction system consisting of an immobilized enzyme column. In the system, aspartase extracted from *E. coli* cells was immobilized on ion exchange resin. *Escherichia coli* cells were immobilized by trapping in acrylamide gel and then the column was used in industrial production (Tosa et al., 1973). In 1978, this matrix was changed to κ-carrageenan. The production of L-aspartate was greatly improved by this method and the yield became 100 tons/month using a 1 kiloliter bioreactor (Chibata et al., 1986). In the United States, *E. coli* cells with high aspartase activity immobilized on polyurethane and polyazetidine were reported and the latter was shown to have high aspartase activity, producing aspartate at the rate of 55.9 mol/h/kg cell (wet weight; Fusee et al., 1981).

A different system for the enzymatic production of L-aspartate was proposed and used by Mitsubishi Petrochemical Co. in Japan in 1985. In this system, resting intact coryneform bacteria, *Brevibacterium flavum*, were used without immobilization in a reactor with an ultrafiltration membrane (Terasawa et al., 1985). The starting material, maleate, was converted to fumarate by maleate isomerase in the cells. The bacterial strain with high maleate isomerase and aspartase activity was obtained by the transformation of its genes. The plasmids introduced were stabilized (Zupansic et al., 1995) and the cells were reused many times without any loss of activity and lysis (Yukawa, 1999).

L-Cysteine

Annual world production of L-cysteine is 1500 tons. Its uses are as an enteral and parenteral

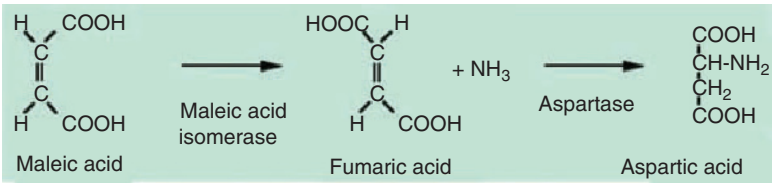

Fig. 3. Enzymatic synthesis of L-aspartate.

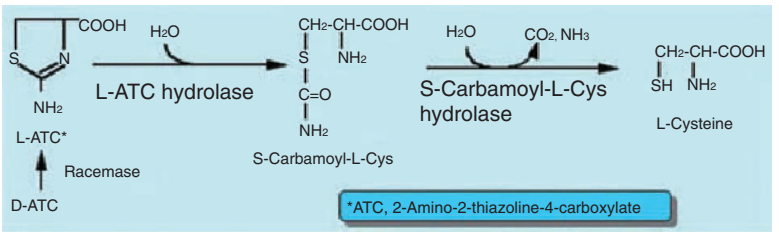

Fig. 4. Enzymatic synthesis of L-cysteine.

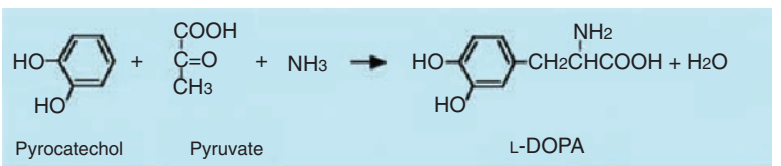

Fig. 5. Enzymatic synthesis of L-3,4-dihydroxyphenylalanine (DOPA).

nutrient, food additive, constituent of hair treatment preparations, and starting material of constituents used in cosmetics.

In 1982, Ajinomoto Co. Ltd. industrially applied a three-step enzymatic process to produce L-cysteine from DL-2-amino-2-thiazoline-4-carboxylate (DL-ATC), a starting material of the chemical synthesis of L-cysteine. The enzymes catalyzing this process are DL-ATC racemase, L-ATC hydrolase, and *S*-carabamoyl-L-cysteine (SCC) hydrolase (Sano et al., 1977; Sano et al., 1978; Sano et al., 1979; Fig. 4).

S-Carboxymethyl-L-cysteine is also produced by the same enzymatic method from the corresponding starting material (Yokozeki et al., 1988).

In screening for high-yield producers, the bacterial strain that produced the most L-cysteine from DL-ATC was isolated from soil and designated "*Pseudomonas thiazolinophilum*." The enzymes responsible for the conversion were inducible and the addition of DL-ATC to the culture medium was essential for enzyme activity. Addition of Mn^{+2} and Fe^{+2} to the medium also contributed to increasing the enzyme activity. The reaction proceeds by adding cells with high enzyme activities but no cysteine-desulfhydrase (a L-cysteine degrading enzyme) to the reaction mixture containing DL-ATC. L-Cysteine produced in the reaction mixture is oxidized to L-cystine by aeration and precipitated as crystals. This increases the efficiency of L-cysteine production, which is 31.4 g/liter obtained from 40 g/liter of DL-ATC, i.e., 95% product yield by molar ratio.

L-DOPA

The annual world production of L-DOPA is around 250 tons. L-DOPA (the precursor of the neurotransmitter dopamine) is useful as a treatment for Parkinson's disease. It had been mainly produced by a chemical synthetic method that included eight reaction steps including an optical resolution step.

L-DOPA is produced from pyrocatechol, pyruvate and ammonia by a one-step enzyme reaction using tyrosine phenol-lyase (TPL). Ajinomoto Co. Ltd. began using *Erwinia* TPL for enzymatic L-DOPA production (by a simple one-step method and one of the most economical processes to date) in 1993.

Tyrosine phenol-lyase (TPL) is a pyridoxal 5′-phosphate dependent multifunctional enzyme and catalyzes degradation of tyrosine into phenol, pyruvate and ammonia. This reaction is reversible, and the reverse reaction is available to produce L-DOPA using pyrocatechol instead of phenol (Fig. 5).

Erwinia herbicola was selected as the most favorable strain for the L-DOPA production out of 1041 microbial strains tested. No enzyme activity was found in yeasts, fungi and actinomycetes. Culture conditions for the preparation of cells containing high TPL activity and reac-

tion conditions for the synthesis of L-DOPA were optimized with *Erwinia herbicola*. Additions of yeast extract, meat extract, polypeptone, and the hydrolyzate of soybean protein to the basal medium enhanced cell growth as well as the formation of TPL. Catabolite repression of biosynthesis of TPL was observed on adding glucose, pyruvate, and α-ketoglutarate to the medium at high concentrations. Glycerol was a suitable carbon source for cell growth as well as for the accumulation of the enzyme in growing cells. TPL is an inducible enzyme and the addition of L-tyrosine to the medium is essential for formation of the enzyme. L-Phenylalanine is not an inducer of TPL biosynthesis but works as a synergistic agent for the induction by L-tyrosine. The activity of TPL increased five times by the addition of L-phenylalanine together with L-tyrosine to the medium. Cells of *E. herbicola* with high TPL activity were prepared by growing them at 28°C for 28 h in a medium containing 0.2% KH_2PO_4, 0.1% $MgSO_4 \cdot 7H_2O$, 2 ppm of Fe^{+2} ($FeSO_4 \cdot 7H_2O$), 0.01% pyridoxine-HCl, 0.6% glycerol, 0.5% succinic acid, 0.1% DL-methionine, 0.2% DL-alanine, 0.05% glycine, 0.1% L-phenylalanine, and 12 ml of hydrolyzed soybean protein in 100 ml of tap water, with the pH controlled at 7.5 throughout cultivation. Under these conditions, TPL was efficiently accumulated in the cells of *E. herbicola* and made up about 10% of the total soluble cellular protein (Yamada and Kumagai, 1975).

The enzymatic synthesis reaction of L-DOPA is carried out in a batchwise system with cells of *E. herbicola* containing high activity of TPL. Since pyruvate, one of the substrates, was unstable in the reaction mixture at high temperature, low temperature was used for the synthesis of L-DOPA. The reaction was carried out at 16°C for 48 h in a reaction mixture containing various amounts of sodium pyruvate, 5 g of ammonium acetate, 0.6 g of pyrocatechol, 0.2 g of sodium sulfite, 0.1 g of EDTA, and cells harvested from 100 ml of broth in a total volume of 100 ml. The pH was adjusted to 8.0 by the addition of ammonia. At 2-h intervals, sodium pyruvate and pyrocatechol were added to the reaction mixture to maintain the initial concentrations. The maximum synthesis of L-DOPA was obtained when the concentration of sodium pyruvate was kept at 0.5%. The addition of substrates, pyrocatechol and pyruvate, was separated by a time interval to prevent the denaturation of TPL and to prevent byproduct formation. Sodium sulfite is added to keep the reactor in a reductive state and to prevent the oxidation of product L-DOPA. The L-DOPA is not soluble in the reaction medium, so it forms a crystalline precipitate (reaching 110 g/liter) during the reaction (Yamada and Kumagai, 1975; Kumagai, 1999a; Kumagai, 1999b).

Induction and repression mechanisms of TPL in *E. herbicola* were studied. It was found that TPL biosynthesis is regulated at the transcriptional level. Tyrosine phenol-lyase mRNA was increased by the addition of tyrosine and decreased by the addition of glucose in the medium. TyrR box and operator-like regions were found in the 5' flanking region of its gene, *tpl*. TyrR box is a typical binding site on DNA where a regulator protein TyrR binds and controls transcription of the regulon of enzyme genes or transporter genes responsible for biosynthesis of aromatic amino acids or transport through cell membrane (Suzuki et al., 1995; Katayama et al., 1999). Katayama et al. reported three point mutations in the *tyrR* gene that caused high-level expression of *lacZ* in *E. coli* and *tpl* in *E. herbicola* (Katayama et al., 2000). The function of the product of *tutB* gene and the gene itself, located just downstream of *tpl* in *E. herbicola*, were analyzed. It was elucidated that *tutB* encodes a tyrosine specific transporter and this is essential for maximum induction of TPL in *E. herbicola* cells (Katayama et al., 2002).

Glutamic Acid

World production of monosodium L-glutamate using so-called "coryneform bacteria" is around one million tons per annum. Monsodium glutamate is used as a flavor enhancer and an intermediate material for chemical synthesis of medicines. Its ester is used as a detergent and the polymer as artificial skin. Two Japanese companies, Ajinomoto and Kyowa Hakko Kogyo, built factories and produced it in other countries, mainly in southeast Asia. China, Korea and Taiwan also are producing large amounts of monosodium L-glutamate.

Glutamic acid is produced by *Corynebacterium glutamicum* in the presence of high concentrations of sugar and ammonium, appropriate concentrations of minerals, and a limited concentration of biotin under aerobic conditions (Kikuchi and Nakao, 1986). In 2-3 days, around 100 g of L-glutamate per liter accumulates in the medium.

Various glutamic acid-producing strains were reported after the first report on *Corynebacterium glutamicum*. They are *Brevibacterium flavum*, *Brevibacterium lactofermentum*, *Brevibacterium thiogenitalis* and *Microbacterium ammoniaphilum*, and all strains are Gram-positive, nonsporulating, nonmotile, cocci or rod-like and all require biotin for growth. Currently, these strains are thought to belong to the genus *Corynebacterium*.

The carbon source most commonly used as a starting material is glucose, which is obtained by enzymatic hydrolysis of starch from corn, potato and cassava. Waste molasses is also used since it is cheap. Acetic acid and ethanol are also good carbon sources to produce glutamate. A high concentration of a nitrogen source is necessary to accumulate glutamate, and ammonia gas, its solution, the inorganic salt, or urea is used in actual production.

Coryneform bacteria generally show high rates of sugar assimilation and highly active glutamate dehydrogenase, which is responsible for glutamate biosynthesis. Glucose incorporated in the cell is metabolized through the Embden-Meyerhof pathway (EMP) and a part of the tricarboxylic acid (TCA) cycle, and 2-oxoglutarate formed in the cycle is aminated to glutamate by the action of glutamate dehydrogenase.

Biotin is an important factor regulating the growth of the bacterium and glutamic acid production. Its suboptimal addition is essential to produce a large amount of glutamic acid in the medium. To use a starting material such as waste molasses, which contains excess biotin, the addition of penicillin to the medium during growth was found to be effective. In the production of glutamic acid, several saturated fatty acids or their esters were also found to function similarly to penicillin. A glycerol-requiring mutant of *Corynebacterium alkanolyticum* was used to produce glutamic acid in appreciable amounts without the addition of penicillin and without the need to control biotin concentration (Kikuchi and Nakao, 1986).

Since these treatments are essential for the glutamate fermentation, it has been suggested that the cell surface of the bacteria is damaged under such conditions, and consequently leaking of glutamate takes place. This leaking theory has been accepted for a long time. But recently another published theory of excretion of glutamate suggested an exporter protein of glutamate was present on the cell surface of the bacterium (Kraemer, 1994).

The amount of 2-oxoglutarate dehydrogenase complex (ODHC), which catalyzes the conversion of 2-oxo-glutarate to succinyl-CoA as the first step of succinate synthesis in the TCA cycle, was reported to be decreased in glutamate-producing bacterial cells. And recently, the enzyme activity was confirmed to be very low in the presence of detergent, or limited amounts of biotin or penicillin (Kawahara et al., 1997). These results suggest that one of the main causes for the glutamate overproduction is the decrease of 2-oxoglutarate dehydrogenase activity (ODH). A disrupted (ODH) gene-bearing bacterial strain produced as much glutamate as the wildtype strain under conditions of glutamate overproduction.

Furthermore, a novel gene *dtsR* was cloned, which rescues the detergent sensitivity of a mutant derived from a glutamate producing bacterium, *Corynebacterium glutamicum* (Kimura et al., 1996). The authors found that this gene encodes a putative component of a biotin-containing enzyme complex and has something to do with fatty acid metabolism. The disruption of this gene causes constitutive production of glutamate even in the presence of excess biotin. The authors suggested that the overproduction of glutamate is caused by an unbalance of the coupling between fatty acid and glutamate synthesis (Kimura et al., 1997). They successfully showed that inducers of glutamate overproduction such as Tween 40 and limited amounts of biotin reduced the level of DtsR, which then triggered overproduction by decreasing the activity of ODHC (Kimura et al., 1999).

Kyowa Hakko Kogyo Co. Ltd., the Research Institute for Innovative Technology for Earth in Japan, and Degussa in Germany completed the analysis of the genomic DNA nucleotide sequence of *Corynebacterium glutamicum*.

D-*p*-Hydroxyphenylglycine

Kaneka Co. Ltd. started the enzymatic production of D-*p*-hydroxyphenylglycine (D-HPG) in 1980 in Singapore, and the immobilized D-carbamoylase reactor was introduced in this process in 1995. The annual production of D-HPG by this method is around 2,000 tons. D-HPG is a starting material for the production of semi-synthetic penicillins and cephalosporins, such as amoxicillin and cephadoxel. D-HPG is produced from DL-*p*-hydroxyphenylhydantoin (DL-HPH) by a two-step enzymatic method (Takahasi, 1986).

The starting material DL-HPH is synthesized by the amidoalkylation of phenol (Ohashi et al., 1981). Only D-HPH is hydrolyzed by hydantoinase to form D-HPG via *N*-carbamoyl-D-*p*-HPG. L-HPH is spontaneously racemized at a slightly alkaline pH. Then during the reaction, only D-HPH is hydrolyzed to form D-HPG via *N*-carbamoyl-D-*p*-HPG. Finally DL-HPH in the reaction mixture is completely hydrolyzed to D-HPG.

D-Hydantoin hydrolase activity was found in some bacteria belonging to the genera *Bacillus*, *Pseudomonas*, *Aerobacter*, *Agrobacterium* and *Corynebacterium* and in actinomycetes belonging to the genera *Streptomyces* and *Actinoplanes*. D-Carbamylase activity was found in various bacteria belonging to the genera *Agrobacterium*, *Pseudomonas*, *Comamonas* and *Blastobacter*.

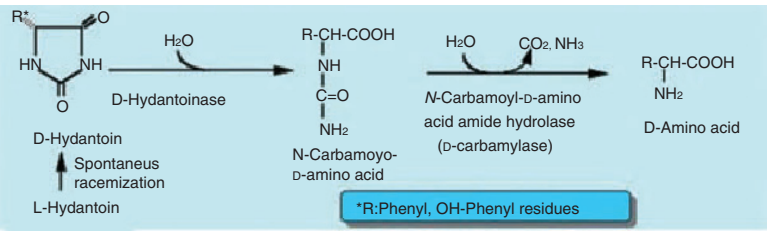

Fig. 6. Enzymatic synthesis of D-hydroxy-phenylglycine.

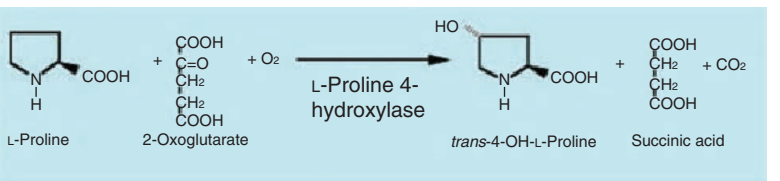

Fig. 7. Enzymatic synthesis of L-hydroxyproline.

The genes of these two enzymes were cloned, and an *E. coli* strain transformed by this gene was used as the practical enzyme source. To obtain stable D-carbamoylase for repeated use, a random mutation technique was applied to the *Agrobacterium* D-carbamoylase. Three heat stable mutant enzymes were obtained. These mutations were found at His 57, Pro203, and Val236. These mutations were combined in one molecule, and the mutant enzyme containing the triple mutation His57Tyr, Pro203Glu, and Val236Ala had 19°C higher heat stability than did the wildtype enzyme (Ikenaka, 1999). *Escherichia coli* cells containing this mutant enzyme were immobilized and used for practical industrial production of D-HPG with the simultaneous use of immobilized D-hydantoinase on line. This immobilized mutant D-carbamoylase reactor can be used for one year without any supply of new enzyme.

D-Phenylglycine is also produced by the same enzymatic method using the corresponding starting material.

Hydroxy-L-proline

The industrial production of *trans*-4-hydroxy-L-proline was started by Kyowa Hakko Kogyo Co. Ltd. in 1997. 4-Hydroxy-L-proline is useful as a chiral starting material in chemical synthesis and as a starting material of medicinals, cosmetics, and food additives. *trans*-4-Hydroxy-L-proline is a component of animal tissue protein such as collagen and was extracted from collagen after hydrolysis with strong acid before this enzyme process was industrially utilized. The discovery of L-proline hydroxylases made the microbial production of hydroxyproline possible. *trans*-4-Hydroxy-L-proline or *cis*-3-hydroxy-L-proline is produced from L-proline by the respective action of L-proline 4-hydroxylase or 3-hydroxylase. The other substrate 2-oxoglutamate is supplied from glucose added to the reaction mixture through the EMP pathway and TCA cycle.

Ozaki et al. developed a specific hydroxyproline detection method with high performance liquid chromatography (Ozaki et al., 1995) and screened strains for microbial proline hydroxylase activity. L-Proline 4-hydroxylase was found in some etamycin-producing actinomycetes belonging to the genera *Streptomyces*, *Dactylosporangium* or *Amycolatopsis* (Shibasaki et al., 1999). L-Proline 3-hydroxylase was found in some telomycin producing actinomycetes belonging to the genus *Streptomyces* and in bacteria belonging to *Bacillus* (Mori et al., 1996).

The genes of these proline hydroxylase-producing organisms were cloned in *E. coli* cells, respectively, and the cells overexpressing the enzyme were used as the enzyme source in the industrial process of L-hydroxyproline production. Since the genes obtained from actinomycetes had some difficulty in being highly expressed in *E. coli* cells, the genetic codons corresponding to the N-terminal of the enzyme protein were changed to match the codon usage in *E. coli*. Furthermore, the promoter of *trp* operon was introduced twice at the promotor site of the gene in the plasmid to achieve the overexpression. These transformants expressed 1400 times higher activity of proline 4-hydroxylase and 1000 times higher activity of proline 3-hydroxylase in comparison with the original strain.

2-Oxoglutarate, one of the substrates of hydroxylation, is made from glucose in the reaction medium via the EMP pathway and TCA cycle in *E. coli*, and the product succinate is recycled. The mutant strain of *E. coli* lacking the L-proline-degrading enzyme was obtained and used for the host cells in the production of L-hydroxyproline.

Using *E. coli* as the host cells in L-proline production, the direct production of L-hydroxyproline from glucose became possible. In this case, the derepressed genes of the L-proline biosynthetic pathway were introduced into *E. coli* cells together with the gene of L-proline hydroxylase.

L-Lysine

The estimated annual world production of L-lysine is around 500,000 tons, almost all supplied by Ajinomoto, Kyowa Hakko Kogyou, Archer Daniels Midland (ADM), and Badische Aniline and Soda-Fabrik (BASF). L-Lysine (an essential amino acid for swine and poultry) is useful as an additive to feeds such as grains and defatted soybeans, which contain less lysine.

L-Lysine is produced by some mutants derived from wild strains of glutamate-producing bacteria including *Corynebacterium glutamicum*, *Brevibacterium lactofermentum* and *B. flavum* in the presence of high concentration of sugar and ammonium, at neutral pH, and under aerobic conditions (Tosaka and Takinami, 1986).

The pathway of biosynthesis of L-lysine and L-threonine including controls of the biosynthesis in *Corynebacterium glutamicum* is shown in Fig. 8. The formation of phosphoaspartate from aspartate is the first step and is catalyzed by aspartokinase. The activity of this enzyme is controlled through concerted feedback inhibition by L-lysine and L-threonine. In 1958, Kinoshita and Nakayama of Kyowa Hakko Kogyo Co. Ltd. reported that the auxotrophic mutant of *Corynebacterium glutamicum*, which lacks homoserine dehydrogenase and is defective in L-homoserine (or L-threonine plus L-methionine) biosynthesis, produced L-lysine in the culture medium (Kinoshita et al., 1958). This was the first report on production of an amino acid by an auxotrophic mutant. Subsequently, amino acid production by auxotrophic mutants expanded greatly. Then, the mutants with the L-threonine- or L-methionine-sensitive phenotype due to the mutation in homoserine dehydrogenase (low activity) were also found to produce appreciable amounts of L-lysine in the culture medium (Tosaka and Takinami, 1986). Furthermore, a lysine analogue (*S*-aminoethylcysteine)-resistant mutant was obtained as an L-lysine producer. In this strain, aspartokinase was insensitive to feedback inhibition (Tosaka and Takinami, 1986). This is the first demonstration of amino acid production by an analogue-resistant mutant.

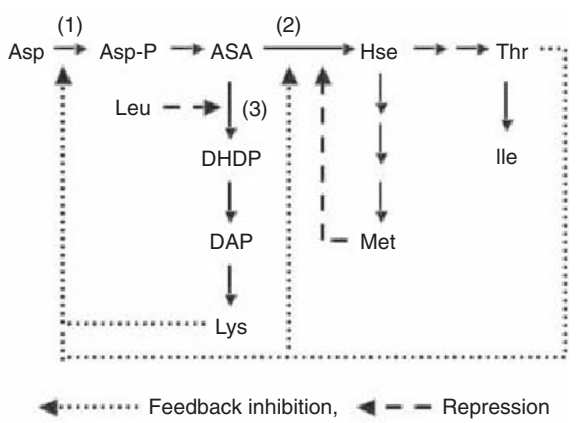

Fig. 8. Regulation of lysine biosynthesis. ASA, aspartate-β-semialdehyde; DHDP, dihydrodipicolinate; DAP, α, ε-diaminopimelate; and Hse, homoserine. (1), Aspartate kinase; (2), Homoserine dehydrogenase; and (3), Dihydrodipicolinate synthase.

These characteristics of lysine production were combined to make strains that were much more efficient producers. In addition, the introduction of a leucine requiring mutation also increases the amount of lysine, since in the mutant dihydrodipicolinate synthase is released from repression by leucine.

The precursors of lysine synthesis include phosphoenol pyruvate, pyruvate, and acetyl CoA. Many mutations are induced in lysine producer cells to supply sufficient amounts of these precursors in good balance. These are deletion mutants of pyruvate kinase, those that show low activity of pyruvate dehydrogenase, etc. Furthermore, an alanine requirement was also reported to be effective in increasing the lysine amount.

The genes of the enzymes responsible for the biosynthesis of lysine in *Corynebacterium* have been cloned and their nucleotide sequences are known. These genes include aspartokinase, aspartate semialdehyde dehydrogenase, dihydrodipicolinate synthase, dihydrodipicolinate reductase, tetrahydrodipicolinate succinylase, succinyl diaminopimelate desuccinylase, diaminopimelate dehydrogenase, and diaminopimelate decarboxylase (Tosaka and Takinami, 1986). A host-vector system of *Corynebacterium* was established, and the introduction of some genes that encode the enzymes responsible for lysine biosynthesis (i.e., aspartokinase and dihydrodipicolinate synthase) was found to be effective in increasing the amount of lysine produced (Cremer et al., 1991).

A new gene *ldc* which encodes lysine decarboxylase (formerly known as *cadA* in *E. coli*) has been identified and the enzyme was purified from the overexpressing strain. The lysine decarboxylase encoded by *ldc* is constitutively produced by *E. coli* cells, although lysine decarboxylase encoded by *cadA* is inducible (Kikuchi et al., 1997). It is interesting to note that

this new lysine decarboxylase is present in lysine producing *Corynebacterium* and to investigate the effects of deleting the gene on L-lysine production.

Vrljic et al. (1996) cloned a new gene *lysE* from *Corynebacterium glutamicum* and showed that it encodes a specific L-lysine exporter. Recently, they analyzed the membrane topology of the gene product and showed that it is a member of a protein family found in some other bacteria such as *E. coli*, *Bacillus subtilis*, *Mycobacterium tuberculosis* and *Helicobacter pylori*. The authors suggested that LtsE superfamily members would be shown to catalyze export of a variety of biologically important solutes including amino acids (Aleshin et al., 1999; Vrljic et al., 1999; Zakataeva et al., 1999).

L-Threonine

The annual worldwide production of L-threonine is around 13,000 to 14,000 tons. L-Threonine is an essential amino acid for humans and some livestock animals, such as pigs and poultry. It is used as an additive for animal feed, medicines, food, and cosmetics.

L-Threonine is produced by some auxotrophic mutants or threonine-analogue resistant mutants, and those are created by genetic engineering techniques. The bacteria used are *Escherichia coli*, *Corynebacterium glutamicum*, *Brevibacterium lactofermentum*, *B. flavum*, *Serratia marcescens* and *Proteus retgerii* (Nakamori, 1986). L-Threonine production by fermentation was started in the 1970s. The auxotrophic mutant and analogue resistant mutant strains obtained for this purpose were cultured in the presence of amino acids required by the mutant.

Auxotrophic mutants of L-lysine, diaminopimelate or L-methionine were found to produce L-threonine in the culture medium, but the amount was not high enough to justify their use in practical production. A resistant mutant to an L-threonine analogue, α-amino-β-hydroxyvaleic acid (AHV), was obtained and shown to be an L-threonine producer. In this strain homoserine dehydrogenase was insensitive to the feedback inhibition by L-threonine (Fig. 8). The much stronger L-threonine producing strains were obtained by the combination of the auxotrophic mutations and AHV resistant mutation. L-Threonine producing mutant of *S. marcescens* was induced by the techniques of phage transduction. The strain has the following properties: deficiency of L-threonine degrading enzymes; a mutation in the aspartokinase and homoserine dehydrogenase genes, making them insensitive to feedback inhibition by L-threonine; mutations in genes for L-threonine biosynthetic enzymes, releasing them from repression by L-threonine; a mutation in the aspartokinase gene, making it insensitive to feedback inhibition by L-lysine; and a mutation in the aspartokinase and homoserine dehydrogenase genes, releasing them from the repression by L-methionine.

Recombinant DNA techniques were employed to improve the L-threonine producer. Genes of the threonine operon obtained from AHV resistant and feedback insensitive mutants were introduced into a threonine deficient mutant of *E. coli* to amplify the expression of enzymes and to increase the amount of L-threonine. *Escherichia coli* mutant strains were also constructed with amplified genes of the threonine operon (obtained from AHV resistant and feedback insensitive mutants) by the action of Mu phage on the chromosomal DNA. This strain is used in France for L-threonine production. Okamoto et al. constructed an L-threonine hyper-producing *E. coli* mutant that can produce L-threonine (100 g/liter) in 77 h. They suggested that uptake of L-threonine in this strain is impaired (Okamoto et al., 1997).

CHAPTER 3.3

Microbial Exopolysaccharides

TIMOTHY HARRAH, BRUCE PANILAITIS AND DAVID KAPLAN

Introduction

The abundant nature and manifold uses of polysaccharides derived from plants and animals are well established. Application of these materials, notably chitosan and cellulose, in food and healthcare products is widespread. Unfortunately, issues of purity and seasononal availability and variability surround the use of these and other materials when obtained from environmental sources. Although several hydrocolloids used widely in the same sectors (i.e., xanthan, gellan, and dextrans) are currently available only from microbial sources, commercial and academic interest in the synthesis and properties of microbial polysaccharides has continued to grow over the past several decades for a source of more economical, consistent, and higher purity raw material (Giavasis et al., 2000). Continuing focus on environmentally benign production techniques and the desire for customizability in bacterially derived products also motivate continued investigation into the molecular biology, polymer science, and process engineering of microbial exopolymer production. While progress continues in the understanding of biosynthetic pathways, substrate transport, and polymer secretion in a variety of organisms, recombinant DNA techniques have also resulted in the elaboration of new, selectively modified polymers that offer the potential for a wide variety of novel materials with more predictable structure and function. The ongoing application of biotechnology to the synthesis, optimization, and customization of bacterial polysaccharides is the focus of this chapter.

While the production of polysaccharides by selected microorganisms was first reported in the 1880s (Whitfield, 1988), large-scale application was not achieved until the middle of the twentieth century, with the production and approval of dextran from *Leuconostoc mesenteroides* in 1947 and the United States Food and Drug Administration (FDA) approval of food grade xanthan from *Xanthamonas campestris* in 1969. Today, both materials continue to be important (although xanthan dominates) in the estimated $253 million market for microbial polysaccharides (Magnani, 1998). In the intervening years, various polysaccharides of microbial derivation have been described and, in a few cases, developed into products. While the production of bacterial polymers continues to expand, a still surprisingly small list of polymers has achieved industrial relevance (Sutherland, 1998; Table 1). This continues to be primarily motivated by factors of organismal productivity, regulatory approval, and thus in both cases, cost. Also at issue are two areas of fundamental relevance, the relatively loose understanding of structure-function relationships that slows the progress of research and development in this area (Sutherland, 2001) and the lack of template-controlled synthesis characteristic of proteins.

It should be mentioned from the outset that this chapter necessarily excludes several very important topics of microbial exopolysaccharides as outside of present scope. The most complex of these topics is that of microbial biofilms, around which an extensive literature continues to evolve. Likewise excluded are the areas of biosurfactants, the use of bacteria in the direct fermentation of food products, and capsular polysaccharides used in vaccines. Reviews on each of these topics are available in this volume.

Scientific Background

Microbiology and Genetics

PUTATIVE NATURAL ROLES OF MICROBIAL EXOPOLYMERS. While the focus of this review is the industrial use of microbial polysaccharides, an understanding of the biological roles of these molecules should lead to more rational control of their synthesis in industrial settings. Microbial exopolysaccharides are largely hypothesized to serve protective roles for the microorganism that produces them. While this hypothesis is logical, definitive experiments demonstrating the essential role in the microorganism's fitness and survival are still needed.

One role often attributed to exopolysaccharides is protection from dessication. The hydra-

Table 1. Present applications of microbial polysaccharides.

Polymer	Application
Xanthan	Emulsion stabilization and suspension agent in foods
	Foam stabilization in foods
	Crystallization inhibitor in foods
	Viscosity control in oil drilling mud and inkjet printing
Bacterial cellulose	Moisture retention in wound dressings
	High strength acoustic diaphragms in sound reproduction
Hyaluronic acid	Hydrating agent in cosmetics and pharmaceuticals
	Replacement for synovial fluid and vitreous humor in biomedicine
Emulsan	Emulsifier and vaccine adjuvant
Curdlan	Gelling agent in foods
Gellan	Gelling agent in foods
Pullulan	Food coatings
Various	Paper coating and water flocculant

Adapted from Sutherland (1998).

tion properties of exopolysaccharides clearly can allow a microorganism to survive drying and subsequent rehydration in industrial applications (Schnider-Keel et al., 2001). In the case of a *Nostoc* commune, expression of exopolysaccharides allowed survival over many years of dessication (Shirkey et al., 2000). The layer of exopolysaccharide would also likely affect the diffusion of nutrients into and waste products away from the cell. This may be especially important in antibiotic resistance of biofilms (Olson et al., 2002).

Evidence of the protective effect of exopolysaccharide is perhaps most clear in the case of pathogenic bacteria avoiding phagocytosis (Fernandez-Prada et al., 2003). This effect is likely a result of not only reduced opsonization of the microorganism, but also the masking of bacterial cell wall ligands that are recognized by the receptors of the phagocyte.

The mucoid properties of the exopolysaccharide capsules formed by many bacteria allow the adhesion and stabilization of biofilms and bacterial colonies. This manifests itself as an important step in the survival of bacteria in many scenarios including biofilm formation in periodontal disease (Kaplan et al., 2003), binding to host lectins in cystic fibrosis patients (von Bismarck et al., 2001), stabilization of the symbiosis of *Rhizobium* bacteria and legumes, and the fouling of pipelines (Fraysse et al., 2003).

COMMON METABOLIC PRECURSORS. The wide variety of exopolysaccharides requires an equally diverse pool of precursor molecules. The most basic of these compounds are energy-rich monosaccharides. Usually nucleoside diphosphate-modified monosaccharides serve this role, although nucleoside monophosphate sugars are utilized in some pathways (Steenbergen and Vimr, 2003). These monosaccharide-nucleoside diphosphates provide the basic assembly unit of the exopolysaccharide as well as the energy necessary for its synthesis. For the most part, the presence of a monosaccharide in an exopolysaccharide indicates the necessity of an analogous nucleoside diphosphate sugar. However, several interconversions of sugars can occur via mechanisms such as epimerization, oxidation, decarboxylation, reduction, and rearrangement.

Aside from the obvious need for activated monosaccharide components, exopolysaccharides often contain modified sugars or are decorated with several non-sugar components. O-methyl sugars have been described in a *Rhodococcus* strain (Neu et al., 1992), but the mechanism of synthesis and the identity of the precursors are not yet known. The chemical decoration of exopolysaccharide by various acyl groups requires activated forms of those groups to be generated by cellular metabolism. Acetyl CoA is required for the addition of acetyl groups in several systems (Leitao and Sa-Correia, 1993; Bossio et al., 1996), and it is likely that acyl CoA derivatives are required for more complicated acyl groups.

Most exopolysaccharides synthesized at the cell membrane are assumed to require a lipid acceptor for assembly. This is likely to be the bactoprenol involved in peptidoglycan and O-antigen synthesis, which has also been shown to be important in the synthesis of the capsular polysaccharide of group B streptococci (Rubens et al., 1993) and of serogroup B *Neisseria meningitidis* (Masson and Holbein, 1985). Phosphate groups may be added to the exopolysaccharide by a standard enzymatic phosphorylation reaction derived from ATP, but it is likely that the phosphate group is derived from the sugar nucleotide. The addition of sulfate groups and amino acids has been documented but not well characterized.

COMMON SYNTHETIC PATHWAYS. The most common pathway for exopolysaccharide synthesis occurs at the cell membrane or in the periplasm. A general scheme of exopolysaccharide synthesis is given in Fig. 1. The metabolic precursors discussed above are generated in the cytoplasm where they are likely used for other processes as well. The repeating sugar units of the exopolysaccharides are added to the growing polymer, likely linked to the membrane via undecaprenyl phosphate as a lipid carrier. Acyl modifications of the exopolysaccharide also likely happen at the cytoplasmic face of the membrane (or in the periplasm), prior to translocation of the polymer through the membrane. The mechanism of periplasmic synthesis is best

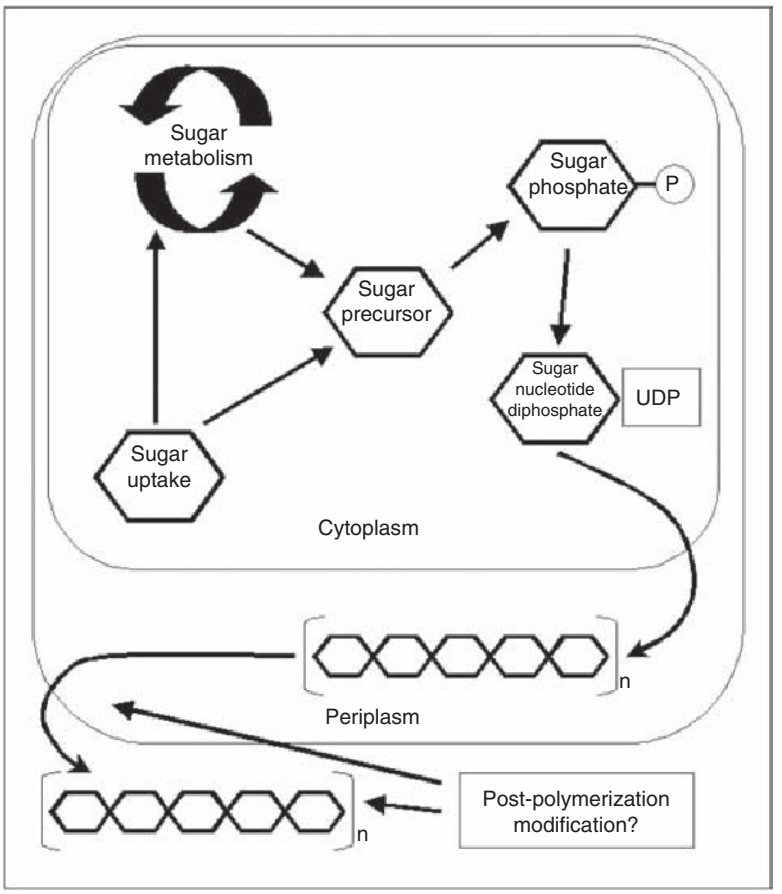

Fig. 1. General exopolysaccharide synthetic mechanism.

described for the *E. coli* K1 capsular polysaccharide (Bliss and Silver, 1997). While the exact mechanism of translocation of the exopolysaccharide is not entirely understood, several genes have been demonstrated to be required for the process (Vojnov et al., 1998; Drummelsmith, 2000; Smith, 2003).

In contrast to the complex of cytoplasmic and/or periplasmic synthesis of many exopolysaccharides, the extracellular synthesis of the levans and dextrans is relatively simple. The dextransucrase enzyme catalyzes the cleavage of the sucrose molecule, the energy source for the reaction, resulting in the addition of the glycosyl group to the growing dextran chain and the release of free fructose. Levansucrase similarly adds fructose to the growing chain of levan, releasing glucose from the sucrose substrate. Dextran synthesis has been demonstrated in nonhomologous cultures transformed with the dextransucrase gene (Neubauer et al., 2003). Levan has also been synthesized by recombinant organisms (Hettwer, 1998).

Bacterial alginate is unique among bacterial exopolysaccharides in that it is modified by a post-polymerization epimerization. Alginate is synthesized as a homopolymer of poly-D-mannuronic acid and subsequently modified by an extracellular epimerase, which converts a number of the mannose residues to L-guluronic acid. The epimerase has been identified in *Pseudomonas* (Gimmestad, 2003) and *Azotobacter* (Rehm et al., 1996).

REGULATION OF ENZYMATIC POLYMERIZATION. The first level of regulation of exopolysaccharide production is the chromosomal organization of the genes required for their synthesis. In most systems studied to date, the genes encoding the synthetic enzymes for a particular exopolysaccharide are contained in a single operon (Table 2). This organization into one or a few loci presumably allows activation of the entire synthetic machinery through one signal, as has been demonstrated in *Lactobacillus* (Lamothe et al., 2002). More complex genetic regulatory mechanisms have been described as well, including exopolysaccharide production dependent on quorum sensing in the alfalfa plant symbiont *Sinorhizobium meliloti* (Marketon et al., 2003) and cellulose production activated by cyclic diguanylic acid in *Acetobacter xylinum* (Weinhouse et al., 1997).

Table 2. Operon structure of synthetic enzymes responsible for exopolysaccharide production.

Species	Exopolysaccharide	No. of loci	Chromosomal or plasmid	Size of operon (kb)	Number of ORFs	Reference
Acetobacter xylinum	Cellulose	1	Chromosomal	9.5	4	Wong et al., 1990

Abbreviations: EPS, exopolysaccharide; and ORFs, open reading frames.

Precursor availability, whether it is the sugars or other necessary components, can clearly affect exopolysaccharide production (Mozzi et al., 2001). This is a complex area, as most of the metabolic precursors for exopolysaccharide production are also required for other cellular processes. This requires a great deal of study to fully understand how modification or disruption of a particular pathway might not only affect exopolysaccharide production, but also cellular metabolism and viability in general.

General Polysaccharide Structures

Microbial exopolysaccharides can most broadly be divided into the categories of hetero- and homopolysaccharides indicating the nature of the monomer repeat structure of the polymer chain. These polymers may be found attached to the outer suface of the cells or extruded into the extracellular space as soluble and insoluble materials. The nature and composition of branching affects many aspects of exopolymer behavior. Non-sugar components may also be present, usually in the form of amino acids and ester- and acyl-like organic acids.

While the universe of known microbial polysaccharide sugar residues is in excess of one hundred unique monomers (Kenne and Lindberg, 1983) and the number of branching structures unknown, in practice, most heteropolysaccharides of industrial interest tend to be regular structures with 2–8 repeating units composed of 2–4 distinct monomers (Sutherland, 2001). Most often, these monomers are the pyranose forms of the simple sugars D-glucose, D-galactose, and D-mannose with L-fucose and L-rhamnose also frequently present. Pentose sugars, while commonly found in eukaryotic organisms, are less frequently encountered in prokaryotic species (Sutherland, 1990). In contrast to the generally regular repeat unit structures, acyl substitutions in varying degrees are often observed in a variety of microbial poysaccharides. Decoration of chains may be regular or random, with acetate esters and pyruvate ketals most commonly observed. Alginates are the notable exception to these generalizations, having a random block repeat structure of D-mannuronic and L-guluronic acid residues in the main chain and being heavily acetylated on the D-mannuronic molecules (Sutherland, 2001).

The combination of different sugar monomers, their linkage, chain branching, and organic modification make for a wide variety of possible conformations. Each hexose can be α- or β-linked at one of the 2,3,4 or 6 positions to the proximal residue (Sutherland, 1990). Extensive compendia of polysaccharide structures are available (Kenne and Lindberg, 1983).

Common Analytic Techniques

Analysis of polysaccharide composition generally requires the reduction of the polymer to monomer via hydrolysis. Typically this involves the digestion of the polymer by acid hydrolysis; however, recombinantly prepared enzyme preparations are increasingly available (Mischnick, 1998). The resultant mixture of monomers may be analyzed by a variety of methods including thin layer chromatography (TLC), high performance liquid chromatography (HPLC) and gas-liquid chromatography (GLC), with GLC methods usually necessitating additional derivatization to ensure adequate volatility (Pierce, 1968). Naturally, much information regarding primary structure and the *in vivo* modification of monomers can be lost in the process of hydrolysis, and care must be taken to not chemically alter the monomeric sugar resides themselves. Specific removal or replacement or both of anticipated side chain substituents may be completed as necessary by chemical or enzymatic treatment. Such side groups, like the polymers themselves, are routinely sized using gel permeation chromatography (GPC), light scattering, and viscometric analysis.The determination of primary structure for an unknown polysaccharide molecule is a difficult analytic task. Methanolysis followed by hydrolysis has been the primary method used to determine the locations of linkages and side chains (Chaplin, 1982). Periodate oxidation is also commonly employed to deduce information regarding glycosidic linkages, since analysis is conducted by spectrophotometric means. Enzymatic digestion by residue specific hydrolyases, with subsequent analysis of the size and identity of resulting fragments, or stepwise digests may be used as well. Determination of the glycosidic linkage conformation can be made by optical rotation. ^{13}C and cross polarization (c.p.)/magic angle spinning (m.a.s.) nuclear magnetic resonance (NMR) have also been employed to characterize both composition and structural features in native and modified polymers (Duus et al., 2000). Matrix-assisted laser desorption/ionization mass spectromety (MALDI) is also increasingly used in the direct analysis of carbohydrate content and linkages, particularly in the area of glycoprotein analysis (Harvey, 1999).

Solution Properties

Many microbial polysaccharides form thick hydrocolloidal suspensions and gels in solution. Such gels, generally the result of extended hydrophilic macromolecular networks, are the principal reason for industrial interest (Nishinari et al., 2000). These properties are modulated in microbial polysaccharides by various chemical modifi-

cations (e.g., acetylation often observed in alginate and xanthan and chain branching) and by solvated cations that assist in the coordination of interactions between chains and gelation of generally anionic carbohydrate chains (Sutherland, 1994). Not surprisingly, temperature and pH are also critical factors, owing to the influence exerted on charge and chain flexibility.

The conformation of associated polymer chains in solution is often indirectly measured in terms of rheological properties, as these are often among the most important physical parameters in most applications of microbial exopolysaccharides. Viscometry and dynamic light scattering may be utilized to estimate effective molecular weight and particle size by various models (i.e., Mark Houwink, Flory, etc.). Atomic force microscopy (AFM) is also often used to investigate the chain conformations and secondary structural features of samples in hydrated and dehydrated states. The use of predictive molecular modeling of solution properties based on putative structure for small oligosaccharides in conjunction with NMR and x-ray data for more complex and flexible polysaccharides has also been reported (Bush et al., 1999; Brisson and Jennings, 2001; Burchard, 2001; Faber et al., 2002).

Solid State Properties

As most exopolysaccharides of industrial interest are utilized in water-based systems, the analysis of dried solids is less often reported in the literature. However, since eukaryotic structural carbohydrates such as cellulose, chitin, and chitosan have been extensively characterized, microbially derived materials have become studied by many of the same techniques (Bohn et al., 2000). Solid state structural analysis is most often performed using wide and small angle x-ray scattering (WAXS and SAXS), Fourier transform infrared spectroscopy (FTIR), scanning probe microscopy (SPM), scanning electron microscopy (SEM), and atomic force microscopy (AFM; Brant, 1999). Crystallinity and self-assembly of monomeric constituents into highly organized liquid crystalline phases and then often insoluble tertiary structures are of particular interest, since such behavior should further a predictive understanding of structural and biochemical influences on bulk material properties and give a means for the control of these behaviors.

Commercial Applications

Homopolysaccharides

DEXTRANS. A class of homopolymers primarily composed of α-1,4 linked D-glucopyranosyl repeating units, dextrans are produced by several species of bacteria. In some species, 1-2, 1-3, and 1-4 linkages as well as significant percentages of side chain branching are also observed. Polymers may be comprised of one type of linkage or of several of those listed. These linkages result in a family of polymers with varying solution properties of generally high molecular weight and neutral charge. Industrial production occurs mainly using *Leuconstoc mesenteroides*, which produces dextrans (relative molecular weight, 4–5 × 10^7 Da) extracellularly via the enzymatic polymerization of sucrose by dextransucrase with approximately 95% 1-6 and 5% 1-3 linkages (Sutherland, 1990). Polymerization is known to occur in one-residue increments, although the exact mechanism of chain elongation remains unclear.

The initial application of microbial dextran was as a blood plasma extender. Since then, a variety of dextrans and post-processed materials have been developed. Sephadex, a commercial separations medium marketed by Amersham Biosciences, utilizes a crosslinked form of this polymer. Dextran sulfate is also sometimes employed as an anti-coagulant and iron transporter (Monsan et al., 2001). Crosslinked dextran gels have been investigated as a biodegradable material for the controlled release of pharmaceuticals (Gumagalieva et al., 1998; Cascone et al., 2001). Dextran conjugates may also be useful in the modulation of the pharmacokinetics and targeting of some injectable pharmaceutical therapies (Mehvar, 2000).

Mutan and alternan are two additional forms of carbohydrate via two additional glucansucrase enzymes produced by some strains of *L. mesenteroides*. Both are insoluble polymers mainly comprised of 1-3 and 1-6 linkages, and while mutan has been identified as a component of bacterial adhesion in dental plaque, no commercial applications of either currently exist (Monsan et al., 2001).

CURDLAN. A β-1,3 linked D-glucopyranosyl homopolymer, curdlan is produced by a number of bacterial species; however, production is generally from *Alcaligenes faecalis*. Curdlan tends to be a rather simple homopolymer of low molecular weight (<100 kDa) and low water solubility which gels above 55°C, forms a firm resilient gel at 100°C, and is a thermally irreversible gel above 120°C owing, in part, to triple helical rearrangement of the polymer (Nishinari et al., 2000; Zhang et al., 2002). Acetyl derivatives of curdlan have been patented for separations applications, and sulfate derivatives have been tested for antiviral and anticoagulant applications (Nakashima et al., 1987; Hatanaka et al., 1991; Sutherland, 1998). Curdlan is also used as a food additive (i.e., coating and texturizer) in Japan.

CELLULOSE. A linear homopolymer of β-1,4 linked D-glucose, cellulose is made in abundance in plants and in several genera of bacteria including *Acetobacter*, *Achromobacter*, *Aerobacter*, *Agrobacterium*, *Alcaligenes*, *Pseudomonas*, *Rhizobium*, *Sarcina* and *Zoogloea*. The principal microbial source of this polymer is the organism *Gluconacetobacter xylinum*, which produces copious amounts of polymer in static culture on a variety of carbon sources. The polymerization of glucose proceeds as cellobiosyl subunits in a membrane associated process. Bacterial cellulose is extruded from the cell as water insoluble fibrils that rapidly assemble into highly structured helical fibers. Mats of these fibers, which form at the gas liquid interface of cultures, are exceptionally hydrophilic and also have higher surface area and tensile strength than plant-derived cellulose has (Yamanaka et al., 1989).

Bacterial cellulose has found medical application as a wound healing skin substitute and dental anti-adhesion material and industrial use in acoustic diaphragms and as inert filler, paper additive, thickener, and insulator material. In addition, bacterial cellulose is the basis of the food Nata de Coco, which enjoys some popularity in Asia (Jonas and Farah, 1998; Vandamme et al., 1998). Chemically modified bacterial cellulose derivatives have been investigated, but the cost differential between bacterial and plant derived polymer is currently prohibitive to wide commercial application.

MISCELLANEOUS: LEVAN AND POLYGALACTOSAMINE. A large number of novel polysaccharide components of exopolysaccharide matrix from a variety of organisms has been identified and studied. Only a few other homopolymers have received industrial attention.

Levan is a neutral β-2,6 linked D-fructofuranosyl homopolymer made extracellularly by a variety of bacterial species through the action of levansucrase on sucrose. It has no established commercial application, but investigations into its production have been conducted and recombinant levansucrase has been successfully demonstrated (Belghith et al., 1996; Song et al., 1996).

Polygalactosamine is a cationic α-1,4 linked polygalactosamine homopolymer. It is generally water insoluble and is sometimes acetylated. Its cationic nature has led to investigations of its suitability as a potential adjuvant coating for targeted DNA uptake in gene therapy and as a conjugate for targeted drug delivery (Ouchi et al., 1994; Sato et al., 1996).

Heteropolysaccharides

XANTHAN. An anionic heteropolymer based on the β-1,4-D-glucopyanosyl backbone of cellulose, xanthan has a five-glucose repeat unit and every other residue contains a regular side chain of two D-mannose and D-glucuronic acid residues, with the glucuronic acid residue in the center of the side chain. The terminal mannose sugars are modified with pyruvic ketal groups at a frequency of approximately 50% and the mannose residue nearest the main chain is acetylated at C-6 with similar regularity. Typical molecular weights are between 10^6 and 10^7 Da (Garcia-Ochoa et al., 2000). Xanthan is synthesized by *Xanthamonas campestris* in stirred fermentations on a variety of carbon sources and using a number of mutants and cultivation techniques which have a significant effect on the side chain density, degree of pyruvation and acetylation and, thus, on the solution properties of the gel.

Xanthan is arguably the most important of the microbial polysaccharides from an industrial perspective, perhaps because it was among the first commercialized, but also because of its wide cost-effective versatility as a viscosifier and texturizer in food and health care applications and consequently its large market. Although developed at the United States Department of Agriculture (USDA) in the 1950s, xanthan continues to be extensively developed and marketed by Kelco. In addition, a notably broad academic literature on production optimization, metabolic engineering, and reactor modeling exists for xanthan fermentations. In fact, many of the principles developed for xanthan processes have been applied to many exopolysaccharide and other fermented products. Xanthan is approved for use as a food additive by the FDA, having obtained generally recognized as safe (GRAS) status, and is used in industrial processes such as ceramic glaze viscosification and applications such as emulsifier in enhanced petroleum recovery (Garcia-Ochoa et al., 2000).

GELLAN, WELAN AND RHAMSAN. A linear polymer of tetrasaccharide repeats, gellan is produced from *Sphingomonas paucimobilis*. The linear polymer of approximately 500 kDa has O-acetyl and glyceryl substituents. The degree of acylation affects the physical properties of gels formed from this exopolysaccharide. Gellan forms thermoreversible gels and has been approved for use in food as a gelling agent. Welan and rhamsan are related polymers with differing side chains.

ALGINATE. Synthesized initially as a polymannuronic acid homopolymer, bacterial alginate is converted by an extracellular epimerase to a heteropolymer of D-mannuronic acid and L-guluronic acid. Alginates currently used in commercial applications are derived from algal sources. However, the potential for significant control over polymer production in a bacterial system has led to significant research of alginate

genetics and production in *Azotobacter* (Rehm et al., 1996; Vazquez et al., 1999) and *Pseudomonas* (Leitao et al., 1993; Gimmestad et al., 2003). While the alginate from *Pseudomonas aeruginosa* has been of interest owing to its association with infection in cystic fibrosis patients, the *Azotobacter* alginate has more potential commercially because of its relatively stable output. Alginate has been studied for a wide array of potential applications including cell encapsulation, drug delivery, wound healing, and tissue engineering.

HYALURONIC ACID. Bacterial hyaluronic acid is apparently identical to that produced by eukaryotic cells. It is composed of 1,4-β-linked disaccharides of D-glucuronosyl-1,3-β-*N*-acetyl-D-glucosamine. Bacterial hyaluronic acid has been commercialized for several applications including cosmetics and a coating for prostheses in veterinary medicine. Future applications may include tissue engineering and drug delivery.

SUCCINOGLYCAN. An anionic polysaccharide, succinoglycan is composed of an octasaccharide repeat unit with three acyl groups (acetate, succinate esters, and pyruvate ketals). The exopolysaccharide produced by *Rhizobium* species contains a 7 : 1 molar ratio of D-glucose to D-galactose and a stoichiometric amount of the pyruvate, which gives it its anionic properties. The succinoglycan produced in *Rhizobium* species is vital for its relationship with its plant symbiont.

EMULSAN. An anionic exopolysaccharide, emulsan is produced from a variety of hydrocarbon sources including fatty acids and ethanol by the Gram-negative bacterium, *A. calcoaceticus* strain RAG-1. Emulsan forms an extracellular cell-associated capsule, which is subsequently released into the fermentation broth. The polysaccharide main chain contains three aminosugars, D-galactosamine, D-galactosaminouronic acid, and a dideoxydiamino hexose, in the ratio 1 : 1 : 1 (Belsky et al., 1979; Gorkovenko et al., 1997). The polymer has O-acyl and N-acyl bound side chain fatty acids ranging in chain length from C10 to C22. These fatty acid substituents constitute 5–23% (wt/wt) of the polymer (Gorkovenko et al., 1997). The emulsan amino groups are either acetylated or covalently linked by an amide bond to 3-hydroxybutyric acid. The combination of the hydrophilic anionic sugar main chain repeat units along with the hydrophobic side groups leads to the amphipathic behavior of emulsan and, therefore, its ability to form stable oil-in-water emulsions. The polymer has been used successfully in environmental cleanup and degradation studies to disperse polluting oils because of its amphipathic structure (Gutnick and Rosenberg, 1977). Emulsions formed with emulsan have been shown to be stable for months and can be broken when desired by enzymatic degradation or at elevated temperatures (Shoham and Rosenberg, 1983; Gutnick and Shabtai, 1987a; Gutnick and Shabtai, 1987b). Aside from its potential industrial applications, more recently its potential use in biomedical applications has been the focus of research (Panilaitis et al., 2002).

Areas of Research and Development

Research and development in the arena of microbial polysaccharide production proceeds in two major categories. The first is the ongoing optimization of cultivation conditions for the efficient production of polymers that are often quite expensive in comparison to natural fibers and synthetic thermopolymers. While traditional fermentation optimization literature predominates, recombinant enzyme and cell free systems are also areas of focus. The second area of work is the screening and identification of novel polysaccharides and, in the search for additional polymers of interest, the genetic modification of coenzymes. Predictability and control in this effort are slowed by a limited understanding of structure-function relationships, because interactions among systems of polymers with varying degrees of polymerization and modification are complex. Structure-function aspects and solution dynamics of polymers in general are widely studied and this literature provides some roadmaps for the biotechnologist.

Fermentation Methods and Issues

The recovery of microbial polysaccharides from fermentation broth is a highly variable process dependent on chain length, surface charge, and end-use purity specification of the polymeric product. Typically, cellular materials are removed by centifugation or filtration. Polymer is then purified by a variety of means including ion exchange chromatography (IEC) and alcohol precipitation.

Genetic Modification and Customization

After years of optimizing culture conditions and selecting for high-level producers, the natural limits of polymer production are often reached. With the significant advances in molecular biology, the focus now turns to modifying the important synthetic and regulatory pathways of exopolysaccharide synthesis at the genetic level. The method of mutant generation is commonly transposon insertion, although more traditional

methods are also utilized. In some specific cases, the expression level of specific enzymes has been altered to enhance the levels of necessary metabolic precursors (Levander et al., 2002; Boels et al., 2003). Modifications have targeted not only the yield of exopolysaccharides, but also specific structural modification. Emulsan structural analogs have been produced from transposon-mutagenized *Acinetobacter calcoaceticus* RAG-1 that vary not only in yield, but also in the modification of the fatty acid acyl chains that decorate the sugar backbone (Johri et al., 2002). It is likely that future improvements in exopolysaccharide yield and functionality will be due to such specific genetic modifications rather than gross mutagenesis.

Prospects

Important future advancements in polysaccharide yields and industrialization will build upon the foundation of genetics touched on above as well as on more rapid and specific screening approaches to identify novel structures suited for selective functional attributes. Perhaps in the long term, an ultimate aim will be template-based synthesis of polysaccharides to explore the limits of the relationship between chain length and distribution and function. Additionally, novel approaches employing traditional polysaccharides that are chemically or enzymatically functionalized in vitro will also become interesting directions in the field. In all of the above scenarios, industrial production will depend on novelty of function coupled with costs of production. In the broadest perspective, the exploitation of polysaccharides to fulfill a wide range of materials science and engineering needs has lagged in comparison to that of proteins. With rapid advancements in genetics, analytical tools, and screening methods, this gap should begin to close and new avenues in the field should continue to expand.

CHAPTER 3.4

Bacterial Enzymes

WIM J. QUAX

Introduction

In the living world, each chemical reaction is catalyzed by its own enzyme. Enzymes exhibit a high specificity, as they are able to discriminate between slightly different substrate molecules. Furthermore, they have the ability to operate at moderate temperature, pressure and pH, which makes them attractive catalysts for industrial and household conversion processes. The first reports on the industrial use of enzyme products go back to the beginning of the last century. It was the German scientist Röhm who introduced the use of bovine pancreas extracts for the removal of stains in dirty clothing (Röhm, 1915; Fig. 1). Around the same time, the Laboratoire Amylo in France experimented with the use of extract from *Bacillus* for conversion of starch into sugars (Fig. 2). As a result, the company Rapidase (Seclin, France), which is now part of the life science division of DSM, was formed. With the development of microbial fermentations in the second half of the last century, the number of industrial processes performed by enzymes and the amount of enzymes produced have increased sharply. At present, a renewed worldwide research effort has been directed to identifying more sustainable and environmentally friendly biocatalytic processes. The availability of highly specific and cheap enzymes resulting from genetic and protein engineering has been very instrumental in reviving interest in the industrial application of enzymes.

Most classically used industrial enzymes are hydrolytic (proteolytic, amylolytic, or lipolytic). Hydrolytic enzymes hardly require any cofactors, which allows their application in a great variety of conditions. These enzymes are usually separated from the cell broth after fermentation and formulated in more or less high concentrations. Recently, more specialized bioconversions have been developed in which enzymatic activity is maintained only by special cofactors that must be regenerated or, even worse, by living cells. In this chapter, the emphasis will be on bacterial enzymes that can be used in isolated form.

The organization of this chapter has focused on application. Owing to the versatility and stability of hydrolytic enzymes, the same enzyme may be used in totally different parts of industrial processes. Table 1 summarizes the current use of enzymes in various industry and household applications. The data are compiled from information provided by enzyme producers, customers, and industry organizations and from information acquired as a result of my involvement with industrial enzyme production for many years. As it relates to products of commercial importance, access to the data is not always possible, and relating the biochemical and genetic characteristics of production strains, which are usually proprietary, to better described strains in the literature is sometimes difficult. Nevertheless, this manuscript should provide an overview of the importance of bacterial enzymes for sustainable and efficient conversion in industrial processes. Of the $1.8 billion annual world sales of industrial enzymes, about 50% are sales of bacterial enzymes and most of the remaining 50% are sales of fungal enzymes.

Scientific Background: the Source of Enzymes

Historically, the selection of microorganisms that produce enzymes has been empirical, starting with samples from very diverse natural sources. Cultures enriched by growth on substrates were used to inoculate fermentations. In a later stage, pure bacterial strains were selected. Intellectual property protections associated with bioprocesses have hampered the taxonomical characterization of industrially used strains. For the same reason, it is not always possible to trace the origin and history of currently used organisms. Once it became possible to protect man-made bacterial strains by a patent (Chakrabarty, 1981), the taxonomy of the bacterial strains became a key element in the development of industrial enzymes. Ever since, the 16S rRNA sequence has been routinely determined for every bacterial

KAISERLICHES PATENTAMT.

AUSGEGEBEN DEN 4. MAI 1915.

PATENTSCHRIFT

— № 283923 —

KLASSE 8i. GRUPPE 5.

DR. OTTO RÖHM IN DARMSTADT.

Verfahren zum Reinigen von Wäschestücken aller Art.

Patentiert im Deutschen Reiche vom 12. Dezember 1913 ab.

Die tryptischen Enzyme haben bekanntlich die Eigenschaft, Eiweiß und Fett abzubauen. Von der Erwägung ausgehend, daß der Schmutz der menschlichen Kleidungsstücke aller Art zu einem großen Teil aus Fett- und Eiweißresten besteht, werden der Waschbrühe tryptische Enzyme zugesetzt. Es zeigte sich, daß die Wäsche viel rascher, mit viel geringerer Kraftanstrengung und bei einer weit unter dem Siedepunkt des Wassers liegenden Temperatur rein wurde und ein viel schöneres Aussehen erhielt, als ohne Zusatz der Enzyme. Auch kommt man mit weniger Seife aus. Der Hauptvorteil der Verwendung von Enzymen gegenüber anderen, namentlich alkalischen Zusätzen beruht darin, daß sie das Gewebe nicht im allermindesten angreifen und auch für die Hände der Wäscherinnen vollkommen unschädlich sind.

Die benötigten Mengen Enzym sind äußerst gering. Für 100 l Waschbrühe genügen z. B. 2 g Pankreatin.

Weiter wurde gefunden, daß die tryptischen Enzyme auch äußerst wichtige Toilettenmittel sind. Denn bekanntlich scheidet der Körper durch die Hauptporen alle möglichen Eiweiß- und Fettreste ab, die sich teilweise in den Hauptporen festsetzen. Die tryptischen Enzyme sind nun hervorragend geeignet, diese Stoffe löslich zu machen. Zusatz von Enzymen zum Waschwasser macht das Wasser weich und übt auf die Haut einen außerordentlich wohltätigen Einfluß aus. Die Haut wird rein und auffallend weich und zart, und obendrein ist der Seifenverbrauch geringer.

Als Zusatz zum Wasch- und Badewasser genügt 0,5 bis 1 g Pankreatin auf 100 l Wasser.

Da derart kleine Mengen schlecht zu handhaben sind, empfiehlt es sich, die Enzyme für den praktischen Gebrauch, sei es als Wasch- oder Toilettenmittel, entsprechend zu verdünnen. Geeignet hierzu ist jedes indifferente, leicht lösliche Mittel, z. B. Kochsalz u. dgl.

PATENT-ANSPRÜCHE:

1. Verfahren zum Reinigen von Wäschestücken aller Art, gekennzeichnet durch den Zusatz tryptischer Enzyme, wie Pankreatin, zur Waschbrühe.

2. Anwendung tryptischer Enzyme, wie Pankreatin, zur Herstellung von Wasch- und Toilettenmitteln.

strain producing an enzyme with interesting properties (Jones et al., 1998b). Later, the DNA sequence of the enzyme-encoding gene and its corresponding amino acid sequence became the key subjects for patent protection (Yamagata and Udaka, 1994; Outtrup et al., 1998; van Solingen et al., 2001) because genetic engineering eliminated restrictions on enzyme production (i.e., the enzymes could be produced by both the original host bacterium and specialized expression hosts).

In general, early important criteria for evaluating enzyme technology included the ease of fermentation and recovery, lack of adverse side-products, yield, and finally the properties of the enzyme (see Table 2). It is no surprise that this emphasis on easily recovered enzymes has resulted in industrial production organisms that are predominantly secreting organisms. Gram-positive species with only a single membrane are highly represented among enzyme host cells. Especially bacilli known for their high secretory capability are often used. Nevertheless, in the absence of good alternatives, some interesting enzymes such as glucose isomerases expressed in *Streptomyces* (Jorgensen et al., 1988) are recovered from the cytoplasm of bacteria. Other products are secreted from Gram-negative organisms such as lipases from *Pseudomonas* (Gerritse et al., 1998a).

Commercial Applications

Starch

Starch, the primary storage polymer in higher plants, consists of a mixture of amylose (15–30% w/w) and amylopectin (70–85% w/w). Amylose is composed of α-1,4-linked glucose units linked in linear chains of molecular weight ca. 60,000–800,000. Amylopectin is a branched polymer containing α-1,6 branch points every 24–30 glucose units (Fig. 3); its molecular weight may be as high as 100 million (Buleon et al., 1998). Corn (maize) starch represents 75% of the world starch production. Virtually all of the 20 million

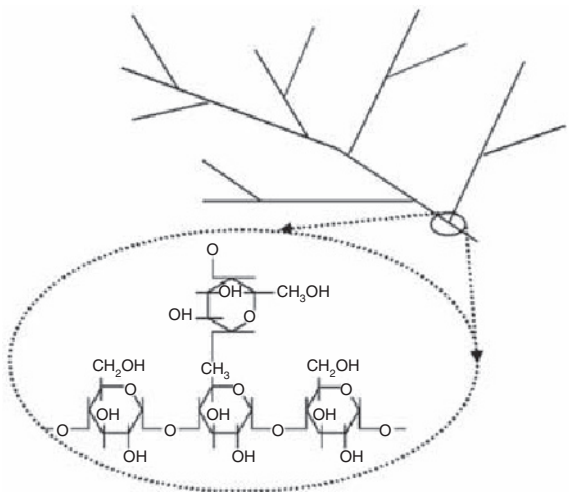

Fig. 3. Starch and actions of amylases on amylopectin. The 1,4 bonds (horizontal) are cleaved by α-amylases and the 1,6 bonds (vertical), which are formed every 24–30 glucose units, can be cleaved by pullulanase (debranching enzyme).

ton world production of corn starch (Economic Research Service, personal communication) is converted into glucose by a two-step enzyme catalyzed process involving 1) liquefaction of solid starch with an endoamylase into dextrins consisting of 7–10 molecules of glucose and 2) saccharification of the resulting liquefied starch with an exoamylase (glucoamylase) into single glucose monomers. The industrially most important endoamylases are α-amylases isolated from bacilli (Welker and Campbell, 1967a; Aiba et al., 1983; Yuuki et al., 1985). The glucoamylase with the best industrial specifications is produced from the fungus *Aspergillus niger* (Reilly, 1979). The produced glucose is used in more or less equal shares for the production of concentrated dextrose syrups, fuel ethanol, and high-fructose corn syrup.

Amylases

α-Amylase (EC 3.2.1.1) hydrolyzes starch, glycogen, and related polysaccharides by cleaving internal α-1,4-glucosidic bonds at random. The reports on the industrial use of bacterial amylase go back to the early 1920s, with a product trade-named "Rapidase," marketed by a European company with the same name. This enzyme, introduced to replace the acid hydrolysis process, which suffered from large salt loads and extreme yield losses, has long been classified as a product of *Bacillus subtilis*. Taxonomic data of the 1970s have revealed, however, that the production organism is a related but distinct species nowadays known as *Bacillus amyloliquefaciens* (Welker and Campbell, 1967b). Notably the amylase (AmyE) from *Bacillus subtilis* 168 has no liquefying activity at all and is in fact unrelated. In the classical process, starch is first heated in a jet cooking treatment that serves to open up the starch granules for gelatinization, and after cooling the mixture to 60°C, the α-amylase is added to the starch.

In the early 1980s, a major change was introduced in the industry. Now the enzyme is added during the first step of the starch degradation process, and gelatinization occurs at high temperature (up to 110°C), allowing the liquefaction during the steam explosion step. This has speeded up hydrolysis rates and decreased conversion costs significantly. The introduction of the more thermostable α-amylase from *Bacillus licheniformis* has been crucial for this improvement (Outtrup and Aunstrup, 1975; Chandra et al., 1980; Edman et al., 1999). Next to the amylase from *Bacillus licheniformis*, the enzyme from *Bacillus stearothermophilus* has been introduced for industrial use. This enzyme, with stability slightly higher than that of the *Bacillus licheniformis* amylase, however, has never been widely used, since it generates maltodextrins in a size distribution that is unfavorable for the subsequent glucoamylase treatment. In an effort to combine the best properties of these two amylases, chimeric enzymes formed of the NH_2-terminal portion of *Bacillus stearothermophilus* α-amylase and the COOH-terminal portion of *Bacillus licheniformis* α-amylase have been made (Gray et al., 1986). The hybrid enzyme molecules, however, were shown to be less stable than each of the parent wildtype α-amylases. Finally, an enzyme mixture composed of the amylases from *Bacillus licheniformis* and *Bacillus stearothermophilus* was introduced with more success. Nowadays most commercial amylases are produced from a small subgroup of *Bacillus* species such as *Bacillus amyloliquefaciens*, *Bacillus coagulans*, *Bacillus licheniformis*, or *Bacillus stearothermophilus*. These enzymes show a high degree of homology and similarity (Yuuki et al., 1985; Nakajima et al., 1986).

Thermostability, pattern of breakdown into dextrins, ease of production, and activity at low pH (<6) are important criteria used industrially for choosing amylases. In recent years, the amylases in commercial use have been optimized by protein engineering and directed evolution. Enzyme properties such as heat stability, substrate specificity, or performance at different pH have been altered (Quax et al., 1991a; see also Future Prospects in this Chapter). The generation of engineered variants and the availability of the corresponding cloned genes have inspired the development of host strains genetically engineered to optimize expression of amylases. To optimize yields in fermentation processes, classical mutagenesis was used to develop industrial strains for many decades, and much effort was

made to develop transformation protocols and genetically stable multicopy systems for industrial host strains such as *Bacillus licheniformis* (Sanders et al., 1985). For efficiency and regulatory reasons, host strains of the same species or genus from which the α-amylase is derived are preferred (Jorgensen and Jorgensen, 1993). Particularly for the production of mutant amylases, a *Bacillus licheniformis* strain without a wildtype α-amylase gene and preferably a strain without other enzymatic activities such as proteases is used (Quax et al., 1991b). The α-amylases are produced throughout fermentation as a precursor with a signal sequence that is cleaved off during secretion, and secretion facilitates recovery. As a matter of fact, the secretion of amylase is so efficient that a potent expression/secretion system based on *Bacillus licheniformis* strain T9 and the amylase expression signals has been developed. This host strain has been at the basis of the PlugBug® concept that was introduced by Gist-brocades in the late 1980s (Quax et al., 1993). This system has been used to produce high amounts of both mutant α-amylases and human interleukin-3 (Van Leen et al., 1991).

Apart from the use of α-amylases for the production of sweeteners, the enzyme has also been applied in fuel ethanol production from liquefied starch (Kosaric et al., 1983). Though the demand for fuel ethanol is fluctuating, fuel ethanol has the potential to become a major product of corn starch and concomitant growth of the amylase supply will be required.

Isomerases A major part of the glucose produced from starch liquefaction and saccharification is processed further into high fructose corn syrup (HFCS). Eight million tons are produced worldwide (Economic Research Service, personal communication). Glucose isomerases (EC 5.3.1.5) catalyze the reversible isomerization of glucose to fructose. Fructose is now commonly used as a sugar substitute because it is sweeter than sucrose or glucose. Many microorganisms are known to produce glucose isomerase; see for example the review article by Wen-Pin Chen (1980), which lists a large number of microorganisms capable of producing glucose isomerase. The best producers of industrial glucose isomerases are from the Actinomyces group including *Streptomyces rubiginosis*, *Actinoplanes missouriensis* and *Ampullariella* spp. (Quax et al., 1991b; Wong et al., 1991; Saari et al., 1997).

Activity on glucose (these enzymes are in fact xylose isomerases), no need for heavy metal cofactors (e.g., cobalt), amenability to immobilization, thermal stability (process conditions are at 55°C), and ease of production are the most important features of glucose isomerases. Generally, the naturally occurring glucose isomerases also show a high affinity for sugars other than glucose, such as D-xylose, D-ribose and L-arabinose. As a matter of fact, the K_m values for xylose are generally significantly lower and the V_{max} values usually higher than those for glucose, which is reflected in the official name of the enzyme (D-xylose ketol isomerase; EC 5.3.1.5). The enzyme causes glucose isomerization to fructose until about a 1:1 equilibrium mixture (the ratio present in natural sucrose) is formed, and the product has the same sweetness as sucrose. Because the enzyme is not secreted, its cost of production is relatively high. Therefore glucose isomerase is immobilized in column reactors, allowing prolonged use of one batch of enzyme. Typically the reactors operate for 60–100 days of continuous conversion at 55–60°C.

Glucose isomerase requires a bivalent cation such as Mg^{+2}, Co^{+2}, or Mn^{+2} for its catalytic activity. Determination of three-dimensional (3D) structures of different glucose isomerases has revealed the presence of two metal ions in the monomeric unit (Kreft et al., 1983; Farber et al., 1987; Henrick et al., 1987). Apart from a role in the catalytic mechanism, bivalent cations are also reported to increase the thermostability of some glucose isomerases (Callens et al., 1988). Although the pH optimum of glucose isomerases is usually 7.0–9.0, use of glucose isomerase at lower pH is beneficial for the following reasons: 1) under alkaline conditions, the formation of colored byproducts and a nonmetabolizable sugar (D-psicose) is a problem, and 2) the process step preceding the isomerization is performed at pH 4.5 (Roels and Tilburg, 1979). Despite an extensive screening of many microorganisms by industry researchers for a glucose isomerase with a higher activity at lower pH (Van Straten et al., 1997), no novel commercial glucose isomerase has been found.

Protein engineering has been used with more success to obtain glucose isomerases with a lower pH optimum (Drummond et al., 1989; Luiten et al., 1990; Zhu et al., 2000). The mutation of lysine253 into arginine253 of the isomerase from *Actinoplanes missouriensis* has almost doubled the operation time of the immobilized product under industrial conditions (Quax et al., 1991b; Fig. 4). In addition, technical optimizations such as an improved immobilization technique have enhanced the performance of traditional glucose isomerases such as that produced from *Streptomyces murinus* (Jorgensen et al., 1988). The mutants by definition are produced in genetically modified host strains. Also the classical nonmodified versions of the enzymes are nowadays being produced efficiently in nonsecreted form in genetically modified *Streptomyces* host cells. However, the exact nature of the strains and the

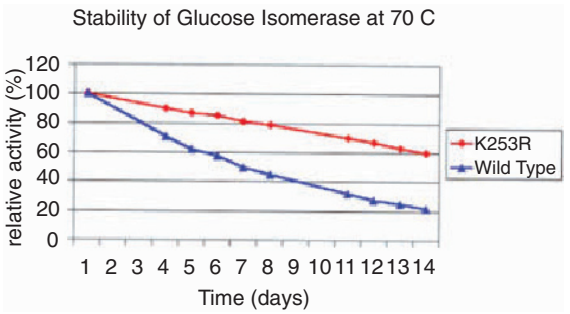

Fig. 4. The application test of protein engineered, thermostable glucose isomerase. The activity of immobilized enzyme is plotted as a function of time. The stability at 70°C indicates how the enzymes will behave under industrial conditions. The variant Lys253Arg of *Actinoplanes missouriensis* glucose isomerase has been shown to have (also under industrial conditions) a doubled half-life.

genetic constructions used by industry for these purposes are poorly documented.

PULLULANASES AND CYCLODEXTRIN-GLUCANOTRANSFERASES The endoamylases cyclomaltodextrinase (CGTase, EC 3.2.1.54), maltogenic amylase (EC 3. 2.1.133), and neopullulanase (EC 3.2.1.135) are minor enzymes capable of hydrolyzing two or three of the following: cyclomaltodextrins, pullulan, and starch. These enzymes hydrolyze cyclomaltodextrins and starch to maltose, and pullulan to panose, by cleavage of α-1,4 glycosidic bonds (see Fig. 3), whereas α-amylases are essentially inactive on cyclomaltodextrins and pullulan. Uniquely, pullulanases are also able to cleave the α-1,6 bonds (see Fig. 3), which makes them especially important for completely converting starch into glucose monomers. Pullulanases have been described from many species, but the enzyme from *Bacillus acidopullolyticus* seems to be specially suited for use in the starch processing industry (Kelly et al., 1994).

The cyclodextrins produced from glucose have applications ranging from the formulation of pharmaceuticals to surfactants (solubility enhancers; Hesselink et al., 1989; Albers and Muller, 1995). The right endoamylase for cyclodextrin production should act quickly and yield the desired product spectrum at high temperatures and low pH. The enzymes from *Bacillus coagulans* and *Bacillus circulans* are well known in the market (Kitahata et al., 1983; Hofmann et al., 1989). Recently, variants of cyclodextrin-glucanotransferases (CGTases) with an altered cyclodextrin product spectrum have been engineered by mutagenesis of specific residues (Norris et al., 1983; Wind et al., 1998).

Detergents

PROTEASES Subtilisins (EC 3.4.21.62), a large class of microbial serine proteases, are responsible for the breakthrough in industrial enzyme development. As early as 1959, the Swiss company Gebränder Schnyder AG marketed the first detergent powder with a protease produced from a *Bacillus* strain under the name Bio 40. Schweizerische Ferment AG in Basel delivered the protease. The name of the enzyme, subtilisin, refers to the producing organism *Bacillus subtilis*. In 1963, the Dutch company Kortmann and Schulte marketed the first bacterial-enzyme cleaning product (Biotex® with Alcalase®) and it became a big success. Alcalase®, the major extracellular serine protease from *Bacillus licheniformis*, was manufactured by the Danish company Novo (now Novozymes). Between 1965 and 1966, the big soap producers (Procter and Gamble, Unilever, Colgate, and Henkel) realized the potential of the hydrolytic action of bacterial protease in removing protein-based stains and they began adding Alcalase® and a similar product, Maxatase®, to their major detergent brands. This has led to the creation of a worldwide industrial enzyme market based on *Bacillus licheniformis* fermentation. Proteases hydrolyze the peptide bonds of proteins staining fabric, releasing smaller polypeptides and individual amino acid units. In 1969, a major drawback (fatal allergic reactions of employees exposed to dust set free during enzyme production) became apparent. Thanks to improved dust-free formulations, the enzyme industry was able to recover. To satisfy the desire to lower the temperature and concomitantly increase the alkalinity of laundry processes, extreme alkaline proteases (Maxacal® originating from *Bacillus alcalophilus* [Van Eekelen et al., 1988; Van der Laan et al., 1991] by Gist-brocades and Savinase® from *Bacillus lentus* [Betzel et al., 1988] by Novo-Nordisk) were introduced into the market in the early 1980s. Interestingly, the gene sequences showed that these proteases differed by only a single amino acid. Recently, the strain producing Savinase® has been reclassified as *Bacillus clausii* (Christiansen et al., 2002). The gene for the Alcalase® serine protease, also known as Carlsberg subtilisin, was cloned in 1985 (Jacobs et al., 1985). The availability of the cloned genes and detailed 3D structures of various subtilisin molecules (Drenth et al., 1972; McPhalen and James, 1988; Van der Laan et al., 1992) has facilitated protein-engineered improvements in enzymes and their adaptation to the detergent matrix. More stable variants and especially more bleach-stable variants, which were obtained by substituting the methionine residue next to the active

site serine, are dominating the marketplace today (Estell et al., 1985; Van Eekelen et al., 1989). For liquid detergent application, the more neutral subtilisin BPN-P originating from *Bacillus amyloliquefaciens* has been the product of choice for many years. In the United States, about 50% of liquid detergents and 25% of powder detergents contain proteases for improved cleaning. In Europe where powder detergents are more popular, virtually all brands have protease additives.

Lipases After the successful introduction of proteases for the removal of proteinaceous stains in laundry detergents, the next challenge was the development of lipases for the removal of greasy stains. The search for suitable lipases however turned out to be far more difficult than the introduction of proteases.

Detergent lipases were selected according to the following criteria: a) broad activity on a variety of fats and lipids, b) stability in alkaline detergent formulations, c) sufficient solubility in water to soak into fabrics, d) compatibility with proteases present in detergent formulations, and e) ease of production. The first lipase introduced in detergent powder is a lipase of fungal origin that fits well with criteria c) and e). However, owing to the acidophilic nature of fungi, the compatibility of their lipases with the alkaline conditions in detergents is poor. Therefore bacterial lipases (EC 3.1.1.3) originating from *Pseudomonas* species have received much attention. Especially the lipase from *Pseudomonas alcaligenes* has an excellent activity in the pH range compatible with detergent conditions. Criterion e) is however far more problematic for fungal lipase production. The expression in heterologous host strains such as *Bacillus* or *Escherichia coli* turned out to be impossible because a lipase-specific chaperone Lif (El-Khattabi et al., 1999) or LipB was required. Furthermore the lipase is secreted via the terminal branch of the general secretion pathway (Xcp-machinery), which involves very specific interactions (for a review, see Filloux et al., 1998; Fig. 5). Apart from the expression yield also the recovery of *Pseudomonas* lipases from the fermentation broth requires special processes owing to the hydrophobic nature of lipases and the presence of lipopolysaccharides. Despite these obstacles, the lipase from *Pseudomonas alcaligenes* was introduced as a detergent additive in 1995 by Gist-brocades under the trade name Lipomax® (Gerritse et al., 1998b; Cox et al., 2001). As a result of a stepwise improvement of the production strain and fermentation process, commercially viable yields of lipase were obtained (Gerritse et al., 1998a, 1998b; Cox et al., 2001).

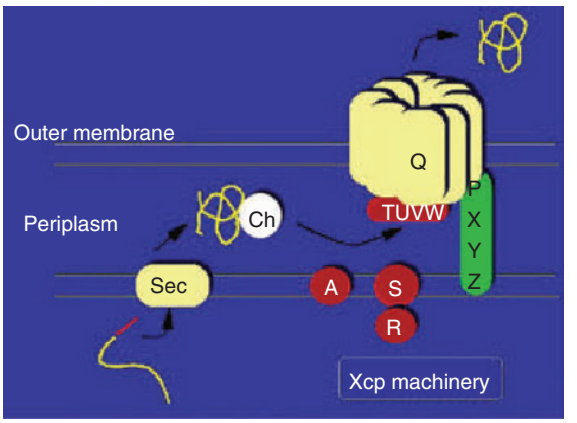

Fig. 5. The secretion machinery of *Pseudomonas alcaligenes*, the producer of Lipomax®, an alkaline lipase for detergent compositions. The XcpQ protein forms a multimeric ring in the outer membrane. The Xcp T, U, V and W proteins are thought to be involved in the gating of the pore, and proteins P, X, Y and Z form a connection between the outer membrane pore and the inner membrane. XcpA, S and P play a role in the processing of other Xcp proteins. Sec is innermembrane translocase; Ch is the periplasmic chaperone.

As most lipases do not meet all the above-mentioned criteria, the first protein engineering of lipases was based on amino acid sequence information only (e.g., the study on lipase from *Pseudomonas mendocina*; Gray et al., 1995). When the first 3D-structures became available in the late 1980s, protein engineering efforts increased dramatically. A European-wide funded project focused on solving new lipase structures, and now more than 15 X-ray structures of lipases are available in the protein database (PDB), of which 12 are microbial and 5 are of prokaryotic origin. The X-ray structure of lipase containing a phosphonate inhibitor covalently bound to its active site serine revealed that a lid was displaced from the active site by a hinge bending movement, creating an increased hydrophobic surface. Many of the lipase structures are solved in both a closed and an open conformation, i.e., with the lid or lids displaced from the active site. A list of selected solved bacterial lipase structures is given in Table 3. The overall structure of the triacylglycerol lipases has a central L-sheet with the active serine placed in a loop termed the "catalytic elbow." Above the serine, a hydrophobic cleft is present or formed after activation of the lipases. Molecular modeling of these structures has been used to construct models of lipase homologues (e.g., the engineering of the *Pseudomonas alcaligenes* lipase; Aehle et al., 1995). The use of lipases for the generation of enzymatic peroxide bleach in detergents has been pioneered but not yet applied.

Cellulases Cellulases are enzymes capable of hydrolyzing the 1,4 β-D-glucosidic linkages in cellulose. Cellulolytic enzymes have been traditionally divided into three major classes: endoglucanases, exoglucanases (or cellobiohydrolases), and β-glucosidases (Knowles et al., 1987). A large number of bacteria, yeasts and fungi is known to produce this group of enzymes. Initially, cellulolytic enzymes have been developed for application in converting wood and cellulose pulp into sugars for bio-ethanol production. Later on, it was discovered that cellulases can be used for the treatment of textiles. For example, repeated washing of cotton-containing fabrics results in a grayish cast to the fabric, which is believed to be due to fibrils disrupted and disordered by mechanical action. This grayish cast, sometimes called "pills," is particularly noticeable on colored fabrics. The ability of cellulase to remove the disordered top layer of the fiber and thus improve the overall appearance of the fabric has been used to recondition used fabrics to make their colors more vibrant.

Despite the availability of fungal cellulases having some of the above properties, new cellulases that are more compatible with the alkaline detergent formulations have been sought. Alkalophilic *Bacillus* species have been found to express cellulases (EC 3.2.1.4) with excellent properties for detergent conditions, and one of these cellulases is now expressed from *Bacillus subtilis* and marketed under the trade name Puradax® (Jones and Quax, 1998a). Also, cellulases from *Thermomonospora fusca* have been found to be of interest (Irwin et al., 1998) to textile decorators. Some of these cellulases can be abundantly expressed in a *Streptomyces lividans* host cell (Jung et al., 1993).

Amylases The thermostable α-amylase (EC 3.2.1.1) from *Bacillus licheniformis* is perfectly compatible with detergent conditions, and nowadays small amounts of this enzyme are widely added to detergent powder formulations for the removal of starch stains. A protein engineered variant, Purastar® Ox, has been developed specifically for inclusion in bleach-containing detergent formulations (Genencor, 2001). This brings the number of different enzyme systems added to modern detergent powders up to four: proteases, lipases, cellulases and amylases.

Food Processing

Microorganisms play a major role in the processing of dairy products, beer, wine and many other food products. Isolated enzymes are also being used in specialized processes, although in much smaller amounts than are used in the immense starch processing industry, which will be discussed in a separate chapter.

The baking of bread is one of the oldest biotechnological processes known to man. Yeast enzymes and endogenous flour enzymes are the primary modifiers and metabolizers of flour sugars and proteins. However, the levels of endogenous enzymes vary considerably depending on wheat growth, harvest and storage conditions. Correction and supplementation of the flour with bacterial enzymes result in more tasteful and better quality bread. *Bacillus amyloliquefaciens* α-amylase (EC 3.2.1.1) is used to obtain an improved loaf volume and crumb structure (Lin and Lineback, 1990). In addition, α-amylase contributes to anti-staling by mildly hydrolyzing starch polymers, which prevents their crystallization and thereby hardening of bread. The neutral protease of the same bacterium is used for improving the rheological properties of biscuit and cracker dough (Lyons, 1982). This protease fragments the gluten protein in wheat flour, which gives the dough its elastic properties. As a result, the dough requires a reduced fermentation time and the resulting biscuits have a prolonged freshness.

Dairy products and beverages are processed under mildly acidic conditions favoring the use of enzymes of fungal origin. However, in the processing of beer the enzymes from selected *Bacillus* strains play an essential role. The α-amylase from *Bacillus amyloliquefaciens* is used to improve the enzymatic liquefaction potential of the malt. A β-glucanase from the same bacterium (Hofemeister et al., 1986) is used to reduce the viscosity of the wort, which improves the filtration of the beer.

Textiles

Amylases Woven fabrics from natural plant and animal fibers represent the oldest forms of textile. The introduction of mechanical processes in the nineteenth century prompted the introduction of protective agents to prevent warp-end breaks. Starch added as a sizing agent strengthens fibers and makes the yarn more resistant to high mechanical stress during the weaving process. Traditionally, malt extracts and animal derived preparations have been used to remove starch-based thickeners in the desizing operation. However, as early as 1917, a high temperature stable bacterial enzyme preparation obtained by dedicated fermentation was introduced (Wallerstein, 1939). Today we know that the bacterium used was *Bacillus amyloliquefaciens* (Welker and Campbell, 1967a). At present both *Bacillus amyloliquefaciens* and *Bacillus licheniformis* α-amylases are being used for this process.

Cellulases In various treatments of cotton fibers, these enzymes have resulted in better wash-down effects, resistance to pilling, softening, and better dye uptake. Later it was discovered that the enzymatic treatment of textiles could result in decorative effects on clothing similar to the stone washing of denim (Gusakov et al., 2000). This has resulted in a large market for cellulases in providing a worn look to jeans. The enzymatic production of stone-washed denim products (no need for pumice) has become a fast growing market with more than $40 million in sales per year. A variety of cellulase products (many of fungal origin) is marketed for this purpose. Recently, enzymes from the actinomycete *Thermomonospora fusca* have been developed (Spezio et al., 1993). The cellulase (EC 3.2.1.4) can be efficiently produced from a genetically engineered *Streptomyces lividans* (Jung et al., 1993). Care needs to be taken to prevent loss of fiber strength from cellulase treatment that is too lengthy or intense.

Proteases These enzymes (e.g., subtilisin [EC 3.4.21.62]) are used to treat protein fabrics such as wool and silk. By breaking down the fibrils on the surface, the look and feel of the fabric can be softened.

Fine Chemicals

In nature, a huge repertoire of chemical transformations is catalyzed by many thousands of enzymes. Its precise 3D architecture allows each enzyme to exhibit a remarkable specificity for the conversion of a particular set of substrates. The introduction of these enzymes as biocatalysts in the industrial production of fine chemicals probably represents the uppermost innovation in the enzyme field in recent years. Since a company produces in-house many of the biocatalysts used within industrial processes (i.e., production for captive use or captive consumption), the information on the actual scale and commercial impact of many of these biocatalytic processes is often limited. Nevertheless, from the scarce publications on industrial use of biocatalysts it can be concluded that numerous energy intensive chemical processes involving a high output of pollutants have now been replaced by environmentally friendly enzymatic processes (Schmid et al., 2001).

Amidases

β-Lactam Acylases Penicillin G acylase (benzylpenicillin amidohydrolase, also named "penicillin amidase;" EC 3.5.1.11) is an enzyme used commercially to produce 6-aminopenicillanic acid (6-APA), the most important intermediate for the industrial production of semisynthetic penicillins. This is achieved by the hydrolysis of penicillin G (for review, see Bruggink et al., 1998; Fig. 6, left column).

Numerous bacterial species have been described in the literature as penicillin G acylase-producing strains, but only certain strains of the species *E. coli*, *Kluyvera citrophila* and *Alcaligenes faecalis* were found to produce an enzyme compatible with the requirements of industrial deacylation (Balasingham et al., 1972; Barbero et al., 1986; Verhaert et al., 1997). Driven by environmental legislation in the past decade, all chemical deacylation processes in industry have been replaced by the less polluting enzymatic cleavage process. Recombinant DNA methods have been applied not only to increase the yields of commercially used penicillin G acylases (Bruns et al., 1985) but also to decipher the complex processing of these enzymes (Schumacher et al., 1986). The penicillin G acylase of *E. coli* ATCC11105 was found to be produced as a large precursor protein, which is secreted into the periplasm and further processed to the mature protein constituting a small (α) and a large (β) subunit. Cloning and sequencing has revealed a close homology (90% identity) to the *Kluyvera citrophila* and a distant homology (50% identity) to the *Alcaligenes faecalis* acylase gene. The heterodimeric structure, however, is evolutionarily preserved not only among penicillin acylases but also within the much larger family of β-lactam acylases.

Whereas the conversion of penicillin-G requires an enzyme with a specificity for the aromatic phenyl acetate side chain, the processing of the second largest β-lactam fermentation

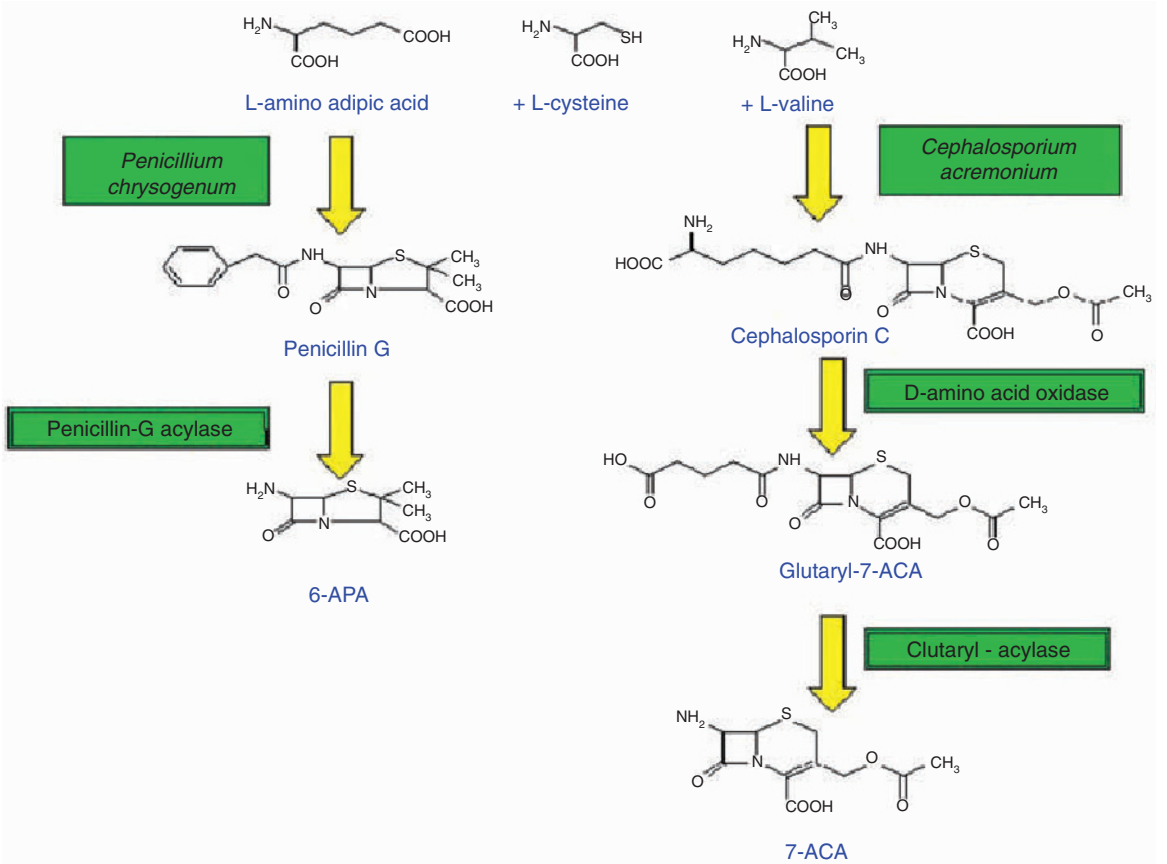

Fig. 6. The role of β-lactam acylases in the manufacturing of semisynthetic cephalosporins and penicillins. In the left pathway, the production of 6-amino penicillanic acid (6-APA) from the fermentation product penicillin-G is shown. In the right pathway, the production of 7-aminocephalosporanic acid (7-ACA) from the fermentation product cephalosporin-C is depicted.

product, cephalosporin-C, requires the cleavage of aminoadipyl, an aliphatic side chain, from the β-lactam nucleus. Since a one-step enzymatic deacylation (Aramori et al., 1991a) was not feasible, a combination of two enzyme-mediated reactions has been introduced to produce 7-aminocephalosporanic acid (ACA). In this process, D-amino acid oxidase and a glutaryl acylase perform an enzymatic deacylation of cephalosporin-C (see Fig. 6, right column). This glutaryl acylase (EC 3.5.1.-) can be obtained from several *Pseudomonas* species (Shibuya et al., 1981; Matsuda et al., 1987; Aramori et al., 1991a; Ishiye and Niwa, 1992; Ishii et al., 1994; Li et al., 1998) or from a *Bacillus* species (Aramori et al., 1991b). Research towards a one-step cephalosporin-C deacylating enzyme so far has been unsuccessful.

A third important intermediate, 7-aminodesacetoxycephalosporanic acid (7-ADCA), is produced from penicillin G by an expensive chemical ring expansion reaction. Subsequent deacylation of cephalosporin G can be achieved enzymatically by a penicillin-G acylase such as the enzyme from *Alcaligenes faecalis*; Fig. 7, left column). The latest development in the field is the use of a genetically modified *Penicillium chrysogenum* equipped with an expandase gene from *Streptomyces clavuligerus* to produce adipyl-7-ADCA upon fermentation with adipate feed (Crawford et al., 1995; Fig. 7, right column). Deacylation of adipyl-7-ADCA cannot be done with penicillin acylases, but requires an enzyme with affinity for the adipate side chain (Schroen et al., 2000; Xie et al., 2001). Some of the aforementioned glutaryl acylase enzymes have a low activity on this substrate. Recently by directed evolution, several mutants of *Pseudomonas* SY-77 acylase (EC 3.5.1) with a high activity on adipyl-7-ADCA have been isolated (Otten et al., 2002; Sio et al., 2002; Fig. 7).

Semisynthetic cephalosporins and penicillins are industrially produced from intermediates depicted in Figs. 6 and 7. As β-lactam acylases are hydrolytic enzymes, in theory the reaction can be reversed under conditions of low water

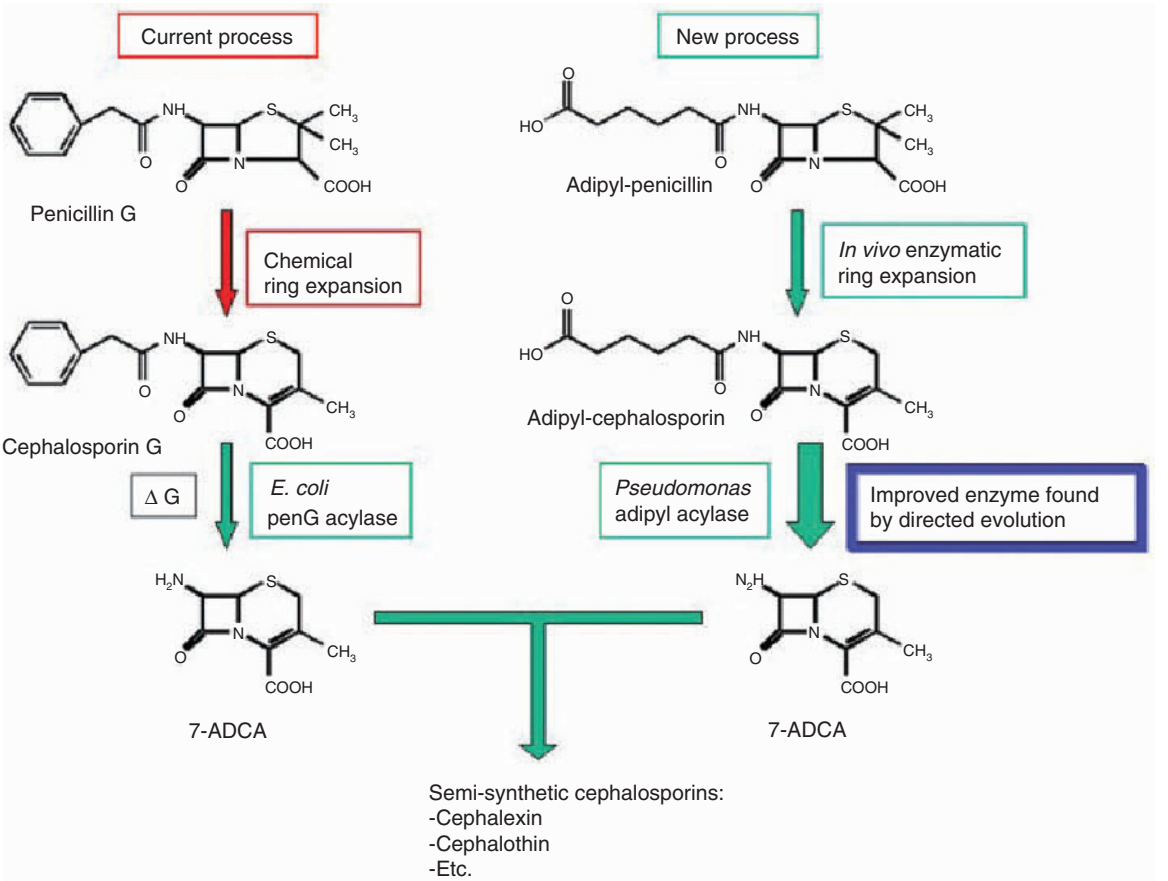

Fig. 7. In the left panel, the classical process for obtaining 7-ADCA is shown. A novel biosynthetic pathway for adipyl-cephalosporin using *Penicillium* is depicted in the right column. The final conversion towards 7-ADCA is done with an adipyl cephalosporin acylase. Using directed evolution, the glutaryl acylase of *Pseudomonas* SY77 has been converted into an adipyl acylase (Otten et al., 2002; Sio et al., 2002).

concentration. Precisely this property of β-lactam acylases is being used for the selective coupling of specific side-chains to form pharmaceutically valuable β-lactams such as ampicillin, cephalexin (Boesten and Moody, 1995), and loracarbef (Koeller and Wong, 2001). Directed evolution will undoubtedly result in the isolation of variants with novel synthetic properties (Alkema et al., 2000).

Other Amidases Aspartame is a dipeptide with an immense sweet taste. The synthesis of this low-calorie sweetener is performed with the neutral protease (EC 3.4.24.27) from *Bacillus thermoproteolyticus* also known as "thermolysin." Applied as a reversal of the hydrolytic reaction, the enzyme shows a remarkable specificity in the coupling of N-protected-L-aspartic acid and D/L phenylalanine methyl ester. Owing its extreme thermostability, the enzyme is very stable in the high solvent conditions used for the reaction. As an alternative to thermolysin, a highly stable variant of *Bacillus stearothermophilus* neutral protease obtained by protein engineering is now available (Mansfeld et al., 1997; Van den Burg et al., 1998).

Amidases are also applied for the chiral resolution of racemic amino-acid amides to allow the biocatalytic synthesis of non-natural L-amino acids, which are important building blocks for pharmaceuticals. An amidase (EC 3.5.1.4) from *Pseudomonas putida* has been developed for the kinetic resolution of a wide range of amino acid amides (Schmid et al., 2001).

Lipases and Esterases Lipases from *Pseudomonas aeruginosa*, *Pseudomonas cepacia* and *Pseudomonas fluorescence* (EC 3.1.1.3) are being used for a large number of different synthetic reactions in organic chemistry with special emphasis on kinetic resolution of chiral compounds (Coffen, 1997). As lipases are active in organic solvents, not only hydrolytic but also transesterification reactions can be performed.

For racemic alcohols, this may be an enantioselective transformation with acyl donors such as vinyl esters, anhydrides or diketenes (Koeller and Wong, 2001; Schmid et al., 2001). Using this process, enantiomerically pure alcohols are produced on a several hundred ton scale by Badische Anilin und Soda Fabriken (BASF). *Pseudomonas* lipase can also react with amines as nucleophiles, allowing the resolution of optically active amines such as *S*-methoxyisopropylamine, an important building block for the herbicide "FrontierX2."

The enzymatic activity of lipases is very comparable to that of esterases, with the main difference being the chain length and hydrophobicity of the acid moiety of the substrate. Therefore in fine chemical applications, lipases and esterases are being used as alternatives for several conversions. For instance, for the kinetic resolution of 2-aryl propionic acids such as naproxen and ibuprofen, both a lipase and an esterase have been found that can perform a stereoselective hydrolysis yielding the pharmaceutically preferred enantiomer *S*-naproxen (Bertola et al., 1992; Hedstrom et al., 1993). High activity and ease of production have made the carboxylesterase from *Bacillus subtilis* Thai I-8 the prime choice of industry (Quax and Broekhuizen, 1994).

The markets for fine chemicals that can be made from esterss are very important and diverse. Thus, the ability to perform ester hydrolysis or esterification reactions in a manner that ensures high specificity and high stereoselectivity is of great importance. Therefore, the use of genomics information to search for new esterases is of great interest (Robertson et al., 1999; Droge et al., 2001).

Areas of Research

Feed

Animal feed is mainly composed of polymeric structures that have to be digested in the gut. Any pretreatment of the agricultural stock may lead to an improved digestibility and hence yield of feedstuffs. It is therefore no surprise that most of the hydrolytic enzymes including the pancreatic extracts used as the first enzyme preparation in the 1920s have been tested in one way or another for the processing of animal feed. Only after an increased understanding of the digestive physiology did realistic applications come within reach. The examples described below are the result of expert advice and evaluation of feed industry experiences.

Phytases Phosphorus is an important component of feed, as it is crucial for bone and skeleton formation. About 70% of phosphorus in vegetable feed ingredients is present in the form of phytate, an inositol-bound organic form of phosphorus that has a low bioavailability in monogastric animals. For this reason, the diet for monogastric animals like pigs and chickens is supplemented with significant amounts of inorganic phosphate that causes eutrophication in regions of the world with a dense monogastric animal population, such as the Netherlands. The addition of microbial phytases (EC 3.1.3.26) has resulted in a doubling of the bioavailability of phytate, obviating the need for addition of inorganic phosphate (Simons et al., 1990). This has led to lowering phosphate in manure to unprecedented levels in the Netherlands and to phosphate pollution reductions that are more significant than the reductions from the detergent phosphate ban in the mid-1970s.

Phytase from fungi has been shown to be extremely compatible with the low pH conditions of the animal gastric tract (Jongbloed et al., 1992), but also phytases from bacteria, such as *Bacillus subtilis*, are being developed for use as a feed additive (Kerovuo et al., 2000b; Park et al., 1999; Kerovuo and Tynkkynen, 2000a).

Xylanases Pentosans present in wheat and rye diets are often poorly metabolized. Especially arabinoxylans negatively influence the digestion and absorption of nutrients in the foregut of animals. When a xylanase (EC 3.2.1.8) treated arabinoxylan fraction was used, the nutritional parameters were similar to those when an arabinose and xylan monomeric mixture was used, indicating that xylanases are a valuable feed additive. Especially sought are enzymes with endo-1,4-β-xylanase activity that are stable in the digestive tract of poultry (Mondou et al., 1986).

Paper and Pulp

In the pulp and paper manufacturing process, elemental chlorine is applied for the bleaching of the pulp. As a byproduct of this process toxic chlorinated phenols as well as polychlorinated biphenyls are formed. Next to alternative bleaching chemicals such as ozone, the use of enzymes has gained more interest. Especially the removal of residual lignin results in a lower required amount of bleaching chemicals, allowing the replacement of elementary chlorine by the less polluting chlorine dioxide. The removal of lignin can be facilitated by a pretreatment of the pulp with xylanases or by laccases. This xylanase pretreatment cleaves the hemicellulose fraction that links the lignin to the cellulose. The laccase treatment results in a direct oxidative degradation of the lignin. The search for sufficiently active laccase systems is still in its infancy,

but xylanases have been developed for commercial use.

The pulping process in a paper mill is performed at temperatures of 65–80°C at pH 9–12. Xylanases (EC 3.2.1.32; endo-1,3-β-xylanase) from some thermophilic bacilli were found to be compliant with these conditions (Gat et al., 1994), and the xylanase from *Bacillus stearothermophilus* T6 was developed and tested on a large scale (Lundgren et al., 1994). This enzyme shows activity at high temperature (60–70°C) and high pH (7–9). The enzyme can be expressed and purified in high yields from *Bacillus subtilis* (Lapidot et al., 1996). The search for even more thermostable and more alkaline-stable xylanases has been targeted towards extremophiles (Saul et al., 1995; Outtrup et al., 1998).

General Expression Hosts

Bacteria are attractive for large scale manufacturing of commercially relevant proteins owing to their fast growth rate and their high protein synthesis capacity. Enhanced levels of gene expression, however, often result in the intracellular accumulation of inactive protein aggregates also known as inclusion bodies. For most enzyme manufacturing processes, the recovery of active protein from these aggregates is uneconomical. The only enzyme process that has been in use for many years has been the manufacturing of bovine chymosin (rennin), with the Gram-negative bacterium *E. coli* as a host (Nishimori et al., 1981; Emtage et al., 1983).

Export of overexpressed heterologous enzymes from the cytoplasm has been explored as a solution to prevent inclusion body formation and to produce functional proteins in an easily recoverable form. With the identification of some periplasmic chaperone and foldase functions in Gram-negative bacteria, the concept of using the periplasm as a "construction compartment" in which chaperones aid the folding and functional assembly of proteins has come within reach. The ultimate goal from the viewpoint of industrial scale recovery—accumulation of proteins on a gram per liter scale in the extracellular medium—requires however the passage through two membranes. Recently described have been some nonpathogenic species such as *Pseudomonas alcaligenes* that have the capacity to secrete commercially important enzymes (lipases, proteases, cellulases and phospholipases) in significant amounts into the extracellular medium (Gerritse et al., 1998a). The outer membrane secretion machinery is crucial for the export of proteins from the periplasm. At high expression levels, the outer membrane can become a barrier as exemplified by the effect on *Pseudomonas alcaligenes* lipase overexpression of selecting the Xcp gene cluster using the phenotype enhancement method (Gerritse et al., 1998b). The *xcp* gene cluster encodes the type II secretion pathway in Gram-negative bacteria, also referred to as the main terminal branch (MTB) of the general secretion pathway (GSP). Proteins secreted via the GSP pass the cell envelope in two separate steps. First, they are translocated across the inner membrane into the periplasm, a process mediated by the Sec machinery. Subsequently, the periplasmic intermediates are translocated across the outer membrane as fully folded proteins (Fig. 5). Several nonspecific chaperones function in the periplasm of *E. coli*. The peptidyl-prolyl-*cis-trans*-isomerases (PPI) catalyze the *cis-trans* isomerization of X-proline peptide bonds, which was found to be rate limiting upon high level production of functional single chain Fv (scFV) fragments in the periplasm of *E. coli* (Jager and Pluckthun, 1997). A second class of nonspecific chaperones, the thiol-disulfide oxidoreductases (Dsb) that catalyze the formation of disulfide bonds, has been shown to play a crucial role in the formation of disulfide bonds in heterologous proteins expressed in *E. coli* (Joly and Swartz, 1997; Joly et al., 1998). Recently homologues of *dsb* genes have been found in *Pseudomonas aeruginosa* to be involved lipase folding (Reetz and Jaeger, 1998).

In addition to nonspecific chaperones, the folding of a variety of extracellular proteins requires the action of specific chaperones. For example, the correct folding of lipases is mediated by the lipase-specific foldases (Lif). It has been shown that folding of the lipase of *Pseudomonas aeruginosa*, when expressed in *E. coli*, is dependent on the coexpression of the *Pseudomonas aeruginosa lif* gene (El-Khattabi et al., 1999). Interestingly, it was found that the amount of Lif can become limiting in an industrial *Pseudomonas alcaligenes* strain upon overexpression of the endogenous lipase gene (Gerritse et al., 1998a).

Bacillus species have always been the paradigm hosts for the production of bacterial enzymes and around 50% of the total worldwide enzyme production is by bacilli. Nevertheless, the protein secretion machinery of *Bacillus* has certain limitations, and in a systematic analysis, members of the European *Bacillus* Secretion Group (EBSG) over the past years have identified bottlenecks in the secretion pathway of *Bacillus subtilis* that relate to different stages in the secretion process. Different proteins can run into different limiting factors (Bolhuis et al., 1999). During transport over the membrane, signal peptidases can become limiting factors in pre-protein processing. For example, overproduction of signal peptidase was shown to be beneficial for the secretion of heterologous β-

lactamase from *Bacillus subtilis* (Van Dijl et al., 1992). Alternatively, signal peptidases can interfere with efficient pre-protein processing under conditions of high-level overproduction of secretory proteins. This is illustrated by the observation that the disruption of the *sipS* gene, encoding one of the five signal peptidases of *Bacillus subtilis*, resulted in highly increased rates of processing of an α-amylase precursor (Tjalsma et al., 1997).

Finally, late stages in the secretion process, including the folding of mature proteins and cell wall passage, can become secretion bottlenecks. It was found that the lipoprotein PrsA becomes limiting under conditions of high-level secretion of α-amylases, as it is required for the folding into a protease-resistant conformation upon translocation (Kontinen and Sarvas, 1993). In another experiment, it was found that the cell wall, which is relatively thick (10–50 nm) and contains a high concentration of immobilized negative charge (e.g., teichoic or teichuronic acids), can act as a barrier in translocation (Saunders and Guyer, 1986; Stephenson et al., 1998b). Thus, proteins with a net positive charge might be retained in the wall. Furthermore, it was shown that the wall-bound serine protease CWBP52, encoded by the *wprA* gene, can degrade slowly folding enzymes at the site of preprotein translocation. Hence, CWBP52 depletion has resulted in an increased yield of secreted α-amylase (Stephenson and Harwood, 1998a).

More successful approaches to remove bottlenecks in the production of proteins from *Bacillus* involve the elimination of detrimental factors, such as extracellular proteases. In a stepwise approach, strains with an increasing number of protease gene deletions have been constructed, resulting in a sevenfold protease negative strain that shows significant higher yields of susceptible bacterial enzymes (Ye et al., 1999).

Patents and Regulatory Systems

Regulations and Enzymes

Bacterial enzymes for food applications must comply with the regulations put forward by the United States Food and Drug Administration (FDA) or comparable bodies in other countries. Most enzymes are considered as food processing aids and usually do not end up in the final consumer end product. Nevertheless all products undergo a strict testing program including toxicity and efficacy testing. Finally the industrial production process has to comply with the regulations stipulated by the Environmental Protection Agency (EPA). These documents may be accessed through at the Office of Pollution Prevention and Toxics' Biotechnology Program homepage (http://www.epa.gov/opptintr/biotech/). Alternatively, the documents are available from the {EPA homepage} (http://www.epa.gov/fedrgstr/) at the Environmental Sub Set entry for this document under "Regulations."

The industrial and household enzyme products not used for food applications must comply with the regulations of the EPA and general product safety regulations. Especially with respect to preventing allergenicity, there are strict specifications for formulating enzymes and preventing dust formation. The production host strains must be nontoxic and preferably with a record of safe use. Most of the enzyme products have Generally Recognized as Safe (GRAS) status.

Patents and Taxonomy

Purified enzyme products can be covered by a broad substance patent claim as long as the disclosure complies with the three elements of a patent application: the substance should be novel, the disclosure should involve an inventive step, and the substance should have a use. The aspect of novelty can be readily checked since the amino acid sequence of a newly described enzyme can be easily compared to a protein or DNA database. As the number of described amino acid and DNA sequences has exploded in the past years and since patent examiners tend to use the criterion of 70% amino acid sequence identity to specify homologous enzymes, it is clear that broad substance patent claims will be difficult to obtain in future. Rather, patent protection will be sought more for specific methods and applications of certain enzymes. Enzymes that have been obtained by protein engineering or directed evolution represent a special group of patent claims. As the sequence identity to existing enzymes will generally be very high (>99%), the variant will need to have a property that distinguishes it from wildtype enzymes to become patentable. Patent claims in those cases have mostly been restricted to the specific examples shown in the description.

With the granting of patent claims on living organisms (Chakrabarty, 1981), a new dimension was added to the intellectual property protection. Patent claims on the bacteria themselves were initially rejected because living things were not considered patentable. Finally the United States Supreme Court reversed the initial decision, making the argument that a genetically engineered microorganism is not a product of nature, but rather a product of a person's work and is thus patentable under the United States law. This decision has added a new element to the patenting of bacterial enzymes and the host cells pro-

ducing them. Now also the bacterial strains as isolated from natural sources could be patented (Collins et al., 1998a; Collins et al., 1998b; Outtrup et al., 1998). A detailed description in the form of a correct taxonomic determination of the strain is now essential to obtain good patent protection. This has led to the development of modern tools for the description of claimed species, such as the 16S RNA identification.

Prospects

Extremophiles

Enzymes isolated from microorganisms living under harsh conditions are adapted to those extreme conditions. For example, an amylase and a protease that are fully stable and active at 95°C have been isolated from *Pyrococcus furiosus*, a hyperthermophile living in a 90°C hotspring (Brown et al., 1990; Eggen et al., 1990). Especially the progress in research on archaea and the ability to culture these strains in the laboratory have generated a lot of enthusiasm for household and industrial uses of enzymes from extremophiles. As the growth conditions for these extremophiles are difficult to create on an industrial scale, the goal is to express the genetic material encoding these enzymes in mesophilic hosts. Numerous novel genes encoding thermostable (Koch et al., 1990; Hakamada et al., 2000), alkali stable (Shendye and Rao, 1993; Kobayashi et al., 1995; Saeki et al., 2000), and acid stable (Tamuri et al., 1997) enzymes have been characterized in recent years. This can result in not only enzymes better suited to existing applications (such as detergents [alkaline] and starch [high temperature]) but also completely new applications such as the enzymatic bleaching of pulp, a process requiring both high temperature and very alkaline conditions. The yields in production of enzymes from extremophiles, however, are generally low because compatibility of these proteins with the folding and secretion machinery of mesophilic hosts is low. The impact of these novel enzymes on the household and industrial enzyme market therefore remains to be seen and "expressibility" must be considered when selecting extremophilic enzymes with desired properties (Van Solingen et al., 2001). The best results have been obtained with enzymes from extremophilic eubacterial origin, such as the thermostable xylanase (produced on a large scale for enzymatic pulp treatment) from *Bacillus stearothermophilus* (Lundgren et al., 1994). In research and diagnostic laboratories, the thermostable DNA polymerases (such as the Taq polymerase from *Thermus aquaticus* and Pfu polymerase from *Pyrococcus furiosis*) have shown their tremendous value already (Peterson, 1988; Picard et al., 1994). The diagnostic enzymes including the huge diversity of restriction enzymes and polymerases are, however, beyond the scope of this chapter.

Directed Evolution

In the past two decades, the technique of protein engineering has allowed investigators to create new enzymes and proteins. Interestingly, some of the most striking commercial successes have not been the result of rational design based on a 3D structure, but merely the payoff of smart combinations of random mutagenesis and screening. The power of this combination resides in the fact that many variants with subtle differences can be probed quickly. In practice, however, major weaknesses are still encountered, as most screening assays for enzymatic activity are rather limited in throughput. A major improvement can be made if a selection instead of a screening can be introduced. This combination of gene pool diversification and selection for function (collectively termed "directed evolution") is now considered as one of the most successful protein engineering strategies. Two processes play a key role in evolution: mutation and selection. Gene mutation methods have been expanded enormously with the advent of the polymerase chain reaction (PCR) techniques (error prone PCR and PCR with spiked oligonucleotide primers and staggered extension process) and DNA shuffling (Crameri et al., 1997; Zhao et al., 1998; Matsumura et al., 1999). However, the selection for function is less obvious as the majority of industrial enzymes are secreted into the extracellular medium, which interferes with growth selection. Most of the newly described directed evolution studies have been on intracellular enzymes with in vivo selectable functions, such as β-lactamase, which can be selected for by increasing the antibiotic concentrations (Stemmer, 1994). Attempts have been made to use display techniques involving coupling of the phenotype of an extracellular enzyme with the genotype. As demonstrated with the industrially important enzyme α-amylase from *Bacillus licheniformis*, it is possible to use phage display for the selection of enzymes with improved substrate binding properties (Verhaert et al., 2002). Binding to substrate transition state analogues has been used to select for enzymes with altered catalytic properties. Although binding of phages to transition state analogues is feasible, the use of this technique to select for industrially relevant catalytic properties remains to be established (Legendre et al., 2000). More success has been obtained with the compartmentalization of bacteria that are secret-

ing mutant enzymes. By fixing the mutant bacterial cells in a solid matrix, the diffusion of the secreted mutant protease was delayed. This provides a way of coupling the phenotype to the genotype, inasmuch as the converted growth substrate remains in the same compartment as the bacterial cell (Tawfik and Griffiths, 1998; Griffiths and Tawfik, 2003). Finally, a novel dimension has been given to evolution techniques by the use of genes isolated directly from soil samples (without culturing the donor organism). In a large experiment, genes encoding amylases were cloned directly from soil and identified by expression on starch plates, and the resulting genes have been "evolved" using DNA shuffling. This has resulted in a very thermostable α-amylase (Richardson et al., 2002). This shows that isolating enzyme encoding genes from extremophiles combined with directed evolution in the laboratory can be a path forward for enzyme engineering.

Acknowledgments. This chapter is a compilation of numerous collaborations that have allowed the author to develop insights and ideas in the bacterial enzyme field. Special thanks to all the colleagues and students who have contributed material and illustrations presented in this chapter. The sponsoring of EU under contracts BIO2-CT950119, BIO4-9-98-0249, QLK3-CT-1999-00413, QLTR-2001-00519 and of NWO/STW under contract GBI.4707 is highly acknowledged.

CHAPTER 3.5

Bacteria in Food and Beverage Production

MICHAEL P. DOYLE AND JIANGHONG MENG

Introduction

Foods are plants and animals (or their products) and each often contain many types of microorganisms. These microbes from natural and external sources contaminate foods by contact, which can occur anytime between production and consumption. Microbial contamination of foods can have many undesirable consequences ranging from spoilage to foodborne illness. However, some microorganisms possess properties that can benefit food production or conversion. Many food-grade microorganisms are used to produce a variety of fermented foods from raw animal and plant materials. The acidic, and in part organolytic, properties of fermented products result from the fermentative activities of these microorganisms. Foods such as ripened cheeses, fermented sausages, sauerkraut and pickles have not only a greatly extended shelf life compared to the raw materials from which they are derived, but also aroma and flavor characteristics contributed directly or indirectly by the fermenting organisms. Consumption of fermented food product has increased dramatically during the last two decades and will continue to increase. The production and availability of fermentative microorganisms (starter cultures) used in food conversion have advanced to meet this demand. This includes the development of novel and better strains through genetic engineering.

Lactic acid bacteria (LAB) are among the most important groups of microorganisms used in food fermentations. LAB contribute to the taste and texture of fermented products and inhibit food spoilage bacteria by producing growth-inhibiting substances (bacteriocins) and large amounts of lactic acid. Many LAB benefit human and animal health, whereas others spoil beer, wine, and processed meats. They can be isolated from the respiratory, intestinal, and genital tracts of humans and animals and from plants.

Fermented dairy products have been made for thousands of years, but only within the last century has the microbiological basis of these fermentations been elucidated. And LAB are the principal organisms involved in fermenting dairy products. Prior to the availability of starter cultures, milk fermentations relied on the LAB naturally present in raw milk. The first commercial starter cultures, unknown mixes of strains most likely from raw milk, were prepared in Denmark just before the end of the 19th century. In the 1930s and 40s, the concept of pure single-strain starter cultures evolved, and a bacteriophage was identified as an important agent of slow fermentation in cheese. With their development in the 1960s and 70s, concentrated (often frozen or freeze-dried) starter cultures could be inoculated directly into the bulk starter vessel without the need for prior preparation in the creamery. In the last two decades, major advances on dairy starter technology have included improved culture selection procedures that enhance bacteriophage resistance. Molecular technology has been applied to map the genetic constructs of starter culture organisms and, by using plasmid/gene transfer mechanisms, to improve starter culture performance.

Sausage is one of the oldest processed meat products. The writings of ancient Egyptians described the preservation of meat by salting and sun drying. The ancient Babylonians, Greeks, and Romans used sausage as a food source during times of war. Microorganisms were recognized as being important to the production of sausages not until about 1921. In the 1940s and 1950s, pure microbial starter cultures became available to processors, and in 1968 frozen culture concentrates became commercially available to the meat industry. Use of these cultures was not widespread until the early 1980s largely because producers clung to the traditional methods of making sausage (using previously fermented meat as the source of LAB) and feared they might lose the quality and consumer acceptance of their final product. Today the importance of the use of starter cultures is recognized in most countries.

The fermentation of vegetables, a practice that originated in the Orient, has been used as a means of preserving food for more than 2,000

years. In the third century B.C. during the construction of the Great Wall of China, the Chinese produced fermented vegetables (cabbages, radishes, turnips, cucumbers, etc.) on a large scale. The most common fermented vegetables available in the United States are pickles, sauerkraut, and olives. Carrots, cauliflower, celery, okra, onions, and sweet and hot peppers also are sold as fermented vegetable products.

Currently, more than 2,000 different fermented foods are consumed by humans worldwide; many are ethnic and produced in small quantities to meet the demand of a group in a particular region. Some are produced commercially, and only a few by large commercial food processors. As consumers' interest in natural and health foods increases, future consumption of fermented foods also will increase significantly worldwide.

Classification of Bacteria in Food and Beverage Products

The classical approach to bacterial classification is based on morphological and physiological features. LAB are Gram-positive, non-sporeforming cocci, coccobacilli, or rods with a DNA base composition of less than 50 mol% G+C (Stiles and Holzapfel, 1997). They generally lack catalase and ferment glucose mainly to lactic acid (homofermentative) or to lactic acid, CO_2, and ethanol or acetic acid or both (heterofermentative). The importance of LAB in the fermentation of food products (dairy, meat, vegetables, fruits, and beverages) has been used as a basis to differentiate the group, although some are also members of normal flora of the mouth, intestine, and vagina of mammals (Klein et al., 1998). Therefore, LAB associated with food are generally restricted to the genera *Carnobacterium*, *Enterococcus*, *Lactobacillus*, *Lactococcus*, *Leuconostoc*, *Oenococcus*, *Pediococcus*, *Streptococcus*, *Tetragenococcus*, *Vagococcus*, and *Weissella*. Table 1 shows differential characteristics of LAB at the genus level (Axelsson, 1998). Bacterial taxonomic classification has been expanded recently to include cell wall composition (de Ambrosini et al., 1996), cellular fatty acids (Gilarova et al., 1994), isoprenoid quinones and other characteristics of cells (Stiles and Holzapfel, 1997). Molecular characteristics also have become important taxonomic tools, such as electrophoretic properties of the gene products, DNA:DNA hybridization studies, and structures and sequence of ribosomal RNA (rRNA; Collins-Thompson et al., 1991; Makela et al., 1992; Stackebrandt and Teuber, 1988; Vandamme et al., 1996). The 16S rRNA data for LAB suggest new groupings that cross the established taxonomic lines. Not all of the new groupings have become established in bacterial taxonomy, but recent phylogenetic considerations indicate that the lactobacilli, leuconostocs and pediococci can be reclassified as three major groups: the *Leuconostoc* group, the *Lactobacillus delbrueckii* group, and the *Lactobacillus casei-Pediococcus* group. The newly established genera *Carnobacteria*, *Tetragenococcus* (previously *Pediococcus halophilus*) and *Vagococcus* (previously motile streptococci) form a phylogenetic cluster with the genus *Enterococcus* (Vandamme et al., 1996). However, generally LAB that are important to food microbiology include only certain species of the genera *Lactobacillus*, *Lactococcus* (*Streptococcus*), *Leuconostoc* and *Pediococcus* (Stiles and Holzapfel, 1997). The genus *Lactobacillus* is by far the largest of the genera included in LAB. It is also very heterogeneous, encompassing species with a large variety of phenotypic, biochemical, and physiological properties.

Based on sugar fermentation patterns, LAB can be further divided into three broad metabolic categories (Axelsson, 1998). The first category includes the group I lactobacilli and some individual species from other genera that are obligately homofermentative, meaning the sugars can only be fermented by glycolysis. The second category includes leuconostocs, group III lactobacilli, oenococci, and weissellas that are obligately heterofermentative, meaning that only the 6-phosphogluconate/phosphoketolase (6-PG/PK) pathway is available for sugar fermentation. The apparent difference on the enzyme level between these two categories is the presence or absence of the key enzymes of glycolysis and the 6-PG/PK pathway. The third category, including the remaining LAB (i.e., group II lactobacilli and most species of enterococci, lactococci, pedicocci, streptococci, tetragenococci, and vagococci), holds an intermediate position. They resemble the obligately homofermentative LAB in that they possess a constitutive fructose-1,6-diphosphate aldolase, resulting in the use of glycolysis form hexose fermentation.

Other Bacteria In addition to LAB, other bacteria also are involved in food fermentations, some of which contribute significantly to flavor development and other characteristics of fermented products. Propionibacteria are probably best known for their role as dairy starter cultures, in which they produce the characteristic eyes and flavor of Swiss-type cheeses (Cogan and Accolas, 1996). The family Propionibacteriaceae, genus *Propionibacterium* and the closely related genus *Corynebacterium*, are classified as members of the Actinomycetaceae group. Five species of dairy propionibacteria are currently

recognized: *P. freudenreichii* subsp. *freudenreichii*, *P. freudenreichii* subsp. *shermanii*, *P. thoenii*, *P. acidipropionici*, and *P. jensenii*. In addition to being important starter organisms in dairy fermentations, propionibacteria also contribute to natural fermentations of silage and olives and can produce a variety of industrially important products (Jay, 1996).

Acetobacters are Gram-negative aerobic rods and cocci and consist of three species, *Acetobacter aceti*, *A. pasteurianus*, and *A. peroxydans* (Lee, 1996). The organisms are widely distributed in nature where they are abundant in plant materials undergoing alcoholic fermentations. They are important for their role in the production of vinegar.

Fundamental Metabolism

The essential feature of LAB metabolism is efficient carbohydrate fermentation coupled to substrate-level phosphorylation. The generated adenosine triphosphate (ATP) is subsequently used for biosynthetic purposes. LAB as a group exhibit an enormous capacity to degrade different carbohydrates and related compounds. Generally, the predominant end product is lactic acid (>50% of sugar carbon). However, LAB adapt to various conditions and change their metabolism accordingly. This may lead to significantly different end-product patterns.

Carbohydrate Metabolism

LAB, as non-respiring microorganisms, principally generate ATP by fermentation of carbohydrates coupled to substrate-level phosphorylation. Many compounds can serve as fermentable growth substrates, and many pathways for their fermentation have evolved (Kandler, 1983). These pathways have the following three general stages (Thompson, 1988): 1) Conversion of the fermentable compound to the phosphate donor for substrate phosphorylation. This stage often contains metabolic reactions in which NAD^+ is reduced to NADH. 2) Phosphorylation of ADP by the energy-rich phosphate donor. 3) Metabolic steps that bring the products of the fermentation into chemical balance with the starting materials. The most frequent requirement in the last stage is a mechanism for oxidation of NADH, generated in the first stage of fermentation, to NAD^+ so that the fermentation can proceed. The two major pathways for metabolism of hexose in lactic acid bacteria are the homofermentative (Embden-Meyerhof) and heterofermentative (phosphoketolase) pathways (Figs. 1 and 2). The transport and phosphorylation of sugars occur according to the following metabolisms: transport of free sugar and phosphorylation by an ATP-dependent glucokinase for glucose; other sugars, such as mannose and fructose, enter the major pathways at the level of glucose-6-phosphate or fructose-6-phosphate after isomerization or phosphorylation or both (Axelsson, 1998). One exception is galactose metabolism in LAB which use the phosphoenolypyruvate:sugar phosphotransferase system (PTS) for uptake of this sugar. Some species of LAB use this system for all sugars, in which phosphoenolypyruvate is the phosphoryl donor.

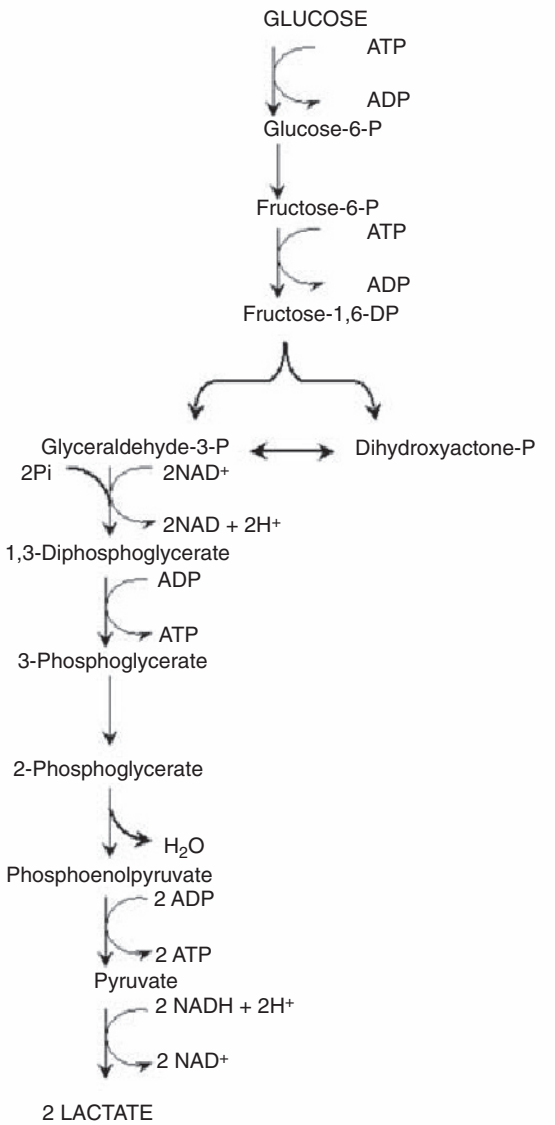

Fig. 1. Homolactic fermentation pathway of glucose (glycosis, Embden-Meyerhof pathway).

Proteolysis LAB have a very limited capacity to synthesize amino acids using inorganic nitrogen sources (Mayo, 1993). They are therefore

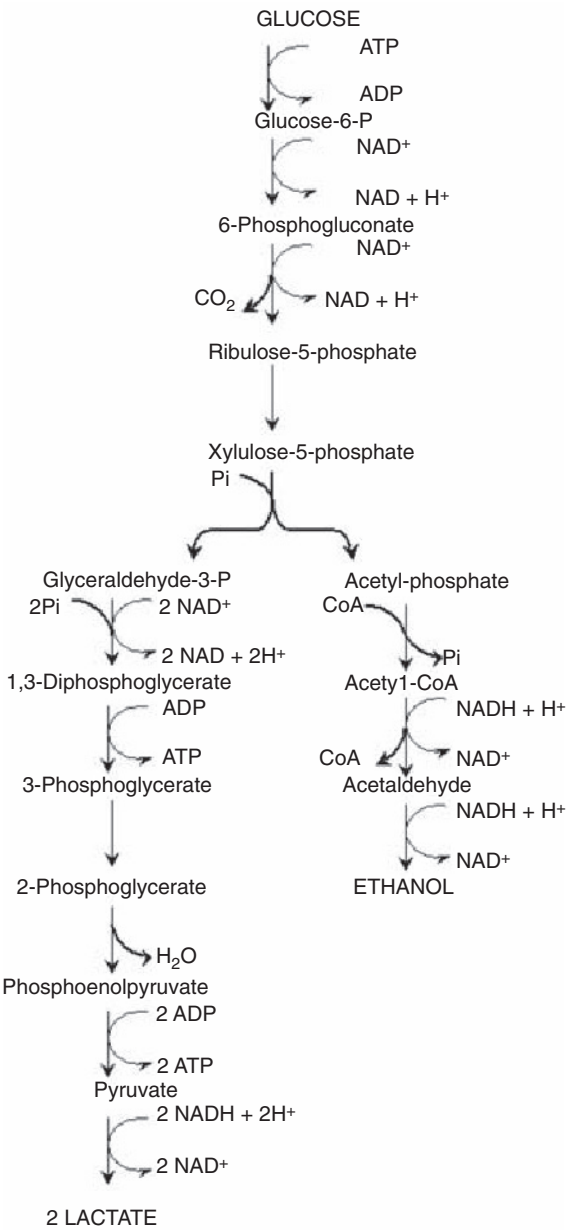

Fig. 2. Heterolactic fermentation pathway of glucose (6-phosphogluconate/phosphoketolase pathway).

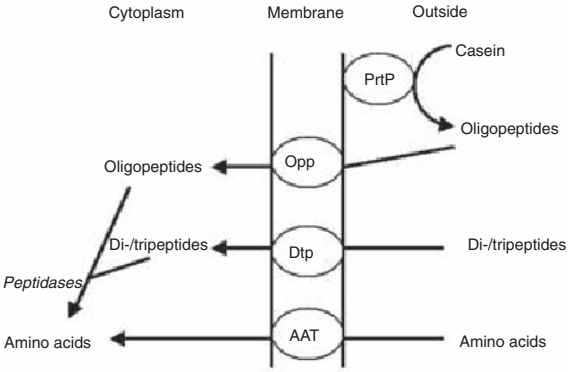

Fig. 3. Model of the lactococcal proteolytic system. Included also is transport of di- and tripeptides and free amino acids, but they contribute very little to the total growth of lactococci. PrtP, membrane-anchored proteinase; Opp, oligopeptide transport system; Dtp, di-/tripeptide transport system; AAT, amino acid transport system.

dependent on preformed amino acids being present in the growth medium as a source of nitrogen. The requirement for amino acids differs among species and strains within species (Chebbi et al., 1977). Some strains are prototrophic for most amino acids, whereas others may require 13–15 amino acids. The quantities of free amino acids present in food often are not sufficient to support the growth of bacteria to a high cell density; therefore, they require a proteolytic system capable of utilizing the peptides and proteins present in food that hydrolyzes proteins to obtain essential amino acids. All dairy lactococci used for acidification of milk (e.g., in cheese manufacture) have proteolytic activity (Poolman et al., 1995). The lactococcal proteolytic system consists of enzymes outside the cytoplasmic membrane, transport systems, and intracellular enzymes. The transport systems on the cell membrane include oligopeptide transport, di/tripeptide transport, and amino acid transport systems (Fig. 3; Pritchard and Coolbear, 1993). The transport of free amino acids contributes very little to the total growth of lactococci in milk. Two general classes of proteolytic enzymes of LAB are proteinases and peptidases. An extracellular, membrane-anchored serine proteinase (PrtP) has been identified as being essential for this activity. Once inside the cell, peptides are hydrolyzed by peptidases.

The proteolytic activity also contributes to the development of the flavor and rheological characteristics of fermented products (Mayo, 1993). For many varieties of cheeses, such as Swiss and Cheddar, desirable flavor tones are derived by proteolysis. However, proteolysis also can lead to undesirable flavors due to the accumulation of bitter peptides.

Bacteriocin Production Bacteriocins are protein antibiotics of relative high molecular weight that affect largely the same or closely related species by adsorption to receptors on the target cells. Bacteriocins can be added as a preservative (e.g., nisin), or they can be produced in the product (e.g., starter culture) or in the gastrointestinal tract (e.g., probiotic strains; De Vuyst and Vandamme, 1994; Montville and Winkowski, 1997). There are four classes of bacteriocins produced by LAB: 1) lantibiotics; 2) small hydrophobic

heat-stable peptides; 3) large heat-labile protein; and 4) complex bacteriocins (Table 2; Ouwehand, 1998).

Class I: Class I bacteriocins or lantibiotics are small peptides containing the unusual dehydroamino acids and thioether amino acids lanthionin and 3-methyllanthionine, which are synthesized by Gram-positive bacteria during posttranslational modifications. These peptides are thought to attach to the membrane of target cells and, by an as yet unknown conformational rearrangement, lead to increased permeability and disruption of the membrane potential. There are two types of lantibiotics, types A and B. The lantibiotics produced by LAB all belong to type A, which are elongated screw-shaped peptides, whereas type B lantibiotics are mainly globular. Nisin produced by *Lactococcus lactis* ssp. *lactis* has been studied extensively. It has a broad spectrum of activity against Gram-positive bacteria. The primary target is believed to be the cell membrane. Unlike some other antimicrobial peptides, nisin does not need a receptor for its interaction with the cell membrane; however, the presence of a membrane potential is required.

Class II: Class II bacteriocins contain a wide variety of small heat-stable peptides and have been subdivided into three subclasses (Table 2; Eijsink et al., 1998). Numerous class II bacteriocins are membrane-active peptides that destroy the integrity of the membrane by forming pores. Lactococcin is an example. In contrast to nisin, lactococcins require a specific receptor protein to act on target cells regardless of their membrane potential.

Classes III and IV: These bacteriocins differ markedly from those of Classes I and II. The larger (>30 kDa) heat-labile antimicrobial proteins such as lacacins A and B are classified as class III bacteriocins. Class IV bacteriocins such as leuconocin S and pediocin SJ-1 have lipid or carbohydrate moieties. The mechanisms of action and immunity of these complex bacteriocins remain unknown.

Starter Cultures

Starter cultures are food-grade microorganisms of known and stable metabolic activities and other characteristics that are used to produce fermented foods of desirable appearance, body, texture and flavor (Ray, 1996). Starter cultures in manufacture of food products were used long before it was known that bacteria were involved at all. Initial development of starter cultures resulted from the need and changes in the cheese industry. Since the early 1900s, there has been a marked worldwide increase in the industrial production of fermented food products. Process technology has progressed toward greater mechanization, larger factory size, shorter processing times, and more food processed daily in the processing plant. All of this relies on the optimization of the starter culture's activity, whereby the culture must maintain stable fermentative properties and resistance to bacteriophage (Lee, 1996). Currently, starter cultures for many types of fermented foods, including dairy products, meat products, vegetable products, and baking products, and for alcohol fermentation are commercially available.

Development of Starter Cultures Starter cultures used in dairy products can be divided into mesophilic and thermophilic cultures based on their optimum growth temperature (Table 3; Cogan and Accolas, 1996). Mesophilic cultures grow at temperatures of 10–40°C, with an optimum of ca. 30°C. Composed of acid-forming lactococci as well as flavor-producing bacteria, these cultures are used to make a variety of cheeses, fermented milk products, and ripened cream butter. Thermophilic cultures have optimum temperatures of 40–50°C and are used for yogurt and cheese varieties with high cooking temperatures. Starter cultures also have been used to produce meat products such as sausages and fermented vegetables. *Pediococcus acidilactici*, *Lactobacillus plantarum* and/or *Staphylococcus carnonsus* are often used as starter cultures

Table 2. Classes of bacteriocins produced by lactic acid bacteria.

Class	Subclass	Description	Bacteriocin producer
I		Lantibiotics	*Carnobacterium*, *Enterococcus*, *Leuconostoc*, *Lactobacillus*, *Streptococcus*
II		Small (<10kDa), heat stable (100–121°C)	*Carnobacterium*, *Enterococcus*, *Leuconostoc*, *Lactobacillus*, *Streptococcus*

	Lactobacillus delbrueckii spp. *bulgaricus*
	Lactobacillus acidophilus
	Streptococcus salivarius spp. *thermophilus*

in sausage production, whereas cabbage, cucumbers, and olives are fermented with *Lactobacillus plantarum*. Starter cultures, usually composed of different species or of several strains of a single species, are often categorized on the basis of their composition (Ray, 1996): 1) single-strain starter: one strain of a certain species; 2) multiple-strain starter (defined-strain starter): different known strains of one species; 3) multiple-mixed-strain starter: different defined strains of different species; and 4) raw mixed-strain starter: species and strains partly or all unknown.

General Requirements for Starter Cultures (Buckenhuskes, 1993)

Safety Starter cultures contain bacteria that lack virulence factors for humans and thus are free of pathogens and toxins.

Technological Effectiveness Starter culture bacteria dominate over naturally occurring microflora. The microorganisms perform the required metabolic activities. Starter culture preparations are free of bacteriophage and microorganisms that may inhibit or reduce starter culture activity.

Economic Aspects The propagation and production of starter cultures must be economically feasible. The starter culture can be preserved by freezing or freeze-drying with little practical loss of activity. Essential properties of starter cultures such as fermentative ability are stable under defined storage conditions for several months.

Frozen concentrated starter cultures were developed in the 1970s for direct inoculation into substrates to be cultured. Efforts have been made to produce freeze-dried concentrated cultures, which have less bulk and don't require transport on dry ice, thereby eliminating the problem of accidental thawing. The dried cultures can be used directly for product manufacture or to produce bulk starters (Cogan and Accolas, 1996). However, many starter culture strains do not survive well in the dried state. Hence, the care of dried cultures in large commercial operations has been limited. A recent advance has been the availability of custom-designed starter cultures to meet the specific needs of a food processor. An understanding of the genetic basis of both desirable fermentative characteristics as well as phage inhibition defenses of starter cultures has advanced the production of designer cultures.

Genetics of LAB Starter Cultures

The characterized genetic elements of LAB starter cultures include chromosomes, transposable elements, and plasmids (Gasson, 1990; Rodriguez and Vidal, 1990). Chromosomes of LAB are smaller than those of other eubacteria, ranging from 1.1 to 2.6 Mbp, depending on the species. Transposable elements, genetic elements capable of moving as discrete units from one site to another in the genome, have been identified in LAB. Insertion sequences, the simplest of transposable elements, are widely distributed in bacteria and also have been found in LAB. Their ability to mediate molecular rearrangements and affect gene regulation has had both positive and negative implications for food fermentations (Gasson, 1990). Plasmids have been identified in many LAB. Some plasmids encode many of the activities essential for food fermentations (de Vos, 1999), including lactose metabolism, proteinase activity, oligopeptide transport, bacteriophage resistance mechanisms, bacteriocin production and immunity, bacteriocin resistance, exopolysaccharide production, and citrate utilization.

Natural gene transfer systems among LAB are largely transduction and conjugation, although transformation also has been reported as a means of genetic exchanges (Rodriguez and Vidal, 1990). Transduction, the transfer of bacterial genetic material by a bacteriophage, has been demonstrated in lactococci, lactobacilli, and *Streptococcus thermophilus*. Usefulness of transduction in construction of strains for the fermentation industry is limited because of the relatively narrow host range of transducing bacteriophage. Conjugation, the transfer of genetic material from one bacterial cell to another, which requires cell-to-cell contact, has been well characterized in lactococci. Most plasmid-encoded characteristics important in the manufacture of fermented dairy products can be transferred by conjugation. Using an approach that does not require antibiotic-resistance markers, conjugation has been used to transfer plasmids that encode bacteriophage-resistance genes into commercial lactococcal strains (Verrips and van den Berg, 1996). These strains have enhanced resistance to infection by bacterioph-

age and have been used successfully in the dairy industry for years.

Starter Culture Improvement Past emphasis on starter culture improvement was largely based on screening natural isolates for traits of interest and monitoring existing strains to select for beneficial variations. More recently, advances in molecular technology have enabled us to understand more about the biology, physiology, and taxonomy of LAB and other microorganisms important to food fermentations (McKay and Baldwin, 1990). In the future, it may be possible to definitively identify and then combine the most desirable nutritional, sensory, and/or therapeutic properties of starter cultures to construct "superior" strains for food fermentations (Geisen and Holzapfel, 1996). At present, however, strain improvement focuses on eliminating problems that beset their use as starter cultures. Features such as bacteriophage infection, genetic instability, variation and unpredictability in performance, and the production of low-grade or poor-quality products all lead to economic losses. These are characteristics that have been examined extensively with interest in identifying and generating strains with superior attributes. Considerable research has been devoted to studying phage and phage-host interactions in LAB, the mechanisms by which lactose, citrate, and protein are metabolized, and the basis for instability and unpredictability in strain performance. Also because of their food-grade, nonpathogenic, generally recognized as safe (GRAS) status, LAB are considered to be ideal hosts for the production of proteins and other compounds that they do not produce naturally and that have medical or food-related applications (Kuipers et al., 1997).

Bacteriophage and Bacteriophage Resistance Food fermentations rely on actively growing LAB that either are added as starter cultures or grow spontaneously in the food matrix. The fermentation capabilities of LAB can be severely inhibited by bacteriophage infection, which has been a major commercial problem (Klaenhammer, 1991). Bacteriophages are bacterial viruses that were first identified as "filter-transmissible" agents at the beginning of 1900. Significant progress has been made toward the characterization of bacteriophages from LAB. All of the bacteriophages examined contain double-stranded linear DNA genomes with either cohesive or circularly permuted terminally redundant ends. Both lytic and temperate bacteriophages have been identified. Bacteriophage infection may lead to a decrease or complete inhibition of lactic acid production by the starter culture. This effect has had a major impact on the manufacture of fermented food products, as lactic acid synthesis is required to produce these products. In addition, slow acid production disrupts manufacturing schedules and typically results in products that are of lower economic value. Therefore, bacteriophage resistance remains one of the most important characteristics of any industrial LAB strain, whether natural or genetically engineered (Klaenhammer, 1991).

Selective environmental pressure placed on LAB by bacteriophages over thousands of years has resulted in strains that possess many bacteriophage defense mechanisms. The best-characterized bacteriophage-resistant LAB is lactococci (Dinsmore and Klaenhammer, 1995; Sanders, 1988). Phage defense mechanisms identified in lactococci include abortive infection mechanisms, the restriction-modification system, and interference with phage adsorption. Abortive phage infection is a powerful defense, acting after phage injection to decrease phage development efficiency and so reduce the number of emerging phages when the cell bursts. This mechanism effectively decreases phage replication rates and results in poor to no plaque formation on agar assays. The restriction modification system is another common phage defense mechanism that reduces plaquing efficiencies of phages on normally permissive hosts by several log cycles. Such systems operate by coordinated activities of a restriction enzyme that recognizes and cleaves foreign DNA and a modification enzyme that labels DNA as host derived. These defense loci are encoded by plasmids capable of conjugal transfer, suggesting that genetic exchange between LAB has an important role in the development of bacteriophage-resistant starter cultures (Sanders, 1988). Recombinant DNA techniques also have been used to engineer starter cultures with enhanced bacteriophage resistance (Daly et al., 1996). An alternative approach to the development of phage-resistant strains uses a designed antisense RNA to control the expression of phage genes.

Flavor Production LAB generate a range of flavor products such as diacetyl, which has a buttery aroma and is a highly desirable product in many foods (Cogan and Accolas, 1996). Strategies involving metabolic engineering, whereby metabolic pathways are manipulated to overproduce specific products, have been used to develop cultures that elaborate elevated levels of diacetyl. Proteolytic activity of LAB is of major significance in contributing to the liberation of small peptides and amino acids which either add flavor directly or are likely to be flavor precursors.

Commercial Application

DAIRY PRODUCTS Fermented dairy products are enjoying increased popularity as convenient, nutritious, stable, natural, and healthy foods. LAB are the principal organisms involved in the manufacture of cheese, yogurt, sour cream, and cultured butter. In some fermented dairy products, additional bacteria, referred to as secondary microflora, are added to produce carbon dioxide, which influences the flavor and alters the texture of the final product (Early, 1998). Two LAB, *Leuconostoc* species and strains of *Lactobacillus lactis* subsp *lactis*, which are capable of metabolizing citric acid, are added to produce aroma compounds and carbon dioxide in cultured buttermilk and certain cheeses. *Propionibacterium freudenreichii* subsp. *shermanii* is added to Swiss-type cheeses primarily to metabolize L-lactic acid to propionic acid, acetic acid, and carbon dioxide. Carbon dioxide forms the eyes in Swiss-type cheeses. Other types of secondary microflora include undefined mixtures of yeasts, molds, and bacteria (Ray, 1996). These microorganisms are added directly to the milk or are smeared, sprayed, or rubbed onto the cheese surface. This group of microorganisms has extremely varied and complex metabolic activities, their main function being to produce unique flavors. LAB and the predominant microbes used to make fermented dairy products are listed in Table 4 (Johnson and Steele, 1997).

Cultured Butter and Buttermilk Cultured butter is made from milk fat to which a mesophilic starter culture has been added to enhance its flavor, principally that of diacetyl. Diacetyl, made from citrate by LAB, enhances buttermilk's storage properties. *Lactobacillus lactis* or mixed cultures that contain *Lb. lactis*, *Leuconostoc citrovurum*, and *Leu. dextranicum* are used (Early, 1998). Fat (cream) is separated from skim milk by centrifugation of milk. The cream is pasteurized and inoculated with selected starter cultures. The ripened cream is then churned. The cream separates again into cream butter and its byproduct sour buttermilk, which has limited use because of its high acidity.

An alternative process has been developed to produce cultured butter without the formation of sour buttermilk. In this process lactose-reduced whey inoculated with *Lactobacillus helveticus*, and skim milk inoculated with a starter culture to produce aroma compounds and lactic acid, are added to the pasteurized cream. The cream is further churned and worked. The resulting butter is known as sour aromatic butter and the liquid phase is sweet buttermilk, which is not as acidic as sour buttermilk.

Yogurt Yogurt is produced by fermenting milk, usually cow's milk, with *Streptococcus thermophilus* and *Lactobacillus bulgaricus* (Chandan and Shahani, 1993). Initial acid production is largely due to *Str. thermophilus*, but the characteristic yogurt flavor is produced by *Lb. bulgaricus*. Both yogurt cultures may produce extracellular polymers, which contribute to the viscosity of yogurt. It is desirable that the starter

Sour cream	*Lactococcus lactis* subsp. *cremoris* *Lactococcus lactis* subsp. *lactis*	None

cultures be present in approximately equal numbers to ensure the characteristic flavor, consistency and odor; otherwise *Lb. bulgaricus* becomes dominant.

Yogurt is generally fermented in batches. Standardized milk, with a fat content of 0.5 to 3.0% and milk solids of 14 to 16%, is homogenized and pasteurized. After cooling to the incubation temperature, the batch is inoculated with starter cultures and incubated for 16 h at 30°C or 4 h at 45°C. The product is then cooled to 2 to 4°C and packaged and stored.

Cheese Cheese making is essentially a dehydration process in which milk casein, fat, and minerals are concentrated 6 to 12-fold, depending on the variety. Although the manufacturing protocols for individual varieties differ, the basic steps common to most varieties are acidification, coagulation, dehydration, and salting. Acid production is the major function of the starter bacteria. Lactic acid is responsible for the fresh acidic flavor of unripened cheese and is of importance in coagulation of milk. Coagulation of the casein is accomplished by the concerted action of rennet and by acidification. Starters play other essential roles in the production of volatile flavor compounds (e.g., diacetyl, aldehydes), the synthesis and release of the intracellular proteolytic and lipolytic enzymes involved in the cheese ripening (Steele, 1995), and the suppression of pathogens and other spoilage microorganisms (Lewus et al., 1991). For cheddar cheese production, starters include mixed strains of *Lactobacillus lactis* subsp. *cremoris* or *lactis*. *Leuconostoc* may be added for flavor development. *Streptococcus thermophilus* and *Lb. helveticus* are used in Swiss cheese primarily for acid production, whereas *Propionibacterium* spp. is a secondary culture added for eye formation, taste, and flavor. Similar to Cheddar cheese production, blue cheese production requires *Lb. lactis* subsp. *cremoris* or *lactis* and *Leuconostoc* spp, but the mold *Penicillium roqueforti* is also added as a secondary culture for flavor and blue appearance.

Meat Products Fermented meat products are defined as meats that are deliberately inoculated during processing to ensure sufficient controlled microbial activity to alter the product's sensory characteristics (Luche, 1994). Dry and semidry sausages represent the largest category of fermented meat products, with many present-day processing practices having their origin in the Mediterranean region. Fermented sausages are chopped or ground meat products that, as a result of bacterial action, reach a pH of 5.3 or less and are then dried. Based on final moisture content, fermented sausages are classified as dry (25–45% moisture content) or semidry (40–50% moisture content). To ensure products of consistent flavor, texture and shelf stability, as well as to improve product safety, most processors have developed pure microbial cultures to control the fermentation of their sausage product. It is evident that with a starter culture, the pH drops much more rapidly, hence the entire manufacturing process is accelerated, leading to economic benefits for the processor. Most starter cultures are natural isolates of the desirable microorganisms found normally in sausage (Egan, 1983). A wide variety of species has been used as starter cultures in meat and poultry products (Table 5; Riche and Keeton, 1997).

Table 5. Bacteria used as starter cultures in meat and poultry products.

Vegetable and Fruit Products The fermentation of vegetables and fruits can be affected by many different microorganisms (Daeschel and Fleming, 1984). LAB and yeasts are preferentially used in the western hemisphere, whereas in the Orient a large number of victuals are fermented by molds. However, the most extensively used procedure for biopreservation of vegetables involves lactic acid fermentation. Almost all vegetables can be fermented through natural processes because they contain fermentable carbohydrates and harbor many types of LAB. Therefore, many fermented vegetable products are produced by natural fermentation, and some such as cucumbers are now being produced by controlled fermentation (Buckenhuskes, 1997). Although many different vegetables are commercially fermented, at present only olives, cabbage for sauerkraut, and cucumbers for pickles are of major economic importance (Buckenhuskes, 1993).

Sauerkraut Sauerkraut is produced from the natural lactic acid fermentation of cabbage that has been shredded and salted. It is a major fermented vegetable food in Europe and the United States. At the beginning of the fermentation, some oxygen remains in the shredded cabbage. Plant cells, aerobic bacteria, yeasts and molds consume this remaining oxygen and then die off as the oxygen supply diminishes. The facultative anaerobes then increase in number. Initially, coliform species (e.g., *Enterobacter cloacae*) and *Flavobacterium* species grow to produce gas, volatile fatty acids and flavors. As the acidity increases, these bacteria are normally replaced by *Leuconostoc mesenteroides*, which become the predominant microbes. They are subsequently succeeded by *Lactobacillus brevis*, *Pediococcus pentosaccus* and *Lb. Plantarum*, which raise the acid level to about 2% and decrease the pH to 3.4–3.6.

Cucumber Pickles The starter culture for cucumber fermentation usually consists of the normal mixed flora of cucumbers, including *Lb. mesenteroides*, *Enterococcus faecalis*, *Pediococcus cerevisiae*, *Lb. brevis*, and *Lb. plantarum*. Of these, the pediococci and *Lb. plantarum* are the most involved, with *Lb. brevis* being undesirable because of its ability to produce gas. *Lb. plantarum* is the most essential species in pickle production, as it is for sauerkraut. The natural fermentation of cucumbers, though in practice for many years, can lead to pickle spoilage and thereby serious economic loss. A controlled fermentation of cucumbers brined in bulk has been developed, and this process not only reduces economic losses but also leads to a more uniform product over a shorter period of time (10–12 days). This method employs a chlorinated brine of 25° salinometer, acidification with acetic acid, the addition of sodium acetate, and inoculation with *P. cerevisiae* and *Lb. plantarum* or with *Lb. plantarum* only.

Olives Like cucumbers, olives are fruits that are categorized as vegetables and are fermented under conditions similar to those of other vegetable products. The microbial population responsible for the fermentation of olives differs from that of sauerkraut and pickles mainly because the higher salt concentration of the brine prevents many salt-sensitive strains from growing and provides an advantage to salt-tolerant strains. LAB become prominent during the intermediate stage of fermentation. *Lb. mesenteroides* and *P. cerevisiae* are the first lactics to become predominant, followed by lactobacilli, with *Lb. plantarum* and *Lb. brevis* being the most important. The fermentation may require as long as 6–10 months to complete, and the final pH of the product is 3.8 to 4.0.

Vinegar Vinegar (acetic acid) is used as an acidulant and flavor compound in processed foods. It is produced by an alcoholic fermentation of sugar-containing plant extracts followed by a microbial oxidation of ethanol to acetic acid (Sievers and Teuber, 1995). The slow process of natural acetification of wines and ciders is the oldest method of making vinegar. The Orleans process, developed in France for the industrial production of vinegar at the end of the 14th century, is also a slow fermentation in which the substrate "wine" is placed in barrels and inoculated with fresh vinegar or with the slimy, thick microbial film formed on the surface of the fermenting mash during acetification. Technological advances have led to a submerged culture process in which a suspension of *Acetobacter* spp. grows in an ethanol-containing substrate with constant agitation and small air bubbles. Commercial strains of *Acetobacter* include low cost, higher yields, less space required and low evaporation loss.

Malolactic Fermentation in Wine Malolactic fermentation (carried out by many LAB) involves the decarboxylation of malic acid to lactic acid and CO_2. In wine making as well as in production of cider and perry, LAB reduce acidity by converting malic to lactic acid and modify flavor and texture, which in part mature a beverage (Henick-Kling, 1995). Red and white wines are commonly produced by a yeast alcoholic fermentation of musts prepared from grapes. After alcoholic fermentation, wines frequently undergo malolactic fermentation. This process occurs naturally at or near the completion of alcoholic

fermentation. Wines produced from grapes cultivated in cool climates generally have higher concentrations of malic acid, which can mask the varietal character of the wine. Decreasing acidity by malolactic fermentation produces a wine with a softer and more mellow taste. LAB resident in wine are responsible for the malolactic fermentation. However, since the early 1980s, commercial starter cultures consisting of *Leuconostoc oenos*, *Lb. plantarum*, and *Lb. hilgardii* as single- or multiple-strain preparations have been available for the induction of malolactic fermentation (Buckenhuskes, 1993). The malolactic fermentation is more commonly used in red wines, although recently it is increasingly used in white wines.

Indigenous Fermented Beverages Production of indigenous fermented beverages (examples listed in Table 6) often involves complex biochemical, sensory and nutritional changes that can result from more or less controlled microbial activity in a range of raw materials (Beuchat, 1997). The preparation of many indigenous or traditional fermented beverages is a household art. Thus, they are often produced regionally or by different ethnic groups and are not commerically available (Steinkraus, 1983). The microbiology of indigenous fermented beverages is less clear. In many cases, LAB and yeasts both contribute to the fermentation process.

Probiotic Bacteria and Competitive Exclusion

A probiotic is a mono- or mixed culture of live microorganisms that, applied to animals or humans, beneficially affects the host by improving the properties of the gastrointestinal normal flora (Abe et al., 1995; Holzapfel et al., 1998; Hove et al., 1999). But it is restricted to products that contain live organisms, improve the health and well-being of animals or humans, and can have their effect on all host mucosal surfaces. Most microbial species used or tested for probiotic efficacy are LAB. Some bifidobacteria and yeasts are also used in the dairy industry. LAB have been used in foods for centuries and most strains are considered commensal microorganisms with no pathogenic potential. Their omnipresence on the intestinal epithelium of the human gastrointestinal tract, their traditional use in fermented foods without significant health-associated problems, and their health-promoting benefits make this group of bacteria ideal candidates for use as a probiotic (Naidu et al., 1999).

Probiotic Bacteria in Food Incorporating probiotic bacteria into foods to counteract harmful bacteria in the intestinal tract has been a renewed interest in health promotion and disease prevention in recent years (Gilliland, 1990; Gorbach, 1990; Holzapfel et al., 1998; Hove et al., 1999). Foods containing probiotic microorganisms range from dairy foods to infant formulas, baby foods, fruit juice-based products, cereal-based products, and pharmaceuticals. New and more specific strains of probiotic bacteria are being sought. Many studies have been conducted during the last 30 years to determine specific health benefits from the consumption of live cells of these organisms (Gorbach, 1990; Hove et al., 1999). There are three major sources of the live cells: 1) fermented milk products, such as yogurt containing live cells of *Lb. delbrueckii* subsp. *bulgaricus* and *Str. thermophilus* and acidophilus milk containing *Lb. acidophilus*; 2) supplementation of foods and drinks with live cells of one or more types of probiotic bacteria, such as *Lb. acidophilus*, *Lb. reuteri*, *Lb. casei*, and *Bifidobacterium* species; and 3) pharmaceutical products in the form of tablets, capsules, and granules. The beneficial effects of probiotic bacteria include protection against enteric pathogens (Jeppesen and Huss, 1993; Lewus et al.,

Table 6. Examples of indigenous fermented beverages.

Product	Geography	Substrate	Microorganism(s)	Product use
Busa	Tartars of Krim, Turkestan, Egypt	Rice or millet, sugar	*Lactobacillus* and *Saccharomyces* spp.	Drink
Mahewu (Magou)	South Africa	Maize	LAB	Sour and nonalcoholic drink
Pito	Nigeria	Guinea corn or maize or both	Yeast, LAB	Drink
Sorghum beer	South Africa	Sorghum, maize	LAB, yeast	Acidic and weakly alcoholic drink
Soybean milk yogurt	China, Japan	Soybeans	LAB	Drink
Pulque	Mexico	Agave	LAB, *Saccharomyces* spp., *Zymomonas mobilis*	Alcoholic drink

LAB, lactic acid bacteria.

1991; Okereke and Montville, 1991; Rodriguez et al., 1997), detoxification and improved digestion by means of enzymes to metabolize some food nutrients (e.g., lactase to hydrolyze lactose; Gilliland, 1990) and remove some harmful food components and metabolites (El-Nezami and Ahokas, 1998), stimulation of the intestinal immune system (Salminen and Deighton, 1992; Salminen and Salminen, 1997), and improvement of intestinal peristaltic activity (Rafter, 1995).

Selection Criteria for Probiotic Bacteria The theoretical base for selection of probiotic microorganisms includes safety, functional aspects (survival, adherence, colonization, antimicrobial production, immune stimulation, antigenotoxic activity, and prevention of pathogens), and technological aspects (growth in milk or other food base, sensory properties, stability, phage resistance, and viability; Salminen et al., 1998).

Competitive Exclusion Concept The competitive exclusion concept was originated by Nurmi and Rantala (1973), based on the study of *Salmonella* in chickens. Newly hatched birds on modern poultry farms are not able to obtain the normal gut flora of adult birds. As a result, the intestines of chicks are easily colonized by pathogens. When the chickens were inoculated immediately after birth with the intestinal content of a *Salmonella*-free adult bird, the frequency of Salmonella infections was radically reduced and the number of *Salmonella* needed to colonize the ceca of chicks increased. Hence, the normal gastrointestinal microflora of adult chickens can competitively exclude *Salmonella* from colonizing the naïve intestinal tract of chicks.

Competitive Exclusion of Foodborne Pathogens After establishment of the basic concept of competitive exclusion, considerable research has been done to identify the mechanisms by which bacteria are competitively excluded from host sites (Nurmi et al., 1992; Zhao et al., 1995). Responsible factors include competition for receptor sites on the intestinal epithelium, production of volatile fatty acids and/or other antibacterial substances, and competition among different bacteria for limited nutrients. The use of LAB as a probiotic for live poultry and livestock has been extensively studied and has potential to reduce carriage of pathogens and increase growth rates (Abe et al., 1995; Hammes and Tichaczek, 1994). Cecum-colonizing bacteria including *Escherichia coli* that produce inhibitory metabolites to *Campylobacter jejuni* have been used successfully to reduce intestinal carriage of *C. jejuni* by poultry (Aho et al., 1992; Schoeni and Doyle, 1992). Similarly, *E. coli* strains that produce antimicrobial metabolites to *E. coli* O157:H7 have been confirmed effective in reducing or eliminating carriage of *E. coli* O157:H7 by cattle (Zhao et al., 1998).

Prospects

For many years bacteria, mainly LAB, have been involved in the fermentation of foods from raw agricultural materials such as milk, meat, vegetables, fruits, and cereals. Fermented foods are a significant part of the food processing industry and are often produced using bacteria that have been selected for their ability to effectively produce desired products or changes. The interaction of LAB and other bacteria in enhancing the physiology, nutrition, and metabolism of humans and animals, and their involvement in promoting health and reducing disease, are additional roles that prokaryotes can serve by their presence in foods. Over the past decade, there have been major developments in furthering our understanding of both the biochemistry and physiology of bacteria involved in food fermentations. Advanced molecular techniques have served as invaluable tools for the development of defined mutants that have enabled basic studies on proteolysis, peptidase action, and peptide transport. Knowledge from such studies is invaluable for the design and modification of commercially useful strains. The application of genetic engineering technology to improve existing strains through enhanced bacteriophage resistance or more efficient metabolic characteristics such as proteolytic activities or to develop novel strains for fermentations has greatly contributed to the success of the fermentation industry through more consistent production of high quality, uniform products and less fermentation failure.

CHAPTER 3.6

Bacterial Pharmaceutical Products

ARNOLD L. DEMAIN AND GIANCARLO LANCINI

Introduction

In contrast to plant metabolites, whose use against diseases has roots in folk and traditional medicine, bacterial pharmaceutical products are the result of large targeted research efforts, carried out by tens of laboratories all around the world. The original approach (later denoted "screening") of Selman Waksman in 1939–1940 (Waksman and Woodruff, 1940) consisted of 1) systematically collecting soil microorganisms, 2) growing them in axenic culture, 3) testing the culture broths for their ability to inhibit the growth of pathogens, and 4) recovering the active substances produced. It was rapidly found that actinomycetes were most frequently positive; in particular, nearly 50% of *Streptomyces* strains isolated were active, mainly against Gram-positive bacteria. This widely applied approach was very fruitful by the early 1960s, and members of all the main families of clinically useful antibiotics were discovered. With the exception of the penicillins, cephalosporins and a few minor products, all were produced by actinomycetes. Their collective spectra of action covered practically all the important bacterial pathogens.

In the 1960s, the need was felt for a substantial revision of the objectives and the methods of the screening. The number of antibiotics isolated was such that repetitions of discovery became more and more frequent. In fact, 1,300 metabolites had been reported in journals or patents by 1960, and over 2,000 by 1965 (data from Biosearch Italia database, courtesy of G. Toppo). General antibacterial activity appeared to be a less attractive target than activity against fungi, viruses or antibiotic-resistant bacterial strains. Antitumor efficacy was also considered as a possible target. Therefore, the search for novel metabolites was slowly changed in the various laboratories. Some devised methods for mass screening of unusual genera of microorganisms (such as rare actinomycetes) or organisms living in different (e.g., marine) environments. Others relied upon the use of new targets, rather than on isolation of novel producers, to select new products. The result was the discovery of novel and important antimicrobial agents, antitumor substances and inhibitors of mammalian enzymes of potential pharmaceutical interest. Mammalian enzymes have been especially targeted in recent years, with the isolation of pharmacologically active metabolites and of antimicrobial agents occurring at present at about the same frequency. However, the number of new products of proven clinical value has been unfortunately declining.

All these natural products are known as secondary metabolites ("idiolites"). They are low molecular weight products of microbial metabolism (such as antibiotics, pheromones, sex hormones, etc.) that differ from primary metabolites (amino acids, vitamins, purines, pyrimidines, etc.) in that they are not involved in growth processes but rather in mechanisms of survival in nature.

The advent of modern biotechnology opened totally new perspectives for the use of microorganisms as producers of pharmaceutical products. Genetic engineering provided methods (such as altering biosynthetic genes or inserting selected genes into the DNA of an antibiotic-producing strain) for obtaining modified secondary metabolites. Moreover, a number of new metabolites could be obtained by randomly combining the genes of two or more gene clusters governing similar biosynthetic pathways. Even more important, the progress of biotechnology made feasible the industrial production of mammalian peptides by bacteria and other hosts. The stages of this development have been: 1) biosynthesis of known clinically useful proteins (e.g., insulin and human growth hormone) and the generation of monoclonal antibodies to them, 2) identification and cloning of genes encoding physiologically important, lesser-known proteins (e.g., interferons, interleukins, colony stimulation factors, cytokines, thrombolytic agents and vaccines), and finally, 3) provision of macromolecules (e.g., receptors, ligands, enzymes, cytoskeleton proteins, adhesion molecules, signalling proteins and regulatory elements) to be used in screening for modulators. We summarize in this chapter the main results obtained during the past sixty years

in the search and development of the various classes of medically useful substances produced by bacteria.

Secondary Metabolites

Bacterial secondary metabolites are relatively small molecules, each produced by a limited number of strains that appear to have no obvious function in growth. In fact, producer strains that by mutation have lost their production ability exhibit perfectly normal growth rates and characteristics. Secondary metabolites include antibiotics, pigments, toxins, effectors of ecological competition and symbiosis, pheromones, enzyme inhibitors, immunomodulating agents, receptor antagonists and agonists, pesticides, antitumor agents and growth promotants of animals and plants. Nature produces an amazing variety and number of such products. At the end of 1999, over 23,400 microbial secondary metabolites were known. Of these, 42.1% were produced by fungi, 42.4% by actinomycetes and 15.5% by other bacteria (Lazzarini et al., 2001). New bioactive products from microbes continue to be discovered at an amazing pace: 200 to 300 per year in the late 1970s increasing to 500 per year by 1997.

Classical Antibiotics

The most important microbial metabolites so far isolated are antibiotics, i.e., substances (produced by microorganisms) that inhibit at low concentrations the growth of different species of microorganisms. They exert a major effect on the health, nutrition and economics of our society. Over 8,100 were reported by the end of 1999, 45.6% of which were produced by streptomycetes, 16.0% by other actinomycetes, 16.9% by other bacteria and 21.5% by fungi (Lazzarini et al., 2001). In addition to their number, another impressive aspect of antibiotics is the variety of their chemical structures. All the different classes of organic chemistry are represented: aliphatic chains, aromatic rings isolated or condensed, heterocyclic rings (all substituted with any imaginable function) and oligopeptides, oligosaccharides and so on.

The property that makes antibiotics veritable "wonder drugs" is the selectivity of their mechanisms of antimicrobial action, which distinguishes them from the plethora of synthetic disinfectants and germicides. We have benefited for almost sixty years from their remarkable property of being selectively toxic to some class of organisms. The successes were so impressive that antibiotics were, with a few exceptions, the only drugs utilized for therapy against most pathogenic microorganisms. By 1996, the world market for antimicrobials amounted to $23 billion and involved some 150–300 products (natural, semisynthetic or synthetic), which included cephalosporins (45%), penicillins (15%), quinolones (11%), tetracyclines (6%) and macrolides (5%), thienamycin and others (Strohl, 1997).

Antibiotics are commonly grouped into families. A family is comprised of all the products having a similar chemical structure and sharing the same mechanism of antimicrobial action. We summarize here the characteristics of the classical antibiotic families used in human therapy (Lancini et al., 1995).

β-Lactams: Typical of the chemical structure of these antibiotics is the presence of a four-membered ring closed by an amide bond. They exert a killing action on many bacterial species by inhibiting the assembly of the peptidoglycan component of the cell wall. Fungi produce the classical subfamilies, penicillins and cephalosporins, although bacteria make modified cephalosporins, e.g., cephamycins, etc. Thienamycin, one of the last commercial antibiotics discovered and which possesses a β-lactam ring and an exceptionally broad spectrum of action, is produced by a prokaryote, *Streptomyces cattleya*.

Aminoglycosides: Chemically, these are oligosaccharides comprising aminosugars and an aminocyclitol moiety, i.e., an alicyclic six-membered ring with hydroxyl and amino substituents. They are mainly active on Gram-negative bacteria and act by irreversibly inhibiting protein synthesis. The main products are streptomycin from *Streptomyces griseus*, and gentamicins, produced by *Micromonospora purpurea*.

Tetracyclines: Characteristically composed of four six-membered rings linearly arranged, these broad spectrum antibiotics act by inhibiting protein synthesis at the ribosomal level, but their binding site on the 30S ribosomal subunit differs from that of aminoglycosides. In clinical use are oxytetracycline produced by *Streptomyces rimosus*, tetracycline and chlortetracycline from *Streptomyces aureofaciens*, and a number of their derivatives.

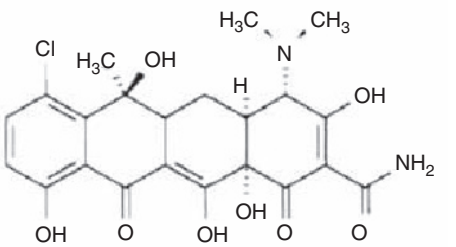
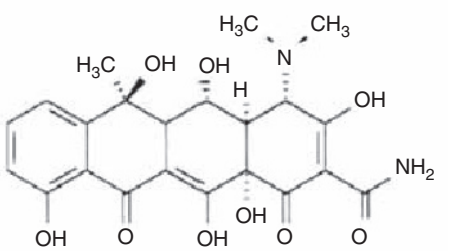
Tetracycline



Chlortetracycline



Oxytetracycline

Fig. 3. Tetracyclines.

Antibacterial macrolides: This is a large family of products characterized by a lactone ring of 12 to 16 atoms bearing two or more sugar substituents. The best-known representative is erythromycin, produced by *Saccharopolyspora erythrea*. It inhibits protein synthesis, binding (unlike tetracyclines) to the 50S ribosomal subunit.

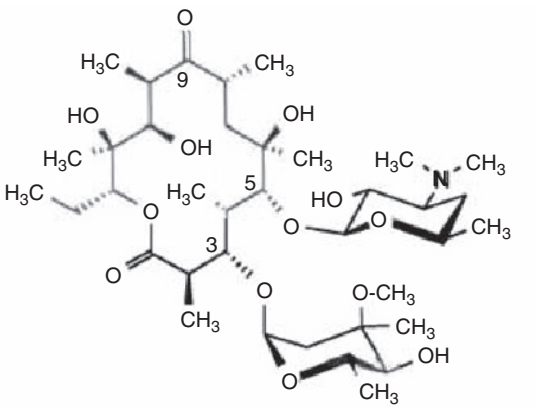
Polyenes: These antifungal macrolides differ from antibacterial macrolides in the size of the lactone ring, ranging from 26 to 38 atoms, and with the presence of a series of conjugated double bonds. The only member systemically used is amphotericin B, produced by *Streptomyces nodosus*. Antifungal activity is due to interference with membrane sterols, resulting in permeability alteration.

Glycopeptides: Among the vast class of peptide antibiotics, the only ones commonly used are members of this family, denoted as "dalbaheptides" in view of their mechanism of action (*D-al*anine-D-alanine *b*inding) and their composition (*he*ptape*ptides*). The most well known are vancomycin and teicoplanin, produced by *Amycolatopsis orientalis* and *Actinoplanes teichomyceticus*, respectively.

Rifamycins: This family belongs to the large class of ansamycins, molecules characterized by an aromatic nucleus spanned by an aliphatic (the ansa) chain. Their mechanism of action is inhibition of RNA synthesis by binding to RNA poly-

merase. Industrially produced are rifamycin B and rifamycin SV, from *Amycolatopsis mediterranei*. These are the starting materials for the synthesis of rifampicin or rifapentine, clinically used semisynthetic derivatives.

There are a few important antibiotics not belonging to any of the large families. These include chloramphenicol and lincomycin, both having a mechanism of action similar to that of erythromycin. Chloramphenicol was isolated from *Streptomyces venezuelae* but is now produced by chemical synthesis. Lincomycin is the product of *Streptomyces lincolnensis*.



Erythromycin A

Non-classical Antibiotics and Products under Development

About 30 years ago, the difficulty and high cost of isolating novel structures and agents with new antimicrobial modes of action became apparent and the field looked like it might enter a phase of decline. This is understandable considering the probability of finding useful antibiotics from microbes is one from 10,000 to 100,000 cultures examined (Fleming et al., 1982; Woodruff et al., 1979; Woodruff and McDaniel, 1958). Indeed, the number of anti-infective investigational new drugs (INDs) declined by 50% from the 1960s to the late 1980s (DiMasi et al., 1994).

Prior to the 1980s, bacterially produced antibiotics were the mainstay of control of pathogenic organisms in humans (β-lactams, chloramphenicol, tetracyclines, erythromycin, streptomycin, gentamicin, rifamycin, vancomycin, lincomycin), in foods (nisin), in animals (monensin) and in plants (polyoxins). However, new antibiotics were clearly needed because of 1) the development of resistance in pathogens, 2) the evolution of new diseases (e.g., AIDS, Hanta virus, Ebola virus, *Cryptospiridium*, Legionnaire's disease, Lyme disease and *Escherichia coli* 0157:H7), 3) the existence of naturally resistant bacteria (Stephens and Shapiro, 1997), e.g., *Pseudomonas aeruginosa* (causing fatal wound infections, burn infections and chronic and fatal infections in the lungs of cystic fibrosis patients), *Stenotrophomonas maltophilia*, *Enterococcus faecium*, *Burkholderia cepacia* and *Acinetobacter baumanni* (Tenover and Hughes, 1996), and 4) the toxicity of some of the approved compounds (Strohl, 1997). Other organisms existed which were not normally virulent but did infect immu-

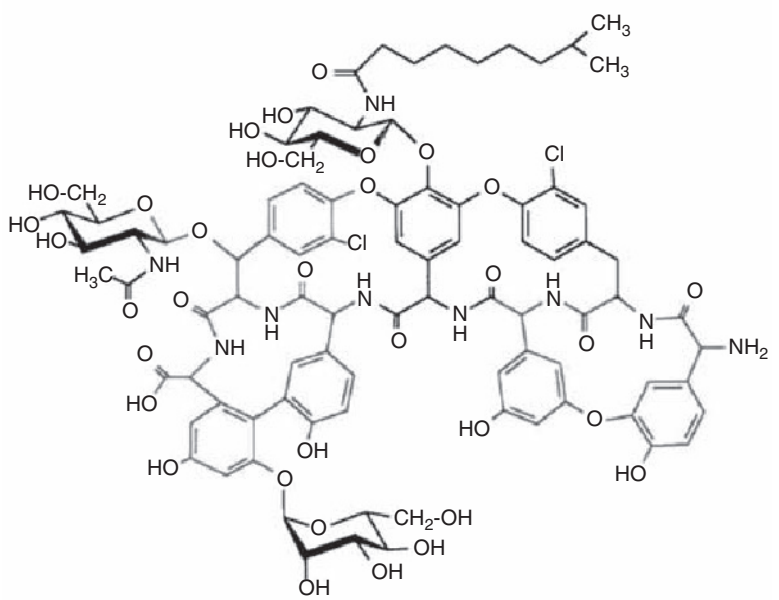
Vancomycin



Teicoplanin

Fig. 6. Glycopeptides.

nocompromised patients (Morris et al., 1998). By the technique of semisynthesis, chemists had been improving antibiotics for many years. Despite the success of many semisynthetic antibiotics, new screening techniques were sorely needed in the 1970s and 1980s to isolate new bioactive molecules from nature. Owing to the development of novel target-directed screening procedures, discovery of new effective antibiotics active against cell-wall biosynthesis led to commercial successes. These included fosfomycin (Hendlin et al., 1969) and thienamycin (Birnbaum et al., 1985).

Thienamycin is the most potent and broadest in spectrum of all antibiotics known today. Although a β-lactam, it is not a member of the penicillins or cephalosporins; rather, it is a carbapenem, differing from the conventional β-lactams by the presence of a carbon atom instead of sulfur in the ring condensed to the lactam ring and by the *trans* configuration of the hydrogen atoms of the lactam ring. It is bactericidal against aerobic and anaerobic bacteria, both Gram-positive and Gram-negative, including *Pseudomonas*. This novel structure was isolated in Spain from a new soil species, which was named *S.*

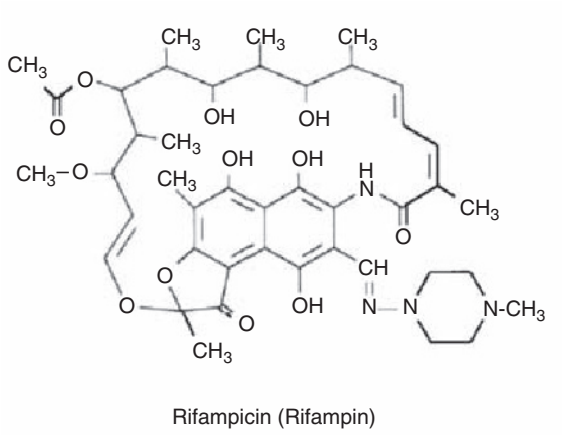


Fig. 7. Rifampicin (Rifampin).

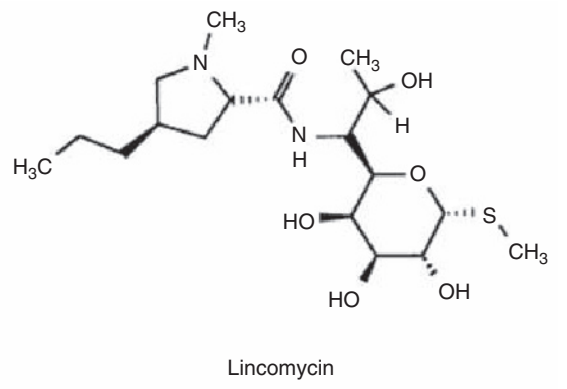

Fig. 8. Lincomycin.

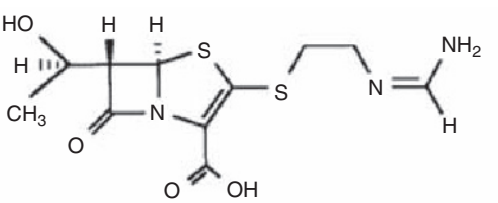

Fig. 9. Imipenem (a semisynthetic thienamycin).

cattleya (Kahan et al., 1979). Interestingly, this culture also produces penicillin N and cephamycin C.

Similar to those of the other bacterial β-lactams, thienamycin's mode of action is inhibition of peptidoglycan synthesis; however, it is not affected by most bacterial β-lactamases and is therefore active against resistant strains. It is chemically rather unstable but chemists were able to eliminate this problem by modifying the molecule. The new derivative, named imipenem, was not only more stable but also twice as active as the original molecule. In humans, imipenem was found to be metabolized by an enzyme in the kidney, renal dehydropeptidase-I, which acts as a β-lactamase.

Because the enzyme appeared to serve no essential role in human metabolism, scientists were able to develop a synthetic competitive inhibitor, cilastatin, which they then used with imipenem to produce the combination drug, primaxin (Tienam). Primaxin was introduced into medical practice in 1985. The unique activity of thienamycin is due to several factors: 1) it permeates the Gram-negative outer cell membrane through porin channels at 10–20 times the rate of classical β-lactams; 2) it is not destroyed by the β-lactamases of the periplasmic space; 3) it binds to and inhibits all penicillin-binding proteins (PBPs) but is principally active against PBPs-2 and -1b; sequential inhibition of PBPs-2 and -1b converts the cells of the pathogen to nongrowing spheroplasts, which rapidly die; and 4) after removal of thienamycin, there is a long delay before regrowth of any unkilled spheroplasts. The only limitation in thienamycin use is that it is not active against methicillin-resistant staphylococcal strains. If thienamycin is so potent, why did it take over 25 years of worldwide screening before it was discovered? Today, we know that carbapenems are not rare. Many members of this family have been isolated in laboratories all over the world although none equals thienamycin in potency and spectrum of activity. The answer probably lies in its extremely low level of production by wild strains and its instability. Conventional screening procedures evidently missed this activity and only after the development of specific and sensitive modern assay procedures was it found. Thienamycin was discovered by a sensitive mode of action screen, the details of which have never been revealed.

Microbiologists knew in the 1970s–1980s that antibiotic technology had not yet defeated infectious microorganisms owing to resistance development in pathogenic microbes. Indeed, antibiotics probably can never win the war against infection permanently and we have to be satisfied to stay one step ahead of the pathogens for a long time to come. Thus, the search for new natural product drugs and their improved semisynthetic derivatives slowed down but, fortunately, was not stopped. As a result, new products are in clinical testing. Clinical isolates of penicillin-resistant *Streptococcus pneumoniae*, the most common cause of bacterial pneumonia, increased in the United States from 1987 to 1992 by 60-fold (Breiman et al., 1994). Methicillin-resistant *Staphylococcus* infections increased to

an alarming extent throughout the world (Goldman et al., 1996). At present, vancomycin is still the molecule of choice to treat these infections; however, resistance is developing to this glycopeptide antibiotic, especially in the case of nosocomial *Enterococcus* infections. Fortunately, some vancomycin-resistant enterococci are treatable by the related glycopeptide, teicoplanin. Teicoplanin is not, at present, available in the United States but is available in Europe only; however, a derivative discovered by Biosearch Italia, BI 397, endowed with similar but improved characteristics, is under clinical development in the United States (Candiani et al., 1999). In addition, ramoplanin, another antibiotic discovered by the same group, is being developed for the prevention of enterococcal infections in patients carrying vancomycin-resistant enterococci in their gastrointestinal tract (Mobarakai et al., 1994).

A number of "old" compounds are now approaching commercialization. These were not previously developed because their antibacterial spectra were restricted to Gram-positive bacteria. At that time (in the 1970s and 1980s), breadth of spectrum was the commercial goal, but today the major aim is to inhibit resistant Gram-positive pathogens. About 90% of natural antibiotics fail to inhibit Gram-negative organisms such as *E. coli* (Vaara, 1993). The reasons include their outer membrane, which contains 1) narrow porin channels that retard the entry into the cell of even small hydrophilic compounds, and 2) a lipopolysaccharide moiety that slows down the transmembrane diffusion of lipophilic antibiotics. Furthermore, Gram-negative bacteria often possess a multiple-drug efflux pump, which eliminates many antibiotics from the cells (Lewis, 1994).

One group of useful narrow-spectrum compounds is the streptogramins, which are synergistic pairs of antibiotics made by single microbial strains. The pairs are constituted by a (Group A) polyunsaturated macrolactone containing an unusual oxazole ring and a dienylamide fragment and a (Group B) cyclic hexadepsipeptide possessing a 3-hydroxypicolinoyl exocyclic fragment. Such streptogramins include virginiamycin and pristinamycin (Barriere et al., 1998). Although the natural streptogramins are poorly water-soluble and cannot be used intravenously, new derivatives have been made by semisynthesis and mutational biosynthesis. Synercid (RP59500) is a mixture of two water-soluble semisynthetic streptogramins, quinupristin (RP57669) and dalfopristin (RP54476), which has recently been approved for resistant bacterial infections (Nichterlein et al., 1996). The two Synercid components synergistically (100-fold) inhibit protein synthesis and are active against vancomycin-resistant enterococci and methicillin-resistant staphylococci (Stinson, 1996). Another product, called RPR106972, is being developed for oral treatment of community-acquired infections and is in phase II clinical trials. It is a co-crystalline association of two minor natural streptogramins (pristinamycin IB and pristinamycin IIB) produced by *Streptomyces pristinaespiralis*.

Another potentially useful compound is a new everninomycin derivative called "ziracin" (Sch27899), which is being developed for drug-resistant Gram-positive infections (Stead, 1997). Everninomycin was discovered in 1979, but this narrow spectrum molecule, containing oligosaccharide and aromatic moieties, was never developed. Semisynthetic tetracyclines, e.g., glycylcyclines, are being developed for use against tetracycline-resistant bacteria (Sum et al., 1998). New screens for further discovery include those for inhibitors of bacterial signal peptidases (Black and Bruton, 1998), non-β-lactam inhibitors of β-lactamase, inhibitors of lipid A biosynthesis and inhibitors of tRNA synthetases (Bush, 1997).

A new and important target for antibiotics is the treatment of ulcers caused by *Helicobacter pylori*. Hundreds of millions of people throughout the world are infected with this Gram-negative bacterium, which causes most gastric and duodenal ulcers. Broths of an actinomycete, *Amycolata* sp., were reported to contain eight novel quinolones that inhibit *H. pylori* at 0.1 ng/ml while not inhibiting other bacteria (Dekker et al., 1997).

Antitumor Agents

Most of the important compounds used for chemotherapy of tumors are antibiotics produced by actinomycetes (Oki and Yoshimoto, 1979; Tomasz, 1995). These include actinomycin D, mitomycin, bleomycins and the anthracyclines, daunorubicin and doxorubicin. A provocative recent finding is that neomycin inhibits human angiogenin-induced angiogenesis in human endothelial cells (Hu, 1998). The mechanism appears to act via neomycin's ability to inhibit phospholipase C. Amazingly, other aminoglycosides (gentamicin, streptomycin, kanamycin, amikacin and paromomycin) are inactive even though paromomycin differs from neomycin by merely having -OH at position 6 of the glucose ring instead of $-NH_2$.

Other Bioactive Metabolites

It was pointed out in the 1970s and 1980s (for review, see Demain, 1983) that compounds with antibiotic activity also exhibit other valuable

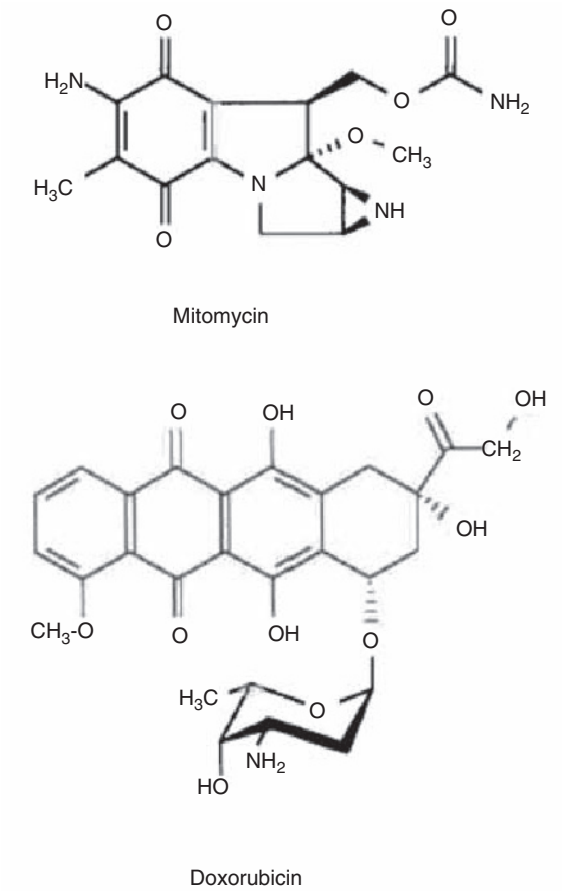

Fig. 10. Antitumor Agents.

activities, some of which had been quietly exploited in the past, and that such broadening of scope should be exploited and expanded in the future. Thus, a broad screening of antibiotically active molecules for activity against organisms other than microorganisms, as well as for activities having other pharmacological applications, was proposed to yield new and useful lives for "failed antibiotics." A large number of simple in vitro laboratory tests were developed to detect, isolate and purify useful compounds. Much of this emphasis was brought about by the writings of Hamao Umezawa (Umezawa, 1972; Umezawa, 1982), who pointed out the potential importance of enzyme inhibitors as drugs. Fortunately, we entered into a new era in which microbial metabolites were applied to diseases (not caused by bacteria and fungi) heretofore only treated with synthetic compounds. Successes were achieved in the following different areas.

Immunosuppressive Agents

Cyclosporin A was originally discovered as a narrow spectrum antifungal peptide produced by a

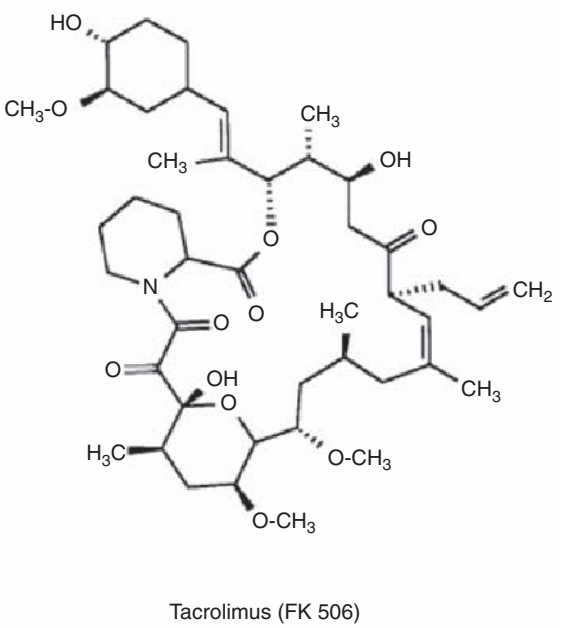

Fig. 11. Tacrolimus (FK-506).

mold (Borel et al., 1976). Discovery of its immunosuppressive activity led to its use in heart, liver and kidney transplants and to the overwhelming success of the organ transplant field. Although cyclosporin A had been the only immunosuppressant on the market for many years, two other products, produced by actinomycetes, are providing new opportunities. These are the polyketides FK-506 (tacrolimus; Kino et al., 1987) and rapamycin (sirolimus; Vezina et al., 1975), both narrow spectrum antifungal agents, which are 100-fold more potent than cyclosporin as immunosuppressants and less toxic. The polyketides FK-506 and rapamycin were approved for use a few years ago and in 1999, respectively.

Studies on the mode of action of these immunosuppressive agents have markedly expanded current knowledge of T-cell activation and proliferation (Liu, 1993). Rapamycin, FK-506 and cyclosporin A all act by a new mechanism of drug action, i.e., interaction with an intracellular protein (an immunophilin) forming a novel complex which selectively disrupts signal transduction events of lymphocyte activation (Dumont and Su, 1996). By binding to its immunophilin (FK506-binding protein; FKBP), rapamycin inhibits a unique growth regulation path utilized by lymphocytes in responding to several cytokines. A previously unknown protein called the "mammalian target of rapamycin" (mTOR; a member of the family of lipid/protein kinases) is part of the rapamycin-sensitive signal transduction pathway.

Enzyme Inhibitors and Chelating Agents

In addition to the enzyme inhibitors produced by fungi used to lower cholesterol (statins), bacterial enzyme inhibitors have also succeeded in the world of medicine. These include clavulanic acid and acarbose. Clavulanic acid is a β-lactam with poor antibiotic activity, produced by *Streptomyces clavuligerus* (Birnbaum et al., 1978). It is an inhibitor of β-lactamases and is thus included with penicillins in combination therapy of penicillin-resistant bacterial infections (Brown, 1986). Acarbose, used as an inhibitor of intestinal α-glucosidase in diabetes and hyperlipoproteinemia, is produced by *Actinoplanes* sp. SE50 (Truscheit et al., 1981). Desferal is a siderophore (produced by *Streptomyces pilosus*; Winkelmann, 1986) whose high level of activity has led to its use in iron-overload diseases (hemochromatoses) and aluminum overload in kidney dialysis patients.

Antiparasitic Agents

One of the major economic diseases of poultry is coccidiosis caused by species of the parasitic protozoan, *Eimeria*. For years, this disease was treated solely by synthetic chemicals and indeed only synthetic compounds were screened for coccidiostatic activity. Although they were generally effective, resistance developed rapidly in the coccidia and new chemical modifications of the existing coccidiostats had to be made. Surprisingly, a parenterally toxic and narrow spectrum antibiotic, monensin, was found to have extreme potency against coccidia (Haney and Hoehn, 1968). Even with this finding, there were grave doubts that the fermentation process for this polyether compound could be improved to the point where monensin would become economical for use on the farm. However, the power of industrial genetics and biochemical engineering is so great that there is almost no limit to the improvements possible in a fermentation process. As a result, the polyether antibiotics, especially monensin (produced by *Streptomyces cinnamonensis*), lasalocid (produced by *Streptomyces lasaliensis*) and salinomycin (produced by *Streptomyces albus*; Westley, 1977) dominate the commercial coccidiostat field today.

Another major veterinary problem has been the infection of farm animals by worms. The predominant type of screening effort over the years was the testing of synthetic compounds against nematodes, and some commercial products did result. Certain antibiotics also had been shown to possess antihelminthic activity against nematodes or cestodes but these failed to compete with the synthetic compounds. Further screening of microbial broths for antihelminthic activity yielded a nontoxic fermentation broth that killed the intestinal nematode, *Nematosporoides dubius*, in mice. The *Streptomyces avermitilis* culture, which was isolated by Omura and coworkers at the Kitasato Institute in Japan (Stapley, 1982; Ikeda and Omura, 1997), produced a family of secondary metabolites having both antihelminthic and insecticidal activities, which were named "avermectins." They are disaccharide derivatives of macrocyclic lactones with exceptional activity against parasites, i.e., at least ten times higher than any synthetic antihelminthic agent known. Despite their macrolide structure, avermectins lack activity against bacteria and fungi, do not inhibit protein synthesis, nor are they ionophores; instead, they interfere with neurotransmission in many invertebrates. They have activity against both nematode and arthropod parasites in sheep, cattle, dogs, horses and swine. A semisynthetic derivative, 22,23-dihydroavermectin B1 (Ivermectin) is one thousand times more active than thiobenzole and is a commercial veterinary product. The avermectins are closely related to the milbemycins, a group of nonglycosidated macrolides produced by *Streptomyces hygroscopicus* subsp. *aureolacrimosus* (Mishima et al., 1983). These compounds possess activity against worms and insects. A new avermectin, called "Doramectin" (cyclohexylavermectin B1), was recently developed by the technique of mutational biosynthesis (McArthur, 1998). Indeed, it was the first commercially successful example of mutational biosynthesis. The natural avermectins contain C-25 side chains of 2-methyl butyryl ("a" components) or isobutyryl ("b" components). Branched-chain 2-keto acid dehydrogenase was eliminated from the parent culture by knocking out gene *bkd* (Hafner et al., 1991). This enzyme normally supplies the 2-methylbutyryl-CoA and isobutyryl-CoA starter units of avermectins from isoleucine and valine, respectively (Chen et al., 1989; MacNeil et al., 1994). The mutant produced no avermectin unless fed isobutyric acid or (S)-2-methylbutyric acid. Upon feeding other fatty acids, novel avermectins were made (Dutton et al., 1991). More than 800 fatty acids were tested, yielding over 60 avermectins including cyclohexyl B1 avermectin (Doramectin), which resulted from incorporation of cyclohexane carboxylic acid. Doramectin is claimed to have some commercial advantages over Ivermectin (Goudie et al., 1993).

A fortunate fallout of the avermectin work was the finding that Ivermectin has activity against the black fly vector of human onchocerciasis (river blindness). It interferes with transmission of the filarial nematode, *Onchocerca volvulus*, to the human population. Because this disease affects 40 million people, the decision by

Merck to supply Ivermectin free of charge to the World Health Organization for use in humans in the tropics was met with great enthusiasm and hope for conquering this parasitic disease.

Biochemical and Genetic Aspects of Secondary Metabolism

There is no longer any doubt that antibiotics and other secondary metabolites are produced under natural growth conditions and have a physiological role. Over 40% of actinomycetes produce antibiotics when they are freshly isolated from nature. Soil, straw and agricultural products often contain antibacterial and antifungal substances. Bacterially produced siderophores have been found in soil, and microcins, enterobacterial antibiotics, have been isolated from human fecal extracts. The microcins are thought to be important in bacterial colonization of the human intestinal tract early in life.

Antibiotic production has been shown in unsterilized, unsupplemented soil, in unsterilized soil supplemented with clover and wheat straws, in mustard, pea, and maize seeds, and in unsterilized fruits. A further indication of natural antibiotic production is the possession of antibiotic-resistance plasmids by most soil bacteria. The widespread nature of secondary metabolite production and the preservation of the multigenic biosynthetic pathways in nature indicate that secondary metabolites serve survival functions in organisms that produce them. There are a multiplicity of such functions, some dependent on antibiotic activity and others independent of such activity. Indeed, in the latter case, the molecule may possess antibiotic activity but may be used in nature for an entirely different purpose. These functions include metal transport, bacteria-plant symbiosis, plant growth stimulation, bacteria-nematode symbiosis, and induction of morphological and chemical differentiation (Demain, 1989).

It is now widely accepted that secondary metabolism represents a form of cellular differentiation. In prokaryotes and in other microorganisms, differentiation is comprised of morphological differentiation (morphogenesis, sporulation and germination) and physiological (or chemical) differentiation (production of secondary metabolites). One important difference is that morphological differentiation is characteristic of a taxonomic group of organisms, normally a genus, whereas production of a given secondary metabolite is a characteristic of one or a few strains not necessarily related taxonomically. In the cases thoroughly studied, such as *Bacillus subtilis* and *Streptomyces coelicolor*, it has been observed that the two forms of differentiation share some of the early genes involved in regulation. In *Bacillus*, the transcription of the sporulation genes, as well as that of genes involved in secondary metabolism, is totally dependent on the *spoOA* gene product. The activated forms of gene products SpoOA and SpoOF set off the sporulation regulatory cascade. In this cascade, one of the steps is the repression by SpoOA of the *abrB* gene. The *abrB* gene product represses transcription of genes *tycA* and *tycB* governing the biosynthesis of tyrocidine. Derepression of transcription initiates the synthesis of this antibiotic. In *S. coelicolor*, inactivation of the *bld* genes hinders both the formation of aerial mycelium and the production of antibiotics. Inactivation of the *whi* genes (that follow the *bld* genes in the morphological differentiation cascade) blocks the development of aerial mycelium into spores but allows the production of the antibiotics. Vice versa, mutations in genes *absA* and *absB* result in normal sporulation but absence of antibiotic production (Chater and Bibb, 1997).

Further evidence on the connection of secondary metabolism and morphological differentiation is provided by the function of a number of small molecules, themselves secondary metabolites, called "autoregulators." The best studied is A-factor, originally isolated from *S. griseus*, the producer of streptomycin. Mutants defective in A-factor production are unable to sporulate and to produce the antibiotic. A-factor acts by binding to a protein (A-factor binding protein), which represses the translation of a gene *x*, coding for a regulatory protein X. In the presence of A-factor, the repression is relieved and protein X can, on the one hand, initiate the cascade leading to morphological differentiation, and, on the other hand, activate the transcription of gene *adp*, encoding another positive regulator protein acting on genes *strR* and *aphD* involved in streptomycin biosynthesis (Horinouchi, 1993).

In prokaryotes, the secondary metabolism genes, whether chromosomal or (very rarely) plasmid-borne, are usually clustered, not necessarily as single operons but also in the form of regulons and even modulons. Each cluster includes, besides structural genes governing the synthesis of the enzymes of antibiotic biosynthesis, regulatory genes and genes determining self-resistance to the antibiotic produced. Expression of these genes is under strong individual and global control by nutrients, inducers, products, metals and growth rate. In the few cases studied, it appears that regulation is normally at the level of transcription, as revealed by the absence of mRNA encoding secondary metabolite synthases until growth rate has decreased; translational control is less common.

Secondary metabolism occurs best at submaximal growth rates after growth has slowed down. The distinction between the growth phase ("trophophase") and production phase ("idiophase") is sometimes very clear, but in many cases, idiophase overlaps trophophase. The timing between the two phases can be manipulated, i.e., the two phases are often distinctly separated in a medium favoring rapid growth, but overlap partially or even completely in a medium supporting slower growth. A secondary metabolite is "secondary" because it has no apparent involvement in the vegetative growth of the producing culture, not because it is produced after growth. Thus, elimination of production of a secondary metabolite by mutation will usually not stop or slow down growth; indeed, it may increase the growth rate.

The factors controlling the onset of secondary metabolism are complex and not well understood (Chater and Bibb, 1997). Growth rate is important, but we do not fully know the mechanism(s) involved. Limitations of certain nutritional factors such as carbon, nitrogen or phosphate sources are important, but again we are unclear on the basic mechanisms involved. The temporal nature of secondary metabolism is certainly genetic in nature, but expression can be influenced greatly by environmental manipulations. Recent experiments have shown that the effect of starvation for certain nutrients on the onset of antibiotic production is mediated by the formation of guanine 5′-diphosphate 3′-diphosphate (ppGpp). However, this requirement is not absolute because mutations in a streptomycin-binding ribosomal protein (L11 in *S. coelicolor*, S12 in *B. subtilis*) result in antibiotic production without involvement of ppGpp (Hosoya et al., 1998). Similarly, certain rifamycin-resistant RNA polymerases possess alterations that make antibiotic production independent of ppGpp.

The delay often seen before onset of secondary metabolism was probably established by evolutionary pressures. Many secondary metabolites have antibiotic activity and could kill the producing culture if made too early. Of course, the resistance of antibiotic producers to their own metabolites is well known. Antibiotic-producing species possess suicide-avoiding mechanisms such as 1) enzymatic detoxification of the antibiotic, 2) alteration of the antibiotic's normal target in the cell, and 3) modification in permeability to allow the antibiotic to be pumped out of the cell and to restrict its reentry. Such mechanisms are often inducible, but in some cases are constitutive. In the case of inducible resistance, death could result when the antibiotic is produced too early and induction is slow. Delay in secondary metabolite production until the starvation phase makes sense if the product is used as a competitive weapon in nature or endogenously as an effector of differentiation. In nutritionally rich habitats, such as the intestines of mammals where enteric bacteria thrive, secondary metabolite production is not as important as in soil and water, where nutrients limit microbial growth. Thus secondary metabolites tend not to be produced by enteric bacteria such as *E. coli* but by soil and water inhabitants such as bacilli, actinomycetes and fungi. Nutrient deficiency in nature often induces morphological and chemical differentiation, i.e., sporulation and secondary metabolism, respectively; both are beneficial for survival in the wild. Thus, the regulation of the two types of differentiation is often related.

The study of the biosynthesis of secondary metabolites requires identification of the sequence of reactions by which one or more primary metabolites is converted into the final molecule. The biosynthetic pathways of a vast number of antibiotics have been elucidated, both as the result of academic interest and for the practical outcome that such research can give, e.g., in increasing production yields of antibiotics of commercial interest and in obtaining molecules modified in their biological activity.

In contrast to the huge variety of chemical structures presented by antibiotic molecules, the sequences of biological reactions by which they are made can be grouped into the following three classes (Lancini and Lorenzetti, 1993).

The Three Classes of Biological Reactions

CLASS I REACTIONS. These are the series of reactions by which a primary metabolite is converted into a small antibiotic molecule or into an intermediate of the synthesis of larger antibiotics. Typically, these series of reactions can be conveniently classified according to the pathways of primary metabolism with which they are related. We thus have antibiotics, or antibiotic moieties, whose biosynthesis is tied to amino acid synthesis or catabolism, nucleoside metabolism or coenzyme synthesis (Lancini and Demain, 1999). An example of the synthesis of a small antibiotic molecule through Class I reactions is the biosynthesis of chloramphenicol: a variation of the pattern of tyrosine biosynthesis leads to formation of *p*-aminophenylalanine, which is subsequently modified by hydroxylation, acylation, reduction and oxidation reactions into the final molecule. An example of the synthesis of an intermediate is the biosynthesis of 3-amino-5-hydroxybenzoic acid, the initiator of several ansamycin and other metabolite biosyntheses, occurring by a series of reactions closely paralleling the well-known shikimate pathway of aromatic amino acid biosynthesis.

CLASS II REACTIONS. The key steps in the biosynthesis of a number of antibiotics are polymerization reactions, by which several similar units are linked together to form the backbone of a larger molecule. On the biochemical basis and according to the similarity of the genes involved, the following types of polymerization reaction are recognized in bacteria:

1. Polyketide Synthesis. This is a mechanism of polymerization of small acid units (most often acetate or propionate; the actual molecules involved in the condensation process are malonate or methylmalonate) closely analogous to the mechanism of fatty acid synthesis (Katz and Donadio, 1993). Two types of polyketide synthases (PKSs) are recognized:

a) Polyketide synthases of type II. These PKSs are characterized by an organization of the enzymes similar to that of fatty acid synthases (FAS) of most bacteria, in which each of the reactions necessary for the addition of a unit (condensation, reduction, etc.) is catalyzed by a structurally distinct and functionally different polypeptide. The mechanism is iterative, in the sense that the same addition operations are repeated several times by the same set of enzymes, giving rise to a chain composed of identical elements. In polyketide antibiotic synthesis, the chain extension molecule is always malonate, and reduction and dehydration steps are generally omitted. The resulting chain is composed of alternating methylene and keto groups (the term "PKS" is derived from the presence of the keto groups). Such a structure is highly unstable and tends to eliminate water by aldol condensation between keto and methylene groups. According to the length of the chain and the nature of the enzymes involved, many different structures can be formed; these tend to be aromatic owing to steric and energy factors. A classical example is the biosynthesis of tetracycline by S. aureofaciens. The initiator molecule in this case is the monoamide of malonic acid and the elongation units are eight molecules of malonic acid. The resulting molecule is methylpreteramide, the earliest identified intermediate in tetracycline biosynthesis, whose structure is comprised of four linearly condensed aromatic rings.

b) Polyketide synthases of type I. These, in contrast to PKSs of type II, are multifunctional enzymes (i.e., one protein may catalyze the several different reactions needed for an elongation step). Various classes of secondary metabolites, each comprising important antibiotics, are biosynthesized by a process similar in its general outline to that of the aromatic polyketides but in which profound modifications may be included. Important sources of variation are the frequent use of methylmalonate as the chain extension unit and the partial or total reduction of most of the keto groups that are formed in the chain extension steps. The chain so formed can thus bear methyl, keto or hydroxy groups and may include double bonds and adjacent methylene groups. As a consequence of these variations in its structure, the chain cannot be converted by the aldol reaction into aromatic rings, and either linear molecules or macrocyclic rings are formed. This is the origin, for instance, of the basic structures of the macrolide antibiotics (e.g., erythromycin), the ansamycins (e.g., rifamycins), and the ionophoric polyethers (e.g., monensin). All of these are synthesized by PKSs of type I having a particular modular organization. It is interesting to note that whereas metabolites made by PKSs of type II are produced by both prokaryotes and fungi, those made by PKSs of type I are produced only by actinomycetes and, to a minor extent, by myxobacteria and pseudomonads. Modular PKSs are multifunctional proteins comprised of a few functional modules; each module possesses all the enzymatic activities needed to perform a given elongation step. Each module recognizes one extension unit (malonate or alkyl malonate), adds it to the growing chain, and performs the appropriate reduction or dehydration reaction. The growing chain is transferred from one module to the adjacent one, so that the order in which the modules are arranged determines the order of the chemical groups on the chain. As an example, erythromycin, a product of *S. erythraea*, is composed of a macrocyclic lactone of fourteen atoms, bearing keto, hydroxy, methyl groups and two sugars. The macrocycle is made by the polyketide process, which consists of extending one propionate (the initiator unit) with six methylmalonate units. The synthase complex, as deduced from the gene organization and sequences, is composed of three multifunctional proteins, each comprising three FAS-like modules. Thus, there are a total of six functional modules, each responsible for one of the six elongation cycles needed to construct the chain. Each cycle includes the condensation of one methylmalonate with the growing chain and the appropriate total, partial, or nonreduction of the α-keto group. The linear chain thus produced is closed, forming the macrocyclic lactone of deoxyerythronolide B, the earliest identified intermediate of the biosynthetic pathway. Subsequent reactions transform it into the antimicrobial erythromycin.

2. Polymerization of Amino Acids by Polypeptide Synthases. Typical of secondary metabolism is a mechanism of formation of polypeptides catalyzed by nonribosomal polypeptide synthetases (NRPSs; Kleinkauf and von Döhren, 1997). The mechanism is similar in several aspects to polyketide synthesis by PKS type I. The NRPSs

catalyze the activation and incorporation of monomers (amino- or hydroxy-acids) into oligomers (peptides or depsipeptides). Similar to PKS I, NRPSs present a modular organization such that one module comprising enzymatic domains is utilized for each monomer incorporated. Therefore, the number of modules corresponds to the number of monomers incorporated and, most relevant, the order in which the monomers are incorporated reflects the order in which the modules are present on the NRPS. Each module generally comprises an adenylation domain, responsible for amino acid recognition and activation; a thiolation domain where the amino acid, and then the growing peptide, are covalently bound; and the condensation domain where the amide bond is formed. Additional specialized domains, such as those for conversion of L- to D-amino acids, also may be present. The steps of the synthesis are as follows: 1) the amino acids are activated by adenylation and each linked, through a thioester bond, to the appropriate module; 2) the first amino acid forms an amide bond with the amino group of the second amino acid, the energy being provided by the breaking of the thioester bond; 3) the dipeptide thioester breaks and the carboxyl group forms a peptide bond with the following monomer; and 4) the cycle is repeated until completion of the chain that is then released by a thioesterase. An important example of oligopeptide synthesis is the formation of the tripeptide δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine (ACV), the first free intermediate in the synthesis of β-lactam antibiotics. The enzyme, ACV synthetase (which has been purified from *S. clavuligerus*), activates and binds the three amino acids as thioesters (α-aminoadipic acid is activated and bound at its γ-carboxyl group), performs the inversion of L-valine into D-valine, and carries out the condensation steps. Sequencing of the genes coding for ACV synthetase has revealed the presence of three highly repetitive regions, each containing sequences corresponding to enzyme domains that activate an amino acid.

3. Ribosomal Peptide Synthesis. A small group of large peptide antibiotics has been described that are made by the general transcription and translation system of ribosomal protein synthesis (Jack et al., 1997). These are known as the lantibiotics, owing to the presence in their molecules of several lanthionine moieties derived from sulfide bridge formation between cysteine and serine (or threonine) residues. Nisin, an antibiotic used in foods, is produced by unicellular bacteria; others, such as ancovenin and actagardine, are made by actinomycetes. Studies on their biosyntheses have demonstrated that the final antibiotic molecules are derived from larger ribosomally synthesized peptides called "prelantibiotics." These comprise a leader peptide and an amino acid sequence that give rise to the antibiotic structure through extensive post-translational processing. The last biosynthetic step is the cleavage of the leader peptide.

4. Condensation of Carbohydrate Units (Often Amino Sugars) to Form Oligosaccharides. In a number of important antibiotics, an aminocyclitol moiety is included instead of a sugar, resulting in the formation of a pseudosaccharide. The available evidence indicates that antibiotics having an oligosaccharide structure are formed by the assembly of monomers activated as nucleoside diphosphates at the anomeric carbon (Piepersberg and Distler, 1997). In this respect, their biosynthesis is not different from that of the normal polysaccharides present in bacterial cell walls or surfaces. The components of the oligosaccharide antibiotics are most often unusual carbohydrates. Two patterns may be distinguished with regard to their formation: a) sugars normally found in primary metabolism are assembled and then modified; typical of this pattern is the biosynthesis of the antibiotics of the gentamicin family; and b) common sugars, such as glucose or glucosamine, are converted into unusual carbohydrates and then condensed stepwise to give the final molecule; this is the case of streptomycin biosynthesis. In the latter case, the transformation reactions also occur, as a rule, on sugars activated as nucleoside diphosphates at the anomeric carbon. However, there is not a rigid distinction between the two cases; both patterns may be present in a single biosynthetic pathway.

These mechanisms of polymerization are similar to those of primary metabolism, which are involved in building molecules that are components of cell envelopes. Polyketide synthesis and, to some extent, nonribosomal polypeptide synthesis appear to be derived from the mechanism of membrane fatty acid biosynthesis, whereas the biosynthesis of sugar-derived antibiotics is similar to that of the polysaccharides present in the external layers of bacterial envelopes, such as the O-antigens of Gram-negative organisms. It is of interest that isoprenoid synthesis, very common in fungal secondary metabolism, is almost absent in biosyntheses of bacterial secondary metabolites.

CLASS III REACTIONS. In general, the basic structure produced by a polymerization mechanism, or by condensation of one or more subunits, is further modified by enzymatic reactions to give the final antibiotic molecule (Lancini and Lorenzetti, 1993). These "tailoring" reactions are normally very common ones: hydroxylations, double-bond saturations and other reductions, methylations, transaminations,

glycosylations and acylations. However, they are most relevant because the modifications are usually essential for activity. Tailoring is often responsible for the production, by many strains, of complexes of antibiotic molecules, i.e., structurally related substances quite similar in their biological activity. A complex may arise when an intermediate of the biosynthesis is the substrate of different reactions and therefore yields different products. One example is teicoplanin produced by *A. teichomyceticus*. The antibiotic is a complex of several molecules differing in the structure of the acyl substituents linked to a glucosamine moiety. The relative amounts of the components depend on the amounts of the fatty acids, which are the substrates of the acylation reaction. A typical example of the importance of tailoring is the formation of tetracyclines. Here, the common intermediate methylpretetramide is converted through reductions, amination and methylation into the final tetracycline molecule. In certain strains, carbon 7 of the molecule is chlorinated, giving rise to chlortetracycline; in contrast, other strains hydroxylate carbon 5, yielding oxytetracycline. Another example is the synthesis of erythromycins: the product of PKS action, deoxyerythronolide B, is first hydroxylated and then glycosylated with two sugars. The resulting molecule can be hydroxylated on the ring, giving erythromycin C, or methylated on one of the sugars, giving erythromycin B, or submitted to both these reactions, giving rise to erythromycin A, thus producing a mixture of the three antibiotics.

Products from Modern Technology

Although industrial microbiology is not a new field, the recombinant DNA discoveries made in 1972 in the laboratories of Stanford University and the University of California at San Francisco propelled the field to new heights and led to the establishment of a new biotechnology industry in the United States and around the world. The revolutionary exploitation of basic biological discoveries did not take place in a vacuum but heavily depended upon the solid structure of the fermentation industry. Before the new biotechnology era began, there had already been a rapid application of fundamental biological knowledge, thanks to the earlier developments of industrial microbiology. The period from 1910 to 1950 had featured the first large-scale anaerobic fermentations devoted to manufacture of chemicals (acetone and butanol) and the aerobic production of citric acid and then those of penicillin and streptomycin. The scale-up investigations of the penicillin and streptomycin fermentations, a joint effort between Merck & Co. and Princeton University, gave birth to the new field of biochemical (we prefer microbiological) engineering. On the heels of this major development was the academic development of mutational microbial genetics, which evolved into the new technology of strain improvement. With microbiological engineering and strain improvement at hand, the pharmaceutical industry wasted no time in bringing laboratory discoveries to the commercial scale.

Modern biotechnology encompasses recombinant DNA technology, enzyme and cell immobilization ("enzyme engineering"), cell fusion, monoclonal antibodies and DNA probes as diagnostics, and in vitro mutagenesis ("protein engineering"). It interacts strongly with industrial microbiology and microbial engineering in areas of fermentation, microbial physiology, high throughput screening for novel metabolites, automation and miniaturization in screening and strain improvement, bioreactor design and downstream processing. Biotechnology is having a major effect on health care, diagnostics and agriculture and promises to make inroads in the practices of other industries such as petroleum, mining, foods and chemicals. The progress in biotechnology has been truly remarkable. Within four years of the development of recombinant DNA technology, genetically engineered bacteria were making human insulin and human growth hormone (hGH). This led to an explosion of investment activity in new companies, mainly dedicated to innovation via genetic approaches. Newer companies entered the scene in various niches such as biochemical engineering and downstream processing. Auxiliary industries also made their mark in the commercial world of biotechnology by offering equipment, supplies, information, mechanisms of communication, and patent protection.

The recombinant DNA pharmaceutical market consists of four principal areas: 1) blood products: thrombolytics, dismutases, septic shock drugs, clotting agents and erythropoeitin (EPO); 2) immunotherapy products: α, β and γ interferons, interleukins, and colony stimulating factors (granulocyte-colony stimulating factor [G-CSF] and granulocyte-macrophage-colony stimulating factor [GM-CSF]); 3) infectious disease combatants: hepatitis B vaccine; and 4) growth factors for mammalian cells: epidermal growth factor (EGF), insulin-like growth factors (IGF I and IGF II), fibroblast growth factors (FGFs), transforming growth factors (TGFa and TGFb), platelet-derived growth factor (PDGF), growth hormone releasing factor (GRF), lung surfactants, and tumor necrosis factor (TNF). By 1998, the biotechnology industry in the United States had revenues of $19.6 billion, sales of $13.4 billion and 153,000 employees. In that year, four-

teen new biopharmaceuticals were approved and more than 300 drugs were in phase II/III and phase III trials.

It became clear that recombinant DNA technology yielded purer proteins and was much more economical than conventional techniques. As a result, a large number of mammalian peptide genes were cloned and expressed in *E. coli*, *B. subtilis* and other bacilli, *Saccharomyces cerevisiae* and other yeasts, *Aspergillus niger*, insect cells and mammalian cells. The benefits of *E. coli* as a recombinant host included 1) ease of quickly and precisely modifying the genome, 2) rapid growth, 3) ease of fermentation, 4) ease of reduction of protease activity, 5) ease of avoidance of incorporation of amino acid analogs, 6) ease of promoter control, 7) ease of alteration of plasmid copy number, 8) ease of alteration of metabolic carbon flow, 9) ease of formation of intracellular disulfide bonds, 10) growth to very high cell densities, 11) accumulation of heterologous proteins up to 50% of dry cell weight, 12) survival in a wide variety of environmental conditions, 13) inexpensive medium ingredients, 14) reproducible performance especially with computer control, and 15) high product yields (Swartz, 1996). As a result, *E. coli* became a preferred host for production of recombinant polypeptides. In 1993, *E. coli* recombinant processes were responsible for almost $5 billion worth of products, i.e., human insulin, hGH, interferons and G-CSF (Swartz, 1996). *Escherichia coli* could produce 5.5 grams per liter of α-consensus interferon (Fieshko, 1989). High cell densities are often the key to successful production of recombinant proteins. The main obstacle to high cell density is production of acetate, which is toxic. Success is attained when acetate production is limited by exponential feeding of glucose, which keeps the specific growth rate below that which brings on acetate production. A literature comparison of different host organisms reveals dry cell concentrations of 110–175 g/liter for *E. coli* (Shay et al., 1987; Lee, 1996), 110 g/liter for *Bacillus megaterium*, 84 g/liter for *Pseudomonas putida*, 130 g/liter for methylotrophic yeasts (Gellissen et al., 1991) and 200 g/liter for *S. cerevisiae* (Fieshko et al., 1987).

Not all mammalian polypeptides are produced best in *E. coli*. Heterologous proteins, often produced as inclusion bodies in *E. coli* are inactive, aggregated and insoluble, usually possessing non-native intra- and intermolecular disulfide bonds and unusual free cysteines. To get active protein, these bodies must be removed from the cell by homogenization, washing, and centrifugation and solubilized by denaturants (guanidine·HCl, urea and sodium dodecyl sulfate [SDS]), which unfold the protein and (with reducing agents) break the disulfide bonds. Refolding is carried out by removal of denaturant and reducing agent. The renaturation processes are 1) air oxidation, 2) the glutathione reoxidation system, and 3) the mixed disulfides of protein-S-sulfonate and protein-S-glutathione systems. However, heterologous recombinant proteins can be made in biologically active soluble form at high levels when their genes are fused to the *E. coli* thioredoxin gene (LaVallie et al., 1993). Many murine and human proteins are produced at levels of 5–20% of total protein as fusions in *E. coli* cytoplasm. Some fusions retain the thioredoxin properties of being released by osmotic shock or freeze/thaw methods and high thermal stability. Thioredoxin is small (11 kDa) and is normally produced at 40% of total cell protein in soluble form (Lunn et al., 1984). Another useful method of reducing the formation of inclusion bodies containing heterologous proteins in *E. coli* is to lower the temperature of growth from 37 to 30°C (Schein, 1989).

Another problem with *E. coli* is the formation of analogue polypeptides. For example, norleucine can enter proteins cloned in *E. coli* by competing with methionine (Bogosian et al., 1989). Because norleucine is formed by the leucine biosynthetic enzymes from pyruvate or by α-ketobutyrate substituting for α-ketoisovalerate, norleucine contamination can be eliminated by elimination of the leucine biosynthetic operon. It also can be eliminated by adding methionine or 2-hydroxy-4-methylthiobutanoic acid (a methionine precursor) to the medium. It should be noted, however, that several enzymes are known to retain full activity when norleucine substitutes for methionine. Also production of recombinant human macrophage colony stimulating factor (M-CSF) by *E. coli* resulted in up to 20% substitution of methionine by norleucine with no loss of activity.

Bacillus species are looked upon as good hosts for recombinant DNA work, owing to their ability to excrete proteins rather than accumulate intracellular inclusion bodies. However, *B. subtilis* produces many recombinant protein-destroying proteases. It has seven known proteases (He et al., 1991), five of which are extracellular: 1) subtilisin (encoded by the *aprE* gene): major alkaline serine protease; 2) neutral protease (*nprE*): major metalloprotease, containing Zn; 3) minor serine protease (*epr*), inhibited by phenylmethylsulfonyl fluoride (PMSF) and ethylenediaminetetraacetic acid (EDTA); 4) bacillopeptidase F (*bpf*): another minor serine protease/esterase inhibited by PMSF; 5) minor metalloesterase (*mpe*); 6) ISP-I (*isp-I*): major intracellular serine protease, requiring Ca; and 7) ISP-II (*isp-II*): minor intracellular serine protease. The first two enzymes account for 96–98% of the extracellular protease activity. Other

research groups have found six extracellular proteases. Wu et al. (1991) removed all six and only 0.32% activity remained. Growth in the presence of 2 mM PMSF eliminated the rest of the activity. A comparison made of host organisms for production of IL-3 (Van Leen et al., 1991) among *E. coli*, *Bacillus licheniformis*, *S. cerevisiae*, *Kluyveromyces lactis* and C127 mammalian cells showed that *B. licheniformis* is best. Owing to its much lower protease activity and production of a proteinase inhibitor, *Bacillus brevis* is another alternative host to *B. subtilis* (Udaka and Yamagata, 1994). Human epidermal growth factor was produced in *B. brevis* at a level of 3 g/liter (Ebisu et al., 1992).

Many benefits to society have resulted from proteins made in *E. coli* (Swartz, 1996). 1) Diabetics do not have to fear producing antibodies to animal insulin. 2) Children deficient in growth hormone no longer have to suffer from dwarfism or fear the risk of contracting Kreutzfeld-Jacob syndrome. 3) Children who have chronic granulomatous disease can have a normal life by taking interferon gamma therapy. 4) Patients undergoing cancer chemotherapy or radiation therapy can recover more quickly with fewer infections when they use G-CSF.

In some cases, unicellular bacteria cannot be used to make recombinant polypeptides because of an inability to glycosylate the polypeptide. Almost all eukaryotic cell-excreted polypeptides are glycosylated. Glycosylation is species, tissue-, and cell-type specific (Parekh, 1989). In some cases, a normally glycosylated protein is active without the carbohydrate moiety and can be made in bacteria. This is the case with interferon-gamma (Rinderknecht et al., 1984). In cases where glycosylation is necessary for stability or proper folding (e.g., of EPO and human chorionic gonadotropin [hGC]), recombinant yeast, mold, insect or mammalian cells provide the means.

Genetic Engineering of Secondary Metabolism

Genetics has had a long history of contributing to the production of bacterial products. The tremendous increases in fermentation productivity and the resulting decreases in costs came about mainly by mutagenesis and screening for higher producing bacterial strains. In the main, this was "brute force" technology, but in recent years, efforts have been devoted to miniaturization and automation of screening procedures and to the development of methods of enhancing the frequency of improved strains by selection procedures (found earlier to be useful in improving production of primary metabolites, e.g., the isolation of antimetabolite-resistant mutants in cases where the natural metabolite is a precursor, an inhibitor, or a corepressor of a biosynthetic pathway). These selective agents include antimetabolites of precursors, 2-deoxyglucose for enzymes and pathways regulated by carbon source regulation, and methylammonium for those regulated by nitrogen source repression. Mutation has served to 1) shift the proportion of metabolites produced in a fermentation broth to a more favorable distribution, 2) elucidate the pathways of secondary metabolism, and 3) yield new compounds. The medically useful products demethyltetracycline and doxorubicin (adriamycin) were discovered by simple mutation of the cultures producing tetracycline and daunorubicin (daunomycin), respectively. The technique of mutational biosynthesis has been used for the discovery of many new aminoglycoside, macrolide and anthracycline antibiotics as well as a commercial antihelminthic agent, Doramectin.

Although mutation was used for forty years to improve antibiotic production, genetic recombination was virtually ignored, the principal reason being the low frequency of recombination, e.g., 10^{-6}. However, application of protoplast fusion changed the situation markedly. Frequencies of recombination increased to even greater than 10^{-1} in some cases, and strain improvement programs routinely incorporate protoplast fusion between different mutant lines. Successes were obtained, for example, in the cephalosporin and cephamycin strain improvement programs. Another use of protoplast fusion involved the recombination of different strains from the same or different species to yield new antibiotic derivatives such as anthracyclines, aminoglycosides and rifamycins. Protoplast fusion has also been useful in elimination of undesirable components from fermentation broths. Of great interest has been the application of recombinant DNA technology to the bacterial production of antibiotics and other secondary metabolites. Many genes encoding individual enzymes of antibiotic biosynthesis have been cloned and expressed. Genes of fungal β-lactam producers such as *Cephalosporium acremonium* and *Penicillium chrysogenum* (e.g., those encoding isopenicillin N cyclase and deacetoxycephalosporin C synthase and hydroxylase) have been cloned in *E. coli* and expressed at levels of 15–20% of total cell protein.

The potential of recombinant DNA technology in antibiotic improvement and discovery has been enhanced by the finding that bacterial antibiotic biosynthetic pathway genes are usually clustered with resistance genes on the chromosome. This arrangement of genes facilitates transfer of an entire pathway in a single manip-

ulation. Continued progress in the application of recombinant DNA to fermentations has led to overproduction of limiting enzymes of important biosynthetic pathways, thus increasing production of the final products. Epirubicin (4′-epidoxorubicin) is a semisynthetic anthracycline with less cardiotoxicity than doxorubicin. A totally biological method of producing it involved genetic engineering of a blocked *Streptomyces peucetius* strain (Madduri et al., 1998). The gene introduced was *avrE* of the avermectin-producing *S. avermitilis* or the *eryBIV* genes of the erythromycin producer, *S. erythrea*. These genes and the blocked one in the recipient are involved in deoxysugar biosynthesis.

Combinational biosynthesis of bacteria is now being used for discovery of new drugs (Hutchinson, 1998). Recombinant DNA techniques are used to introduce genes coding for antibiotic synthases into producers of other antibiotics or into nonproducing strains to obtain modified or hybrid antibiotics. In 1985, this was described in a breakthrough paper by Hopwood et al. (1985). Gene transfer from a streptomycete strain producing the isochromanequinone antibiotic actinorhodin into strains producing granaticin, dihydrogranaticin and mederomycin (which are also isochromanequinones) led to the discovery of two new antibiotic derivatives, mederrhodin A and dihydrogranatirhodin. Since then, many hybrid antibiotics have been produced in bacteria by recombinant DNA technology (Khosla et al., 1993; Katz and Donadio, 1993; Hopwood, 1993) as shown by the following examples.

1) The hybrid antibiotic, isovalerylspiramycin, was obtained by introducing the *carE* gene from the carbomycin producer, *Streptomyces thermotolerans*, into the spiramycin producer, *Streptomyces ambofaciens* (Epp et al., 1989). These are both 16-membered macrolides but one of the two sugars in carbomycin is isovalerylmycarose and the corresponding sugar in spiramycin is mycarose. When the acylating gene was cloned into the non-macrolide producer, *Streptomyces lividans*, the recombinant was capable of converting spiramycin to isovalerylspiramycin.

2) Hybrid anthraquinones and anthracyclines have been obtained by cloning DNA fragments from one polyketide producer into various blocked mutants of anthracycline-producing streptomycetes (Strohl et al., 1989). Cloning of the *actI*, *actIV* and *actVII* genes from *S. coelicolor* into the 2-hydroxyaklavinone producer, *Streptomyces galilaeus* 31671, yielded the novel hybrid metabolites desoxyerythrolaccin and 1-*O*-methyl-desoxyerythrolaccin (Strohl et al., 1991). Cloning of *actI*, *actIII* and *actVII* genes from *S. coelicolor* into other streptomycetes led to the production of the novel metabolite aloesaponarin II (Bartel et al., 1990).

3) Five novel polyketides were produced by combining polyketide-forming genes from different actinomycetes to construct recombinant PKS systems in an *S. coelicolor* host (McDaniel et al., 1993a; McDaniel et al., 1993b).

4) New antibiotic molecules have been produced by genetic manipulation of the erythromycin PKS and other PKSs (Donadio et al., 1993). The manipulations are of the following types (Staunton, 1998): a) Deletion of one of the domains of a particular module; b) adding a copy of the thioesterase (TE) domain to the end of an earlier module, resulting in a shortened polyketide; c) replacing an acyltransferase (AT) domain of a PKS by an AT domain from another PKS, thus changing an extender unit and resulting in addition of a methyl group at a particular site or removal of a methyl group; d) adding a reductive domain or two or three reductive domains to a particular module, thus changing a keto group to a double bond or to a methylene group; e) use of synthetic diketides delivered as *N*-acetylcysteamine thioesters to load onto the active site of the ketosynthase (KS) domain in module 2 and taking them all the way to a novel final product; f) replacing the loading module of one PKS with the loading module of another PKS, thus changing the starter unit from propionate to acetate, for example; and g) replacing the genes encoding hydroxylase or glycosylase enzymes from one pathway to another, thus modifying the ring structure with respect to OH groups and/or sugars.

Genetic engineering of actinomycetes has been limited by restriction barriers hindering DNA introduction and by inhibition of secondary metabolism contributed by self-replicating plasmid-cloning vectors. Despite these problems, remarkable progress has been made (Baltz and Hosted, 1996). Recently, bacterial artificial chromosomes have been developed to transfer 100 kb DNA segments into *Streptomyces* (Sosio et al., 2000a). A useful review on the use of recombinant microorganisms in the industrial production of antibiotics has been published by Diez et al. (1997).

Closing Remarks

The antibiotics produced by bacteria have been useful in our battles against infectious bacteria and fungi for almost 60 years. In addition, many antibiotics are used commercially or are potentially useful in medicine for activities other than their antibiotic action. There has been a major change in the field of discovery and application of secondary metabolites over the past twenty years. This change is characterized by the broadening of the scope of the search. No longer are

bacterial sources looked upon solely as potential solutions for microbial diseases. This change in screening philosophy has been followed by ingenious applications of molecular biology to detect receptor antagonists and agonists and other agents inhibiting or enhancing cellular activities on a molecular level (Tanaka and Omura, 1997).

Secondary metabolites are employed as antitumor agents, immunosuppressive agents, enzyme inhibitors, antiparasitic agents, etc. Many of these products were first discovered as antibiotics that failed in their commercial development as such, although a few successful secondary metabolites appear to have no antibiotic activity. The recently increased development of resistance to older antibacterial and antifungal drugs is being met with the use or clinical testing of older underutilized or previously nondeveloped narrow-spectrum antibacterial products.

Natural products have been an overwhelming success in our society. The doubling of our life span in the twentieth century is mainly due to the use of plant and microbial secondary metabolites (Verdine, 1996). They have reduced pain and suffering and revolutionized medicine by allowing for the transplantation of organs. Natural products are the most important anticancer and antiinfective agents. Over 60% of approved and pre-NDA (new drug application) candidates are natural products or related to them, not including biologicals such as vaccines and monoclonal antibodies (Cragg et al., 1997). Almost half of the best selling pharmaceuticals are natural or are related to natural products. Often, the natural molecule was not used itself but served as a lead molecule for manipulation by chemical or genetic means.

Secondary metabolism has evolved in nature in response to needs and challenges of the natural environment. Nature is continually carrying out its own version of combinatorial chemistry (Verdine, 1996). Bacteria have inhabited the earth for over 3 billion years (Holland, 1998). During that time, there has been an evolutionary process going on in which producers of secondary metabolites have evolved according to their local environments. When the metabolites were useful to the organism, the biosynthetic genes were retained and genetic modifications further improved the process. Combinatorial chemistry practiced by nature is much more sophisticated than combinatorial chemistry in the laboratory, yielding exotic structures rich in stereochemistry, concatenated rings and reactive functional groups (Verdine, 1996). We hear today that combinatorial chemistry will replace natural product efforts for discovery of new drugs. Some companies are even dropping their natural product programs to support combinatorial chemistry efforts. This makes no sense considering that the role of combinatorial chemistry, like those of structure-function drug design and recombinant DNA technology two and three decades ago, is that of complementing and assisting natural product discovery and development, not replacing them. Natural product research is at its highest level now, owing to unmet needs, remarkable diversity of structures and activities, utility as biochemical probes, novel and sensitive assay methods, improvements in isolation, purification and characterization, and new production methods (Clark, 1996). Enormous diversity exists in secondary metabolism, as illustrated by the following example: 10,000 polyketides are known, many of which are produced by bacteria (Rawls, 1998). These include antibiotics, antitumor agents, immunosuppressants, antiparasitic agents, antifungals and agricultural products. Many new polyketides have been made by genetic methods involving modification or exchange of polyketide genes between organisms to create hybrid polyketides, i.e., by combinatorial biosynthesis (Hutchinson, 1997; McAlpine, 1998). We should also keep in mind the enormous diversity of bacteria and that only a minor proportion have thus far been examined for secondary metabolite production. It has been estimated that 1 gram of soil contains 1,000 to 10,000 species of undiscovered prokaryotes (Torsvik et al., 1996). In addition, surprisingly, it has been found that well-known actinomyetes (either producing or not producing polypeptide antibiotics) harbor an unsuspected number of gene clusters coding for polypeptide synthases (Sosio et al., 2000b). It is conceivable that these could be activated to produce novel metabolites. The main factors important for the discovery of useful compounds in the future are commitment, ingenuity, and the ability to exploit nature's biodiversity and to devise simple in vitro high-throughput screening procedures for desirable activities.

Genetic engineering and its associated disciplines, as first developed in bacteria, have already made major impacts in the world of medicine and finance and are changing the face of agriculture and industry today and will continue to do so. Bacteria have been employed to produce many mammalian polypeptides as pharmaceuticals of major importance to modern medicine. The improvement of secondary metabolite production processes and the discovery of new drugs (by combinatorial biosynthesis) can be attributed to the remarkable developments of recombinant DNA technology.

Molecular biology of bacteria led the way for the development of the biotechnology industry and today molecular biology is the major driving force in pharmaceutical research. In addition to natural polypeptides, analogues can be produced

by recombinant DNA technology. Second generation recombinant polypeptides include modifications of first generation products to alter specificity of targets, distribution in tissues, pharmacokinetics, side effects and stability (Huber, 1989). Third-generation peptides will fuse coding sequences of different genes, e.g., an enzyme's catalytic sequence to a cell-specific receptor-binding sequence, to achieve targeted drug delivery. In the future, we shall see the replacement of polypeptide drugs by small molecules (Moore, 1992) produced by chemical synthesis or by bacteria. Protein drugs are difficult to use because delivery systems are often inappropriate. They cannot be orally administered because they are enzymatically degraded in the stomach. Market size is limited by the need for injection. Polypeptides generally have to be administered by intravenous injection of hospitalized patients. Low molecular mass drugs might be given by intradermal, intraperitoneal or oral route and will probably be more stable and nonimmunogenic. Because bacteria are such excellent producers of small peptides, we can expect full use of these prokaryotes as means of production of these pharmaceuticals of the future.

CHAPTER 3.7

Biosurfactants

EUGENE ROSENBERG

Introduction

Microorganisms are specialists. In any particular ecological niche, one microorganism or a limited number of strains dominates. These microorganisms have evolved the ability to survive in this niche for long periods when growth is impossible, and then when nutrients become available, they can outgrow their competitors. The fast growth of microorganisms depends largely on their high surface-to-volume ratio, which allows for the efficient uptake of nutrients and release of waste products. The price that the microorganism pays for the high surface-to-volume ratio is that it is totally exposed. All the components outside of the cell must function under the specific conditions of the ecological niche. Probably for this reason, the diversity of the microbial world is best expressed on the outside of the cell.

In any heterogenous system, boundaries are of fundamental importance to the behavior of the system as a whole. Therefore, it is not surprising that microorganisms, having a large surface-to-volume ratio, produce a variety of surface active agents (surfactants) that adsorb to and alter the conditions prevailing at interfaces. Surfactants concentrate at interfaces because they are amphipathic, i.e., they contain both hydrophobic and polar groups. Biosurfactants can be divided into low molecular weight molecules that efficiently reduce surface and interfacial tensions and high molecular weight polymers that bind tightly to surfaces. Table 1 and Table 2 list some microbially produced surfactants that have been studied.

During the last few years, numerous reviews have examined various aspects of biosurfactants such as their role in bacterial adhesion (Neu, 1996) and in growth of bacteria on hydrocarbons (Rosenberg and Ron, 1996), surface active polymers from the genus *Acinetobacter* (Rosenberg and Ron, 1998), biochemistry of surfactin (Peypoux et al., 1999), microbial surfactants (Rosenberg and Ron, 1999), biosurfactant assay (Lin, 1996), surfactants from *Rhodococci* (Land and Philp, 1998), production (Wang and Wand, 1990), molecular genetics (Sullivan, 1998), and commercial applications (Fiechter, 1992), including enhanced oil recovery (Banat, 1995) and bioemulsans (Rosenberg and Ron, 1997). In this review we will present some of the chemical and surface properties of biosurfactants and the genetics and regulation of their production, and then we will discuss what functions they may play for the producing strains and what their potential is for commercial application.

When considering the natural roles and potential applications of biosurfactants, it is important to emphasize that a wide variety of diverse microorganisms (only some of which are shown in Table 1 and Table 2) make these molecules and that biosurfactants have very different chemical structures and surface properties. It is therefore reasonable to assume that different groups of biosurfactants have different natural roles in the growth of the producing microorganisms. Similarly, since their chemical structures and surface properties are so different, it is likely that each group of biosurfactants will have a specific use. This diversity makes it difficult to generalize about the natural role of biosurfactants and provides both advantages and disadvantages for potential commercial exploitation.

Chemical and Surface Properties of Biosurfactants

Glycolipids

The low molecular weight biosurfactants are generally glycolipids or lipopeptides (Table 1). The best studied glycolipid bioemulsifiers, rhamnolipids, trehalolipids and sophorolipids, are disaccharides that are acylated with long-chain fatty acids or hydroxy fatty acids (Figure 1, Figure 2, and Figure 3). Interest in trehalose lipids as general surfactants can be traced back to the discovery that the emulsion layer of *Arthrobacter paraffineus* culture broths contained trehalose dimycolates when the cells were grown on hydrocarbon substrates (Suzuki et al., 1969). Wagner and co-workers (1983) have studied trehalose dimycolates produced by

Rhodococcus erythropolis extensively with special reference to their interfacial activities and possible application in enhanced oil recovery (Kim et al., 1990). When *R. erythropolis* was grown in batch fermentor cultures on 2% (w/w) C_{12}-C_{18} n-alkanes, the maximum amounts of trehalose lipids and dry cell mass were 2.1 and 19 g/liter, respectively (Rapp et al., 1979). Yields of trehalose lipids were increased to 4 g/liter when the bacteria were grown on 10% (w/v) n-alkanes and the trehalose lipids were continuously extracted. Recently, the yield of rhamnolipids

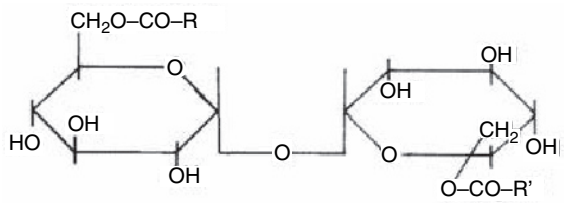

Fig. 1. β, β-Trehalose-6,6′-dicarboxylic ester. Trehalose lipids differ in the structure of the R and R′ groups.

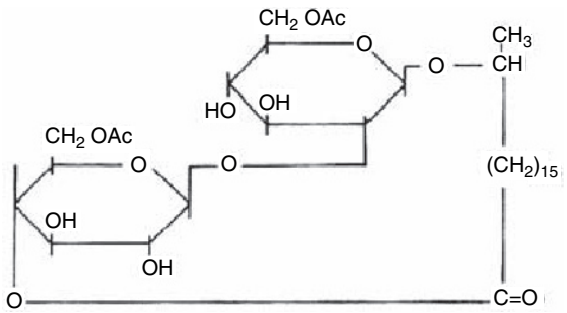

Fig. 2. Structure of the lactonic sophorose lipid of *Torulopsis bombicola*.

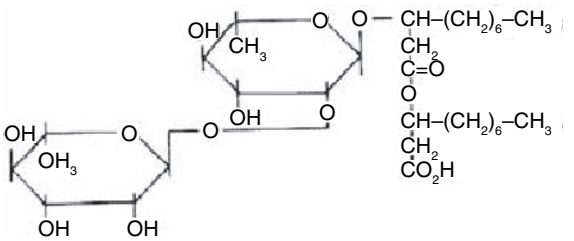

Fig. 3. Structure of the rhamnolipid of *Pseudomonas aeruginosa*.

was increased to 24.3 g/liter in media containing 6% canola oil (Sim et al., 1997). Surfactant production is growth associated (Espuny et al., 1996). Essentially all of the trehalose lipids of *R. erythropolis* are cell bound and extractable with n-hexane. The surfactant properties of the fractionated cell-bound lipids of *R. erythropolis* were measured by Kretschmer et al., 1982. The minimal interfacial tensions (between aqueous salt solutions and n-hexadecane) achieved with corynomycolic acids, trehalose monocorynomycolates, and trehalose dicorynomycolates were 6, 16, and 17 mN/m, respectively. However, the critical micelle concentration (CMC) for the trehalose lipids (ca. 2 mg/liter) was more than 100 times lower than that for the free corynomycolic acids. Trehalose mycolates reduced the surface tension of water from 72 to 26 mN/m (Lang and Philip, 1998).

Different species of the yeast *Torulopsis* produce extracellular sophorolipids, which consist of two glucose units linked β-1,2. The 6 and 6′ hydroxyl groups are generally acetylated. The lipid portion is connected to the reducing end through a glycosidic linkage. The terminal carboxyl group of the fatty acid can be in the lactonic form (as shown in Figure 2) or hydrolyzed to generate an anionic surfactant. High yields of sophorose lipids can be obtained from the extracellular fluid of cultures of *T. bombicola* grown on glucose and oil. For example, Itoh and Inoue, 1982 reported yields of 32 g/liter of a crude sophorolipid mixture when the bacteria were grown in shaker flasks on a glucose-safflower oil medium. Under controlled conditions in a 7-liter fermentor, the maximum yield of sophorose lipids from *T. bombicola* ATCC 22214 was about 70 g/liter when the medium contained both glucose and a vegetable oil as substrates (Cooper and Paddock, 1983). More recently, yields have improved to over 150 g/liter (Davila et al., 1997; Rau et al., 1996; Zhou and Kosaric, 1995), making potential commercial exploitation more feasible. The sophorose lipids lower surface and interfacial tensions, although they are not effective emulsifying agents (Cooper and Paddock, 1983). The pure lactonic sophorose lipid (10 mg/liter) lowered the interfacial tension between n-hexadecane and water from 40 to about 5 mN/m, relatively independently of pH (6 to 9), salt concentration and temperature (20 to 90°C). The minimum interfacial tensions brought about by a mixture of acidic sophorose lipids against hexadecane or several vegetable oils were 1 to 2 mN/m.

Certain species of *Pseudomonads* are known to produce large quantities of a glycolipid (Hauser and Karnovsky, 1954) consisting of 2 mol of rhamnose and 2 mol of β-hydroxydecanoic acid. The hydroxyl group of one of the acids is involved in glycosidic linkage with the reducing end of the rhamnose disaccharide, whereas the hydroxyl group of the second acid is involved in ester formation. Since one of the carboxylic groups is free, the rhamnolipids are anions above pH 4. Rhamnolipid was reported (Hisatsuka et al., 1971) to lower surface tension, emulsify hydrocarbons and stimulate growth on n-hexadecane of *P. aeruginosa* strains but not other hydrocarbon-degrading bacteria. Formation of rhamnolipids by *P. aeruginosa* has been studied (Wagner et al., 1983; Guerra-Santos et al., 1986; Lang and Wullbrandt, 1999). More than 100 g/liter rhamnolipids were produced from 160 g/liter soybean oil (Lang and Wullbrandt, 1999). The pure rhamnolipid lowered the interfacial tension against n-hexadecane to about 1 mN/m and had a CMC of 10 to 30 mg/liter,

depending on the pH and salt conditions (Lang and Wagner, 1987; Parra et al., 1989).

Zhang and Miller, 1995 reported that the interfacial tension between hexadecane and water was decreased to less than 0.1 mN/m by a methyl ester of rhamnolipid, whereas the free acid decreased the interfacial tension only to 5 mN/m. Mannosylerythritol lipids (extracellular microbial surfactants) have several interesting biological properties. They inhibit growth of human promyelocytic leukemia cell lines and induce monocytic differentiation (Isoda et al., 1997). Furthermore, the surfactant inhibited serine/threonine phosphorylations in intact leukemia cells. The authors suggest that the differentiation-inducing ability of mannosylerythritol lipids is not due to a simple detergent-like effect, but rather is the result of a specific action on the plasma membrane.

Recently, a new class of glycolipid, glucose lipids, has been described (Yakimov et al., 1998; Abraham et al., 1998). These glucose lipids are produced by a new bacterial genus and species, *Alcanivorax borkumensis* (Golyshin et al., 1998). During cultivation on n-alkanes as sole source of carbon and energy, this novel marine bacterium produced extracellular and cell-bound surface-active glucose lipids which reduced the surface tension of water from 72 to 29 mN/m. Ten different glucose lipids were separated and their structures elucidated. They all consist of an anionic glucose lipid with a tetrameric oxyacyl side chain. The glucose lipids extracted from the cell envelope were N-terminally esterified with glycine. The glucose lipids differ in the chain length of one or two of the four β-hydroxy fatty acids.

Lipopeptides

Several lipopeptide antibiotics show potent surface active properties. *Bacillus subtilis* produces a cyclic lipopeptide called surfactin or subtilysin (Peypoux et al., 1999; Bernheimer and Avigad, 1970; Arima et al., 1968), which is reputedly the most active biosurfactant known to date (Cooper and Zajic, 1980). The structure of surfactin is shown in Figure 4. Surfactin has a CMC in water of 25 mg/liter and lowers the surface tension to 27 mN/m. The minimum interfacial tension against hexadecane was 1 mN/m. The yield of surfactin produced by *B. subtilis* can be improved to around 0.8 g/liter by continuously removing the surfactant by foam fractionation and addition of either iron or manganese salts to the growth medium (Cooper et al., 1981). Recently, Wei and Chu, 1998 obtained a yield of 3.5 g/liter by carefully controlling iron concentration and pH. A recombinant *B. subtilis*, carrying a gene

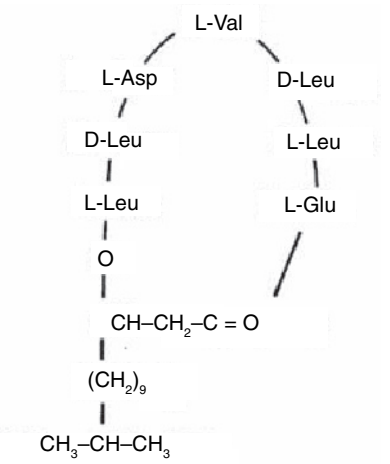

Fig. 4. Surfactin.

for surfactin production, produced new surfactin variants (Nakayama et al., 1997). The amphipathic nature of surfactin may contribute to some of its interesting biological properties, such as the formation of ion-conducting pores in membranes (Grau et al., 1999).

Streptomycestendae produces an extracellular hydrophobic peptide referred to as streptofactin (Richter et al., 1998). Streptofactin is a mixture of structurally related peptides ranging in molecular mass from 1,003 to 1,127 Da. Streptofactin reduced the surface tension of water from 72 mN/m to 39.4 mN/m and had a critical micelle concentration of 36 mg/liter. Interestingly, streptofactin restored the ability of mutants defective in aerial mycelium formation to develop normally. It was suggested that streptofactin plays a role in *Streptomyces* development by allowing for the erection of aerial hyphae by lowering the surface tension of water films enclosing the colonies.

The synthesis of one or more peptide antibiotic during the early stages of sporulation is common to most, if not all, members of the genus *Bacillus* (Katz and Demain, 1977). *B. brevis* produces the cyclosymmetric decapeptide antibiotic gramicidin S. In solution, gramicidin S exists in the form of a rigid ring with the two positively charged ornithine side chains constrained to one side of the ring, an average of 8 nm apart, and the side chains of the remaining hydrophobic residues oriented toward the opposite side of the ring (Krauss and Chan, 1983). As a result, gramicidin S will bind strongly to negative surfaces and polyanions, causing them to become lipophilic. For example, two moles of gramicidin S form a stable coordination complex with one molecule of ATP, which partitions into organic solvents.

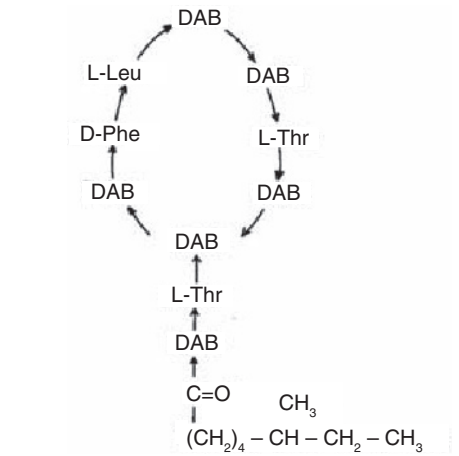

Fig. 5. Polymyxin B. DAB is 2,4-diaminobutyric acid.

The polymyxins are a group of closely related lipopeptide antibiotics produced by *B. polymyxa* and related bacilli. As seen in Figure 5, polymyxin B is a decapeptide in which amino acids 3 through 10 form a cyclic octapeptide. A branched-chain fatty acid is connected to the terminal 2,4-diaminobutyric acid (DAB). The structures of polymyxins differ in substituents at residues 3 (DAB or D-Ser), 6 (D-Leu or L-Ileu), or 7 (D- or L-DAB) (Suzuki et al., 1965). The cationic 7γ-amino groups of the DAB residues, together with the hydrophobic side chain of the fatty acid, give these antibiotics the surface active properties of a cationic detergent. *Pseudomonas* strains produce viscosin, a peptidolipid biosurfactant which lowers surface tension of water to 27 mN/m (Neu et al., 1990).

Fatty Acids and Phospholipids

Fatty acids derived from alkanes have received considerable attention as surfactants. Rehm and Reiff, 1981 have published a detailed list of fatty acids resulting from the microbial oxidation of alkanes. The hydrophilic-lipophilic balance (HLB) of fatty acids is clearly related to the length of the hydrocarbon chain. For lowering surface and interfacial tensions, the most active saturated fatty acids are in the range of C-12 to C-14. In addition to straight-chain fatty acids, microorganisms produce complex fatty acids containing hydroxyl groups and alkyl branches. Some of these complex fatty acids, e.g., the corynomycolic acids, are potent surfactants (MacDonald et al., 1981). Similar to 2-hydroxy fatty acid surface properties, the surface properties of corynomycolic acids are relatively insensitive to pH and ionic strength.

Phospholipids are major components of microbial membranes. When certain hydrocarbon-degrading bacteria or yeast are grown on alkane substrates, the level of phospholipid increases greatly. In the case of hexadecane-grown *Acinetobacter* sp. HO1-N, phospholipid-rich (mainly phosphatidyl ethanolamine) extracellular membrane vesicles accumulate in the medium (Kaeppeli and Finnerty, 1979). The potent surfactant properties of these vesicles are evident from the observation that they are able to generate optically clear microemulsions of alkanes in water (Kaeppeli and Finnerty, 1980). Surfactant properties of cellular phospholipids of *Rhodococcus erythropolis* grown on n-alkanes were examined by Kretschmer et al., 1982. The phosphatidyl ethanolamine fraction was the most potent, lowering the interfacial tension between water and hexadecane to less than 1 mN/m and having a CMC of 30 mg/liter. The surface properties of phospholipids are influenced greatly by changes in pH and ionic strength. Phospholipids produced by *Thiobacillus thiooxidans* have been reported to be responsible for wetting elemental sulfur, which is necessary for growth (Beebe and Umbreit, 1971).

High Molecular Weight Biosurfactants

A large number of bacterial species from different genera produce exocellular polymeric surfactants composed of polysaccharides, proteins, lipopolysaccharides, lipoproteins or complex mixtures of these biopolymers (Table 2). The best studied are the bioemulsans produced by different species of *Acinetobacter* (Rosenberg and Ron, 1998). The RAG-1 emulsan is a complex of an anionic heteropolysaccharide and protein (Rosenberg et al., 1979b; Rosenberg and Kaplan, 1987). Its surface activity is due to the presence of fatty acids, comprising 15% of the emulsan dry weight, that are attached to the polysaccharide backbone via *O*-ester and *N*-acyl linkages (Belsky et al., 1979). Table 3 summarizes the chemical and physical properties of RAG-1 emulsan. *A. calcoaceticus* RAG-1 excretes maximum amounts of emulsan in shaker flasks when grown in a minimal medium containing 2% ethanol as the sole carbon and energy source. Under these conditions, approximately 80% of the emulsan produced is released when the cells are in stationary phase (Goldman et al., 1982). Emulsan is an effective emulsifier at low concentrations (0.01–0.001%), representing emulsan-to-hydrocarbon ratios of 1:100–1:1000, and exhibits considerable substrate specificity

Fig. 6. The polysaccharide structure of the *A. calcoaceticus* BD4 emulsan (Kaplan et al., 1985)

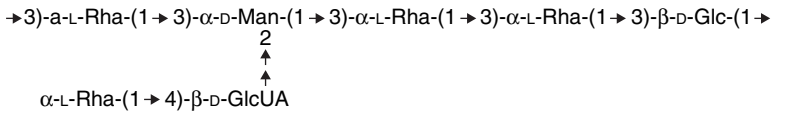

Table 3. Chemical and physical properties of RAG-1 emulsan.[a]

Measurement	Result
Chemical composition	D-galactosamine, 25% L-galactosaminournia acid, 25% Dideoxy-diaminohexose, 25% 3-hydroxydodecanoic acid, 10% 2-hydroxydodecanoic acid, 10% Water and ash, 10%
Intrinsic viscosity	55 cc/g
Diffusion constant	5.3×10^{-8} cm^2/g
Partial molar volume	0.71 cm^3/g
Molecular weight	98×10^5 Da
Dimensions	30 Å × 2000 Å

[a]Data taken from Rosenberg et al., 1979a

(Rosenberg et al., 1979a). The RAG-1 emulsan does not emulsify pure aliphatic, aromatic, or cyclic hydrocarbons; however, all mixtures that contain an appropriate mixture of an aliphatic and an aromatic (or cyclic alkane) are emulsified efficiently. Maximum emulsifying activity is obtained in the presence of divalent cations (2–10 mM Mg^{2+}) at pH values of 5.0–7.5.

Acinetobacter calcoaceticus BD4, initially isolated and characterized by Taylor and Juni, 1961, produces a large polysaccharide capsule. Under certain growth conditions (e.g., 2% ethanol as the carbon and energy source), an enhanced release of the capsules was obtained (Sar and Rosenberg, 1983). However, in contrast to RAG-1, no decrease in capsular polysaccharide was observed; rather, capsular polysaccharide levels remained constant when enhanced levels of extracellular polysaccharide were obtained (Kaplan and Rosenberg, 1982). When the crude capsule was applied to a Sepharose 4B column, it eluted in a single peak containing a polysaccharide-protein complex. The pure polysaccharide component was obtained by deproteinization and its chemical structure elucidated (Fig. 6). The protein component was obtained from the extracellular supernatant fluid of strain BD4-R7, a capsule-negative mutant of BD4 that produces no extracellular polysaccharide. The polysaccharide and protein components had no emulsifying activity by themselves. Mixing the protein and polysaccharide fractions led to a reconstitution of the emulsifying activity (Kaplan et al., 1987). Apparently the protein, which is hydrophobic, binds to the hydrocarbon initially in a reversible fashion. The polysaccharide then attaches to the protein and stabilizes the oil-in-water emulsion.

Alasan, produced by a strain of *Acinetobacter radioresistens*, is a complex of an anionic polysaccharide and protein with a molecular weight of approximately 1×10^6 (Navon-Venezia et al., 1995). However, the polysaccharide component of alasan is unusual in that it contains covalently bound alanine. The protein component of alasan appears to play an important role in both the structure and activity of the complex (Navon-Venezia et al., 1998). Deproteinization of alasan with hot phenol or treatment with specific proteinases caused a loss in most of the emulsifying activity. When a solution of alasan was exposed to increasing temperatures, there were large changes in the viscosity and emulsifying activity of the complex. Between 30 and 50°C, the viscosity increased 2.6 times with no change in activity. Between 50 and 90°C, the viscosity decreased 4.8 times and the activity increased fivefold. None of these changes occurred with the protein-free polysaccharide, indicating that they were due to the interactions of the protein and polysaccharide portions of the complex. Alasan lowers interfacial tension from 69 to 41 mN/m at 20°C and has a CMC of 200 μg/ml (Barkay et al., 1999). Alasan enhanced the aqueous solubility and biodegradation rates of polyaromatic hydrocarbons (Barkay et al., 1999). In the presence of 0.5 mg alasan per ml, the apparent solubilities of phenanthrene, fluoranthene and pyrene were increased 6.6-, 25.7- and 19.8-fold, respectively. Alasan binds polyaromatic hydrocarbons in a reversible manner. The presence of alasan more than doubled the rate of [^{14}C] phenanthrene mineralization by *Sphingomonas paucimobilis*. The solubilization of polyaromatic hydrocarbons and emulsification of hydrocarbons can be accomplished with the purified alasan proteins (Rosenberg et al., 1999).

A. calcoaceticus A2 produces an extracellular anionic polysaccharide surfactant of molecular mass 51.4 kDa that effectively disperses limestone and titanium dioxide (Rosenberg et al., 1988a, b). The biopolymer, referred to as biodispersan, binds to powdered calcium carbonate and changes its surface properties in a way that allows for better dispersion in water. In addition to being a surfactant, biodispersan acts also as a surfractant, aiding in the fracturing of limestone during the grinding process (Rosenberg et al., 1989).

Sar and Rosenberg, 1983 reported that the majority of *Acinetobacter* strains produce extracellular nondialyzable emulsifiers. These strains included both soil and hospital isolates. Marin et al., 1996 have reported the isolation of a strain of *A. calcoaceticus* from contaminated heating oil that emulsifies that substrate. Neufeld and Zajic, 1984 demonstrated that whole cells of *A. calcoaceticus* 2CA2 have the ability to act as emulsifiers, in addition to producing an extracellular emulsifier.

Other High Molecular Mass Biosurfactants

A large number of high molecular weight complex biosurfactants has been reported. In general, little is known about these emulsifiers other than the producing organism and the overall chemical composition of the crude mixture. *Halomonas eurihalina* produces an extracellular sulfated heteropolysaccharide (Calvo et al., 1998). *Pseudomonas tralucida* produced an extracellular acetylated polysaccharide that was effective in emulsifying several insecticides (Appaiah and Karanth, 1991). Several recently reported biosurfactants are effective at high temperature, including the protein complex from *Methanobacterium thermoautotrophium* (De Acevedo et al., 1996) and the protein-polysaccharide-lipid complex of *Bacillus stearothermophilus* ATCC 12980 (Gunjar et al., 1995). An extracellular surfactin with a molecular weight greater than one million was obtained from the culture broth of *Pseudomonas marginalis* PD-14b (Burd and Ward, 1996). The active fraction appeared to be a complex of protein with a very low amount of aromatic amino acids and a lipopolysacccharide.

Yeasts produce a number of emulsifiers, which is particularly interesting because of the food grade status of several yeasts. Liposan is an extracellular emulsifier produced by *Candida lipolytica* (Cirigliano and Carmen, 1984). It is composed of 83% carbohydrate and 17% protein. Mannan-protein emulsifiers are produced by *Saccharomyces cerevisiae* (Cameron et al., 1988). A variety of polymeric bioemulsifiers for potential use in foods was studied by Shepherd et al., 1995.

Genetics and Regulation of Bioemulsifier Production

The genetics of bioemulsifier production has been studied using mutants, naturally occurring or induced by transposition. The screening for such mutants is made difficult by the fact that the loss of ability to produce the emulsifier usually does not result in an easily selectable phenotype. In addition, the genetics of many emulsifier-producing bacteria has not been adequately worked out and important genetic tools (plasmids, transposons, gene libraries) are still to be developed. The regulation of bioemulsifier production has been worked out at the molecular level for the glycolipid rhamnolipid of *P. aeruginosa* and for the lipopeptides of *Bacilli*. In these bacteria, it was shown that emulsifier production is induced by molecular signals involved in quorum sensing. This regulatory feature appears to be general and probably applicable also for the production of high molecular weight emulsifiers, since emulsifier production is concurrent with the onset of the stationary phase of growth.

Lipopeptides of Gram-Positive Bacilli

The two well-studied lipopeptide bioemulsifiers produced by *Bacilli*—surfactin (Peypoux et al., 1999) and lichenysin (Yakimov et al., 1995)—are structurally similar. As already mentioned, both are composed of a cyclic heptapeptide linked to a fatty acid and differ in the last amino acid of the peptide—leucine and isoleucine, respectively. The peptide moiety, like many small peptides in microorganisms, is synthesized non-ribosomally by a multi-enzyme peptide synthetase complex (Marahiel, 1997). The *srfA* operon of *B. subtilis* was defined by a transposon Tn917 insertion and is required for production of surfactin (Nakano et al., 1991). It is an operon of over 25 kb that codes for the peptide synthase and is composed of repeating domains, whose function and order parallel those of the amino acids in the peptide (Cosmina et al., 1993; Fabret et al., 1995; Galli et al., 1994; Marahiel, 1997; Menkhaus et al., 1993). The *sfp* gene is also required for surfactin synthesis and codes for a phosphopantetheinyl transferase that activates the synthetase by post-transcriptional modification (Borchert et al., 1994; Lambalot et al., 1996; Nakano et al., 1992). Still unidentified is the acyl transferase that transfers the fatty acid to the peptide. Lichenysin synthesis is encoded for by the *lchA* operon, which is highly homologous to the *srfA* operon (Konz et al., 1999; Yakimov et al., 1998).

The production of surfactin is regulated by cell density and is involved with the development of competence—a physiological state that enables the uptake of DNA—and with sporulation. Therefore the control of its synthesis is very complex and is affected by cell density. The high cell

density is communicated by several quorum-sensing control elements that either stimulate or inhibit surfactin production. Initiation of transcription from the *srfA* operon is induced by binding of the phosphorylated response regulator, ComA. The ComA molecule and the membrane-bound histidine kinase ComP make up a two-component signal transduction system, which is activated at the membrane by a signal peptide ComX that accumulates at high cell density.The phosphorylation of ComA is also controlled by a signal peptide CSF—competence stimulating factor that is transported across the membrane and inhibits *srfA* expression at high cell densities (Cosby et al., 1998; Grossman, 1995; Lazazzera et al., 1999; Marahiel et al., 1993; Solomon et al., 1995). The involvement of at least two other proteins (a positive regulator ComR and a negative regulator SinR) also has been demonstrated (Liu et al., 1996; Luttinger et al., 1996).

The regulation of lichenysin seems to follow a similar pattern, inasmuch as a homologue of ComA was also identified in *B. licheniformis* and shown to be involved in production of lichenysin (Yakimov and Golyshin, 1997).

Rhamnolipids

The genes required for the synthesis of rhamnolipids in *P. aeruginosa* were identified by Tn5 transposition and screening for transposants that were unable to produce rhamnolipid biosurfactants (Ochsner et al., 1994). Two genes *(rhlAB)* were identified, one coding for the Rh1A protein (32.5 kDa), which has a putative signal sequence, and the other for RhlB protein, which is located in the periplasm. The expression of the *rhlAB* genes in *Escherichia coli* led to the formation of active rhamnosyltransferase. Recently, another gene—*rhlG*—essential for the biosynthesis of rhamnolipids has been identified by insertional mutation (Campos-Garcia et al., 1998). This gene is homologous to the *fabG* gene, which encodes the NADPH-dependent β-ketoacyl-acyl carrier protein (ACP) reductase required for fatty acid synthesis. Insertional mutants in this gene grew normally and the mutation had no apparent effect on the total lipid content of the cells, but the production of rhamnolipids was completely inhibited. These results suggest that the synthetic pathway for the fatty acid moiety of rhamnolipids is separate from the general fatty acid synthetic pathway, starting with a specific ketoacyl reduction step catalyzed by the RhlG protein. The existence of synthetic pathways for emulsifiers that are homologous but distinct from the general fatty acid synthetic pathway may well be a general characteristic of emulsifier biosynthesis, as a *fabG* homologue that is nonessential for growth was also identified in a hydrocarbon-degrading strain of *A. junii* (Sapir, 1998).

Production of rhamnolipids occurs at the stationary phase of growth, and recent experiments demonstrated that it is controlled by quorum sensing (Brint and Ohman, 1995; Ochsner and Reiser, 1995; Pearson et al., 1997). The *rhlAB* gene cluster coding for the biosynthesis of rhamnolipids contains two additional genes that encode regulatory proteins (RhlR and RhlI). These proteins share significant sequence similarity with bacterial autoinducer synthetases of the LuxI type. The RhlR is a putative transcriptional activator and the RhlI protein directs the synthesis of the quorum-sensing inducer N-butyryl homoserine lactone (PAI-2). The RhlR-RhlI regulatory system is essential for the regulation of rhamnolipid production. Moreover, rhamnolipid synthesis also is regulated by another regulatory system, the LasR-LasI system, which controls the biosynthesis of elastase. This is also a quorum-sensing system that consists of a transcriptional activator, LasR, and LasI, which directs the synthesis of the autoinducer *N*-(3-oxododecanoyl) homoserine lactone (PAI-1). There is sequence homology between the LasR-LasI proteins and the RhlR-RhlI proteins and there is cross-communication between the two quorum-sensing systems. It has been shown that LasR together with PAI-1 regulates transcription of the *rhlR* gene (Campos-Garcia et al., 1998; Latifi et al., 1996; Latifi et al., 1995; Ochsner et al., 1994; Pearson et al., 1997; Pesci et al., 1997; Van Delden et al., 1998).

Polymeric Bioemulsifiers

Polymeric bioemulsifiers are more complex than the low molecular weight lipopeptides and rhamnolipids. The synthesis of high molecular weight heteropolysaccharides requires a large number of genes, and the genetics is even more complex for polysaccharide-protein complexes. From the genetics point of view, the best studied polysaccharide bioemulsifier is the one produced by *A. calcoaceticus* BD4. The genes involved in its synthesis were identified in a cosmid library that was used to complement nonproducing mutants (Stark, 1996). These biosynthetic genes are organized in a cluster of about 60 kilobases. The first gene in the biosynthesis of the BD4 emulsifier (Accession no. X89900) was identified as a homologue of genes coding for phosphoglucoisomerase (*pgi*). The product of this gene is a protein of about 60 kDa in molecular weight that carries out the bidirectional conversion of glucose-6-phosphate to fructose-6-phosphate. The gene is highly conserved from bacteria to mam-

mals, with about 40% homology in amino acids. Additional genes in the cluster (*epsX* and *epsM*, Accession no. X81320) show homology to the genes coding for GDP-mannose pyrophosphorylase and phosphomannose isomerase of enteric bacteria (Stark, 1996). It is interesting to note that mutants in the *epsX* and *epsM* genes grow poorly under conditions that favor the formation of the bioemulsifier, and these deleterious mutations can be overcome by an additional (suppressor) mutation in the first gene in the pathway: *pgi*. These results suggest that mutants in the biosynthesis of the polysaccharide accumulate a toxic intermediate, probably fructose-6-phosphate (Fraenkel, 1992). The accumulation of the toxic substance, as well as the inhibition of growth, can be overcome by a mutation in a previous metabolic reaction, since the mutation blocks the synthesis of this toxic intermediate. The finding that some mutants in capsule synthesis grow poorly under conditions that favor capsule synthesis may explain the difficulty often encountered in getting such mutants (as an example, mutants unable to synthesize alasan were not obtained after screening more than 7,000 transposants of *A. radioresistens* KA53; Dahan, 1998). As screening for the mutants is usually performed on media that maximize the contrast between the capsule-producing wild type and mutant organisms (i.e., media that favor capsule formation), it is possible that these conditions are strongly inhibitory, or even lethal, for many of the mutants.

In *Acinetobacter*, the production of polysaccharide bioemulsifiers is concurrent with stationary phase. It has also been suggested that UDP-glucose, one of the precursors in the synthesis of polysaccharide bioemulsifiers, is a signal molecule in the control of σ-S and σ-S-dependent genes (Bohringer et al., 1995). The bioemulsifier of *A. calcoaceticus* BD4 (Kaplan and Rosenberg, 1982), emulsan of *A. calcoaceticus* RAG-1 (Rubinovitz et al., 1982), biodispersan of *A. calcoaceticus* A2 (Rosenberg et al., 1988), alasan of *A. radioresistens* (Dahan, 1998; Navon-Venezia et al., 1995) and an uncharacterized bioemulsifier from *A. junii* (Goldenberg-Dvir, 1998) can be detected in cultures only after more than 10 hours of growth, and maximal production occurs when the cultures have progressed well into the stationary phase. These results suggest the possibility that the high molecular weight bioemulsifiers are also controlled by quorum sensing, although there is, as yet, no direct proof.

The results presented here suggest that production of bioemulsifiers by bacteria is correlated with high bacterial density. This finding may be fortuitous or may reflect an indirect correlation with one or more physiological factors affected by high bacterial density such as availability of energy, nitrogen or oxygen. However, it is possible that the production of bioemulsifiers at high bacterial density has a selective advantage. For emulsifiers produced by pathogens, Sullivan, 1998 suggested that, being virulence factors, they are produced when the cell density is high enough to cause a localized attack on the host. It is easier to explain the need for bioemulsifiers in bacteria growing on hydrocarbons. As these bacteria are growing at the oil-water interphase, production of emulsifiers when the density is high will increase the surface area of the drops, allowing more bacteria to feed. Furthermore, when the utilizable fraction of the hydrocarbon is consumed, as in the case of oil that consists of many types of hydrocarbons, the production of the emulsifiers allows the bacteria to detach from the "used" droplet and find a new one (Rosenberg et al., 1983).

Natural Roles of Biosurfactants

The question "what is the natural role of microbial surfactants" would appear to be of fundamental significance in microbial physiology and of practical value in designing selection methods for improved molecules. However, the question has a basic flaw. There is no reason to suspect that surfactants have *one* natural role. As described in this chapter, microbial surfactants have very different structures, are produced by a wide variety of microorganisms, and have very different surface properties. Thus, it will be necessary to analyze each surfactant, or group of surfactants, separately. Only then may it be possible to draw any generalizations.

There are relatively few data available on the natural roles of biosurfactants, i.e., what function they play for the producing organisms. In only a few cases have nonbiosurfactant-producing mutants been generated and compared to the parent strain (Itoh and Suzuki, 1972; Koch et al., 1991). Thus, most of the concepts have been derived from a consideration of the surface properties of the biosurfactants and experiments in which biosurfactants are added to microorganisms growing on water-insoluble substrates. At least three general hypotheses have emerged.

Increasing the Surface Area of Hydrophobic Water-Insoluble Substrates

Theoretical and experimental studies on the production of single-cell protein from hydrocarbons in fermentors demonstrated that the growth rate can be limited by the interfacial surface area between water and oil (Sekelsky and Shreve,

1999). When the surface area becomes limiting, biomass increases arithmetically rather than exponentially. The evidence that emulsification is a natural process brought about by extracellular agents is indirect, and understanding how emulsification can provide an (evolutionary) advantage for the microoganism producing the emulsifier has certain conceptual difficulties. Stated briefly, emulsification is a cell density-dependent phenomenon; that is, the greater the number of cells, the higher the concentration of extracellular product. The concentration of cells in an open system, such as an oil-polluted body of water, never reaches a high enough value to effectively emulsify oil. Furthermore, any emulsified oil would disperse in the water and not be more available to the emulsifier-producing strain than to competing microorganisms. One way to reconcile the existing data with these theoretical considerations is to suggest that the emulsifying agents do play a natural role in oil degradation, but not in producing macroscopic emulsions in the bulk liquid. If emulsion occurs at or very close to the cell surface, and no mixing occurs at the microscopic level, then each cell creates its own microenvironment and a local cell density dependence would be expected.

Increasing the Bioavailability of Hydrophobic Water-Insoluble Substrates

One of the major reasons for the prolonged persistence of high molecular weight hydrophobic compounds is their low water solubility, which increases their sorption to surfaces and limits their availability to biodegrading microorganisms. When organic molecules are bound irreversibly to surfaces, biodegradation is inhibited (van Loosdrecht et al., 1990). Biosurfactants can enhance growth on bound substrates by desorbing them from surfaces or by increasing their apparent water solubility (Deziel et al., 1996). Surfactants that lower interfacial tension dramatically are particularly effective in mobilizing bound hydrophobic molecules and making them available for biodegradation. Low molecular weight biosurfactants that have low CMCs increase the apparent solubility of hydrocarbons by incorporating them into the hydrophobic cavities of micelles (Miller and Zhang, 1997). Data have been reported which indicate that biosurfactants can stimulate, inhibit, or have no effect on biodegradation of hydrocarbons (reviewed in Bruheim et al., 1997). In this regard, Arino et al., 1998 have reported that a rhamnolipid-producing strain of *P. aeruginosa* is involved in the degradation of PAHs by a bacterial community. Much less is known on how polymeric biosurfactants increase apparent solubilities of hydrophobic compounds. Recently, it has been demonstrated that alasan increases the apparent solubilities of PAHs 5-20 fold and significantly increases their rate of biodegradation (Rosenberg et al., 1999; Barkay et al., 1999).

Regulating the Attachment-Detachment of Microorganisms to and from Surfaces

One of the most fundamental survival strategies of microorganisms is their ability to locate themselves in an ecological niche where they can multiply. This is true not only for microbes that live in or on animals and plants, but also for those that inhabit soil and aquatic environments. The key elements in this strategy are cell surface structures which are responsible for the attachment of the microbes to the proper surface. Neu, 1996 has reviewed how surfactants can affect the interaction between bacteria and interfaces. If a biosurfactant is excreted, it can form a conditioning film on an interface, thereby stimulating certain microorganisms to attach to the interface while inhibiting the attachment of others. In the case where the substratum is also a water insoluble substrate, e.g., sulfur and hydrocarbons, the biosurfactant stimulates growth (Beebe and Umbreit, 1971; Bunster et al., 1989). If the biosurfactant is cell bound, it can cause the microbial cell surface to become more hydrophobic, depending on its orientation. For example, the cell surface hydrophobicity of *P. aeruginosa* was greatly increased by the presence of cell-bound rhamnolipid (Zhang and Miller, 1994), whereas the cell surface hydrophobicity of *Acinetobacter* strains was reduced by the presence of its cell-bound emulsifier (Rosenberg et al., 1983). These data suggest that microorganisms can use their biosurfactants to regulate their cell surface properties to attach or detach from surfaces according to need. This has been demonstrated for *A. calcoaceticus* RAG-1 growing on crude oil (Rosenberg, 1993). During exponential growth, emulsan is cell-bound in the form of a minicapsule. This bacterium utilizes only relatively long chain n-alkanes for growth. After these compounds are utilized, RAG-1 becomes starved, although it is still attached to the oil droplet enriched in aromatics and cyclic paraffins. Starvation of RAG-1 causes release of the minicapsule of emulsan. It was shown that this released emulsan forms a polymeric film on the n-alkane-depleted oil droplet, thereby desorbing the starved cell (Rosenberg et al., 1983). In effect, the "emulsifier" frees the cell to find fresh substrate. At the same time, the depleted oil droplet has been "marked" as used, because it now has a hydrophilic outer surface to which the bacterium cannot attach.

Potential Commercial Applications

Bioemulsifiers have several important advantages over chemical surfactants, which should allow them to become prominent in several industrial and environmental uses. Bioemulsifiers are produced from renewable resources, are biodegradable, and are active under a variety of conditions. Of special interest are the emulsifiers produced by thermophilic and halophilic bacterial species (Trebbau-de and McInerney, 1996; Makkar and Cameotra, 1997). Although not extensively studied so far, they present unique possibilities for applications involving extreme conditions of pH, salinity and temperature (Desai and Banat, 1997). It is interesting that an arctic strain, *Arthrobacter protophormiae*, produces a heat-stable bioemulsifier (Pruthi and Cameotra, 1997).

One obvious application is in the oil and petroleum industries (Rosenberg, 1993). As surfactants increase the oil-water surface area, they accelerate degradation of various oils by bacteria and improve bioremediation of water and soil (Banat, 1995; Bruheim et al., 1997; Volkering et al., 1997). Surfactants are important for microbially enhanced oil recovery as well as for cleanup of storage tanks and pipes. Moreover, some bioemulsifiers are capable of increasing the bioavailability of poorly soluble organic compounds, such as polycyclic aromatics (PAHs). One such emulsifier—Alasan (Navon-Venezia et al., 1995)—increases the solubility of several PAHs, such as phenanthrene, flourene and pyrene, and significantly accelerates the rate of their mineralization (Barkay et al., 1999). Similar results were obtained for the biodegradation of polychlorinated biphenyls (PCBs) in the presence of a bioemulsifier produced on sunflower (Fiebig et al., 1997; Robinson et al., 1996).

In the detergent and cleaning industries, it is important to remove hydrocarbons or fatty materials. Bioemulsifiers have three major advantages for these applications: the environmental consequences of their use are minimal and their addition can reduce the concentration of chemical detergents that are much more harmful. In addition, the biosurfactants are compatible with the variety of enzymes that are used in the "bio"-detergents that are often inactivated by the chemical detergents. Bioemulsifiers also can be used as substitutes for chlorinated solvents for cleaning of electronic boards, cutting devices and delicate instruments that can be damaged by standard detergents.

Bioemulsifiers are potentially useful in agriculture, especially in various formulations of herbicides and pesticides. The active compounds in these formulations are hydrophobic, and emulsifiers are required for dispersing them in the aqueous solutions. One example is the use of bioemulsifiers—probably glycolipopeptides—produced by strains of *Bacillus* for emulsifying immiscible organophosphorus pesticides (Patel and Gopinathan, 1986).

The class of polymeric (high molecular weight) bioemusifiers offers additional advantages. These emulsifiers coat the droplets of oil, thereby forming very stable emulsions that never coalesce. This property is especially useful for making oil-in-water emulsions for cosmetics and for food (such as salad dressings; Klekner and Kosaric, 1993; Shepherd et al., 1995). In dairy products (soft cheeses and ice creams), the addition of polymeric emulsifiers improves the texture and creaminess. This quality is of special value for low-fat products. Because polymeric emulsifiers adhere to the oil, they concentrate in the oil-water interphase and stay with the oil when the water is removed. Consequently the emulsions are stable even in very dilute solutions. In addition, the emulsifier concentrations in the water are very low, allowing the water to be recycled. These properties are of special importance for various applications in the textile or paper industries (Rosenberg et al., 1989).

At present, the cost of production and insufficient experience in applications limit the use of bioemulsifiers. However, inasmuch as awareness of water quality and environmental conservation is increasing and demand for natural products is expanding, it appears inevitable that the high quality, microbially produced bioemulsifiers will replace the currently used chemical emulsifiers in many of the applications outlined above.

CHAPTER 3.8

Bioremediation

RONALD L. CRAWFORD

Introduction

As a result of human ignorance in the safe use of chemicals, carelessness in manufacture of synthetic compounds, occasional accidents, and improper disposal of chemical wastes, toxic anthropogenic chemicals have become ubiquitous contaminants of soils and waters worldwide. These compounds include thousands of individual molecules. They are found in the environment sometimes individually but more often as complex mixtures. Many are overtly toxic (e.g., the metal mercury or the herbicide dinoseb). Many more are chronic toxins, some of them carcinogens (e.g., organic polynuclear aromatic hydrocarbons or metals such as arsenic). They are derived from sources such as petroleum, synthetic organic chemicals, mining activities, and natural or man-made radionuclides. Governments now regulate the use and disposal of toxic chemicals more rigorously than in the past. However, the legacy of environmental damage from previous decades of improper practice now requires cleanup to mitigate, insofar as possible, hazards to human health and the environment.

Traditional environmental cleanup methods include approaches such as excavation and incineration of contaminated soil or pumping and aboveground treatment of groundwater. These techniques are both expensive and politically unpopular. Affordable, innovative technologies are needed by the environmental restoration industry. Bioremediation is such a technology.

Bioremediation

Bioremediation employs living organisms, most often microorganisms, plants, or both, or products produced from living organisms to degrade, detoxify, or sequester toxic chemicals present in natural waters and soils. Bioremediation can be adapted for use to treat soil, sediment, sludge, water, or even air. Treatments can be either ex situ or in situ. Ex situ procedures involve removal of contaminated materials from a polluted site prior to treatment in another location. In situ approaches treat contaminants in place without moving them to a treatment facility. Bioremediation sometimes can be speeded or, in very difficult circumstances, even made possible by augmenting natural systems with exogenous biological materials. This process is called *bioaugmentation*. Bioaugmentation usually involves the use of natural microorganisms or plants grown to large numbers in fermenters or greenhouses and can include the use of genetically engineered microorganisms (GEMs) or plants developed specifically for the purpose. More often bioremediation can be accomplished most efficiently by simply stimulating natural, indigenous, contaminant-transforming microbial or plant populations by providing them the necessary nutrients, environmental conditions, or both needed for growth and metabolism. This process is called *biostimulation*. Yet another bioremedial option is called *intrinsic bioremediation*. This encompasses natural microbial processes that occur without human intervention (self-restoration). Finally, abiotic processes sometimes can be used in combination with biotic processes to degrade particularly recalcitrant molecules. Examples of abiotic catalysts that may enhance biodegradative processes include ultraviolet light, inorganic reductants, and Fenton reagent (iron and hydrogen peroxide). The bioremediation industry has developed many novel approaches for biostimulation, bioaugmentation, combined abiotic/biotic processes, and for monitoring and quantifying intrinsic bioremediation.

Areas of Research and Development

Bioremediation

BIOREACTORS Bioreactors are vessels of various configurations and arrangements (Admassu and Korus, 1996) that contain degradative microbes and possibly other catalytic agents that function cooperatively with microbial systems. They are a common means of ex situ treatment of contami-

nated soil that has been excavated from a polluted site or groundwater that has been pumped from a polluted aquifer.

A common bioreactor design seen in the field is a vessel containing a slurry of soil and water to which nutrients have been added to stimulate indigenous bacteria. Common nutrient additions include sources of nitrogen, phosphorus, and carbon that support the growth and metabolism of desirable indigenous degradative microorganisms. For example, nitrogen can be added to stimulate the growth of bacteria that grow on hydrocarbon contaminants such as polynuclear aromatic compounds and aromatic compounds derived from creosote (Barbeau et al., 1997; Shuttleworth and Cerniglia, 1997). Additions also may include inducer substrates to stimulate particular types of microorganism or microbial activities. For example, biphenyl has been used to stimulate the growth of bacteria able to degrade chlorinated compounds and polychlorinated biphenyls (PCBs; Focht, 1997). If appropriate microorganisms are not present to be stimulated, they can be added (Brunsbach and Reineke, 1994). *Slurry reactors* can be run aerobically by stirring and mixing in either air or pure oxygen (LaGrega et al., 1994). Alternatively, they can be run anaerobically (anoxic conditions) with the economic advantage that little or no mixing is required (Funk et al., 1995a, b). Slurry-phase reactors can be designed to hold a few thousand or millions of gallons of material (Korus, 1997). Aeration systems for aerobic slurry reactors are usually designed to maintain dissolved oxygen concentrations of at least 2.0 mg/liter. Since aeration requires considerable power consumption (pumps, mixers, spargers, etc.) and may require special mechanical designs, it is a major expense for any treatment system. For example, to increase oxygen transfer rates, a system may be sparged with air or pure oxygen introduced through a series of special eductors. At the same time, such systems must minimize air emissions, which often are regulated by state or federal agencies or both. Anaerobic slurry systems usually also require some mixing devices to evenly distribute soil or sediment materials throughout the vessel. However, anoxic processes need not move large amounts of oxygen into the aqueous phase. The choice of anaerobic versus aerobic processes involves, however, more than economic considerations. Some contaminants are degraded poorly or not at all under normal aerobic conditions (e.g., the chlorinated solvent tetrachloroethylene; Wackett, 1997). Other contaminants are not degraded under anaerobic conditions, e.g., many aromatic compounds (polynuclear aromatic hydrocarbons [PAHs]; Shuttleworth and Cerniglia, 1997). Thus, aerobic slurry reactors have been used most commonly to treat soil or water contaminated with compounds such as PAHs and chlorinated compounds (chlorinated phenols; Barbeau et al., 1997). Anaerobic slurry reactors have been used to treat soil- or water-containing compounds such as highly chlorinated solvents and nitrated munitions like 2,4,6-trinitrotoluene (TNT, Figure 1; Funk et al., 1995b) or aerobically recalcitrant herbicides like dinoseb (Kaake et al., 1992).

Water often is treated in simple vessels known as batch reactors, which hold from a few hundred to many thousands of liters. Nutrients, microorganism, or both may be added to promote degradation of particular contaminants. Another variation on reactors designed for treatment of water is the fluidized bed. Fluidized beds usually contain biomass immobilized on or within carriers (e.g., polysaccharide-based beads, plastic saddles, sand particles, etc.). These carrier matrixes are circulated continuously within the vessel to ensure that environmental conditions are maintained uniformly throughout the system. Fluidized beds are particularly useful and frequently used for water treatment (Nyer, 1992). They are run either aerobically or anaerobically (Voice et al., 1995; Sayles and Suidan, 1993). Even very toxic and recalcitrant compounds such as nitrobenzene or aniline have been treated successfully in microbiologically acclimated fluidized beds.

Biomass also can be cultivated on a supporting, but stationary, matrix. The matrix is packed into a vessel such as a column. Such an arrangement is known as a packed bed reactor. Contaminated water passes through the packed matrix where biomass (usually bacteria) eliminates the

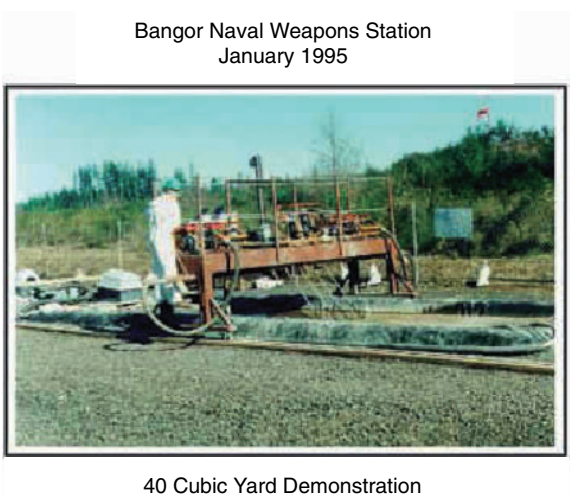

Fig. 1. Anaerobic slurry reactor for treating TNT-contaminated soil (photograph courtesy of Tom Yergovich, J. R. Simplot Company).

contaminants by degradation, absorption, or both (King, 1992). Packed beds work well for water, but also have been successful for the removal of contaminants from the vapor phase. For example, some chlorinated solvents in their vapor phase can be sparged through a packed-bed reactor. Microorganisms on or within the packed matrix material take in and degrade the gaseous molecules as they pass through the bed (Marsman et al., 1994). A particularly useful variation of the packed-bed reactor is the *biotrickling filter*, which also can be employed for treatment of vapor-phase pollutants (Unterman et al., 1996). Within a biotrickling filter the gaseous phase containing contaminants flows through the packed bed in one direction, and an aqueous nutrient solution flows in the opposite direction.

The *up-flow sludge-blanket reactor* is a water treatment approach that uses unique *biogranules* containing anaerobic bacteria that have been acclimated for the degradation of waste components within a particular waste stream (Wu et al., 1993). The granules contain a mixed microflora consortium that acts as a community with biodegradative capacities far beyond those of individual members.

As mentioned previously, bioreactors can be used in unique combinations as treatment trains that vary conditions to obtain specific results not possible with single reactors. The most common approach is the simple system of alternating anaerobic and aerobic conditions for treating mixtures of oxidized and reduced contaminants. Such systems also may work for some highly chlorinated compounds that are first reductively dehalogenated (in an anaerobic reactor), producing products that are then mineralized by aerobic microorganisms in a second reactor (Evans et al., 1996). Aerobic and anaerobic series reactors have been proposed for contaminants like PCBs and solvents like the tetrachloroethylene (perchloroethylene, also known as PCE). Many other variations of serial reactors are possible. For example, an abiotic reactor (UV light or Fenton reagent) can precede a biotic reactor (Büyüksönmez et al., 1998a; Büyüksönmez et al., 1998b).

BIOFILTRATION Another established method for treatment of gas-phase contaminants is biofiltration. An ex situ process (Deshusses, 1997; Leson and Winer, 1991), as shown in Figure 2, biofiltration requires the passing of contaminated air through a bed of soil, peat, or compost. These materials first must be pre-acclimated to the contaminants being treated to select a microbial consortium that can detoxify or completely mineralize the targeted pollutants (Yudelson and Tinari, 1995). Biofiltration works particularly

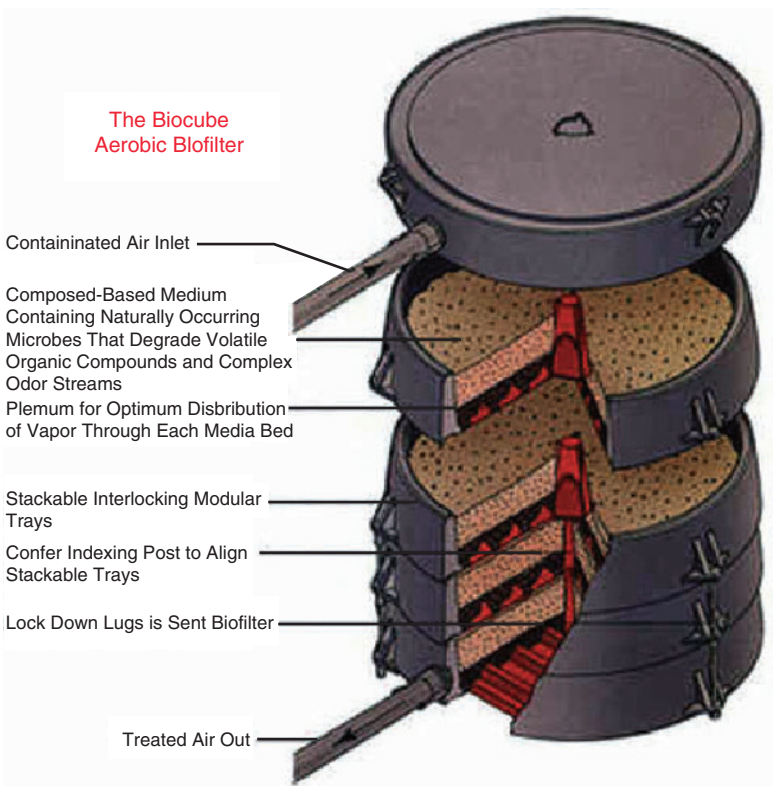

Fig. 2. Example of design of a biofiltration unit for removal of vapor-phase contaminants; illustration from ProAct Services Corporation (http://www.proact-usa.com/biocube.html).

well for volatile components of petroleum. It is commonly used in Europe for odor control (Ottengraf, 1986), and use of the method in the United States is increasing due to its simplicity and effectiveness. The following lists some Internet sites that discuss biofiltration technology:

(http://www.kumc.edu)

[194.178.172.97/aboutgrn.htm]
[online.awma.org]
(http://www.proact-usa.com)

Biofiltration works to degrade a diversity of airborne contaminants, including industrial chemicals like styrene (Arnold et al., 1997), pentane and isobutane mixtures (Barton et al., 1997), toluene (Matteau and Ramsay, 1997), chlorinated benzenes (Oh and Bartha, 1994), dimethylsulfide (Pol et al., 1994), ethylene (Elsgaard, 1998), and other volatile organic compounds (VOCs; Leson and Winer, 1991). Maintenance of good degradative activity of biofilter microbial communities sometimes requires the addition of nutrients to the biofiltration matrix, since materials like peat or wood chips are generally nutrient poor. Adjustments and careful control of environmental variables such as temperature, pH, and availability of moisture (humidity) also are often required (Arnold et al., 1997; Matteau and Ramsay, 1997). Removal rates for contaminants by biofilters can be impressive. For example, removal of vapors of chlorinated compounds (chlorinated benzenes, in one instance) was measured at 300 g of solvent vapor $\cdot$ h^{-1} $\cdot$ m^3 of filter volume (Oh and Bartha, 1994).

Air Sparging Biodegradation of many contaminants requires the availability of an electron acceptor to be reduced at the expense of oxidation of the contaminant(s). In groundwater, electron acceptor concentrations often are limited, especially for oxidative processes. Though numerous compounds can serve as electron acceptors for respiratory processes (oxygen, nitrate, Fe^{3+}, Mn^{3+}, and others), the most effective electron acceptor for the bioremediation of many contaminants is oxygen. Oxygen is present in pristine ground water at only 8–10 mg/liter, and in most ground water the levels are even lower. Oxygen can be introduced into ground water by a process called *air sparging*, an in situ technology (Raymond et al., 1975). Air or even pure oxygen is injected into an aquifer through specially designed sparging wells or infiltration galleries (Bowlen and Kosson, 1995). Oxygen is such a good electron acceptor (effective energy production for cellular metabolism) that air sparging runs the risk of overstimulating microbial growth. A resulting problem can be *biofouling*, where injection wells become plugged with biomass, which obstructs well screens and seals off the aquifer formation from further aeration. Additional problems include the plugging of subsurface geologic formations by iron-containing precipitates formed by the oxidation of ferrous ions (Fe^{2+}) to ferric ions (Fe^{3+}) and the subsequent formation of ferric oxyhydroxides or other highly insoluble iron minerals. Hydrogen peroxide can be used as a convenient source of oxygen, since it decomposes in the presence of iron or biomass to produce oxygen (Frankenberger et al., 1989). Another potential advantage of hydrogen peroxide is that some iron minerals may catalyze its decomposition to hydroxyl radicals by the well-known Fenton process (Haber and Weiss, 1934).

$$H_2O_2 + Fe^{2+} \rightarrow \cdot OH + {}^{-}OH + Fe^{3+}$$

Hydroxyl radicals produced by Fenton reactions are exceptionally reactive and can attack contaminants in groundwater (Tyre et al., 1991), degrading them to products that may be more susceptible to breakdown by microbial populations than the original contaminants. In fact, hydroxyl radicals generated by modified Fenton reactions react with most environmental contaminants at near diffusion-controlled rates ($>10^9$ M^{-1} $\cdot$ s^{-1}). The degradation of xenobiotic chemicals by hydroxyl radicals then proceeds via either hydroxylation or hydrogen atom abstraction:

$$\cdot OH + R \rightarrow \cdot ROH \text{ (reaction 1)}$$

$$\cdot OH + RH_2 \rightarrow \cdot RH + H_2O \text{ (reaction 2)}$$

More work is required to determine how effective this "abiotic/biotic" approach to in situ bioremediation might be (Büyüksönmez, 1998a; Büyüksönmez, 1998b).

Even when oxygen is supplied by sparging, it can be used so rapidly that its supply can still be rate-limiting for bioremediation processes. Thus, the bioremediation industry has developed oxygen-releasing compounds (ORCs) composed of materials such as magnesium peroxide that allow controlled, long-term release of oxygen when introduced into boreholes as a slurry (Kao and Borden, 1994). Most successes with air sparging, as with many other bioremediation systems, have been reported in petroleum-contaminated aquifers. The reintroduction of indigenous microorganisms isolated from a contaminated site after culturing is one approach to in situ hydrocarbon bioremediation. It is effective especially when microorganism growth is supple-

mented by addition of oxygen and nitrogen (Korda et al., 1997). At the Moffett Field (Sunnyvale, Calif.) groundwater test site, in situ removal of *c*-DCE (*cis*-dichloroethylene) and TCE (trichloroethylene) coincided with biostimulation through phenol and oxygen injection and utilization, with *c*-DCE removed more rapidly than TCE. Greater TCE and *c*-DCE removal was observed when the phenol concentration was increased. Over 90% removal of *c*-DCE and TCE was observed in a 2-meter biostimulated zone (Hopkins et al., 1993). Thus, introduction of oxygen into contaminated aquifers can be of use even for recalcitrant compounds such as VOCs.

BIOVENTING Bioventing is an in situ technique and a cousin of air sparging (Kidd, 1996). The objectives of air sparging and bioventing are similar: to provide oxygen to the microbial populations in the subsurface. Bioventing systems use pumps, blowers, and piping systems similar to those used for *soil vapor extraction* (SVE). Where the primary goal of SVE is simply to remove contaminants from the subsurface for physical destruction (e.g., combustion) or adsorption (e.g., to activated carbon), the purpose of bioventing is to promote biological degradation of the vapors as they move through the soil (Kramer and Cullen, 1997). Injection- or extraction wells or specially designed trenches are connected to vacuum pumps or blowers, which either pull or push air through the unsaturated soil horizons (the vadose zone). The movement of air (oxygen) stimulates the microorganisms naturally present that are capable of degrading the targeted contaminants, using them as energy and carbon sources. Oxygen is used as the terminal electron acceptor for oxidation of the pollutants. Enough oxygen must be supplied to the subsurface to promote in situ contaminant degradation. However, the use of too much flow may force undegraded contaminant into the atmosphere. Flows must be carefully regulated to avoid this loss. Thus, bioventing is most effective when applied to sites containing contaminants that are moderately volatile. Examples of such contaminants include diesel or jet fuels and residues of aged petroleum (Bowlen and Kosson, 1995). Bioventing does not work for all sites, even if the site contains an appropriate contaminant. As a general guide, the vadose zone must be permeable enough to allow air to be exchanged at least every 24 hours (Hinchee and Ong, 1992). For some impermeable soils, such as those containing lots of clay or silt, methods have been developed to make soils more porous for better air flow. For example, this has been accomplished by fracturing soils with pressurized hydraulic fluids or by the use of pressurized air injection (Kaplan, 1990). After fractures are

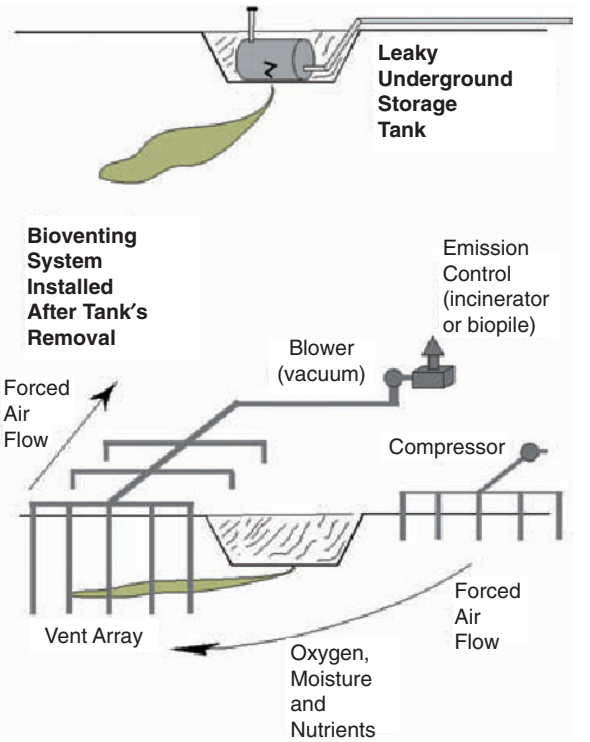

Fig. 3. Typical bioventing operation.

formed, bioventing becomes possible. Bioventing has been employed frequently with great success worldwide in the past decade (Bowlen and Kosson, 1995; Dupont, 1993; Hinchee et al., 1991; Bossert and Compeau, 1995). A typical bioventing system is shown in Figure 3.

During bioventing operations, it is important to ensure that the soil does not become too dry to support microbial growth. Thus, neutron probes sometimes are used for soil moisture monitoring. Soil moisture must be maintained within a range of 6 to 12% for biological processes to proceed effectively. An impermeable liner, usually made of plastic, is commonly placed over the surface of a contaminated area. This prevents infiltration of air that might bypass the desired path of air to the vent wells. Extra phosphorus or nitrogen or both may be needed if the soils being treated are poor in these essential nutrients. Nitrogen, in the form of ammonia, can be provided in the gas phase. It is desirable, if possible, to maintain a carbon/nitrogen/phosphorus ratio of about 100 : 10 : 1. It is not always possible to ensure that all of the contaminant vapors at a particular site are degraded as they pass through a soil column. Also, most engineered systems are subject to occasional failures in operation or design. Thus, a catalytic incinerator to destroy extracted vapor that was not degraded by microbes in the vadose zone is often

installed as a safety device. As mentioned above, not all sites are amenable to bioventing. The Battelle Corporation (Battelle Memorial Institute, Columbus, Ohio) has developed an evaluation protocol that is useful for determining whether a site is suited for remediation by bioventing (Hinchee and Ong, 1992). The evaluation involves four steps, performed sequentially:

A soil-gas survey is conducted to determine if the subsurface is oxygen-limited. Soil gas is analyzed for concentrations of oxygen and carbon dioxide.

1. A soil-gas permeability test is conducted. This determines if air can be injected at sufficient rates to aerate the vadose zone. The actual test involves injection and withdrawal of air, measuring changes in subsurface pressures at specific distances from the injection point.
2. If a soil is found to be oxygen-limited but permeable, it is next subjected to an in situ respiration test. This test measures biological contaminant degradation rates as compared to respiration rates in similar but uncontaminated control soils. For this test, soils are aerated while monitoring the oxygen and carbon dioxide concentrations in the soil-gas phase. Oxygen utilization rates are calculated and used to estimate contaminant degradation rate. These rates can be used later to estimate the time that will be required to treat a site by bioventing.
3. If a site remains a candidate for bioventing after the initial three tests, a pilot-scale bioventing demonstration may be conducted at the site. However, it may be possible to move directly to a full-scale process. This is determined on a site-by-site basis.

Among its advantages, bioventing: 1) uses readily available equipment, easy to install; 2) creates minimal disturbance to site operations; 3) can be used in inaccessible areas (e.g., under buildings); 4) requires short treatment times, usually 6 months to 2 years under optimal conditions; 5) is competitively priced ($45–140 per ton of contaminated soil); 6) is easily combinable with other technologies (e.g., air sparging, groundwater extraction); and 7) may not require costly offgas treatment. Its disadvantages are: 1) high constituent concentrations initially may be toxic to microorganisms; 2) certain site conditions (low soil permeability, high clay content, and others) preclude its use; 3) very low cleanup standards cannot always be achieved; 4) permits are generally required for nutrient injection wells (if used); and 5) only unsaturated (vadose) zone soils can be treated.

LANDFARMING Landfarming is an ex situ process where contaminated soil is excavated, supplemented with nutrients, and spread in layers on a prepared site to promote biodegradation. The nutrients added usually are nitrogen or phosphorus sources or both, which support the microbial catabolism of the added contaminant carbon. The soils are kept moist by irrigation and aerated by periodic tilling (Bowlen and Kosson, 1995). Depending on the contaminants present, soils may or may not be spread directly on the ground at a landfarm site. If there is a danger that the contaminants will leach through the vadose zone to groundwater or vaporize to dangerous levels in the atmosphere, then additional precautions must be considered. For example, soils may be spread on pre-installed plastic liners or clay barriers. Aqueous leachate collection systems may be constructed to prevent the movement of contaminants off-site or to groundwater. Vapor containment structures may be required, especially if the landfarm is located near populated areas. Petroleum, which is readily biodegraded by soil microbial communities, has been commonly treated by landfarming (Bossert and Compeau, 1995). However, highly toxic and/or biologically recalcitrant compounds generally cannot be successfully landfarmed. The presence of heavy metals, such as lead found in some older petroleum products, usually is a negative indication for landfarming. Using this method to treat petroleum-contaminated soil has some advantages: 1) design and implementation are relatively simple; 2) treatment times (usually 6 months to 2 years under optimal conditions) are short; 3) cost ($30–60 per ton of contaminated soil) is competitive; and 4) treatment is effective for organic constituents with slow biodegradation rates. The disadvantages of landfarming of petroleum-contaminated soil are: 1) concentration reductions >95% and constituent concentrations > 0.1 ppm are very difficult to achieve; 2) high constituent concentrations (>50,000 ppm total petroleum hydrocarbons) may reduce or preclude effectiveness; 3) presence of significant heavy metal concentrations (>2,500 ppm) may inhibit microbial growth; 4) volatile constituents tend to evaporate rather than biodegrade during treatment; 5) treatment requires a large land area; 6) dust and vapor generation during aeration may pose air quality concerns; and 7) bottom liners may be required if leaching from the landfarm is a concern. (The data are from US EPA http://www.epa.gov/swerust1/cat/landfarm.htm).

The presence of plants sometimes can enhance the degradation of contaminants during landfarming operations. For example, the degradation of aromatic compounds (PAHs) can be greater in the presence of vegetation than without it. Enhanced microbial activity in the plant root zone seems to contribute to the increased

removal of PAHs. Though PAHs can be detected in the tissues of plants grown on landfarms, overall uptake is generally thought to be insignificant. Planting of vegetation not only may increase contaminant degradation rates but also helps control erosion and can be an esthetic addition to a treatment site. Use of plants therefore can be an inexpensive means of speeding landfarm-based remediation of sites contaminated with petroleum (Schwab and Banks, 1994).

Biopiles Biopiles are variants of landfarms that permit treatment conditions to be more directly controlled. Also known as *soil-heaping* operations, biopiles use less land area and produce fewer air emissions than landfarms. Volatile compounds lost from biopiles are readily captured and treated, a major advantage of this technology (Bossert and Compeau, 1995). To produce a biopile, soil is excavated and then mounded and covered by a plastic sheet within a lined treatment cell. An internal system of perforated pipes is placed within the pile and used to draw air in by means of vacuum pumps. Air also may be blown into a biopile through the internal pumping system. Alternatively, oxygen can be supplied from oxygen-releasing compounds (ORCs, see Air Sparging) and mixed into the piles as they are formed. As for all biological processes, careful control of moisture content and nutrient status (particularly the nitrogen to phosphorus to carbon ratio) is required. Water and nutrients are added as needed. Special microbial cultures can be added (Walter, 1997), though this is rarely done in practice. Most contaminants treated in biopiles are degradable by natural microbial populations already present in the soil, if conditions are made favorable for their growth. Leachates and gaseous emissions are collected for separate treatment. Biopiles can be used for most biodegradable contaminants, but most of the limitations of landfarming still apply. To date, most biopile operations have treated petroleum-contaminated soils (Bossert and Compeau, 1995).

Biomounds are lower cost variations of biopiles and also have been used to treat petroleum-contaminated soil. Biomounding is the addition of bulking materials like animal manure and wood chips to help retain moisture, provide good aeration, and supply readily available sources of nitrogen, phosphorus, and trace nutrients for growing microbial populations capable of hydrocarbon degradation. This simple process usually can reach stringent soil cleanup standards in the range of 10 ppm of residual petroleum in the soil (known as *total petroleum hydrocarbons*, or TPH). As with biopiles, indigenous bacteria present in petroleum-contaminated soil proliferate under biomounding conditions. Addition of exogenous microbes is not normally required. Biomounds thus are relatively inexpensive to manage and fairly fast at the breakdown of petroleum residues in soil. Though the construction seems much like that of a standard compost heap, biomounds are designed not to require continual turning of the soil as is done during traditional composting. Simple passive aeration systems are used that usually include a grid, sometimes with multiple layers of horizontal piping constructed of flexible, perforated drain tile, along with vertical piping (risers) of PVC. Biomounds generate heat from their biological activity, and it is usually desirable to retain much of this heat, along with moisture, by covering mounds with plastic sheeting.

Composting Composting is a familiar and effective process for preparing high quality soil additives from organic materials. It also is of value in treatment of hazardous wastes. In composting of contaminated soil, excavated soil is first mixed with bulking agents like straw, horse manure, or other agricultural residues. The mixture then is formed into piles that are aerated by periodic turning with specially designed machines. Microbial activity in composts can be very vigorous, generating considerable heat. Composts thus often are termed *thermophilic*, since they may operate at temperatures of 50–60°C. Composting has been examined as a treatment for a variety of contaminants. Examples include petroleum sludges (McMillin et al., 1993), chlorophenols (Valo and Salkinoja-Salonen, 1986; Mueller et al., 1991), and residues of explosives (Williams, et al., 1992). Some questions remain as to the overall efficacy and effectiveness of composting for treating certain types of contaminants. For example, during composting some compounds such as the munition compound 2,4,6-trinitrotoluene, or TNT, are polymerized and/or incorporated into compost humus fractions. Thus there is little or no conversion of these contaminants to carbon dioxide or products that might themselves be degradable to carbon dioxide (Williams et al., 1992). The long-term stability and potential for release of toxic compounds from such uncharacterized materials in soil are not known. Some work has implied that mutagenic metabolites of explosives are formed and incompletely degraded during the composting process (Jarvis et al., 1998). In another study, [^{14}C]-TNT was subjected to composting. Much of the ^{14}C became incorporated into the "humic" fraction of the compost. When the composted TNT was fed to rats, about 2.3% of the total ^{14}C dose appeared in the rats' urine during the first 3 days after feeding, and excretion of ^{14}C in the urine

continued for more than 6 months (Palmer et al., 1997). Thus, it is clear that composted TNT is not irreversibly immobilized in the humic fraction of the compost. TNT, or one or more of its biotransformation products in compost, is still bioavailable. Clearly, composting is not the treatment of choice for some wastes, especially when little mineralization of the target pollutant occurs. Thus, composting is still an experimental approach for most hazardous wastes and should be evaluated individually for each new pollutant prior to extensive use. The fates and mechanisms of removal of chemicals like pesticides and other exotic compounds in composting processes are largely a mystery (Fogarty and Tuovinen, 1991; Michel et al., 1995; Kastner et al., 1995). Continued research on composting for treatment of hazardous wastes is slowly building on our knowledge base and overcoming some of the prior limitations. Recent work, for example, indicates that TNT can be degraded more effectively if the compost is allowed to undergo a fairly long anaerobic phase before traditional aerobic composting (Breitung et al., 1996).

Microbiological agents also can pose a hazard in composted materials (Marsh et al., 1979; Millner et al., 1977). The presence of pathogenic bacteria and fungi is of particular concern. Their presence depends largely on composting methods, and additional research is needed on the risks to human health and the environment of exposure to potentially hazardous chemical residues, heavy metals (Keller and Brunner, 1983), and microorganisms in composted waste (Deportes et al., 1995). The danger from pathogenic microorganisms centers on fungi such as *Aspergillus fumigatus*. Spores of this causal agent of the lung disease aspergillosis are abundant in the air near some composting sites (Marsh et al., 1979; Millner et al., 1977). Thus, site location is of considerable importance during design of composting operations. Overall, though the simplicity and affordability of composting for hazardous waste treatment are attractive, the efficacy and safety of this method for treatment of many wastes are still an open question.

Intrinsic Bioremediation Intrinsic remediation is result of the combined effects of all natural processes in contaminated environments that reduce the mobility, mass, and risks of pollutants (Hinchee et al., 1995). The mechanisms of intrinsic remediation include 1) biodegradation or biotransformation of contaminants by indigenous microbial populations, 2) sorption to or trapping within matrixes or on mineral phases that make toxic compounds non-bioavailable, and 3) loss of toxicity by dilution or volatilization (Frankenberger and Karlson, 1991). Intrinsic remediation of petroleum hydrocarbons has been well documented (Rifai et al., 1995; Wiedemeier et al., 1995). Intrinsic remediation also has been confirmed for chlorinated compounds (chlorinated solvents) in anoxic environments that promote reductive dehalogenation of chlorinated hydrocarbons (Hinchee et al., 1995; Rifai et al., 1995). Evidence indicates that natural evolution by genetic exchange within the environment can lead to novel microbial populations that degrade xenobiotic contaminants (van der Meer et al., 1998).

Risk-based assessments become the basis for determining cleanup end-points when intrinsic processes are considered as methods for site remediation. In such cases, the distribution of contaminants must be determined. These analyses include obtaining data that allow an understanding of the extent of contaminant plume migration in relation to sensitive receptors, such as groundwater. These analyses require extensive sampling at most sites of the vadose zone and aquifers. Analyses also must confirm that pollutant remediation is proceeding at a rate sufficient to reduce risks to human health and the environment in an acceptable period. Measurements that can provide the required information include: 1) the contaminant mass and its environmental distribution; 2) the abundance of contaminant-degrading or -transforming microorganisms, as indicated by actual microbial counts or other evidence of their presence; 3) the temperature and pH of the environment to show that they are appropriate for microbial activity; 4) types of electron donors and acceptors present, and changes in their concentrations (e.g., concentrations of nitrate, nitrite, redox-active metal species like iron, methane, ammonia, carbon dioxide, and sulfate); 5) redox potential; and 6) other factors, including abiotic ones, that must be determined on a site-by-site basis and will depend on what contaminant(s) is present. Ideally, the efficacy of intrinsic remediation processes should be predictable at individual sites using computer models, though modelers are a long way from this ideal. It is obvious, however, that intrinsic remediation has its place in the repertoire of environmental restoration tools, but it requires specific, extensive, and long-term activities at a site. It is never a "do-nothing" option.

Phytoremediation Phytoremediation involves the use of plants to remove contaminants from soil or water. Though proposed primarily as a means to remove toxic metals from environmental systems, phytoremediation also has been suggested for bioremediation of some organic pollutants (Bolton and Gorby, 1995). Through a process called *phytoextraction*, contaminants are taken into a plant and concentrated within the

plant tissues (Kelly and Guerin, 1995; Cunningham et al., 1995). When the plants are harvested, the sequestered contaminants are thereby removed from the environment. Some investigators have suggested that bacteria associated with root zones (the rhizosphere) of plants may degrade organic contaminants, also indicating a potential to use phytoremediation for removal of organic pollutants from soil or water. However, additional research is needed to confirm which plants degrade or sequester which contaminants. Plants, particularly those with deep roots, may remove volatile contaminants from soil as they transpire water. The contaminants are carried through the vascular tissue of the plant and released to the atmosphere with transpired water vapor. Recently, Rugh et al. (1998) developed a genetically engineered yellow poplar tree that expresses the bacterial mercury reductase gene (*merA*) in the plant's tissue. Mercury reductase converts nonvolatile Hg^{2+} to volatile Hg^0, which the tree pumps into the atmosphere. Thus, this deep-rooted tree has the potential for use in mercury phytoremediation, if it proves to be effective at getting to the mercury bound in soil, and the release of mercury vapor to the air is judged to be safe. Besides their direct effects on contaminants, plants also serve a useful function in the stabilization of polluted sites. Plant cover reduces soil erosion and the infiltration of water into soil. The latter process may decrease or eliminate the leaching of mobile contaminants into groundwater (Bolton and Gorby, 1995; Cunningham et al., 1995). Plants appear to have special potential for the challenging task of removal of radionuclides from soil or water (Cornish et al., 1995).

In practice, plants are grown on a contaminated site and allowed to concentrate contaminants like metals or radioactive compounds into their tissues. After an appropriate time, they are harvested and burned to reduce the volume of collected material, typically by about 95%. This volume reduction, and the accompanying concentration of hazardous material in the ash, greatly decreases the ultimate cost of waste disposal. Though usually not economically feasible, useful metals might be extracted from the ash as industrial products. For example, after harvest a plant may contain as much as 1% or more by weight of a particular metal. The ash of this plant would contain about 20% by weight of that metal, a higher metal content than is found in many ores. Unfortunately, the amounts of metals that might be obtained in this way are small compared to those obtained from traditional mining processes.

Phytoremediation is not a panacea. It can be a very slow process. Thus, it is not an acceptable option for sites that represent an immediate public health or environmental threat and require immediate cleanup. Plant roots also may not grow deep enough to access contaminants at many sites. Most plants used for phytoremediation send their roots to depths of 0.3–10 m. Some trees used in phytoremediation may send their roots somewhat deeper. However, it is improbable that plant roots, even under the best of circumstances, can contact all the soil within a contaminated zone. Thus, several cropping seasons may be required to phytoremediate any particular site. Furthermore, plants require a narrow range of growth temperatures. They also grow well only in the presence of favorable soil qualities (texture, water-holding capacity, pH, presence of oxygen, etc.). They must obtain enough water to support growth and metabolism, so irrigation may be required at dry sites. Plants also may be inefficient at taking up some pollutants, allowing contaminants to reach groundwater. All of these potentially negative factors must be considered before phytoremediation is chosen as a remedial option for any particular site.

Some plants proposed for use in phytoremediation (http://www.ecological-engineering.com/phytorem.html) are shown in Table 1.

White-Rot Fungi Fungi have been used for bioremediation (Bennett and Faison, 1997). White-rot fungi, as shown in Figure 4, are wood-degrading microorganisms that produce special oxidases, enzymes that help degrade the plant polymer ligninasa as well as a great variety of chemicals, including many environmental pollutants (Paszczynski and Crawford, 1995). Thus, these fungi have been examined extensively as potential bioremediation agents. The peroxidases (known as ligninases or manganese peroxidases) of the basidiomycete *Phanerochaete chrysosporium* are the most thoroughly investigated of the xenobiotic-compound-degrading fungal enzymes. These and other oxidative fungal enzymes like laccase appear to initiate degradation of many xenobiotic molecules, such as the chlorinated compounds (including PCBs; Novotny et al., 1997).

For application in the field, white-rot fungi are grown on a cellulosic substrate such as wood chips. Some commercial companies have developed specially formulated proprietary lignocellulosic (lignocellulose) materials for growing fungal mycelia. These colonized materials provide both a carrier for the organism and a carbon and energy source (cellulose) to support pollutant cometabolism. The carriers are mixed directly into a polluted soil, which then is tilled, watered, and managed to encourage the growth and lignin-degrading activity of the introduced

Table 1. Plants proposed for use in phytoremediation.

Plant	Comment
Alfalfa	Symbiotic with hydrocarbon-degrading bacteria
Arabidopsis	Genetically engineered to carry a bacterial gene that transforms mercury into a gaseous state
Bladder campion	Accumulates zinc and copper
Indian mustard greens (*Brassica juncea*)	Accumulates selenium, sulfur, lead, chromium, cadmium, nickel, zinc, and copper
Boxwood (Buxaceae)	Accumulates nickel
Compositae	Symbiotic with bacteria, accumulates cesium and strontium
Euphorbiaceae	Succulent plants that accumulate nickel
Tomato	Accumulates lead, zinc, and copper
Poplar	Used in the absorption of the pesticide atrazine and solvents like carbon tetrachloride
Alpine pennycress (*Thlaspi caerulescens*)	Accumulates zinc and cadmium

Fig. 4. The white-rot fungus *Fomitopis pinicola* (common name, red-banded conk). Photographed by Dr. Andrzej Paszczynski in the University of Idaho Experimental Forest, Moscow Mountain, Moscow, Idaho.

fungus. As the fungus consumes its lignocellulosic carrier, it simultaneously degrades the contaminants through the fortuitous activities of its oxidases. This technology is still experimental. The fungi used thus far can be inhibited by the contaminant concentrations found in some soils. With some contaminants degradation may be incomplete. Thus, more development work is required before white-rot fungi see significant use in the treatment of contaminated soil.

The focus of many recent studies has been the fungus *Phanerochaete chrysosporium*. For example, this fungus was shown to enhance the indigenous rate of mineralization of aromatic compounds (such as PAHs) in one soil system (Brodkorb and Legge, 1992). Among the P. chrysosporium genes implicated in pollutant degradation are two lignin peroxidase genes. The mRNA transcripts of these genes were detected directly in a soil being treated by fungal inoculation (Lamar et al., 1995). Thus, the use of white-rot fungi appears most promising for specific classes of contaminants including the PAHs (Brodkorb and Legge, 1992) and some chlorinated phenols (Paszczynski and Crawford, 1995). Additional research, however, is required before use of white-rot fungi becomes common practice. There remains the possibility of identifying many more strains of white-rot fungi that might be suitable for use as bioremediation agents. Hundreds of species of white-rot fungi have never been examined in this regard.

Limitations of Bioremediation

Bioremediation has the limitations inherent in any biological system. Thus, bioremediation is not always an appropriate approach for restoration of a contaminated site. The first requirement for use of bioremediation is that environmental conditions must support biological activity. For example, the extreme ranges of pH, temperature, or radioactivity seen at some sites generally are not tolerated by degradative organisms. Microorganisms require nitrogen, phosphorus, sulfur, and a number of trace elements. These must be present and in forms that are available to microbial cells. The presence of overly toxic concentrations of heavy metals like mercury, lead, and zinc or of other antimicrobial substances may inhibit or even prevent bioremediation processes. In other instances the concentrations of contaminants may be so low that they do not provide sufficient energy for microbial growth. If alternative energy sources are unavailable and cannot be added, then even cometabolism may not be an option. Contaminants may not be accessible to microorganisms. This might occur, for example, if they are tightly adsorbed to clays or soil organic matter or have found their way into pores that are smaller than bacteria. Even such non-bioavailable contaminants still may be subject to very stringent remediation standards set

and enforced by regulatory agencies. Contaminants more often than not occur in mixtures. Sometimes these are so complex that the most likely bioremediation processes may remove only some of the waste components. Those that remain still may be regulated. In other instances the site to be treated (e.g., a large, deep aquifer) may not be accessible to manipulations needed to promote bioremediation. Despite the amazing versatility of microorganisms for the degradation of xenobiotic molecules, some man-made compounds simply are not biodegradable. In summary, bioremediation is just one tool in the environmental engineer's repertoire. It will be used frequently, but not for all sites or situations.

CHAPTER 3.9

Biodeterioration

JI-DONG GU AND RALPH MITCHELL

Introduction

Bacteria were the first life-forms to appear on Earth and they have a long history of association with mineral surfaces. Surfaces of clay minerals played an important role in the initial evolutionary processes of bacteria and the diversification of their physiology (Kluyver and van Niel, 1956; Mayr, 1998; Wächtershäuser, 1988; Woese, 1987; Woese, 1990; Woese, 1998; Woese and Olsen, 1986). Bacteria also adapt themselves to a mode of living on physical surfaces and at interfaces (Angles et al., 1993; Bitton, 1980; Brune et al., 2000; Caldwell et al., 1997; Fenchel and Finlay, 1995; Fletcher, 1980; Glagolev, 1984; Hugenholtz et al., 1998; Margulis, 1981; Marshall, 1992; Moat and Foster, 1988; Pace, 1997; Wolfaardt et al., 1994; Zavarzin et al., 1994; Zinder, 1993). In addition, they are capable of degrading a wide range of pollutants (Gibson, 1984; Gu and Berry, 1991; Gu and Berry, 1992a; Gu et al., 1992b; Young and Cerniglia, 1995). It is well recognized that degradation of organic chemicals and nutrient cycling are more rapid on surfaces. Unfortunately, microbial association with surfaces also has a potential negative economic impact, when it accelerates degradation and deterioration of a wide range of materials, including inorganic minerals (Gu et al., 2000b; Mitchell and Gu, 2000), concrete and stone (Gebers and Hirsch, 1978; Gu et al., 2000b; Moosavi et al., 1986; Padival et al., 1995; Piervittori et al., 1994; Prieto et al., 1995); metals (Ford and Mitchell, 1990b; Gu et al., 2000a; Miller, 1970); and natural and synthetic polymers (Gu et al., 2000d; Guezennec et al., 1998; Swift et al., 1979). In all cases, the essential ingredient is the close association between the microflora and the material surface.

Under natural conditions, all surfaces are covered with microorganisms except for extremely clean rooms. Biofilm formation is the process by which a complex community of microorganisms becomes established on a surface. Biofilms can exist in many different forms and have many different compositions (Fig. 1). They are ubiquitous on surfaces in soil and aquatic environments (Ford, 1993) and are also present on materials exposed to humidity, particularly in tropical and subtropical climates. For example, microbial biofilms are common on surfaces of ancient archaeological limestone in Southern Mexico (Fig. 2). This process of biofilm formation is prerequisite to substantial corrosion and/or deterioration of the underlying materials (Arino et al., 1997; Saiz-Jimenez, 1995; Saiz-Jimenez, 1997; Walch, 1992).

Biofilms on surfaces are highly structured (Breznak, 1984; Costerton et al., 1978; Costerton et al., 1994; Dalton et al., 1994; Davey and O'Toole, 2000; Kelly-Wintenberg and Montie, 1994; Lappin-Scott et al., 1992; L'Hostis et al., 1997; O'Toole et al., 2000; Wimpenny and Colasanti, 1997). Architectural structure and the organization of microorganisms on a particular surface are generally material specific, dependent on surface properties (Fletcher and Leob, 1979; van Loosdrecht et al., 1987; van Loosdrecht et al., 1990; Wiencek and Fletcher, 1995) and ambient conditions, including externally supplied electrical current, cation concentration, solution chemistry and hydrodynamic conditions (Caldwell and Lawrence, 1986; Korber et al., 1989; Lawrence et al., 1987; Lewandowski et al., 1995; Leyden and Basiulis, 1989; Little et al., 1986b; Marshall et al., 1971; Martrhamuthu et al., 1995; Neu, 1996; Pendyala et al., 1996; Power and Marshall, 1988; Rijnaarts et al., 1993; Schmidt, 1997; Sneider et al., 1994; Stoodley et al., 1997). All surfaces may act as substrata for bacterial adhesion and biofilm formation (Busscher et al., 1990; Costerton et al., 1995; Geesey and White, 1990; Geesey et al., 1996; Marshall, 1980), and microbial attack on materials can take place either directly or indirectly, depending on the specific microorganism and on the biology, chemistry and physical properties of the materials and their environment (Gu et al., 2000c). Specifically, these factors may include material composition (Bos et al., 1999; Busscher et al., 1990; Wiencek and Fletcher, 1995), the nature of the surface (Becker et al., 1994; Caldwell et al., 1997; Callow and Fletcher, 1994), and the indigenous microflora. In addition, other factors affecting the physical environ-

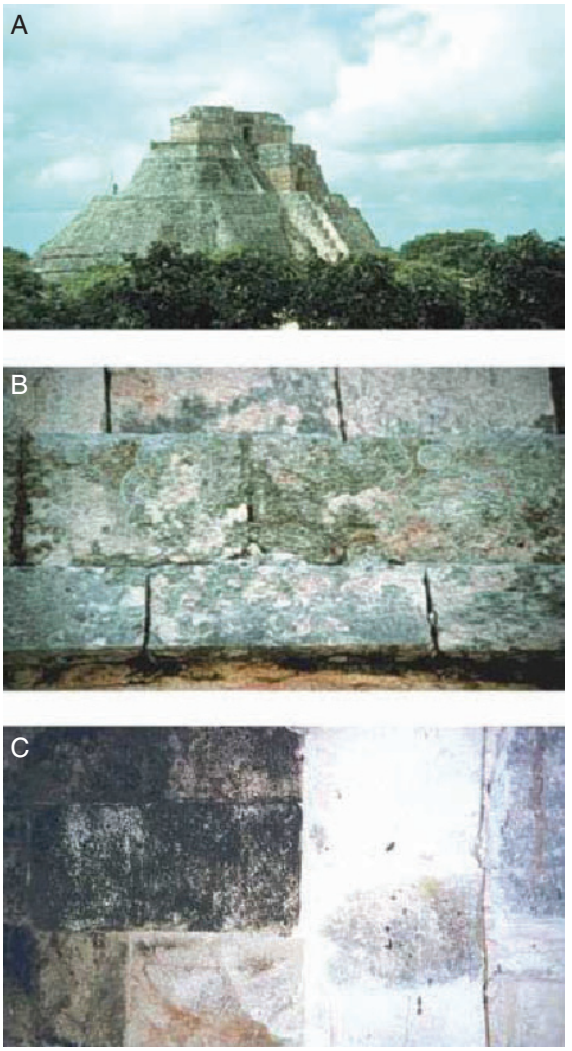

Fig. 2. Photographs showing A) an ancient Mayan temple made of limestone covered by microbial biofilms, B) a close-up view near the base, and C) the contrast between newly replaced and original stone.

ment influence the extent of bacterial adhesion, including ionic strength of the solution, type of cation, hydrodynamic force, and surface properties (e.g., hydrophobicity or hydrophilicity; Bos et al., 1999; Fletcher, 1996; Marshall, 1976). Recently, chemical signaling has been found to play a role in bacterial attachment on surfaces (Davies et al., 1998; McLean et al., 1997; Reynolds and Fink, 2001).

Microbial biofilms immobilized on solid materials are exploited in pollutant biodegradation, wastewater treatment and bioleaching (Bryers, 1990a; Bryers, 1994; Osswald et al., 1995; Sharp et al., 1998). In contrast, biofilms are undesirable in food processing, energy production and on submerged mechanical equipment surfaces. Biofouling is generally defined as the undesirable accumulation of microorganisms, their products, deposits such as minerals and organic matter, and macroorganisms on a substratum surface (Novikova and Zalogoyev, 1985; Nefedov et al., 1988; Solomin, 1985; Sunesson et al., 1995; Viktorov, 1994; Viktorov and Novikova, 1985; Viktorov and Ilyin, 1992; Viktorov et al., 1993; Zaloguyev, 1985). The thin film on fouled surfaces usually consists of microorganisms embedded in an organic matrix of biopolymers, which are produced by the microorganisms under natural conditions. In addition, microbial precipitates, minerals, and corrosion products may be present (Beveridge et al., 1997; Konhauser et al., 1994; Liken, 1981; Lovley, 1991; Pierson and Parenteau, 2000; Zehnder and Stumm, 1988). Industrial fouling is a complex phenomenon involving interactions between chemical, biological and physical processes. Materials immersed in aqueous environments or under high humidity conditions are susceptible to biofouling (Characklis, 1990; Gu et al., 1998c; Jones-Meehan et al., 1994a; Jones-Meehan et al., 1994b; Knyazev et al., 1986; Little et al., 1990; Thorp et al., 1994). These include medical implants (Dobbins et al., 1989; Gu et al., 2001b; McLean et al., 1995; Mittelman, 1996), water pipes (Rogers et al., 1994), artificial coatings (Edwards et al., 1994; Gu et al., 1998b; Jones-Meehan et al., 1994b; Stern and Howard, 2000; Thorp et al., 1997), rubber (Berekaa et al., 2000), ultrapure systems (Flemming et al., 1994; Mittelman, 1995a), porous media (Bouwer, 1992; Cunningham et al., 1990; Cunningham et al., 1991; Mills and Powelson, 1996; Rittman, 1993; Vandevivere, 1995; Vandevivere and Kirchman, 1993; Williams and Fletcher, 1996), water and wastewater treatment equipment (Bryers and Characklis, 1990b; Gillis and Gillis, 1996; Rethke, 1994; Tall et al., 1995), oilfield water systems (Lynch and Edyvean, 1988), equipment on the space station (Gazenko et al., 1990; Meshkov, 1994; Novikova et al., 1986; Pierson and Mishra, 1992; Stranger-Joannesen et al., 1993; Zaloguyev, 1985) and magnetic diskettes (McCain and Mirocha, 1995).

In general, biodeterioration is described as the undesirable degradation of materials by microorganisms. The term "biodeterioration" also implicitly includes biocorrosion and biodegradation. All three terms, "corrosion," "degradation" and "deterioration," will be used in this review. In the following sections, microbial deterioration of metals, polymeric materials, concrete and stone will be discussed.

Corrosion of Metals

Biodeterioration of materials includes the corrosion of metals, a process commonly called

"microbiological induced/influenced corrosion" (MIC) by corrosion engineers. This process affects a wide range of industrial materials, including those in oil fields, offshore drilling platforms, pipelines, pulp and paper factories, armaments, nuclear and fossil fuel power plants, chemical manufacturing facilities, and food processing plants (Corbett et al., 1987; Evans, 1948; Hill et al., 1987; Kobrin, 1993; Pope et al., 1989; Sequeira and Tiller, 1988; Widdel, 1992; Zachary et al., 1980). Significant economic loss has resulted from undesirable processes caused by the growth of microorganisms and subsequent accumulation of fouling organisms (Jensen, 1992; Ross, 1994). Corrosion has severe economic consequences. It was estimated that 70% of the corrosion in gas transmission lines is due to problems caused by microorganisms. The American oil refining industry loses $1.4 billion a year from microbial corrosion (Knudsen, 1981). The terminology of microbiological corrosion and the term "microfouling" have frequently been used interchangeably. The term "MIC" is not clearly defined and is commonly misused.

Biocorrosion of metals was first reported by von Wolzogen Kuhr and van der Vlugt (1934) more than sixty years ago. A wide variety of microorganisms are capable of degradation of metal alloys: the causative microorganisms include both aerobic and anaerobic bacteria. In the early studies, most attention was given to the strictly anaerobic sulfate-reducing bacteria (SRB; see the reviews by Dexter, 1993; Dowling and Guezennec, 1997; Dowling et al., 1992; Eashwar et al., 1995; Evans, 1948; Ford and Mitchell, 1990b; Ford and Mitchell, 1990a; Gu et al., 2000a; Hamilton, 1985; Lee et al., 1995). In addition to SRBs, thermophilic bacteria, iron-oxidizing bacteria, and exopolymer- and acid-producing bacteria were found to participate actively in corrosion processes by mechanisms in which metal ions are either transformed by or complexed with functional groups of the exopolymers, resulting in release of metallic species into solution (Chen et al., 1995; Chen et al., 1996c; Clayton et al., 1994; Ford and Mitchell, 1990b; Little et al., 1986b; Paradies, 1995; Schmidtt, 1986; Siedlarek et al., 1994).

Corrosion of metals is a result of both electrochemical and biological processes occurring on or near material surfaces, initiated and accelerated by microbial activity (the formation of complex microbial biofilms and metabolism of microorganisms on surfaces; Breslin et al., 1997; Ford and Mitchell, 1990b; Gu et al., 1998a; Gu et al., 1998c; Walch, 1992). In the process, surface-attached microorganisms alter the chemical and biological environments on the substratum. The microbial communities, in turn, form differential aeration zones under aerobic conditions because dissolved oxygen is consumed beneath microbial colonies (Uhlig and Revie, 1985).

The difference in oxygen concentrations on two localized and adjacent areas generates an electrochemical potential and electron flow (Fig. 3). The area more exposed to oxygen serves as a cathode, whereas the area underneath the microbial biofilm serves as an anode, resulting in dissolution of metallic matrices, crevice corrosion and pitting (Ford and Mitchell, 1990b; Gu et al., 2000a; Vaidya et al., 1997; Videla, 1996; Walch et al., 1989; Wang, 1996). Subsequently, the decrease in oxygen levels provides an opportunity for anaerobic microorganisms to become established within biofilms. In particular, activity of anaerobic sulfate-reducing bacteria has been shown to directly cause corrosion of underlying metals by a process of cathodic depolarization. In addition, methanogenic microorganisms may participate in the corrosion process (Daniels et al., 1987; Kim et al., 1996). Overall, the interactions between chemistry and biology create unique niches for the propagation of corrosion. Methods used to study biocorrosion are available in the literature (Hungate, 1969; Murray et al., 1993; Peng and Park, 1994; Tatnall, 1986; Wagner and Ray, 1994). The participating microorganisms and their corrosive processes under different environmental conditions are discussed below.

Microorganisms Involved in Corrosion

Aerobic Microorganisms Several groups of aerobic microorganisms play an important role in corrosion, including the sulfur bacteria, the iron- and manganese-depositing and exopolymer-producing bacteria, and fungi and algae. Figure 4 shows bacteria and corrosion products on the surface of a stainless steel cold water pipe. The "iron bacteria" include *Sphaerotilus*, *Leptothrix*, *Gallionella* and *Siderocapsa* (Ehrlich, 1996). Ghiorse and Hirsch (Ghiorse and Hirsch, 1978; Ghiorse and Hirsch, 1979) also observed that two *Pedomicrobium*-like budding bacteria deposit Fe and Mn ions on their cell walls. Most

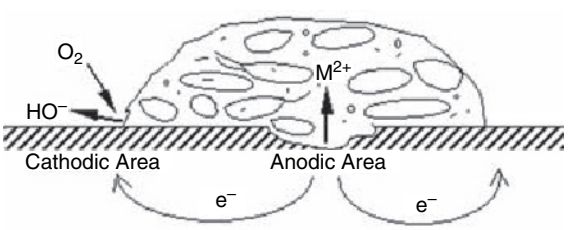

Fig. 3. Schematic of an aeration zone created by a biofilm, with resultant corrosion. Metallic cations (M^{2+}) are released from the anodic area.

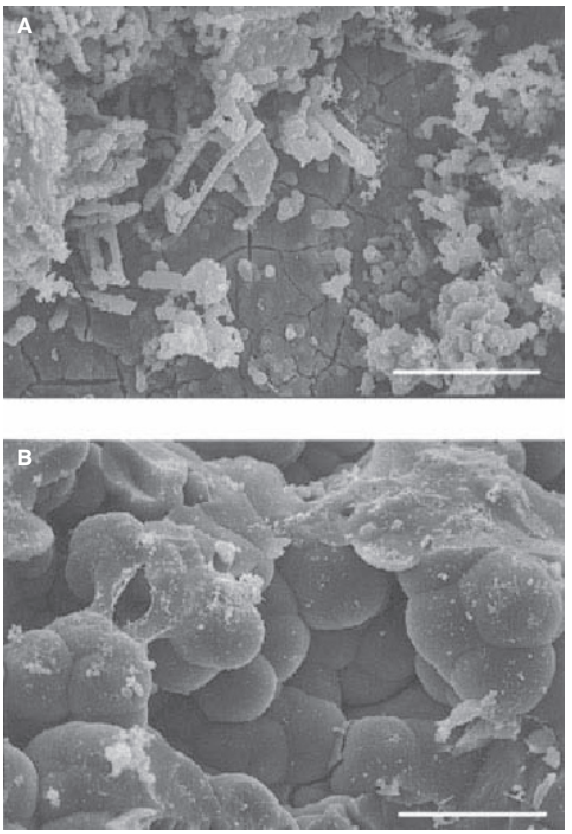

Fig. 4. Scanning electron micrographs of A) an aerobic microbial biofilm on a stainless steel surface (bar = 10 μm) and (b) the associated corrosion products (bar = 5 μm).

of these bacteria are difficult to culture under laboratory conditions (Hanert, 1981). Elucidation of their impact on corrosion is still limited by availability of culturing techniques. At neutral pH, Fe^{2+} is not stable in the presence of O_2 and is rapidly oxidized to the insoluble Fe^{3+} state. In fully aerated freshwater at pH 7, the half-life of Fe^{2+} oxidation is less than 15 minutes (Ghiorse, 1989; Stumm and Morgan, 1996). Because of the rapidity of this reaction, the only neutral pH environments where Fe^{2+} is present are interfaces between anoxic and oxic conditions.

Improved microbiological techniques permit the isolation of new Fe^{2+}-oxidizing bacteria under microaerophilic conditions at neutral pH (Emerson and Moyer, 1997). Ferric oxides may be enzymatically deposited by *Gallionella ferruginea* and nonenzymatically deposited by *Leptothrix* sp., *Siderocapsa*, *Naumanniella*, *Ochrobium*, *Siderococcus*, *Pedomicrobium*, *Herpetosyphon*, *Seliberia*, *Toxothrix*, *Acinetobacter* and *Archangium* (Ehrlich, 1996; Ghiorse and Hirsch, 1978). Iron-depositing bacteria include *Acholeplasma*, *Actinomyces* spp., *Arthrobacter*, *Caulococcus*, *Clonothrix*, *Crenothrix*, *Ferrobacillus*, *Gallionella*, *Hypomicrobium*, *Leptospirillum*, *Leptothrix*, *Lieskeela*, *Metallogenium*, *Naumaniella*, *Ochrobium*, *Peloploca*, *Pedomicrobium*, *Planctomyces*, *Seliberia*, *Siderococcus*, *Sphaeotilus*, *Sulfolobus*, *Thiobacillus*, *Thiopedia* and *Toxothrix* (Ford and Mitchell, 1990b). However, questions remain as to the extent of microbial involvement in specific processes of corrosion involving iron oxidation. Further investigation requires integrated approaches including microbiology, materials science, and electrochemistry.

Microorganisms in the genus *Thiobacillus* are also responsible for oxidative corrosion. Because they oxidize sulfur compounds to sulfuric acid, the acid surrounding the cells may attack alloys. Similarly, organic acid-producing microorganisms, including bacteria and fungi, are of concern. A number of acid-tolerant microorganisms are capable of Fe^0 oxidation. *Thiobacillus* is the most common. *Thiobacillus ferrooxidans* oxidizes Fe^{2+} to Fe^{3+}. However, the product limits growth of the organisms (Ehrlich, 1996; Kuenen and Tuovinen, 1981). Sulfate (SO_4^{2-}) is required by the Fe-oxidizing system in *T. ferrooxidans*. The role of sulfur is probably to stabilize the hexa-aquated complex of Fe^{2+} as a substrate for the Fe-oxidizing enzyme system, with the Fe^{2+} being oxidized at the surface of the bacterium. The electrons removed from Fe^{2+} are passed to periplasmic cytochrome *c*. The reduced cytochrome *c* binds to the outer plasma membrane of the cell, allowing transport of electrons across the membrane to cytochrome oxidase located in the inner membrane.

Most microorganisms accumulate Fe^{3+} on their outer surface by reacting with acidic polymeric materials. Such mechanisms have important implications not only for the corrosion of metals, but also for the accumulation of heavy metals in natural habitats. *Aquaspirillum magnetotacticum* is capable of taking up complexed Fe^{3+} and transforms it into magnetite (Fe_3O_4) by reduction and partial oxidation (Blakemore, 1982; Schüler and Frankel, 1999). The magnetite crystals are single-domain magnets. They play an important role in bacterial orientation to the two magnetic poles of the Earth in natural environments. However, magnetite can also be formed extracellularly by some nonmagnetactic bacteria (Lovley et al., 1987). The role of these bacteria in metal corrosion is unkown.

Manganese deposition by microorganisms also affects the corrosion behavior of alloys. Growth of Leptothrix discophora resulted in ennoblement of stainless steel by elevating the open circuit potential to +375 mV (Dickinson et al., 1996; Dickinson et al., 1997). Further examination of the deposits on surfaces of coupons using X-ray photoelectron spectroscopy (XPS) confirmed that the product was MnO_2. The MnO_2 can also

be reduced to Mn^{2+} by accepting two electrons generated by metal dissolution. The intermediate product is MnOOH (Olesen et al., 1998). Manganese-depositing bacteria may include *Aeromonas*, *Bacillus*, *Caulobacter*, *Caulococcus*, *Citrobacter*, *Clonothrix*, *Cytophaga*, *Enterobacter*, *Flavobacterium*, *Hypomicrobium*, *Kuznetsovia*, *Lepothrix*, *Metallogenium*, *Micrococcus*, *Nocardia*, *Oceanspirillum*, *Pedomicrobium*, *Pseudomonas*, *Siderocapsa*, *Streptomyces* and *Vibrio* spp.

Strictly Anaerobic Microorganisms The sulfate-reducing bacteria are mostly responsible for corrosion under anaerobic conditions, as described earlier (and in Fig. 5). Currently, eighteen genera of dissimilatory sulfate-reducing bacteria have been recognized (Balow et al., 1992; Campaignolle and Crolet, 1997; Clapp, 1948; Enos and Taylor, 1996; Holland et al., 1986; Krieg and Holt, 1984). They are further divided into two physiological groups (Madigan et al., 2000; Odom, 1993a; Odom and Singleton, 1993b; Postgate, 1984). One group utilizes lactate, pyruvate, or ethanol as carbon and energy sources and reduces sulfate to sulfide. Examples are *Desulfovibrio*, *Desulfomonas*, *Desulfotomaculum* and *Desulfobulbus*. The other group oxidizes fatty acids, particularly acetate, and reduces sulfate to sulfide. This group includes *Desulfobacter*, *Desulfococcus*, *Desulfosarcina* and *Desulfonema*. Some species of *Desulfovibrio* lack hydrogenase. For example, *D. desulfuricans* is hydrogenase negative and *D. salexigens* is positive (Booth and Tiller, 1960; Booth and Tiller, 1962a). Booth et al. (Booth et al., 1962b; Booth et al., 1968) observed that the rate of corrosion by these bacteria correlated with their hydrogenase activity. Hydrogenase negative SRBs were completely inactive in corrosion. Apparently, hydrogenase-positive organisms utilize cathodic hydrogen, depolarizing the cathodic reaction, which controls the kinetics. In contrast to this theory, it has been suggested that ferrous sulfide (FeS) is the primary catalyst (Lee et al., 1995; Sanders and Hamilton, 1986; Weimer et al., 1988; Westlake, 1986; White et al., 1986).

Other microorganisms should be noted for their role in anaerobic corrosion. They include methanogens (Daniels et al., 1987; Ferry, 1995), acetogens (Drake, 1994; Nozhevnikova et al., 1994), thermophilic bacteria (Ghassem and Adibi, 1995; Little et al., 1986a; Torres-Sanchez et al., 1997) and obligate proton reducers (Tomei et al., 1985). More work is needed to elucidate the role of their contributions to corrosion.

Mechanisms of Microbial Corrosion

Aerobic Conditions Iron is the most abundant element in the Earth's crust and is present in two oxidative states, ferrous (Fe^{2+}) and ferric (Fe^{3+}). Metallic iron is a product of human activity by smelting. When molecular oxygen (O_2) is available as an electron acceptor for oxidation of reduced organic compounds or metallic iron (Fe^0), the area beneath the microbial colonies acts as an anode, whereas the area further away from the colonies, where oxygen concentrations are relatively higher, serves as a cathodic site. Electrons flow from anode to cathode and the corrosion process is initiated, resulting in the dissolution of metal. Depending on the species of bacteria present and the chemical conditions, dissociated metal ions form ferrous hydroxides, ferric hydroxide and a series of Fe-containing minerals in the solution phase. It should be noted that oxidation, reduction, and electron flow must all occur for corrosion to proceed. However, the electrochemical reactions never proceed at theoretical rates because the rate of oxygen supply to cathodes and removal of products from the anodes limit the overall reaction (Dowling and Guezennec, 1997; Lee et al., 1993a; Lee et al., 1993b; Little et al., 1990; Uhlig and Revie, 1985), although the corrosion reaction is thermodynamically favorable. Electrolytes in the adjacent environments affect the resultant distance between the anode and cathode, being shorter at low salt and longer at high salt concentrations. In addition, impurities and contaminants of the metal matrices also stimulate corrosion by initiating the formation of differential cells and accelerated electrochemical reactions.

Under aerobic conditions, corrosion products usually form a typical structure consisting of three layers called "tubercles." The inner green layer is almost entirely ferrous hydroxide ($Fe[OH]_2$). The outer one consists of orange ferric hydroxide ($Fe[OH]_3$). In between these two, magnetite (Fe_3O_4) forms a black layer (Lee et al., 1995). The most aggressive form of corrosion is

tuberculation caused by the formation of differential oxygen-concentration cells on material surfaces. The overall reactions are summarized as follows:

$$Fe^0 \rightarrow Fe^{2+} + 2e^- \quad \text{(anode)} \tag{1}$$

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad \text{(cathode)} \tag{2}$$

$$2Fe^{2+} + \tfrac{1}{2}O_2 + 5H_2O \rightarrow 2Fe(OH)_3 + 4H^+ \quad \text{(tubercle)} \tag{3}$$

Initial oxidation of Fe^0 of mild steel at near neutral pH is driven by dissolved O_2 (Uhlig, 1971). Subsequent oxidation of Fe^{2+} to Fe^{3+} is an energy producing process carried out by a few bacterial species including Gallionella, Leptothrix and Thiobacillus spp. Since the amount of free energy from this reaction is quite small for these microorganisms, approximately –31 kJ, large quantities of Fe^{2+} have to be oxidized to support the microbial growth. Because the Fe^{2+} oxidative reaction is rapid under natural conditions, microorganisms must compete with chemical processes for Fe^{2+}. As a result, biological involvement under aerobic conditions may be underestimated (Ford and Mitchell, 1990a; Ford and Mitchell, 1990b).

Anaerobic Conditions Adhesion to surfaces is a strategy microorganisms use for survival and multiplication (Marshall, 1992), and it provides an opportunity leading to corrosion. In all submerged environments including freshwater and marine, surfaces are covered with microorganisms and their exopolymeric layers. Within this gelatinous matrix of a biofilm, there are oxic and anoxic zones, permitting aerobic and anaerobic processes to take place simultaneously within the biofilm layer. Aerobic processes consume oxygen, which is toxic to the anaerobic microflora, whereas anaerobes benefit from the decrease in oxygen tension. In the absence of oxygen, anaerobic bacteria, including methanogens, sulfate-reducing bacteria, acetogens and fermentative bacteria are actively involved in corrosion processes. Interactions between these microbial species allow them to coexist under conditions where nutrients are limited.

Sulfate-reducing bacteria (SRBs) are among the most intensely investigated groups of microorganisms causing biological corrosion (Angell et al., 1995; Audouard et al., 1995; Hadley, 1948; Iverson, 1984a; Little et al., 1994; Pope et al., 1989; Starkey, 1986; Walch and Mitchell, 1986; Widdel, 1988). Characteristic corrosion by SRBs on metal surfaces results in pitting corrosion. Since molecular oxygen is not available to accept electrons under anaerobic conditions, SO_4^{2-} or other compounds (CO_2, H_2 and organic acids) are used as electron acceptors. Each type of electron acceptor is unique in the pathway of microbial metabolism. When corrosion begins, the following reactions take place:

$$4Fe^0 \rightarrow 4Fe^{2+} + 8e^- \quad \text{(anodic reaction)} \tag{4}$$

$$8H_2O \rightarrow 8H^+ + 8OH^- \quad \text{(water dissociation)} \tag{5}$$

$$8H^+ + 8e^- \rightarrow 8H \quad \text{(adsorbed)} \quad \text{(cathodic reaction)} \tag{6}$$

$$SO_4^{2-} + 8H \rightarrow S^{2-} + 4H_2O \quad \text{(bacterial consumption)} \tag{7}$$

$$Fe^{2+} + S^{2-} \rightarrow FeS\downarrow \quad \text{(corrosion products)} \tag{8}$$

$$4Fe + SO_4^{2-} + 4H_2O \longrightarrow 3Fe(OH)_2\downarrow + FeS\downarrow + 2OH^- \tag{9}$$

Von Wolzogen Kuhr and van der Vlugt (1934) suggested that the above set of reactions is caused by SRBs. This electrochemical generalization has been accepted and is still prevalent. During corrosion, the redox potential of the bacterial growth medium is –52 mv (Hadley, 1948). After inoculation of a corrosion testing cell with SRBs, the electrochemical potential decreases from the initial value of –470 mv to approximately –538 mv (Fig. 6).

Several changes take place in the electrical potential of steel after inoculation with the SRBs. Before inoculation, the value is determined by the concentration of hydrogen ions in the medium. A film of hydrogen forms on surfaces of Fe^0 and steel, inducing polarization. Immediately after inoculation, SRBs begin growth and depolarization occurs, resulting in a drop in the anodic direction. The SRBs, by means of their hydrogenase system, remove the adsorbed hydrogen, depolarizing the system. The overall process was described as depolarization, based on the theory that these bacteria remove hydrogen that accumulates on the surfaces of iron. The electron removal as a result of hydrogen utilization results in cathodic depolarization and forces more iron to be dissolved at the anode.

The direct removal of hydrogen from the surface is equivalent to lowering the activation energy for hydrogen removal by providing a depolarization reaction. The enzyme, hydrogenase, synthesized by many species of *Desulfovibrio* spp., is involved in this specific depolarization process (Starkey, 1986). Under aerobic conditions, the presence of molecular oxygen serves as an electron sink; under anaerobic conditions, particularly in the presence of SRBs, SO_4^{2-} in the aqueous phase can be reduced to S_2^- by the action of the microflora. The biogenically produced S_2^- reacts with Fe^{2+} to form a

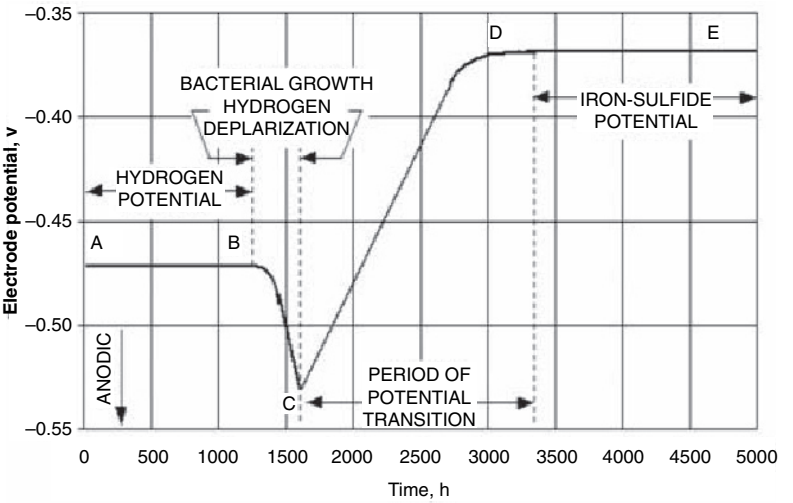

Fig. 6. Cathodic depolarization potential after inoculation of sulfate-reducing bacteria.

precipitate of FeS. Controversy surrounding the mechanisms of corrosion includes more complex mechanisms involving both sulfide and phosphide (Iverson, 1981; Iverson, 1984a; Iverson and Olson, 1983; Iverson and Olson, 1984b; Iverson et al., 1986) and processes related to hydrogenase activity (Li and Lü, 1990; Starkey, 1986). The addition of chemically prepared Fe_2S and fumarate as electron acceptors also depolarizes the system. However, higher rates are always observed in the presence of SRBs.

As a result of the electrochemical reactions, the cathode always tends to be alkaline with an excess of OH^-. These hydroxyl groups also react with ferrous irons to form precipitates of hydroxy iron. Precipitated iron sulfites are frequently transformed into minerals, such as mackinawite, greigite, pyrrhotite, marcasite and pyrite. Lee et al. (Lee et al., 1993a; Lee et al., 1995) suggest that biogenic iron sulfides are identical to those produced by purely inorganic processes under the same conditions. Little et al. (1994) showed evidence that biogenic minerals are microbiological signature markers.

Alternation Between Aerobic and Anaerobic Conditions Constant oxic or anoxic conditions are rare in natural or industrial environments. It is more common that the two alternate, depending on oxygen gradient and diffusivity in a specific environment. Microbial corrosion under such conditions is quite complex, involving two different groups of microorganisms and an interface that serves as a transition boundary between the two conditions. Resultant corrosion rates are often higher than those observed under either oxic or anoxic conditions. Microbial activity reduces the oxygen level at interfaces, facilitating anaerobic metabolism. The corrosion products (such as FeS, FeS_2 and S^0) resulting from anaerobic processes can be oxidized when free oxygen is available (Nielsen et al., 1993).

During oxidation of reduced sulfur compounds, more corrosive sulfides are produced under anoxic conditions, causing cathodic reactions. The corrosion rate increases as the reduced and oxidized FeS concentrations increase (Lee et al., 1993a; Lee et al., 1993b). Cathodic depolarization processes also can yield free O_2 which reacts with polarized hydrogen on metal surfaces.

Other Processes Contributing to Corrosion Bacteria produce copious quantities of exopolymers which appear to be implicated in corrosion (Ford et al., 1986; Ford et al., 1987b; Ford et al., 1988; Ford et al., 1990d; Ford et al., 1990c; Ford et al., 1991; Little and Depalma, 1988; Paradies, 1995; Roe et al., 1996; Whitfield, 1988). The process is shown in Fig. 7. These exopolymers are acidic and contain functional groups capable of binding to metal ions. Paradies (1995) recently reviewed this subject. The exopolymers faciliate adhesion of bacteria to surfaces. They are involved in severe corrosion of copper pipes and water supplies in large buildings and hospitals (Fischer et al., 1987; Paradies et al., 1990). Some materials also play an important role in cueing the settlement of invertebrate larvae and others in repelling larvae from surfaces (Gu et al., 1997b; Holmström et al., 1992; Maki et al., 1989; Maki et al., 1990a; Maki et al., 1990b; Mitchell and Maki, 1989; Rittschof et al., 1986). They primarily consist of polysaccharides and proteins and influence the electrochemical potential of metals (Chen et al., 1995; Chen et al., 1996c). Surface analysis using XPS showed that these functionality-rich materials can complex metal ions from the surface, releasing them into aqueous solution. As a result, corrosion is initiated.

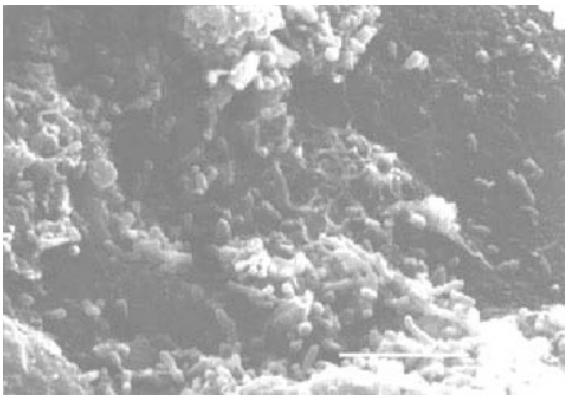

Fig. 7. Scanning electron micrograph showing a biofilm and large quantities of exopolysaccharide on the surface of stainless steel (bar = 5 μm).

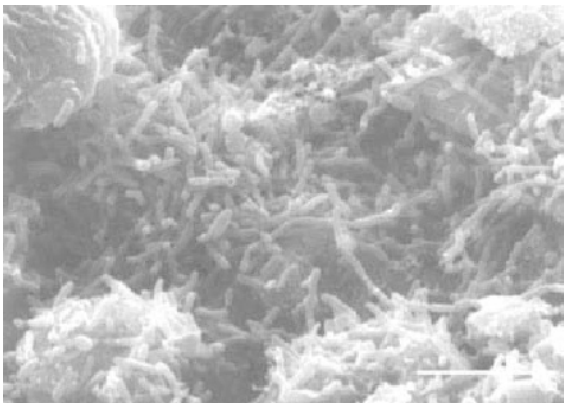

Fig. 8. Scanning electron micrograph of a bacterial biofilm of the type that is inhibiting corrosion of underlying stainless steel (bar = 5 μm).

Proteins in polymeric materials use their disulfide-rich bonds to induce corrosion.

Bacterial polymers were recently found to promote corrosion of copper pipes in water supplies (Fischer et al., 1987; Mittelman and Geesey, 1985; Paradies et al., 1990), owing to the high affinity of the polymeric materials for copper ions (Mittelman and Geesey, 1985; Ford et al., 1988). The corrosion processes are accelerated when the pipes are filled with stagnant soft water. Cations influence the production of bacterial exopolymers. Polysaccharide production by *Enterobacter aerogenes* is stimulated by the presence of Mg, K and Ca ions (Wilkinson and Stark, 1956). Toxic metal ions (e.g., Cr^{6+}) also enhance polysaccharide production. Synthesis is positively correlated with Cr concentration. These bacteria also can be used in the mining and recovery of precious metals, a process called "bioleaching" (Clark and Ehrlich, 1992; Davidson et al., 1996; Dunn et al., 1995).

The role of bacteria in embrittlement of metallic materials by hydrogen is not fully understood. During the growth of bacteria, fermentation processes produce organic acids and molecular hydrogen. This hydrogen can be adsorbed to material surfaces, causing polarization. Some bacteria, particularly the methanogens, sulfidogens, and acetogens, can also utilize hydrogen (Gottschalk, 1986). Walch and Mitchell (1986) proposed a possible role for microbial hydrogen in hydrogen embrittlement. They measured permeation of microbial hydrogen into metal, using a modified Devanathan cell (Devanathan and Stachurski, 1962). In a mixed microbial community commonly found in natural conditions, hydrogen production and consumption occur simultaneously. Competition for hydrogen between microbial species determines the ability of hydrogen to permeate metal matrices, causing crack initiation.

Microbial hydrogen involved in material failure may be explained by two distinct hypotheses: pressure and surface energy change (Borenstein, 1994; Gangloff and Kelly, 1994). The kinetic nature of hydrogen embrittlement of cathodically charged mild steel is determined by the competition between diffusion and plasticity. The greater the strength of the alloy, the more susceptible it is to embrittlement. However, microstructures were also proposed to be the more critical determinant of material susceptibility. Hydrogen permeation may increase the mobility of screw dislocations, but not the mobility of edge dislocations (Luu et al., 1997; Wang, 1996). On the other hand, corrosion may also be inhibited by the presence of biofilms on surfaces (Hernandez et al., 1994; Jayaraman et al., 1997; Jayaraman et al., 1999; Mattila et al., 1997; Potekhina et al., 1999).

Inhibition of Corrosion by Microorganisms

The mechanisms involved during microbial corrosion of metals are: 1) stimulation of an anodic or cathodic process by bacterial metabolites, 2) breakdown of the protective layers, and 3) enhanced conductivity near the surface liquid environment. However, bacteria may also inhibit corrosion processes (Fig. 8) by electrochemical processes (Hernandez et al., 1994; Jayaraman et al., 1997; Jayaraman et al., 1999; Mattila et al., 1997; Potekhina et al., 1999). Bacteria may also 1) neutralize the corrosive substances, 2) form protective layers on materials, or 3) decrease the corrosiveness of the aqueous environment.

Nonferrous Metals

Metals other than Fe are commonly used in alloys to inhibit corrosion and enhance mechanical properties. They include Mo, Cr, Ni, Cu, Zn and Cd. The selection of metal species and the quantities in the iron matrices are based on the engineering properties of the materials. Pure metals in common use are limited to Fe, Al, Cu and Ti. We know very little about biocorrosion of Al and Ti (Gu et al., 2000a). Alumininum (Al) reacts with molecular oxygen (O_2) under ambient conditions, forming an oxidized layer of protective aluminum oxide on the outer surface of the material matrix. When Al ions are released, the free Al^{3+} is toxic to both the microflora (Appanna and Piperre, 1996; Illmer and Schinner, 1999) and animals (Nieboer et al., 1995). Because of their corrosion resistance, titanium (Ti) alloys are used in water cooling systems on ships and in water recycling systems in space. Biofilm formation on these materials has been documented (Gu et al., 1998c). However, the extent of attack by microorganiams is unknown.

Recent research on microbial interactions with metals has focused on the precipitation (Cunningham and Lundie, 1993; Fortin et al., 1994), mineral formation (Bazylinski et al., 1993; Douglas and Beveridge, 1998; Klaus et al., 1999), and oxidation/reduction processes (Kessi et al., 1999; Lovley and Phillips, 1994; Santini et al., 2000; Stoltz and Oremland, 1999; Sugio et al., 1988; Sugio et al., 1992; Tebo and Obraztsova, 1998; Wang et al., 1989). Surprisingly, information on Zn, one of the most widely used metals, is very limited.

Microorganisms may affect transitional metals in several ways, including precipitation by metabolic products (Fortin et al., 1994), cellular complexation (Schembri et al., 1999; Schultzen-Lam et al., 1992), and concentration and mineral formation of internal cellular structures. Sulfate-reducing bacteria can effectively immobilize a wide range of soluble metals by forming sulfide precipitates (Sakaguchi et al., 1993). Recently, bacterial exopolymers have been found to be capable of complexing metals, leading to accumulation at the cell surface. This ability is not restricted to a specific group of microorganisms and has been documented in the aerobic bacterium *Deleya marina* and an anaerobe *Desulfovibrio desulfuricans* (Chen, 1996a). Since many transitional metals exist in several oxidation/reduction states, both bacterial oxidation and reduction are possible.

Chromium (Cr) can exist in either the hexavalent or trivalent form. Reduction of Cr^{6+} to Cr^{3+} is mediated by both aerobic and anaerobic microorganisms. A change of phenotypic expression in *Pseudomonas indigoferas* (*Vogesella indigofura*) has been observed in the presence of Cr^{6+} (Gu and Cheung, 2001a). Intracellular partition of Cr was reported using bacteria from a subsurface environment. Reduction of Cr^{6+} is a process in which the toxicity of the metal is greatly reduced. Bacteria possessing this ability include *Achromobacter eurydice*, *Aeromonas dechromatica*, *Agrobacterium radiobacter*, *Arthrobacter* spp., *Bacillus subtilis*, *B. cereus*, *Desulfovibrio vulgaris*, *Escherichia coli*, *Enterobacter cloacae*, *Flavobacterium devorans*, *Sarcina flava*, *Micrococcus roseus* and *Pseudomonas* spp. (Ehrlich, 1996).

Similarly, Mo exists in a number of oxidation states, with Mo^{4+} and Mo^{6+} being most common. *Thiobacillus ferrooxidans* is capable of oxidizing Mo^{5+} to Mo^{6+}, whereas *Enterobacter cloacae*, *Sulfolobus* sp. and *Thiobacillus ferrooxidans* can reduce Mo^{6+} to Mo^{5+} (Sugio et al., 1988; Sugio et al., 1992). Microbiological oxidation or reduction of other metals, including Cd, Ni, and Zn, has not been fully established. Microbial exopolymers have a significant effect on the solubilization of metals from material matrices through complexation and chelation. Because of this property, wastewater containing these metals ions can be purified through biomass adsorption, a process in which metal ions are concentrated on a biosorbent (Gelmi et al., 1994; Matis et al., 1996; Sánchez et al., 1999).

Our knowledge of microbial transformation of metals is very limited. Recent developments in isolation of Bacteria and Archaea may provide new tools to investigate metal transformations in natural habitats (Amann et al., 1995). Molecular techniques, including DNA probes and in situ hybridization, permit the identification of physiologically unique bacteria without the need to culture the organisms. Microbial resistance to metals is widespread in nature (Lin and Olsen, 1995; Mergeay, 1991; Sandaa et al., 1999). Elucidation of the genetic structure of these bacteria should provide new insights into the processes involved in resistance.

Biodeterioration of Polymeric Materials

Microorganisms also contribute to the deterioration and degradation of synthetic and natural polymers (Lee, 1948; Gu et al., 2000d). Very little is known about the biodegradation of synthetic polymeric materials, probably because of their relatively recent widespread use and very slow rate of degradation in natural habitats. Since chemically synthesized polymeric materials have become an indispensable part of human activities and have more diversified applications than

metals, issues related to polymer deterioration will receive more attention in the future.

Polymeric materials are very diversified in their chemical composition, physical forms, mechanical properties and applications. Variations in their chemical structure result from the versatility of the hydrocarbon (C—C, C—R and C—H) bonds and substituent groups and their possible configurations, stereochemistry and orientation (Odian, 1991). These small variations in strucure result in large differences in biodegradability. Because of their versatility, they are widely used in product packaging, insulation, structural components, protective coatings, medical implants, drug delivery carriers, slow-release capsules, electronic insulation, telecommunications equipment, aviation and space industry applications, sporting and recreational equipment, and building consolidants. In service, they are constantly exposed to a range of natural and artificial conditions often involving microbial contamination, resulting in aging, disintegration and deterioration over time (Lemaire et al., 1992; Pitt, 1992).

Microorganisms and Degradation of Synthetic Polymers

Polymers are potential substrates for heterotrophic microorganisms. Microbial utilization of polymers depends on their chemical structure, molecular weight, crystallinity and physical form (Gu et al., 2000d). Generally, an increase in molecular weight results in a decreased degradation rate of the polymer. By contrast, monomers, dimers, and oligomers of a polymer's repeating units are easily degraded and mineralized. High molecular weights result in a decrease in solubility and are unfavorable for microbial attack because bacteria require that the substrate be assimilated through the cellular membrane and then further degraded by intercellular enzymes. Both abiological and biological processes may faciltiate degradation of polymers.

At least two types of enzymes are active in biological degradation of polymers: extracellular and intracellular depolymerases (Doi, 1990). During degradation, exoenzymes from microorganisms break complex polymers to yield short units including oligomers, dimers and monomers that are small enough to pass through permeable outer bacterial membranes and subsequently be utilized as carbon and energy sources (Fig. 9). The more similar a polymeric structure is to a natural analog, the more easily it is degraded and mineralized. Cellulose, chitin, pullulan and poly β-hydroxybutyrate (PHB) are all biologically synthesized and can be completely and rapidly biodegraded by heterotrophic microorganisms

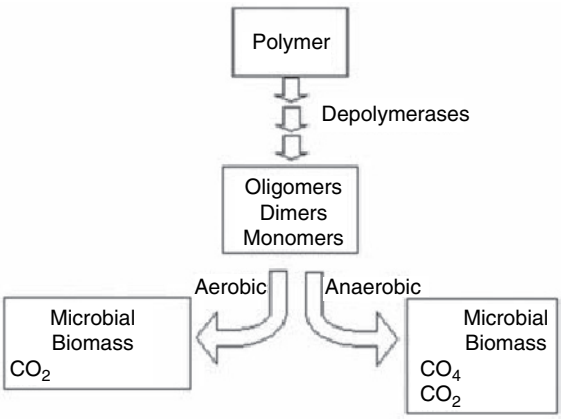

Fig. 9. A schematic of polymer degradation under aerobic and anaerobic conditions.

(Bérenger et al., 1985; Byrom, 1991; Chahal et al., 1992; Frazer, 1994; Gamerith et al., 1992; Gujer and Zehnder, 1983; Gunjala and Sulflita, 1993; Hamilton et al., 1995; Hass et al., 1992; Hespell and O'Bryan-Shah, 1988; Kormelink and Voragen, 1993; Lee et al., 1985; Lee et al., 1987a; Lee et al., 1987b; Lee et al., 1993c; Lüthi et al., 1990a; Lüthi et al., 1990b; MacDonald et al., 1985; MacKenzie et al., 1987; Nakanishi et al., 1992; Sonne-Hansen et al., 1993; Sternberg et al., 1977; Törrönen et al., 1993; Wong et al., 1988; Yoshizako et al., 1992). The complete decomposition of a polymer to CO_2 and H_2O under aerobic conditions or to organic acids, CO_2, and CH_4 under anaerobic conditions is rare. Degradation and mineralization of a polymer substrate rarely are complete, because of the utilization of a portion of the partially degraded polymer to form humus and other natural products (Alexander, 1977; Narayan, 1993).

Environmental conditions may determine the dominant groups of microorganisms and the degradative pathways associated with polymer degradation. Under high redox conditions, aerobic microorganisms are mostly responsible for destruction of complex materials, with microbial biomass, CO_2, and H_2O as the final products (Fig. 9). In contrast, under low redox conditions, anaerobic consortia of microorganisms are involved in polymer deterioration, and the primary products will be microbial biomass, CO_2, CH_4 and H_2O (Barlaz et al., 1989a; Barlaz et al., 1989b; Gu et al., 2000d; Gu et al., 2000e; Fig. 9). These conditions are widely found in natural environments and can be simulated in the laboratory with appropriate inocula. Both aerobic and strictly anaerobic microorganisms also coexist in natural environments.

We can divide synthetic polymers into three groups: 1) relatively degradable, 2) recalcitrant, and 3) completely resistant. We have excluded

natural polymers, e.g., cellulose, chitin, chitosan, lignin and polysaccharides.

Degradable Polymers

Microbial degradability of polymers depends on their molecular composition and molecular weight. Some can be almost completely utilized as a source of carbon and energy, whereas others are only partially degraded. Examples of the former include the polyhydroxyalkanoates (PHAs; Anderson and Dowes, 1990; Brandl et al., 1988; Choi and Yoon, 1994; Doi, 1990; Nakayama et al., 1985; Stenbüchel, 1991; Stuart et al., 1995; Tanio et al., 1982), γ-polyglutamates (Cromwick and Gross, 1995), cellulose acetates (Buchanan et al., 1993; Gross et al., 1993; Gross et al., 1995; Gu et al., 1992c; Gu et al., 1992d; Gu et al., 1993a; Gu et al., 1993b; Gu et al., 1993c; Gu et al., 1994b), polyethers (Kawai, 1987; Kawai and Moriya, 1991; Kawai and Yamanaka, 1986), polylactides (Gu et al., 1992c; Gu et al., 1992d), polyurethanes (Blake et al., 1998; Crabbe et al., 1994; El-Sayed et al., 1996; Filip, 1978; Gillatt, 1990; Gu et al., 1998c; Mitchell et al., 1996; Nakajima-Kambe et al., 1995; Szycher, 1989), and rubbers (Berekaa et al., 2000; Heisey and Papadatos, 1995). A general rule is that biologically synthesized polymers are readily biodegradable in natural environments, whereas synthetic polymers are either less biodegradable or degrade very slowly, depending on their chemical composition, structural complexity, and molecular weights. However, the rate of degradation is largely determined by the chemical structure, e.g., the C—C and other types of bonds, molecular weight, structure and configuration, as well as the participating microorganisms. It is also determined by the environment, specifically the presence of an active microbial population capable of utilizing all or part of the polymer.

Chemical structure of a polymer determines its biodegradability. As a general rule, high molecular weight synthetic polymers are less biodegradable or degrade at a slower rate than those with low molecular weights. The same principal may also apply to the polymers mentioned above. In addition, the rate of hydrolytic chain cleavage is dependent on the copolymer composition. For example, Doi (1990) determined that the most susceptible polyhydroxybutyrates to hydrolysis (from highest to lowest hydrolysis rate) are: poly(3-hydroxybutyrate-co-27% 4-hydroxybutyrate), also known as (P[3HB-co-27% 4HB]) > (P[3HB-co-17% 4HB]) > (P[3HB-co-10% 4HB]) > poly(3-hydroxybutyrate-co-45% 3-hydroxyvalerate), also known as (P[3HB-co-45% 3HV]) > (P[3HB-co-71% 3HV]). Similarly, Parikh et al. (1993) in another series arranged PHBs in the order of their rates (from highest to lowest) of enzymatic hydrolysis as follows: (P[HB-co-16% HV]) > (P[HB-co-32% HV]) > PHB (Fig. 10). The crystallinity of the polymer also affects the rate of degradation but is rarely taken into account (Budwill et al., 1992).

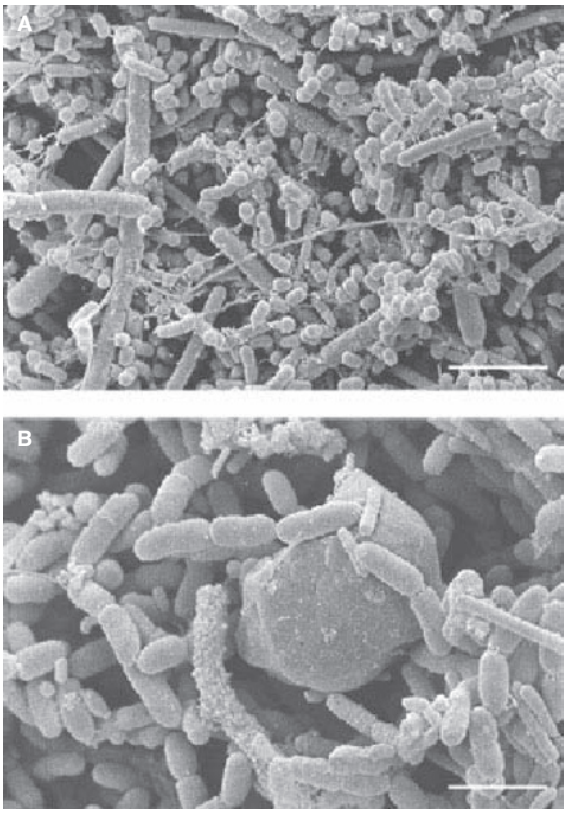

Fig. 10. Scanning electron micrographs of (a) an aerobic microbial biofilm on the surface of poly-β-hydroxybutyrate (PHB; bar = 10 μm) and (b) bacteria surrounding a PHB granule (bar = 5 μm).

BIOPOLYMERS Bacterial poly(β-hydroxyalkanoates) are formed as energy storage materials during nutrient-limited growth when the carbon source is in excess, e.g., high C/N ratio (Anderson and Dawes, 1990; Brandl et al., 1988; Doi, 1990; Holmes et al., 1985; Kim et al., 1995; Lemoigne, 1926; Stenbüchel, 1991). They consist of homo- or copolymers of [R]-β-hydroxyalkanoic acids. The polymer forms intracellular inclusions (granules 0.3–1.0 μm in diameter) in the bacterial cytoplasm, and it can comprise as much as 30–80% of cellular biomass. The polymer is isolated from *Bacillus megaterium* by extraction in chloroform and has a molecular weight of approximately 10^5–10^6 with more than 50% in crystalline form (J-D. Gu et al., unpublished observation). Unlike other biopolymers,

such as polysaccharides, proteins and DNAs, P(3HB) is a thermoplastic with a melting temperature around 180°C, making it a good candidate for thermoprocessing. Poly-β-hydroxyalkanoates (PHAs) and copolymers have also been produced through genetic engineering in plants (John and Keller, 1996) and by chemical synthesis (Kemnitzer et al., 1992; Kemnitzer et al., 1993).

Homopolymers and copolymers can be degraded in biologically active environments, e.g., soil (Albertsson et al., 1987; Mas-Castellà et al., 1995; Tsao et al., 1993), sludge, compost (Gilmore et al., 1992; Gilmore et al., 1993; Gross et al., 1993; Gross et al., 1995; Gu et al., 1993b), river water (Andrady et al., 1993; Iman et al., 1992) and seawater (Andrady et al., 1993; Sullivan et al., 1993; Wirsen and Jannasch, 1993). Extracellular P(HB) depolymerases have been isolated from Pseudomonas lemoignei (Lusty and Doudoroff, 1966) and A. faecalis (Saito et al., 1989; Tanio et al., 1982). Other bacteria capable of degrading these polymers include *Acidovorax facilis*, *Variovorax paradoxus*, *Pseudomonas syringae* subsp. *savastanoi*, *Comamonas testosteroni*, *Cytophaga johnsonae*, *Bacillus megaterium*, *B. polymyxa* and *Streptomyces* spp. (Mergaert et al., 1993). The enzymatic degradation occurs at the surfaces of the polyester film (Fig. 11), and the rate of surface erosion is highly dependent on the molecular weight (degree of polymerization), composition of the polyester, crystallinity and the dominant species of bacteria.

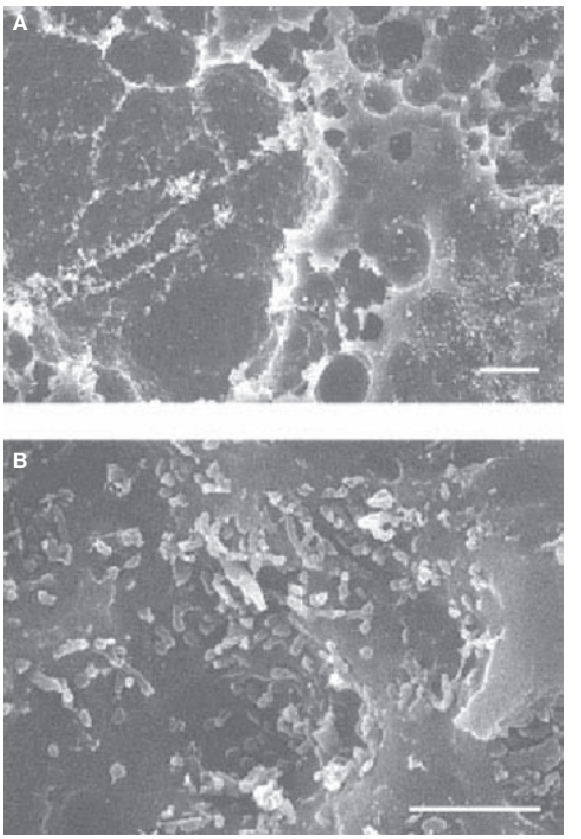

Fig. 11. Scanning electron micrographs showing A) extensive surface erosion by surface colonizing bacteria in soil (bar = 1 μm) and B) a close-up of the eroded area (bar = 5 μm).

Chemically Modified Biopolymers Cellulose acetates (CAs) are a class of chemically modified natural polymers designed to improve their processibility and mechanical properties for different applications (Bogan and Brewer, 1985). Theoretically, they carry substitution values from as low as near zero to 3.0. Generally, CAs with a degree of substitution less than 2.5 have been shown to be degraded in thermophilic compost (Gross et al., 1993; Gross et al., 1995; Gu et al., 1992c; Gu et al., 1992d; Gu et al., 1993a; Gu et al., 1993b; Gu et al., 1993c; Gu et al., 1994b) or transformed through biologically catalyzed reactions (Downing et al., 1987). Increasing the degree of substitution (DS) value on a repeating unit makes the CA less degradable. It is also apparent that deviation from the natural structure increases resistance of degradation.

Cellulose acetate (CA) degradation occurs more rapidly under aerobic conditions. The mechanisms of degradation are deacetylation, which releases the substituted groups, followed by cleavage of the C–C backbone. It is believed that the molecular weight decrease and deacetylation proceed simultaneously during degradation, after CA reaches a critical value of substitution. Structural substitution groups, and their number per repeating unit, also affect the degradation kinetics. For example, cellulose acetates (CAs) with lower degree of substitution (DS) values are more quickly degraded than more substituted ones under both aerobic and anaerobic conditions (Buchanan et al., 1993; Gross et al., 1993; Gross et al., 1995; Gu et al., 1992c; Gu et al., 1992d; Gu et al., 1992c; Gu et al., 1993a; Gu et al., 1993b; Gu et al., 1993c; Gu et al., 1994b). Cellulose acetates (CAs) with lower substitution values also show relatively higher solubility. During degradation of CA, both molecular weight and degree of substitution decreased, suggesting that deacetylation and decomposition of the polymer backbone proceed simultaneously (Gu et al., 1993c). Earlier data suggested that CA with DS values greater than 0.82 are recalcitrant to biodegradation and that the limiting step is deacetylation, followed by breaking of the polymer carbon-carbon bonds (Reese, 1957). Obviously, degradation of CA can proceed at DS values higher than 0.82.

Chemically Synthesized Polymers The most common group of synthetic polymers are polyethers. These polymers include polyethylene glycols (PEGs), polypropylene glycols (PPGs) and polytetramethylene glycols (PTMGs). They are widely used in pharmaceuticals, cosmetics, lubricants, inks and surfactants. They frequently contaminate natural waters, including coastal waters and streams where wastewater is discharged.

Degradability of this class of polymers has been studied under both oxic (Kawai and Moriya, 1991; Kawai and Yamanaka, 1986; Kawai, 1987) and anoxic conditions (Frings et al., 1992; Schink and Stieb, 1983; Dwyer and Tiedje, 1983). Their degradability is dependent on molecular weight. Molecules with molecular weights higher than 1,000 have been considered resistant to biodegradation (Kawai, 1987). However, degradation of PEGs with molecular weights up to 20,000 has been reported. The ability of a microflora to degrade larger PEG molecules is dependent primarily on the ability of a syntrophic association of bacteria to metabolize the chemicals. For example, *Flavobacterium* and *Pseudomonas* (acting in concert) can degrade PEG. After each oxidation cycle, PEG molecules are reduced by a glycol unit.

The central theme of PEG degradation is cleavage of an aliphatic ether linkage. In a coculture of aerobic *Flavobacterium* and *Pseudomonas* species, PEG degradation proceeds through dehydroxylation to form an aldehyde and continues through a dehydrogenation to a carboxylic acid derivative (Kawai, 1987; Kawai and Yamanaka, 1986). Either of these bacteria in pure culture cannot degrade PEG alone. Cellular contact between them seems to be essential for effective activity.

In the *Flavobacterium* and *Pseudomonas* system, three enzymes (PEG dehydrogenase, PEG-aldehyde dehydrogenase and PEG-carboxylate dehydrogenase) are involved in the complete degradation of PEG (Kawai, 1987). All three were found in *Flavobacterium*, whereas only PEG-carboxylate dehydrogenase was present in *Pseudomonas*. The polymer PEG 6000 cannot be degraded by either bacterial species alone. The ether cleavage is extremely sensitive to the presence of glyoxylic acid. However, *Pseudomonas*, though not directly involved in the degradation, utilizes the toxic metabolite that inhibits the activity of the *Flavobacterium*. This appears to be the essential link for their syntrophic association in the degradation of PEG.

Recalcitrant Polymers

Electronic Insulation Polymers Generally, polymers in this category are chemically synthesized with the objective of high strength and resistance to degradation. They include thermosetting polyimides (Brown, 1982; Ford et al., 1995; Gu et al., 1994a; Gu et al., 1995b; Gu et al., 1996b; Gu et al., 1996e; Gu et al., 1998b; Gu et al., 1998c; Mitton et al., 1993; Mitton et al., 1996; Mitton et al., 1998), corrosion protective coatings (Mitchell et al., 1996), and fiber reinforced polymeric composites (Gu et al., 1994a; Gu et al., 1995b; Gu et al., 1995c; Gu et al., 1995d; Gu et al., 1995e; Gu et al., 1996c; Gu et al., 1996a; Gu et al., 1996e; Gu et al., 1997a; Gu et al., 1997b; Wagner, 1995; Wagner et al., 1996). Wide acceptance of polyimides in the electronics industry (Brown, 1982; Jensen, 1987; Lai, 1989; Verbicky, 1988; Verbiest et al., 1995) has drawn attention to the stability of these materials. The National Research Council in 1987 (NRC, 1987) emphasized the need to apply these polymers in the electronics industries because data acquisition, information processing and communication are critically dependent on materials performance. The interlayering of polyimides and electronics in integrated circuits prompted several studies on the interactions between these two materials (Hahn et al., 1985; Kelley et al., 1987).

Polyimides are also widely used in load bearing applications (e.g., struts, chassis, and brackets in automotive and aircraft structures), owing to their flexibility and compressive strength. They are also used in appliance construction, cookware, and food packaging because of their chemical resistance (to oils, greases, and fats), microwave transparency, and thermal resistance. Their electrical properties are ideally suited for use in the electrical and electronics markets, especially as high temperature insulation materials and passivation layers in the fabrication of integrated circuits and flexible circuitry. In addition, the flammability resistance of this class of polymers may provide a halogen-free flame-retardant material for aircraft interiors, furnishings, and wire insulation. Other possible uses may include fibers for protective clothing, advanced composite structures, adhesives, insulation tapes, foam, and optics operating at high temperatures (Verbiest et al., 1995).

Electronic packaging polyimides are particularly useful because of their outstanding performance and engineering properties. However, they are susceptible to degradation by fungi (Ford et al., 1995; Gu et al., 1994a; Gu et al., 1995b; Gu et al., 1996b; Mitton et al., 1993; Mitton et al., 1998; Fig. 12).

Polyimide degradation occurs through biofilm formation and subsequent physical changes in the polymer. Using electrochemical impedance spectroscopy (EIS) (Mansfeld, 1995; van Westing et al., 1994), fungi growing on polyimides have been shown to yield distinctive EIS spectra, indicative of failing resistivity. Two steps are

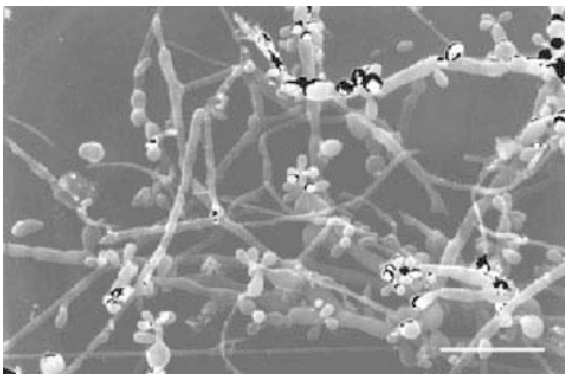

Fig. 12. Scanning electron micrograph showing a fungal community growing on the surface of electronic insulation polyimides (bar = 10 μm).

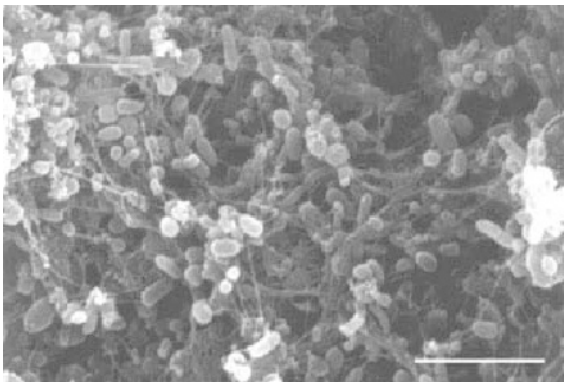

Fig. 13. Scanning electron micrograph of microorganisms colonizing the surface of a fiber-reinforced polymeric composite (bar = 10 μm).

involved during degradation: an initial decline in coating resistance is related to the partial ingress of water and ionic species into the polymer matrices. This is followed by further deterioration of the polymer by activity of the fungi, resulting in a large decrease in resistivity. The data support the hypothesis that polyimides are susceptible to microbial degradation resulting in the corrosion of underlying metal. They also confirm the versatility of EIS as a method in evaluation of the biosusceptibility of polymers.

Our studies showed that the dielectric properties of polyimides could be altered drastically following growth of a microbial biofilm (Ford et al., 1995; Gu et al., 1995b; Gu et al., 1996b; Mitton et al., 1993; Mitton et al., 1998). This form of deterioration may be slow under ambient conditions. However, the deterioration processes can be accelerated in humid conditions or in enclosed environments, e.g., submarines, space vehicles, aircraft and other closed facilities. Very small changes in material properties may have serious consequences.

Fiber-Reinforced Polymeric Composite Materials

Fiber-reinforced polymeric composite materials (FRPCMs) are also susceptible to biological attack. Impurities and additives that can promote microbial growth are potential sources of carbon and energy for the microorganisms (Fig. 13). Recently, two groups reported microbial degradation of FRPCMs (Gu and Mitchell, 1995a; Gu et al., 1995c; Gu et al., 1995d; Gu et al., 1995e; Gu et al., 1996c; Gu et al., 1996e; Gu et al., 1997a; Gu et al., 1997b; Wagner et al., 1996). Wagner and her collaborators (Wagner et al., 1996) used a mixed culture of microorganisms including a sulfate-reducing bacterium. Gu and colleagues (Gu et al., 1994a; Gu et al., 1996b; Gu et al., 1996c; Gu et al., 1996e; Gu et al., 1997a; Gu et al., 1997b) used a fungal consortium originally isolated from degraded polymers. This consortium consisted of *Aspergillus versicolor*, *Cladosporium cladosorioides*, and a *Chaetomium* sp. Physical and mechanical tests were not sufficiently sensitive to detect any significant physical changes in the materials (Gu et al., 1997a; Thorp et al., 1994). However, the resins were actively degraded, indicating that the materials were at risk of failure.

The increasing usage of FRPCMs as structural components of public structures and aerospace applications has generated an urgent need to evaluate the biodegradability of this class of new material. It has become clear that FRPCMs are not immune to adhesion by microorganisms (Ezeonu et al., 1994b; Gu et al., 1998c; Mitchell et al., 1996).

Recently, natural populations of microorganisms were found capable of growth on surfaces of FRCPM coupons at both relatively high (65–70%) and lower humidity (55–65%; Gu et al., 1998c). The accumulation of bacteria on surfaces of composites develops into a biofilm layer, providing some initial resistance to further environmental changes. However, the resistivity of composite materials was found to decline significantly during a year of monitoring using EIS (Gu et al., 1996e; Gu et al., 1997a). Clear differences resulting from biofilm development were detected on FRCPMs used in aerospace applications (Gu et al., 1997a). Further study indicated that microorganisms utilize chemicals introduced during composite manufacture as carbon and energy sources (Gu et al., 1996c). Lignopolystyrene graft copolymers were also susceptible to attack by fungi (Milstein et al., 1992).

A critical question remains about the effect of FRCPM degradation on the mechanical properties of the composite materials. Thorp et al. (1994) attempted to determine mechanical changes in composite coupons after exposure to a fungal culture. No mechanical changes could be measured after 120 days of exposure. They suggested that methodologies sufficiently sensitive to detect surface changes need to be utilized. Acoustic techniques also have been proposed as a means of detecting changes in the physical properties of the composite (Wagner et al., 1996).

Corrosion Protective Coatings

Polymeric coatings are designed to prevent contact of the underlying materials with corrosive chemicals and microorganisms. However, microbial degradation of coatings may accelerate and severely damage the underlying metals. Natural bacterial populations were found to readily form microbial biofilms on surfaces of coating materials, including epoxy and polyamide primers and aliphatic polyurethanes (Blake et al., 1998; Gu et al., 1998c; Thorp et al., 1997; Fig. 14). Surprisingly, the addition of biocides to polyurethane coatings may not inhibit bacterial attachment or growth of bacteria (Gu et al., 1998c; Mitchell et al., 1996).

Using EIS, both primers and top-coatings were monitored for their response to biodegradation by fungi. Results indicated that primers are more susceptible to degradation than are top-coats (Gu et al., 1998c).

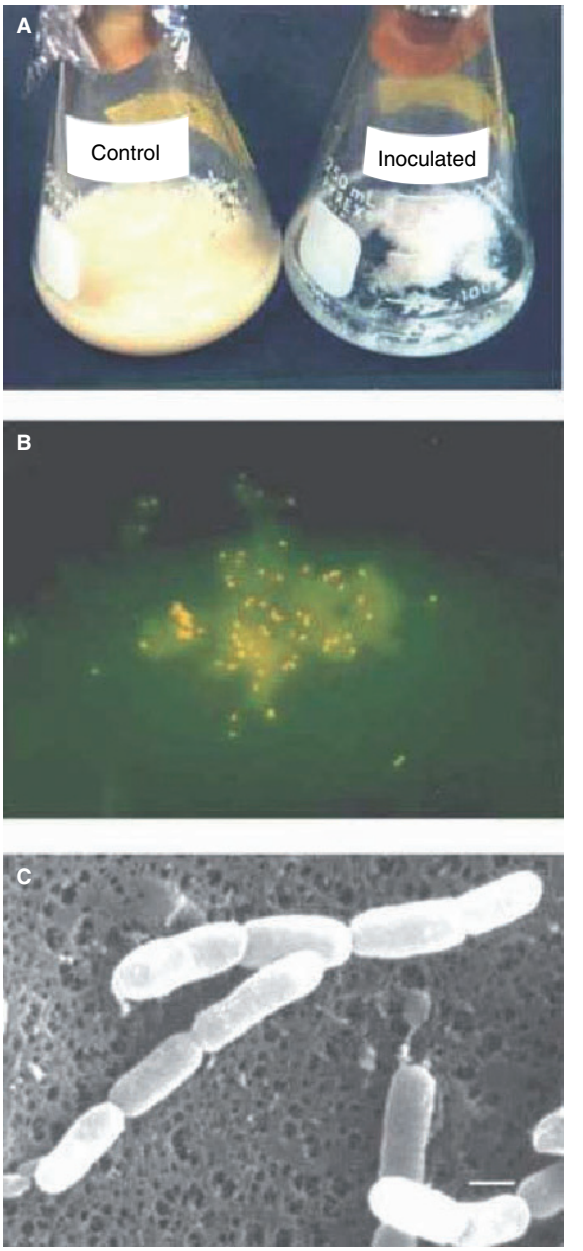

Fig. 14. A polyurethane-degrading bacterium isolated and in pure culture. A) Photograph shows clearing in the inoculated flask and a homogeneous emulsion in the control flask. B) An epifluorescence photomicrograph of the precipitated materials from the inoculated flask shows surface-associated bacteria (magnification 1,300×), and C) a scanning electron micrograph shows a bacterium capable of degrading polyurethane in pure culture (bar = 1 μm).

Nondegradable Polymers

Polyethylenes (PEs) of high and low density are primarily used in product packaging as sheets and thin films. Their degradability in natural environments poses serious environmental concerns, owing to their slow degradation rate under natural conditions and the hazard they present to freshwater and marine animals. Biodegradation of PEs has been studied extensively (Albertsson, 1980; Breslin, 1993a; Breslin and Swanson, 1993b; Iman and Gould, 1990). Prior exposure of PEs to UV promotes polymer degradation. It is believed that polymer additives, such as starch, antioxidants, coloring agents, sensitizers and plasticizers, may significantly alter the biodegradability of the parent polymers (Karlsson et al., 1988). Degradation rates may be increased by 2–4% following photosensitizer addition. However, degradation is very slow (estimated in decades). Crystallinity, surface treatment, additives, molecular weight and surfactants are all factors affecting the fate and rate of PE degradation, and they may accelerate the process.

In one study, extracellular culture concentrates of three *Streptomyces* species were inoculated to starch-containing PE films (Pometto et al., 1992; Pometto et al., 1993). It was claimed

that the PE was degraded. However, degradation may have been minimal. Other data describing degradation of PE-containing starch are questionable. Microbial metabolites may contaminate the PE surfaces and could be interpreted as degradation products of the parent PE. Abiotic degradation of PE is evident by the appearance of carbonyl functional groups in abiotic environments. In contrast, an increase of double bonds was observed when polymers showed weight loss resulting from biodegradation (Albertsson et al., 1994). It was proposed that microbial PE degradation is a two-step process: an initial abiotic photo-oxidation, followed by a cleavage of the polymer carbon backbone. However, the mechanism of the second step needs extensive analysis before plausible conclusions can be drawn. Lower molecular weight PEs including paraffin can be biodegraded. Paraffin undergoes hydroxylation oxidatively to form an alcohol group, followed by formation of carboxylic acid. At higher temperatures, ketones, alcohols, aldehydes, lactones, and carboxylic acids are formed abiotically in six weeks (Albertsson et al., 1994). Polyethylene (PE) pipes used in gas distribution systems may fail because of cracking. It is unlikely that biological processes are involved (Zhou and Brown, 1995).

Polypropylenes (PPs) are also widely utilized in engineering pipes and containers. Degradation of PPs results in a decrease of their tensile strength and molecular weight. The mechanism may involve the formation of hydroperoxides which destabilize the polymeric carbon chain to form a carbonyl group (Cacciari et al., 1993; Severini et al., 1988). Degradability of pure and high molecular weight PPs is still an open question.

Corrosion of Concrete and Stone

Concrete and stone are the most widely used materials in construction and infrastructures. Biodeterioration of these materials has important economic consequences, especially when replacement or repair of infrastructures such as bridges or municipal sewer systems is involved (Biczók, 1968; Diercks et al., 1991; Ford, 1993; Mansfeld et al., 1990; Sand and Bock, 1984; Sand et al., 1983; Sand et al., 1987b; Sand et al., 1991; Yao and Li, 1995). In addition, biodeterioration plays an important role in deterioration of stone in historic buildings, monuments and archeological sites (Arino et al., 1997; Bianchi et al., 1980; Bock et al., 1989; Cariola et al., 1987; Danin, 1993; Feddema and Mererding, 1991; Garcia de Miguel et al., 1995; Kumar and Venkataraman, 1996; Mitchell and Gu, 2000; Ortega-Calvo et al., 1993; Ortega-Calvo et al., 1995; Tiano, 1993; Tomaselli et al., 2000; Urzì and Realini, 1998). Degradation of these materials is a complex phenomenon involving chemical, physicochemical, electrochemical, and biological processes (Ascaso et al., 1998). Microorganisms have been implicated for many years (Dutton and Evans, 1996; Ezeonu et al., 1994a; Parker, 1945a; Parker, 1945b), but their involvement is poorly understood. Bacteria in the genus *Thiobacillus* were initially identified as the major culprits through biologically produced sulfuric acid, resulting in dissolution of materials. Other chemolithotrophs have been implicated in the deterioration process, including inorganic acid-producing (Atlas and Bartha, 1997; Jazsa et al., 1996a; Jazsa et al., 1996b; Sand et al., 1991), organic acid-producing (Gu et al., 1996a; Gu et al., 1998a) and exopolymer-producing bacteria (Freeman and Lock, 1995; Gehrke et al., 1998; Gu et al., 1996a; Gu et al., 1998a). Macroscopic organisms, invertebrates in particular, also participate in degradation of concrete in submerged structures, but no detailed study has been reported.

As early as 1900, corrosion of concrete sewer pipes was detected by Olmstead and Hamlin (1900). Hydrogen sulfide, an anaerobic decomposition product of sulfur-containing organic compounds and reduction of SO_4^{2-} in wastewater during microbial metabolism, was identified as the cause of corrosion (Fig. 15). The corrosion reaction was initially regarded as a purely chemical process (Lea and Desch, 1936), in which hydrogen sulfite produced under anaerobic conditions in wastewater is oxidized chemically to sulfuric acid in the presence of oxygen (Biczók, 1968). The sulfuric acid then reacts with calcium in concrete to form $CaSO_4$ or gypsum. Parker and his coworkers established the relationship

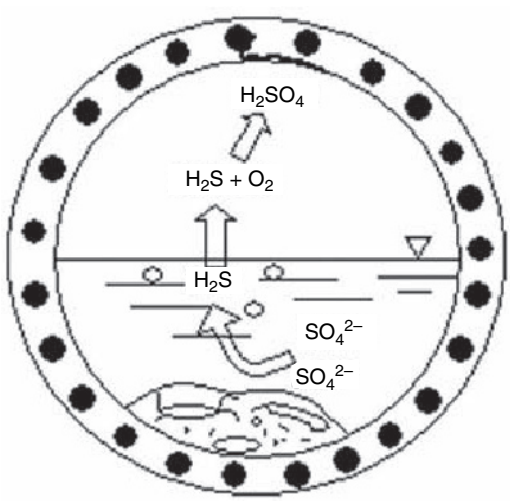

Fig. 15. A schematic of concrete corrosion by bacteria.

between acidophilic thiobacilli and concrete degradation by isolating *Thiobacillus concretivorus* (renamed "*Thiobacillus thiooxidans*") and another *Thiobacillus* species from corroded concrete (*T. neopolitabus*; Parker, 1945a; Parker, 1945b; Parker, 1947; Parker and Jackson, 1965; Parker and Prisk, 1953). The extent of corrosion correlates positively with the population of these microorganisms.

In the early 80s, rapid deterioration of newly replaced sewer systems in Hamburg, Germany, renewed interest in the corrosion processes (Milde et al., 1983; Sand and Bock, 1984; Sand et al., 1983; Sand et al., 1987b; Sand et al., 1991). In these investigations, positive correlations were observed between the extent of concrete corrosion and the numbers of *T. thiooxidans*. Sand (Sand, 1987a; Sand, 1997) also observed that *T. ferrooxidans* was associated with oxidative activity of H_2S. In the presence of sodium thiosulfate, the dominant microorganisms were *T. neapolitanus*, *T. intermedius* and *T. novellus*.

Biological corrosion of sewer pipes can be a serious problem in coastal cities, owing to the abundance of SO_4^{2-} in the wastewater. At the time of the Hamburg failure, coastal cities in the United States faced similar problems with newly installed concrete sewer systems, especially the city of Los Angeles (Mansfeld et al., 1990; Morton et al., 1991). A reason for the reemergence of the problem was the advent of the National Pollution Discharge Elimination Systems (NPDES) in 1972, which bans discharge of toxic metals and chemicals into sewers. As a result of this legislation, inorganic and organic toxic wastes were no longer permitted to be discharged directly to sewers, with a resultant increased activity of microorganisms producing large quantities of H_2S (Bitton, 1994; Somlev and Tishkov, 1994; Widdel, 1988; Fig. 15). In addition to sewers, concrete corrosion problems today involve highway bridges, historic buildings and monuments (Eckhardt, 1978; Islam et al., 1995; Jain et al., 1993; May et al., 1993), river dams (Mittelman and Danko, 1995b) and nuclear depositories (Pedersen, 1996; Stroes-Gascoyne et al., 1996) where corrosion rates are unacceptably high.

Microorganisms Responsible for Deterioration

Recent findings suggest that microorganisms participate actively in the degradation of buildings by utilization of pollutants deposited from the atmosphere as primary substrates (Corvo et al., 1997; Hutchinson et al., 1993; Lefebvre-Drouet and Rousseau, 1995; Mitchell and Gu, 2000; Ortega-Calvo, 1991; Saiz-Jimenez, 1995; Warcheid et al., 1991; Fig. 16). The predominant groups of microorganisms are those capable of sulfur oxidation (Kulpa and Baker, 1990; Sand, 1987a) and nitrification (Bock et al., 1986; Hirsch et al., 1995a; Hirsch et al., 1995b; Jazsa et al., 1996a; Sand et al., 1983; Sand et al., 1987b; Sand et al., 1991). Reported microorganisms associated with biodeterioration of building stone include *Thiobacillus*, *Desulfovibrio*, *Nitrosomonas*, *Nitrosococcus*, *Nitrobacter*, *Bacillus*, *Pseudomonas*, *Micrococcus* and *Staphylococcus*. Actinomyces include *Nocardia*, *Micropolyspora*,

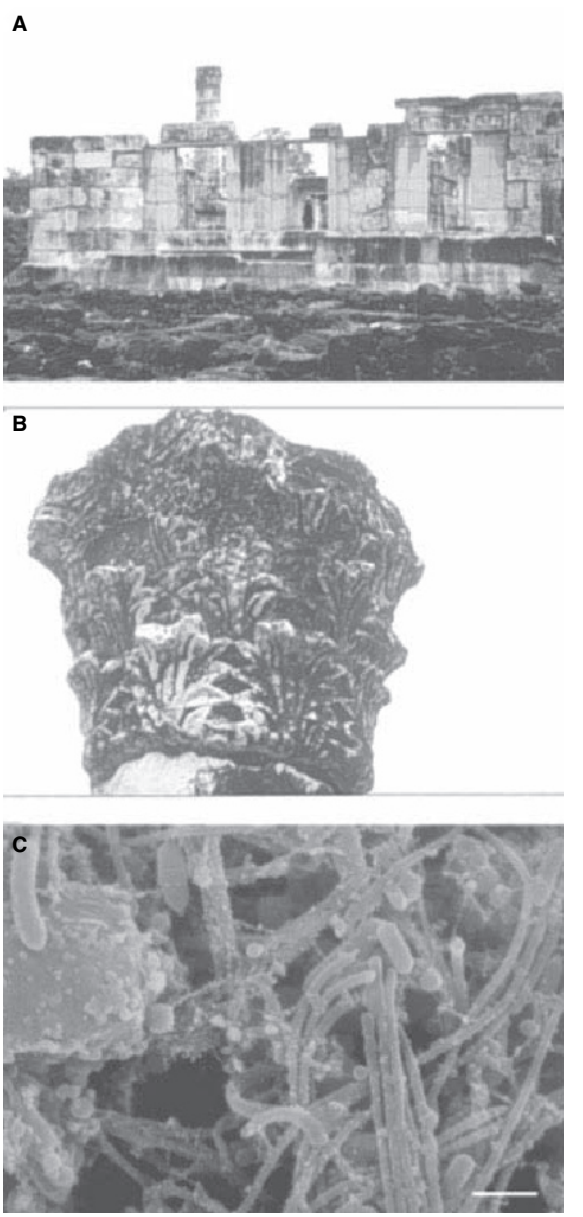

Fig. 16. Deterioration of an ancient building by microorganisms. A) A view of the building, B) a close-up of a black layer of microorganisms on the stone, and C) a scanning electron micrograph illustrating the dense complex microbial community (bar = 1 μm).

Micromonospora, *Microbispora* and *Streptomyces*. *Cyanobacteria* include *Anabaena*, *Anacystis*, *Aphanothece*, *Aulosira*, *Calothrix*, *Chlorogloea*, *Chorococcus*, *Entophysalis*, *Gloecocapsa*, *Gomphosphaeria*, *Heterohormogonium*, *Lyngsa*, *Microcystis*, *Nostoc*, *Oscillatoria*, *Phormidium*, *Porphyrosiphon*, *Schizothrix*, *Scytonema*, *Stignoema*, *Synechocystis*, and *Tolypothrix*. Organic acids, particularly from fungi, were also found to contribute to building and concrete corrosion (Gu et al., 1996a). Bacterial exopolysaccharides may also be involved in degradation of building materials (Ford et al., 1986, 1987a, 1995; Gu et al., 1998b).

Chemical and biological processes interact, resulting in the corrosion of the materials (Chen et al., 1995; Chen et al., 1996c). However, a systematic approach that integrates the role of both acid deposition and microbial activity with degradation of concrete and stone has not been attempted. Data describing stone degradation in the presence of various natural microbial populations have been made available in recent years (Flores et al., 1997; Hirsch et al., 1995b; Krumbein, 1968; Tayler and May, 1991; Tayler and May, 1994; Tiano et al., 1995; Torre et al., 1991; Torre et al., 1993a; Torre et al., 1993b). Pollutants in the air may become a source of microbial substrates on building materials and monuments (Mitchell and Gu, 2000), in the form of not only sulfurous and nitrogenous oxides but also hydrocarbons and other sulfur- and nitrogen-containing compounds (Gómez-Alarcón et al., 1995a; Gómez-Alarcón et al., 1995b; Jorgensen, 1988; Jazsa et al., 1996a; Kelley, 1981; Kelley, 1987; MacDonald, 1986; Ortega-Morales et al., 1999; Saiz-Jimenez, 1995; Schmidt, 1982). Information regarding the interaction of the natural microflora with these chemicals on concrete surfaces is still very limited.

Bock and Sand (1990) found that the nitrifying bacteria play an important role in the degradation of concrete as a result of nitric acid production during nitrification (Jazsa et al., 1996a). Nitrifying bacteria were also found to be the predominant contributors to the deterioration of other stone materials (Ehrich and Bock, 1996; Gómez-Alarcón et al., 1995a; Gómez-Alarcón et al., 1995b). These bacteria differ from the thiobacilli in that the former are capable of growth on nonimmersed surfaces (such as buildings), whereas the latter require an aqueous environment in the presence of sulfate.

Microbial Exopolymers

Microorganisms produce large quantities of exopolymeric materials in late growth phase and/or in high carbon/nitrogen (C/N) ratio environments or during adhesion to surfaces. These polymeric materials are important carbon and energy reserves and are utilized during periods of nutrient deficiency. Bacterial exopolymeric materials also play an important role in the formation of microbial biofilms (Bonet et al., 1993; Davies et al., 1998), subsequent corrosion of metals, and transport of metal ions in porous media (Chen et al., 1995; Chen et al., 1996c; Ford and Mitchell, 1992; Ford et al., 1986; Ford et al., 1987a; Ford et al., 1995). They are multifunctional group molecules (Ford et al., 1991; Paradies, 1995). The activity of these molecules and their functional groups in chelation and dissolution of calcium from concrete is still not understood. Ford and Mitchell (1992) and Geesey et al. (1986) proposed that bacterial exopolymers bind metals and promote formation of ionic concentration cells, accelerating dissolution and corrosion of metallic materials. Similarly, negatively charged carboxylic and hydroxyl groups of exopolymeric materials from thiobacilli (Fig. 17) may form complexes with calcium and leach the calcium from concrete matrices. This process may contribute to concrete degradation, particularly when biofilms grow in close proximity to the surface (Fig. 18). Further research is needed to identify a possible role for these exopolymers in concrete degradation.

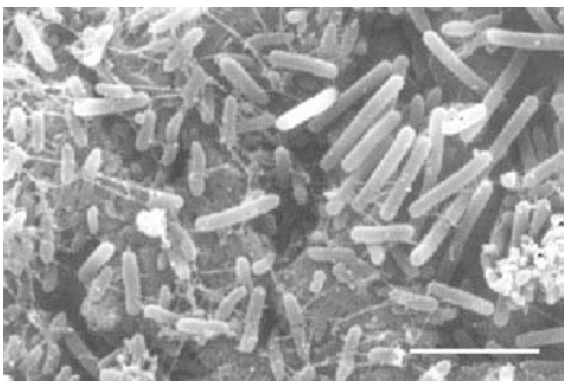

Fig. 17. Scanning electron micrograph of *Thiobacillus ferrooxidans* on the surface of corroding concrete (bar = 5 μm).

Corrosion of Reinforcing Materials

Concrete is often formulated with steel reinforcement for a wide range of applications. Reinforcement of concrete with steel bars may accelerate concrete corrosion because of the growth of SRBs and the resultant production of H_2S in submerged environments. Both SRBs and the H_2S are detrimental to steel (Gu et al., 2000a). The corrosion products expand in volume, generating stress for surrounding concrete materials and resulting in cracks in the concrete

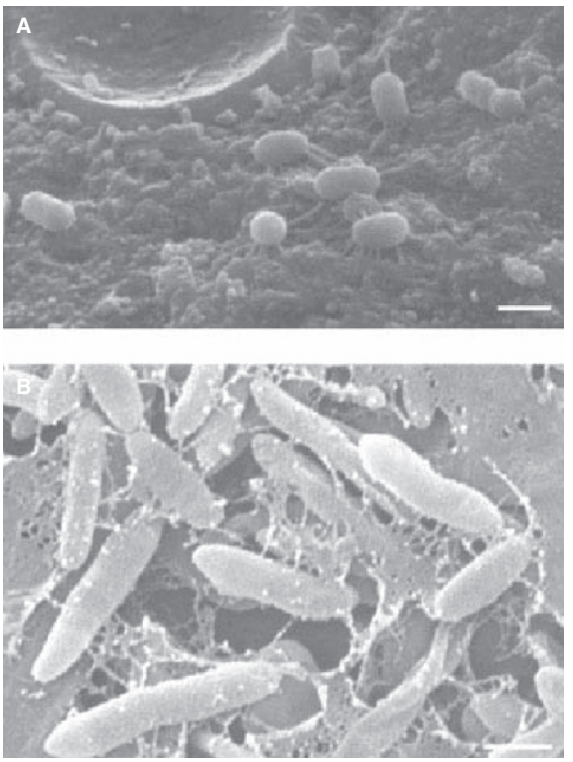

Fig. 18. Scanning electron micrographs of A) a bacterial attachment on a concrete surface (bar = 1 μm) and B) bacteria and their exopolymers (bar = 5 μm).

(Broomfield, 2000; Millard et al., 1995; Nakagawa et al., 1993; Saito et al., 1995). In this case, biological and physicochemical processes act in concert. Preventive measures involve the use of polymeric coating or reinforced polymeric sheets to prevent moisture reaching the steel reinforcing bars. Microbial activity is significantly reduced at low moisture levels (Gu et al., 1998c).

Hydrogen-producing bacteria may also contribute to the stress cracking of high strength steel. Ford and Mitchell (1990b) reported the presence of bacteria in the cracking areas of a high strength steel bar under loading conditions. They suggest that metabolites of these bacteria, particularly molecular hydrogen, would significantly weaken the strength of steel, owing to permeation of the alloy with microbially produced hydrogen (Ford et al., 1990d).

Biodeterioriation of Cultural Heritage Materials

Additional materials of interest and importance to society for protection from biodeterioration are objects with historical and cultural value. Examples of these materials are bronze (Wang et al., 1991; Wang et al., 1993; Wu et al., 1992; Zuo et al., 1994), jade, ceramic and glass (Fuchs et al., 1991), lacquer, silk, papers (Adamo et al., 1998; Arai, 2000; Fabbri et al., 1997; Florian, 1996; Zyska, 1996), paintings (Fabbri et al., 1997; Lauwers and Heinen, 1974; Rölleke et al., 1998), animal bones and shells, wood (Blanchette, 1995; King and Eggins, 1972), and mummified bodies. Figure 19 shows ancient script on paper, a textile and a bronze object, and a modern book from a library in the tropics. These materials suffer from potential biodeterioration due to the growth of microorganisms. Preservation of a variety of historic cultural materials presents a major challenge, especially where microbial activities are involved.

Wood is susceptible to a wide range of biodeteriogens including rodents, insects and microorganisms (Blanchette, 1995). Common treatment involves deep freezing and biocides. Maintenance of low humidity and low temperature are important factors in the inhibition of microbial deterioration.

Staining of historic paper manuscripts, known as "foxing," appears to have a microbial origin. Though several mechanisms of foxing found in museums and libraries (Fabbri et al., 1997; Florian, 1996) have been proposed, the cause is still not understood. In one proposed mechanism, fungal spores are believed to contribute to the development of color, and melanin synthesis may be involved (Williamson et al., 1998). Treatment using biocides is widely debated on the basis of their effectiveness, potential adverse effects on the materials, and the environmental impact of the chemicals (Hugo, 1995).

Leather and mummified materials are polymers that were dehydrated for long-term preservation. When they are being kept under low humidity and sealed conditions, long-term preservation is feasible. However, deterioration may be due to oxidation by atmospheric oxygen and adsorption of moisture. When the moisture level is increased, further growth of microorganisms occurs. One example is the deterioration of recovered mummies after their archaeological excavation.

Organic polymers are widely used in consolidation of monuments (Selwitz, 1992). Utilization of these materials by microorganisms has been documented (J-D. Gu and R. Mitchell, unpublished data) and guidelines are needed for systematic evaluation of candidate polymers and their suitability in specific applications. Polymer additives are also probable sources of carbon and energy for microbial growth (Gu et al., 1998c; Gu et al., 2000d; Tilstra and Johnsonbaugh, 1993). Physical conditions for biodeterio-

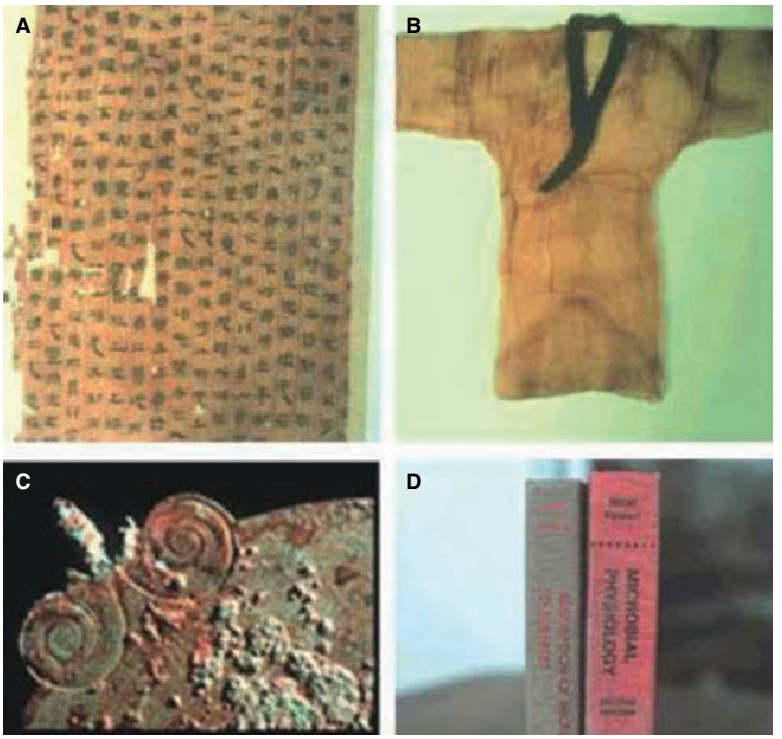

Fig. 19. Photographs showing A) an ancient script, B) textile, C) bronze, and D) a moldy book from a library in the tropics.

ration are favorable, particularly in tropical and subtropical developing countries.

The application of biocides has become a routine practice in the conservation of cultural heritage materials (Fig. 20). However, environmental issues have severely limited the number of available effective biocidal chemicals for use in conservation (Bingaman and Willingham, 1994).

Detection and Preventive Strategies

Microbial growth and propagation on material surfaces can be controlled by physical or chemical manipulation of the material or the environment. Prevention includes surface engineering to prevent microbial adhesion (Mansfeld, 1994; Matamala et al., 1994; Scamans et al., 1989; Williamson, 1994; Young, 1948). Methods of detection of growth on surfaces are well described in the literature (e.g., Madigan et al., 2000; Balow et al., 1992; Krieg and Holt, 1984; Sneath et al., 1986; Staley et al., 1989; Williams et al., 1989). Humidity control is commonly used to inhibit growth of microorganisms on surfaces in enclosed environments (Gu et al., 1998c).

Control measures require information about the biofilm population. Molecular methods permit early detection of growth on surfaces (Amann et al., 1995). Using the principle of

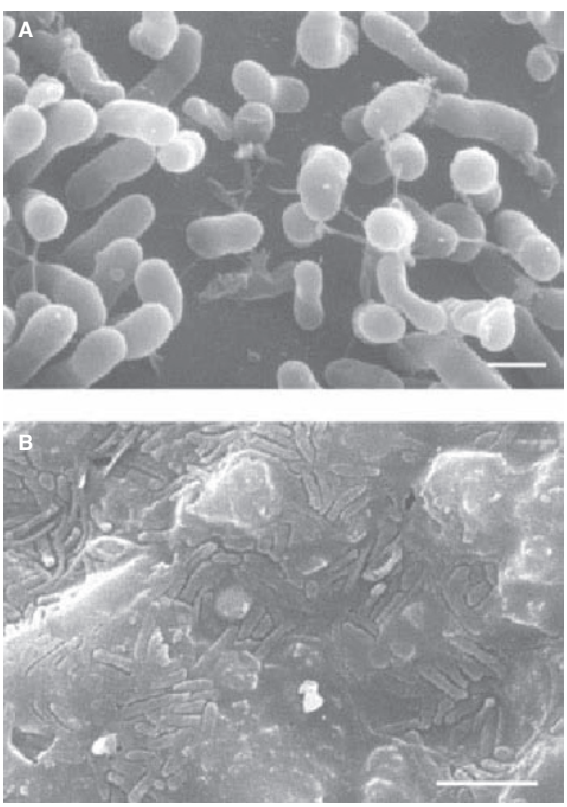

Fig. 20. Scanning electron micrographs showing A) bacterial biofilm developed on the surface of a protective coating (bar = 5 μm) and B) biofilm on the same coating, containing a biocide, but with the bacteria killed (bar = 5 μm).

modification of the microbial community, Sand et al. (1991) proposed oxygenation as a means of alleviating the propagation of SRBs. Alternatively, biocides can be effective in controlling biofilms and subsequent deterioration of materials (Bell and Chadwick, 1994; Bell et al., 1992; Wakefield, 1997). Other attempts at community modification include precipitation of microbially produced H_2S by ferrous chloride (Morton et al., 1991) and displacement of *Thiobacillus* by heterotrophic bacteria (Padival et al., 1995). All of these efforts have met with limited success.

Biocides are commonly applied in repairing, cleaning and maintenance of artworks. Chlorine and iodine compounds are used widely and routinely in controlling biofilms that cause corrosion of a wide range of industrial materials (Bloomfield and Megid, 1994; Cargill et al., 1992; Chen and Stewart, 1996b). These chemicals have been shown to be ineffective as means of killing biofilm bacteria (Huang et al., 1996; Keevil and Mackerness, 1990; Koenig et al., 1995; Liu et al., 1998; Lü et al., 1984; Lü et al., 1989; McFeters, 1991; McFeters et al., 1995; Moore and Postle, 1994; Myers, 1988; Pyle et al., 1992; Reinsel et al., 1996; Rossmoore and Rossmoore, 1993; Srinivasan et al., 1995; Stewart, 1996a; Stewart et al., 1996b; Suci et al., 1998; Wakefield, 1997; Xu et al., 1996; Yu and McFeters, 1994). In addition to their environmental unacceptability, biocides induce the development of biofilms that are highly resistant to the levels of biocide normally utilized to prevent biocorrosion. Organic biocides, used to prevent bacterial growth in industrial systems, may selectively enrich populations of microorganisms capable of biocide resistance (Fig. 21). No solution to these problems is currently available. Alternative biocides have been screened from natural products (Abdel-Hafez and El-Said, 1997; Bell and Chadwisk, 1994; Bell et al., 1992; Brözel and Cloete, 1993). Current research by materials scientists is focused on the prevention of adhesion of corrosive microorganisms to surfaces through surface treatment and modification (Costerton et al., 1988).

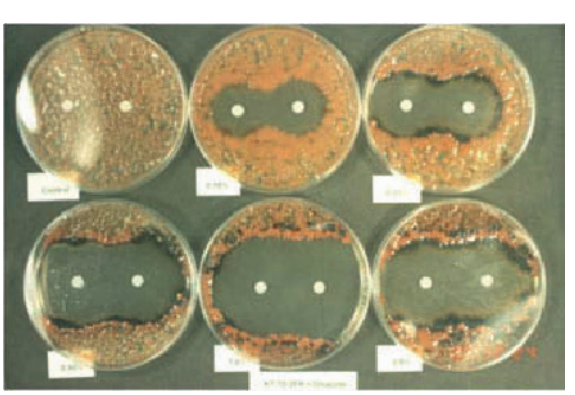

Fig. 21. At low concentrations of biocide, resistant bacteria are selected.

Since bacteria are capable of forming biofilms on most surfaces, future tests should be focused on biofilm quantification. In assaying biocide efficacy, tests should be conducted based on biofilm populations rather than on liquid culture efficacy (Gu et al., 1998c; Gu et al., 2000c). Planktonic cells are not representative of conditions on surfaces of materials.

Unfortunately routine analysis is not effective in the development of control strategies. Simulation testing of microbial growth on materials frequently includes only selected species of fungi (ASTM, 1993a; ASTM, 1993b; ASTM, 1993c; ASTM, 1993d; ASTM, 1993e). In addition, biodeterioration assessment is rarely quantitative. Modern methods are available to determine biodeterioration kinetics (Gross et al., 1993; Gross et al., 1995; Gu et al., 2000a). Recently, a sensitive method was introduced to evaluate polymer integrity using electrochemical impedance spectroscopy (Gu et al., 1998b).

Surface engineering also provides a means of preventing adhesion of microorganisms and subsequent material deterioration (Mansfeld, 1994; Matamala et al., 1994; Scamans et al., 1989; Williamson, 1994; Young, 1948; Fig. 22). Protection can be enhanced by early detection (Li et al., 1997). New detection technologies include optical fibers (Bacci, 1995). DNA probes and microarrays (Raychaudhuri et al., 2001; Salama et al., 2000) are being increasingly utilized to control biodeterioration of materials.

Conclusions

Microorganisms are involved in the corrosion of metal and the degradation and deterioration of polymers, concrete and stone under both aerobic and anaerobic conditions. They may influence the surface electrochemical properties, resulting in corrosion of metals under aerobic conditions, and induce hydrogen embrittlement by microbial production of hydrogen. Indirectly, degradation and deterioration of metals, stone and concrete are often associated with complexation mechanisms of microbial exopolysaccharides with substratum materials. We have only recently begun to understand the complex nature of interactions between the microflora and metals leading to corrosion. Modern methods in molecular biology, specifically gene technology, combined with recently developed techniques in materials science, such as laser confocal scanning microscopy and atomic force microscopy, should permit us to understand more fully the role of microorganisms in metal corrosion.

Fig. 22. Microbial adhesion and consequent deterioration only occurred at the top (dark) part of the building. The lower, protected portion was free of bacteria and deterioration.

Protection of materials can be achieved to some extent through surface engineering and control of the physical, chemical and biological environments. Application of biocides presents major challenges. A better understanding of the microbial ecology on material surfaces will be needed before a suitable control strategy can be identified. Utilization of molecular techniques to detect specific groups of microorganisms involved in the degradation process will permit a more complete view of the organization of the microbial community involved in the attack of materials. Passivation mechanisms of metals by bacteria should be further elucidated. Control methods should be developed based on combined information about both the material characteristics and the microbial community.

Acknowledgments. Preparation of this manuscript was partially supported by the "One-Hundred Talent Project" of the Chinese Academy of Sciences to J.-D.G. This work was also supported in part by grants No. BES-990 6337 from the U.S. Natural Parks Service, National Center for the Preservation Technology and Training to Harvard University. We would like to thank Jessie Lai and Yanzhen Fan for the digitalization of images and Yanzhen Fan for preparation of the references.

CHAPTER 3.10

Microbial Biofilms

DIRK DE BEER AND PAUL STOODLEY

Introduction

Biofilms are usually thought of as the slimy layer of microorganisms that covers solid surfaces. However, there are a number of features that distinguish biofilm populations from their planktonic (suspended or free floating) counterparts, namely: the association with a surface, high population densities (on the order of 10^{10} cells per ml of hydrated biofilm), an extracellular polymer (EPS) slime matrix, and a wide range of physical, metabolic and chemical heterogeneities. However, some biofilms may not have all features. Indeed a concise universal definition of biofilms has yet to emerge; in part this is because of the wide diversity of biofilm populations. Although much of contemporary microbiology is based on the study of planktonic "cells," it is now thought that biofilms are the primary habitat for many microorganisms. Microbial mats associated with sediment and suspended microbial flocs or aggregates, although different in appearance from conventional biofilms, have many important features in common and thus are included in the definition of "biofilm." Often biofilm cells are embedded within a highly hydrated EPS matrix, and in the absence of corrosion products or scale, biofilms are estimated to be primarily water. The physical properties of the biofilm are largely determined by the EPS, while the physiological properties are determined by the bacterial cells.

Characklis (1990a) identified up to eight processes in the development of biofilms. These can be condensed to three main processes: the attachment of cells to a surface (colonization), growth of the attached cells into a mature biofilm, and the detachment of single cells (erosion) or large pieces (sloughing).

Since free convection is hindered within biofilms, the chemical environment to which the cells are exposed differs from the surrounding water phase. Also, mass transfer to the cells often limits conversion rates. All natural biofilms, mats, aggregates, and flocs can consist of complex microbial communities, and their function is characterized by interactions between different populations within these communities. Many experimental methods to study aggregated biomass are similar, i.e., microscopic and staining techniques. We will refer therefore in this review to all types of aggregated microorganisms. Table 1 gives some examples of biofilm types.

Biofilms, flocs, and microbial mats are responsible for most microbial conversions in natural environments. Natural biofilms can develop on solid surfaces under all conditions facilitating microbial growth thus biofilms are ubiquitous in nature, covering rocks and plants in seawater and freshwater, sediment grains, and sediment surfaces. Microbial mats are formed on most sediments, especially under extreme conditions (temperature, salinity) that inhibit the activity of grazers (Karsten and Kühl, 1996). Flocs are highly fragile structures suspended in fresh and seawater (called river- and marine snow) and typically occur during bloom periods after an increased input of nutrients. Consequently, biofilms exist almost everywhere, and microbial aggregates, are responsible for the majority of the microbial conversions in many aquatic ecosystems. Biofilms have been associated with a wide range of problems both in industry and in medicine (Table 2) and have been utilized for various processes (Table 3).

Microbial cells, living in biofilms are much more difficult to eradicate or control than suspended cells. Yet the susceptibility of biofilm cells to antibiotics and industrial antimicrobial agents is rarely assessed. In part this is due to convention and in part because standard testing protocols against suspended cultures are much easier to develop. Cell density and growth phase can be easily controlled in both batch and chemostat cultures, whereas biofilms are highly variable.

Currently, the most important practical use of biofilms is for biological wastewater treatment, while many emerging technologies are utilizing biofilms for biodegradation and bioremediation in bioreactors. Municipal wastewater is treated in activated sludge plants that are based on the activity of flocs. Their relevance in natural element cycles as well as their economical and med-

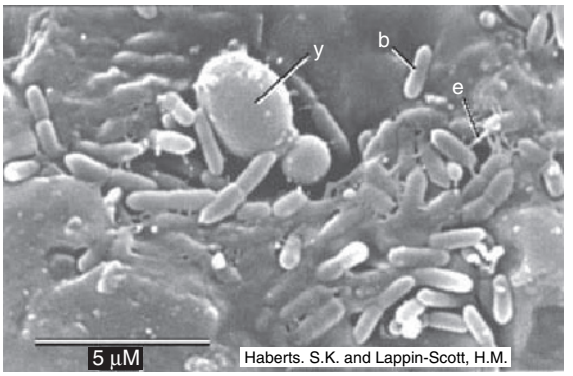

Fig. 1a. Scanning electron photomicrograph showing biofilm formation after 24-h growth on stainless steel AISI 321. The biofilm was established under laminar pipe flow (Re = 2.72) using a modified Robbins device (MRD). The inocula were all environmental isolates and consisted of four Gram-negative rod-shaped bacteria, *Stenotrophomonas maltophilia*, *Pseudomonas alcaligenes*, *Alcaligenes denitrificans*, and *Flavobacterium indologenes*; one nonfermentative yeast, *Rhodotorula glutinis*; and two filamentous fungi, *Fusarium solani* and *Fusarium oxysporum* (Elvers, 1998). The image shows a budding yeast cell "y" and bacterial rods "b" attached to the surface. The bacteria are embedded in an EPS matrix. During preparation for SEM the dehydrated EPS has formed characteristic strands "e." Scale bar = 5 µm. Image supplied by Sara K. Roberts, Biological Sciences, Exeter University.

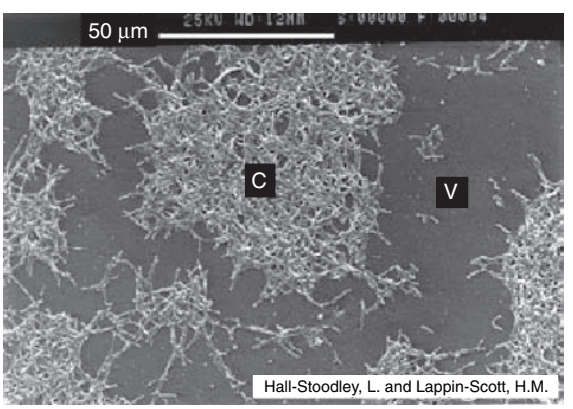

Fig. 1b. Scanning electron photomicrograph showing biofilm formation of *Mycobacterium fortuitum* after 24-h growth on silicone rubber (Hall-Stoodley, 1998). The biofilm was grown under laminar flow in a MRD. The biofilm was composed of cell clusters "c" surrounded by voids "v." Scale bar = 50 µm. Image supplied by Luanne Hall-Stoodley, Biological Sciences, Exeter University.

ical impact has been recognized, and the study of immobilized cell systems has gained considerable momentum in the last decade. The knowledge has been advanced because of new techniques to determine the functioning, structure and microbial populations in biofilms.

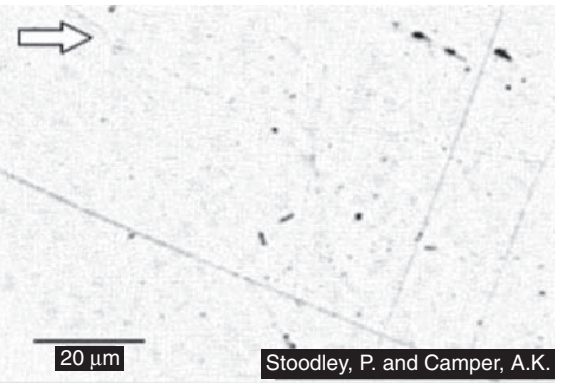

Fig. 2a. Time-lapse movie showing the initial events of biofilm formation. *Pseudomonas aeruginosa* cells are attaching to a 316L stainless steel coupon over 6.5 h. The *Ps. aeruginosa* cells were initially grown in a chemostat with a residence time of 5 h. The stainless steel coupon was mounted in a flat plate flow cell and the inoculum was delivered with an average flow velocity of 2.8 cm $\cdot s^{-1}$ (Re = 6). Note how some of the cells divide, detach and move around on the surface. Arrow indicates flow direction. Scale bar = 20 µm. Images were enhanced for clarity using NIH-Image 1.59 (available at http://zippy.nimh.nih.gov). For the Fig. 2a, see the online version of *The Prokaryotes*.

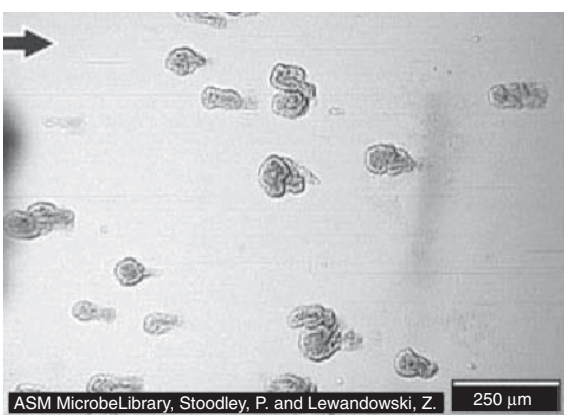

Fig. 2b. Time-lapse movie showing the accumulation of a bacterial biofilm on a glass surface over 14 days. The biofilm was composed of *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, and *Klebsiella pneumoniae* and was grown in a glass flow cell (average flow velocity = 1.8 m $\cdot s^{-1}$) to simulate conditions in an industrial pipeline. Note the complex structure of biofilm patches (dark) and water channels between them. After 12 days much of the biofilm detached from the surface in a "sloughing event." There was a corresponding decrease in pressure drop across the flow cell, which had been building up as the biofilm accumulated (Lewandowski and Stoodley, 1995). The arrow shows the direction of fluid flow. Scale bar = 250 µm. This sequence of images has been accepted for use in the ASM Biofilms Collection (http://www.asmusa.org/edusrc). For the Fig. 2b, see the online version of *The Prokaryotes*.

Table 1. Examples of different types of biofilm.

Environment	Biofilm type	Thickness (m)	Community	References
Natural	Photosynthetic microbial mats, hot springs and hypersaline lakes	10^{-3}–1	Mixed algal and bacterial community	Stal, 1994
	Stromatolites	1	Bacterial	Stal, 1994
	Benthic/river sediments	10^{-6}–10^{-3}	Mixed bacterial, algal and protozoan communities	Baty, 1996 Costerton, 1994
Medical	Dental plaque	10^{-6}–10^{-4}	Mixed bacterial community	Kinnement, 1996
	Infectious	10^{-6}–10^{-3}	Often bacterial or fungal mono-cultures	Morck, 1994 Buret, 1991
Industrial	Heat exchangers	10^{-6}–10^{-3}	Mixed bacterial and fungal communities	Characklis, 1990
	Drinking water pipes	10^{-6}–10^{-2}	Mixed bacterial and fungal communities	Camper, 1994 Van Der Kooij, 1994
	Wastewater treatment	10^{-4}–10^{-3}	Mixed bacterial and fungal communities, biofilms, aggregates and flocs	Lemmers, Griebe, 1995
	Filtration units	10^{-5}–10^{-4}	Mixed bacterial and fungal biofilms	Flemming, 1996
	Ship hulls	10^{-4}–10^{-2}	Mixed bacterial and algal and marine macroorganisms	Cooksey, 1995

Table 2. Problems associated with biofilms.

Problems	Consequences
Fouling of heat exchangers	Loss of heat exchange efficiency and reduction of flow capacity
Fouling of ships	Energy losses
Oil reservoirs	H_2S souring by sulfate–reducing bacteria
Industrial and drinking water pipelines	Energy losses, pitting and general corrosion, product contamination, pathogen reservoirs
Dental plaque	Dental caries
Medical infections	Colonization of indwelling devices (catheters, artificial joints, contact lenses) —endocarditis

Table 3. Processes which utilize biofilms.

Processes	Uses
Wastewater treatment	Bioremoval of pollutants
Biobarriers[a]	Immobilization of ground water contaminants; microbially enhanced oilfield recovery (MEOR)
Metals leaching	Enhanced recovery of metals

[a]See MacLeod, 1988.

Biofilms and microbial mats are thus important microbial communities in most aquatic ecosystems today. Interestingly, the first known fossils of single microbes and microbial communities share almost identical structural characteristics to those found in recent biofilms and microbial mats (Schopf and Klein, 1992).

Because of their ubiquity in natural and industrial environments, the study of biofilms lends itself to a multidisciplinary approach involving microbiology and engineering. Originally, an engineering approach was used to study biofilm performance on the macro-scale (i.e., for optimization of wastewater treatment plants). Subsequently, engineering concepts were applied to further our understanding of biofilm processes on the micro-scale. An important task for microbiologists studying biofilms is to determine the types of organisms present and to determine their in situ activities. This chapter will focus on recent findings on biofilm structure, mass-transfer phenomena, microbial activities and community structure. Brief descriptions of biofilm cultivation methods and new techniques to determine biofilm structure in situ, community structure and population distributions and in situ microbial activity distributions will be given.

Biofilm Structure

Biofilm structure is the spatial arrangement of bacteria, cell clusters, EPS and particulates. Since the structure can influence transport resistance, it is a significant determinant in the activity of the biofilm. Various conceptual and mathematical models have been proposed to describe the structure and function of biofilms (Characklis, 1990a; Rittmann and Manem, 1992; Wanner and Gujer, 1986). Mathematical models describing transport, conversion, cell growth and biofilm development are based on conceptual models. Biofilms were initially considered as planar structures, impermeable and with homogeneous cell distribution. Mass transfer through the mass boundary layer and within the biofilm was assumed to be diffusional and perpendicular to the surface to which it was attached (the substratum).

Biofilms and mats are matrices of cells and extracellular polymers (EPS). The EPS is produced by the cells and consists of polysaccharides, polyuronic acids, proteins, nucleic acids and lipids (Schmidt and Ahring, 1994; Decho, 1990; Decho and Lopez, 1993). EPS holds the cells together and to the substratum. Owing to the dimensions of microbial mats and biofilms, their structural analysis is strongly dependent on microscopic methods that are briefly discussed and listed in Table 4.

Heterogeneity

Recent microscopic observations indicated that biofilms are not flat and the distribution of microorganisms is not uniform. Instead, multispecies biofilms were observed with complex structures containing "voids," channels, cavities, pores, and filaments and with cells arranged in clusters or layers. Such complex structures were found in a wide variety of biofilms such as methanogenic films from fixed-bed reactors (Robinson et al., 1984), aerobic films from wastewater plants (Eighmy et al., 1983; Mack et al., 1975), nitrifying biofilms (Kugaprasatham et al., 1992), and pure culture biofilms of *Vibrio paraheamolyticus* (Lawrence et al., 1991) and *Pseudomonas aeruginosa* (Stewart et al., 1993).

Depending on growth conditions and age, the thickness of biofilms can range from a few micrometers (a monolayer) up to a centimeter. Owing to the microscopic dimensions of microbial mats and biofilms, their structural analysis strongly depends on the microscopic methods used. Most microscopic techniques involve preparation of the sample, such as dehydration and

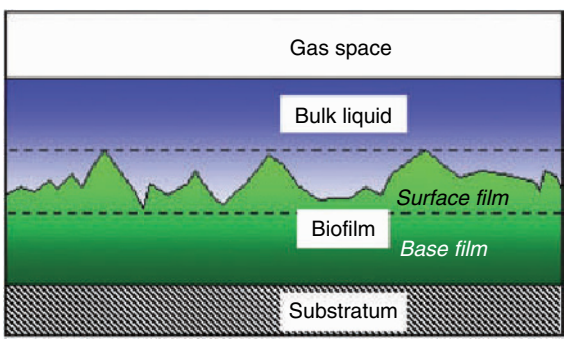

Fig. 3. Conceptual model for biofilm structure proposed at the 1988 Dahlem conference (Wilderer, 1989). The model divides the biofilm system into specific compartments: the substratum, the biofilm, the bulk liquid and a possible head space. The biofilm compartment was further subdivided into a base film and a surface film. Although the model recognized a certain degree of biofilm roughness, it was essentially a planar layered model.

Table 4. List of microscopic techniques for studying biofilms and mats.

Microscopy technique	Spatial resolution	Application	Sample treatment	References
LM	1 µm	EPS and cells	Dehydration, freezing, sectioning, staining	Chayen, 1973
FM	1 µm	EPS and cells	Dehydration, freezing, sectioning, staining	Stewart, 1995; Griebe, 1995; De Beer, 1996
SEM	1 nm	Cell and EPS surfaces	Dehydration, sputter coating	Beeftink, 1986; Paterson, 1995
ESEM	10 nm	Cell and EPS surfaces	None	Little, 1991
TEM	1 nm	Cells and EPS	Dehydration, sectioning, staining	Beeftink, 1986; Bakke, 1984; Sanford, 1995
CSLM	1 µm	EPS, cells, voids	Staining	Lawrence, 1991; De Beer, 1994
AFM	0.1 µm	Cell and EPS surfaces	None	Bremer, 1992; Gunning, 1996

Abbreviations: LM, light microscopy; EPS, extracellular polymer slime; FM, fluorescence microscopy; SEM, scanning electron microscopy; ESEM, environmental scanning electron microscopy; TEM, transmission electron microscopy; CSLM, confocal scanning laser microscopy; AFM, atomic force microscopy.

embedding,which causes the soft biofilm structure to collapse and often to be observed as flattened (Stewart et al., 1995). Because this structure most conveniently agreed with the basic assumption for one-dimensional (1-D) modeling, it was accepted as the general structure of biofilms. However, a study by Siebel and Characklis (1990) using interference contrast (Nomarsky) microscopy challenged this assumption. They reported that binary population biofilms of *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* could form uneven biofilms consisting of patchy clusters of cells surrounded by a smooth monolayer. After the introduction of confocal scanning laser microscopy (CSLM), however, the perception changed drastically. The findings with new microscopic techniques indicate that the assumptions for 1-D geometry need to be carefully analyzed. CSLM images of undisturbed biofilms show that biofilms can consist of biomass clusters separated by interstitial voids (De Beer et al., 1994). [Voids were made visible with a negative staining by fluorescein that is strongly quenched by biomass. Cells (stained with a DNA stain) and EPS (stained with calcofluor and Alcian blue) were observed in the clusters, while no cells or EPS could be detected in the voids.] Fluorescent beads (0.3 μm) added to the medium immediately penetrated the voids, but not the cell clusters. It was concluded that voids were water channels in open connection with the bulk water phase. Fluid flow in the biofilm was later directly demonstrated, and quantified, by using the beads as particle tracers to visualize flow through the water channels (Stoodley et al., 1994). The flow velocity of individual beads at various depths in the biofilm channels were calculated by measuring the bead track length, using confocal microscopy. The resulting flow profiles were consequently used to determine the fluid shear stress acting on the channel wall and the surface of the biofilm cell clusters (deBeer et al., 1994; Stoodley et al., 1994). These observations were made on biofilms grown in the lab, either as undefined culture or as mixed pure culture. Similar observations were reported from both pure culture biofilms and biofilms with undefined microbial communities from various sources (Massol-Deya et al., 1995; Gjaltema et al., 1994; Zhang, 1994; Neu and Lawrence, 1997; Okabe et al., 1996; Okabe et al., 1997). The presence of voids has considerable consequences for mass transfer inside the biofilms (advection) and exchange of substrates and products with the water phase (effective exchange surface), as will be discussed in the relevant section. These new findings have led to a concept that incorporates two key features: structural heterogeneity and the water flow within the biofilm.

Extracellular Polymeric Substances (EPS)

The proportion of EPS can vary between 50–80% of the organic matter and is the main structural component of biofilms. The physical properties of the biofilm are largely determined by the EPS, while the physiological properties are determined by the bacterial cells. A common perception was that EPS consists mainly of polysaccharides, and many detection techniques focus on this group of compounds (Christensen and Characklis, 1990; Neu and Lawrence, 1997; Beeftink and Staugaard, 1986; Williams and Wimpenny, 1978; De Beer, 1996). Also, research relating EPS to biofilm functioning, cell-cell and cell-surface interactions was concentrated on the polysaccharide fraction of EPS. However, recent analyses showed that biofilms contain EPS consisting of a mixture of protein, polysaccharides, lipids and nucleic acids (Nielsen et al., 1997; Schmidt and Ahring, 1994; Jahn, 1995; Frolund et al., 1996). Protein appeared the most abundant EPS component (50% or more) in activated sludge (Frolund et al., 1996); biofilms (Jahn and Nielsen, 1995), and anaerobic aggregates (Ahring et al., 1993), while polysaccharides were much less abundant (5–20%). Detailed knowledge is available on the polysaccharide content of both laboratory grown and natural biofilm EPS (Sutherland, 1994; Sutherland, 1996); however, data on the actual composition of nonpurified biofilm EPS as it occurs in situ are lacking. Thus we face the situation that the actual composition of EPS, including the protein fraction, is largely unknown, as are its chemical and physical properties. Since EPS is the second important fraction of biofilms, beside cells, research on the chemistry and properties of EPS has a high priority.

More research on the composition and function of EPS is needed, since EPS has been linked with many processes and properties integral to biofilm behavior, i.e., attachment, detachment, mechanical strength, antibiotic resistance, and exo-enzymatic degradation activity. The mechanical stability of a biofilm is important for stable process maintenance (sloughing of biofilms, floc stability). To remove unwanted biofilms, surfactants are used to weaken the strength of the matrix. Furthermore, there is evidence that biofilms maintain their structural heterogeneity by releasing EPS-degrading enzymes (Davies et al., 1998). This interesting process is thought to involve cell-cell communication, i.e., quorum-sensing, through the generation of homoserine lactones (Greenberg, 1997).

Binding of water is important for dehydrating activated sludge (Nielsen et al., 1996). Pollutants may bind considerably to the EPS of biofilms; 60% of biofilm-bound BTX, but less than 20%

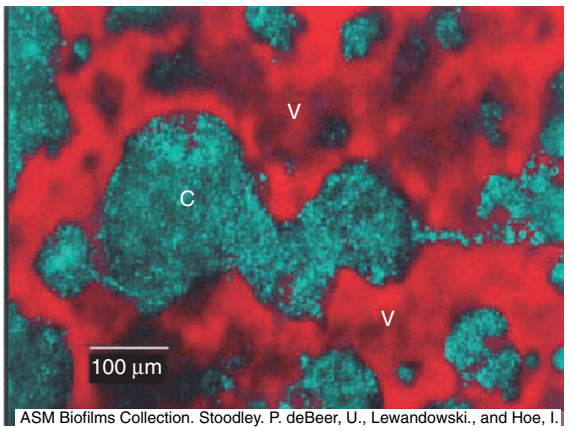

Fig. 4a. Biofilm composed of *P. aeruginosa*, *P. fluorescens*, and *K. pneumoniae* grown in a glass flow cell for 5 days (de Beer et al., 1994a). The image was taken using CSLM which allows high resolution 3-D imaging of fully hydrated samples. Differential staining with propidium iodide (a nucleic acid stain) and fluorescein (red) showed that the biofilm consisted of cell clusters "c" separated by interstitial voids "v" or water channels. Scale bar = 100 µm. Image available from the ASM Biofilms Collection (http://www.asmusa.org/edusrc/edu34.htm).

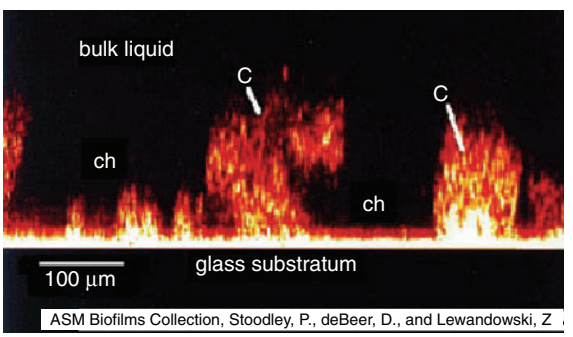

Fig. 4b. Side view of the same biofilm in Fig. 4a. Cells appear red and orange and are grouped in distinct cell clusters "c" separated by water channels "ch." Some of the cell clusters formed "mushroom" shapes, which greatly increase the available surface area for nutrient and waste product exchange with the bulk liquid. The horizontal white line is the glass surface. Scale bar = 100 µm. Image available from the ASM Biofilms Collection (http://www.asmusa.org/edusrc/edu34.htm).

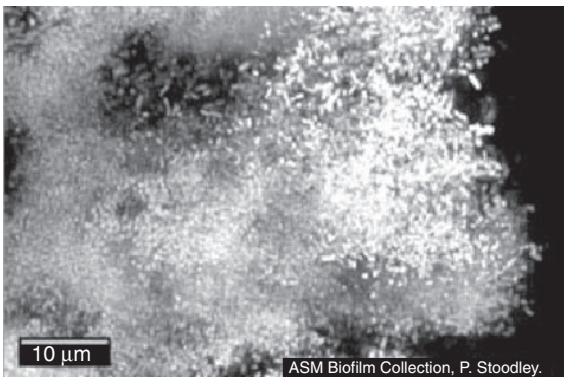

Fig. 4c. Movie sequence showing 3-D structure of a mixed-species biofilm taken by CSLM. The biofilm was composed of *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, and *Klebsiella pneumoniae* and was grown in a flow cell with an average liquid flow velocity of 6.6 cm · s^{-1}. The biofilm was heterogeneous and was made up of microbial cell clusters (individual cells are stained with propidium iodide and appear as bright dots) held in an EPS matrix (not stained in this image). The biofilm was approximately 150-µm thick and protrudes out towards the viewer. The image is composed of 27 overlaid optical sections taken at 6-µm depth intervals. The motion is an artifact used to give the 3-D effect. Scale bar = 10 µm. For the Fig. 4c, see the online version of *The Prokaryotes*.

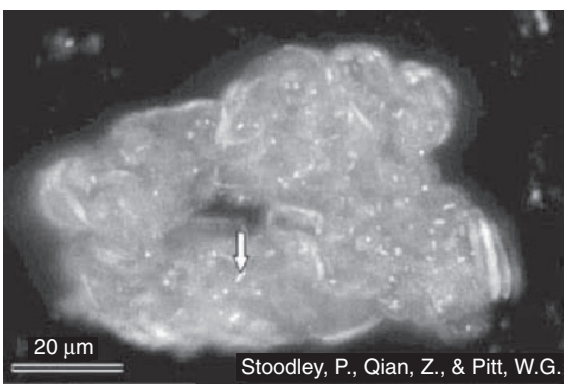

Fig. 4d. Movie sequence showing 3-D structure of a pure culture *Pseudomonas aeruginosa* biofilm taken by CSLM (Qian et al., 1996). The biofilm was heterogeneous and consisted of cell clusters and surrounding water channels. This image shows a donut-shaped cell cluster that protrudes out towards the viewer. The bright dots are stained bacterial cells (representative cell indicated by arrow) and the lighter, hazy material is probably EPS slime. The biofilm was grown in a polycarbonate flow cell on a glass slide. Scale bar = 20 µm. For the Fig. 4d, see the online version of *The Prokaryotes*.

of the biofilm-bound heavy metals (Späth et al., 1998), was located in the EPS.

EPS can mask the original surface properties of the cells and render hydrophobic surfaces hydrophilic. The phenomenon of flotation of anaerobic aggregates occurs by attachment of gas bubbles to the hydrophobic aggregate surface. Aggregates with low amounts of EPS showed a strong tendency to float, leading to severe biomass losses from the reactors. The presence of carbohydrates in the feed increases the amount of EPS, especially on the aggregate surface, inhibiting attachment of gas bubbles and preventing flotation (De Beer, 1996; Neu and Lawrence, 1997).

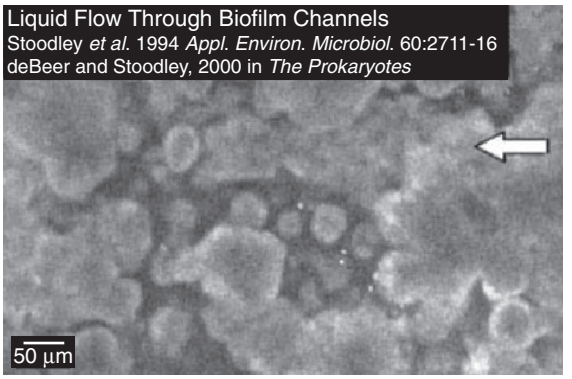

Fig. 5. Time lapse CSLM movie sequence showing fluorescent latex beads moving through biofilm water channels (Stoodley et al., 1994). The bacterial biofilm, composed of *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, and *Klebsiella pneumoniae*, was grown in a flow cell on a glass cove slip. The sequence of images was taken over 44 s. The beads were moving with a velocity of approximately 15 µm · s^{-1}, the average liquid flow velocity of the bulk liquid was 6.6 cm · s^{-1}. The arrow indicates flow direction of the bulk liquid. Note that in some cases the flow around the cell clusters is counter that of the channel current. The biofilm clusters were autofluorescent and appear lighter than the surrounding water channels. The optical section was taken at a depth of 70 µm in the 175-µm thick biofilm. Scale bar = 50 µm. For the Fig. 5, see the online version of *The Prokaryotes*.

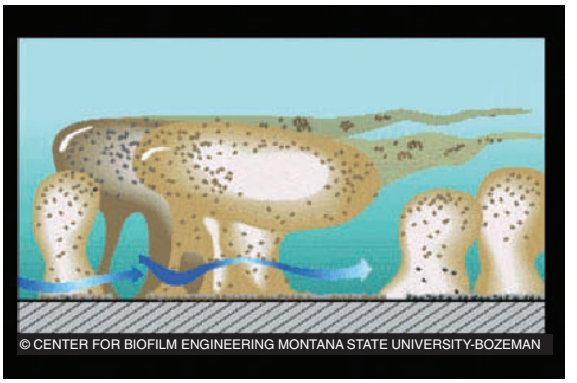

Fig. 6. Recent "Center for Biofilm Engineering" conceptual biofilm model incorporating structural complexity and liquid flow through biofilm channels. The model also incorporates biofilm streamers, which form as a function of fluid shear. The schematic was composed by Peg Dirckx of the Center for Biofilm Engineering (with permission from the Center for Biofilm Engineering, Bozeman, Montana, USA).

The diffusion coefficient of solutes in biofilms is influenced by the microstructure of EPS (Neu and Lawrence, 1997; De Beer et al., 1997). Biofilms have been considered to be highly porous polymer gels (Christensen and Characklis, 1990) and diffusion studies demonstrate their gel-like characteristics (De Beer et al., 1997). Also, recent in situ rheological testing of *P. aeruginosa* biofilms, grown in the absence of divalent cations, showed that the biofilm behaved like a non-cross-linked polymer gel (Stoodley et al., 1999c). In this case, the EPS matrix can be considered to be a two-phase system with a solid network of polymers and free interstitial water as depicted by Stewart (Stewart, 1998). Only then does the structure of the network effect diffusivity (Westrin, 1991), particularly when the pore size of the network is of the same order of magnitude as the molecular diameter of the solute. Based on this assumption, it is possible to infer some properties of the microstructure of EPS from the diffusional behavior of large molecules. It was found that the diffusion of small molecules is not strongly inhibited by the biofilm matrix, whereas diffusion of large molecules is impeded (Bryers and Drummond, 1996). Similar effects of the molecular size were found using microinjection of fluorescent dyes (fluorescein, MW 332, Ø > 1 nm, diffusivity not affected, and phycoerithrin, MW 240,000, Ø = 11 nm, 40% reduction of diffusivity; De Beer et al., 1997). The pore size of the biofilm matrix (ca. 80 nm) was calculated from these data.

However, it has been reported that the forces keeping the polymers together are not strong covalent bonds, but weak hydrophobic and electrostatic interactions and hydrogen bonds (Flemming, 1998). These forces are weakened by surface active agents, complexing agents, pH and ionic strength. Flemming concluded that a significant portion of the EPS may not be in bound form; if so, the polymers would increase the viscosity and reduce the diffusion coefficient, which could explain in part contradictory findings on D_{eff}. Boyd and Chakrabarty (1994) hypothesized that altering the length of polymer chains through the activity of alginate lyase may control the viscosity of *P. aeruginosa* biofilms. It is clear that further research is needed on both the physical and chemical properties of EPS, which appears to play a critical role in the structure and function of biofilms.

Morphogenetic Factors

In conclusion, the architectural features of biofilms can be viewed in terms of a hierarchical arrangement, the basic components of the biofilm being the cells and the EPS. These can combine to form secondary structures such as discrete cell clusters (which may take on various forms and dimensions) and a base film. Finally, the arrangement of base film, cell clusters, and the void areas between the clusters gives the overall biofilm architecture. The relative impor-

tance of each of these features in determining the biofilm heterogeneity can be highly variable.

HYDRODYNAMICS Hydrodynamic conditions control two interdependent parameters (mass transfer and shear stress) and will, therefore, significantly influence many of the processes involved in biofilm development. Two types of flows are relevant to most natural and industrial processes: laminar flow and turbulent flow. Generally, when the flow rate of a liquid is low, flow will be laminar, and when the rate is high, it will be turbulent. Transition between these two types of flow will be dependent on channel geometry and fluid properties and, in many cases, can be predicted by the Reynolds number (*Re*), a dimensionless parameter commonly used by engineers (Vogel, 1994). In closed pipes, flow is generally turbulent at a *Re* above 1200. The *Re* is also useful as a comparative indicator of flow conditions in a diverse range of systems. Briefly, in laminar flow shear stresses are low and mixing is poor, whereas in turbulent flow shear stresses are high and mixing is good. Under these conditions, shear and mixing have opposing influences on biofilm accumulation and on the resulting biofilm structure (van Loosdrecht et al., 1995). Increased shear tends to increase the detachment rate by the physical removal of individual cells (erosion) or larger pieces of biofilm (sloughing), while increased mixing tends to increase the growth rate by reducing transport limitations and increasing the nutrient supply. The rate of transport of dissolved and particulate species (nutrients, biocides, etc.) into the biofilm and the removal of waste products from the biofilm also will have a profound influence on the chemistry (pH and eH, etc.) of the local microenvironment. It has been hypothesized that there may be an optimal flow for biofilm formation below which accumulation would be limited by mass transfer and above which accumulation would be limited by detachment (Lewandowski, 1991).

To date most of the detailed investigation on biofilm structure has been conducted on biofilms grown in the laboratory under laminar flows. These biofilms tend to be cell clusters which are roughly circular or amorphous and in which there is no obvious axial alignment. However, in turbulent flows, the influence of drag becomes apparent, and biofilms are form-filamentous "streamers" which can oscillate rapidly in the flow (Bryers and Characklis, 1981; McCoy et al., 1981; Siegrist and Gujer, 1985; Stoodley et al., 1998; Stoodley et al., 1999a; Stoodley et al., 1999b). The increased energy losses in pipelines have been attributed to the possible formation of streamers (Picologlou et al., 1980). More recently, it has been shown that mixed biofilms growing in turbulent flow can form ripple structures that steadily migrate downstream (Stoodley et al., 1999d). The ripple morphology and migration velocity varied with bulk liquid flow velocity, with a response time on the order of minutes. The ripples had a maximum migration velocity of approximately 1 $mm \cdot h^{-1}$. Dalton et al. (1996) have observed cyclical colonization by marine *Vibrio* and *Pseudomonas* species growing in laminar flow, in which microcolonies repeatedly formed and dispersed over periods between 1 and 2 days. However, in this case, it appears that the structural changes were caused by gliding motility of the individual cells, possibly in response to nutrient conditions in the biofilm. It is generally assumed that microcolonies (also termed cell clusters) are formed mainly through cell division during the early stages of biofilm formation. The observation by Dalton et al. (1996) reveals that clusters also can form by the grouping together of attached cells. Both of these observations (Dalton et al., 1996; Stoodley et al., 1999d) demonstrate that the structural arrangement of biofilms is not only spatially but also temporally complex.

Influence of hydrodynamics on the structure of a *Pseudomonas aeruginosa* PAO1 biofilms grown in parallel glass flow cells under laminar and turbulent pipe flow (Stoodley et al., 1999b). The biofilms were grown on a minimal salts medium with glucose ($400 mg \cdot liter^{-1}$) as the carbon source. Images were taken 7 days after inoculation. Black arrow indicates direction of bulk liquid flow. Scale bar = 50 μm.

It may be possible to predict biofilm morphotypes from theoretical consideration of the relative influences of mass transfer and shear (Stoodley et al., 1999a). At high shear flows, where the influence of drag is high but mass transfer limitations are low, drag-reducing planar structures may be expected. In low shear flows, where the mass transfer limitations are high but drag is low, highly porous structures with high surface exchange areas might be expected. Intermediate forms may exist between these extreme conditions.

BIOFILM VISCOELASTICITY In addition to the long-term influence of hydrodynamics on the structure of biofilms grown under steady shear, biofilm structure also can be influenced by short-term changes in fluid shear. Structural changes to mixed and pure culture biofilms caused by variations in fluid shear demonstrate that biofilms can be visco-elastic and have a very low elastic modulus (ca. 30 Pa, i.e., biofilms are highly compliant; Stoodley et al., 1999c). The biofilms exhibited liquid flow when the fluid

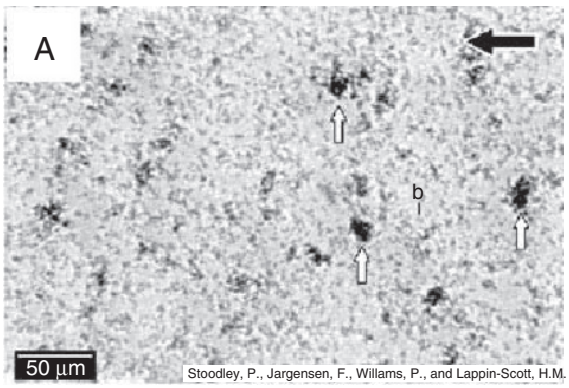

Fig. 7a. The biofilm grown under laminar flow (flow velocity = 0.033 m · s^{-1}, *Re* = 120) was composed of small cell clusters (white arrows) with single cells "b" in the void spaces.

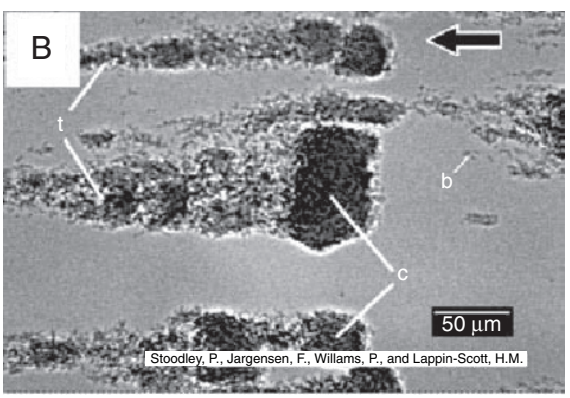

Fig. 7b. The biofilm grown under turbulent flow (flow velocity = 1.0 m · s^{-1}, *Re* = 3600) was composed of larger clusters which had become elongated in the downstream direction to form tapered streamers. Each streamer consisted of an upstream "head" cell cluster "c," which was attached to the glass surface, and a downstream tail "t." Some of the tails were free to oscillate in the flow, while others were more firmly attached to the substratum. The void spaces between the streamers were almost devoid of single cells "b."

shear stress exceeded the yield point. The yield point occurred between 1.2 and 2.0 times the shear at which the biofilm was grown. It is possible that liquid-like behavior may explain the formation of flowing ripples in similar biofilms (see Fig. 8).

Also, the thickness of cell clusters was reduced by up to 30% when the flow velocity was increased from 0 to 1.5 m · s^{-1}. It is thought that the flexibility of certain seaweeds, anemones and other benthic macroorganisms may allow the organisms to withstand the large variations in drag to which they are subjected by wave action (Koehl, 1984). In these types of organisms, drag reduction can be achieved when the organisms "collapse" into a more streamlined shape. It is possible that the flexibility of some biofilms is an adaptive characteristic, which allows these biofilms to remain attached when exposed to varying shears (as would be expected in turbulent flow and many natural flowing water systems).

Biofilm rheology also may help explain the large energy losses that biofilms can cause in water pipelines. High-pressure drops (δP) have been linked to the observed formation of filamentous streamers, and it has been calculated that the measured δP was significantly greater than that expected from an equivalent rigid structure (Picologlou et al., 1980). It is known that rigid structures that are anchored in flowing fluids can dissipate the kinetic energy of the fluid through skin friction and pressure drag (Vogel, 1994). Skin friction is dependent on surface area and is more significant in laminar flows. Pressure drag is shape-dependent and is more significant in turbulent flows. Biofilms that are behaving visco-elastically also can dissipate kinetic energy through both elastic and viscous action (Stoodley et al., 1999c). Rapid elastic deformations, which may occur when biofilm streamers oscillate, would result in the generation of heat in the biofilm matrix as bonds repeatedly stretch and contract. It is expected that, because of the thin nature of the biofilm, this heat would be quickly transferred to the bulk liquid. Viscous behavior also can generate heat through friction as individual polymer strands move past each other when biofilm flows. As yet, it is not clear what the relative contribution of each of these mechanisms is to the formation of pressure drops in pipe flow.

In addition, biofilm structure may be influenced electrochemically. It has been found that electrical fields can cause biofilms to rapidly contract and expand (Stoodley et al., 1997). It was found that the thickness of a mixed species biofilm cell cluster was reduced to 74% of the original thickness when the platinum wire which it had been grown on was cathodic. This change was similar to that caused physically by hydrodynamic shear (see above). This effect is common in gels and may lead to increased exchange between water phase and biofilm and partly explain the bioelectric effect (Wellman, 1996).

Growth and Detachment Detailed studies on growth and detachment have been performed by van Loosdrecht and his group. Tijhuis et al. (1996) suggested that the degree of heterogeneity is determined by the balance between the growth rate and abrasion. Indeed, slow growing organisms (e.g., nitrifiers and methanogens)

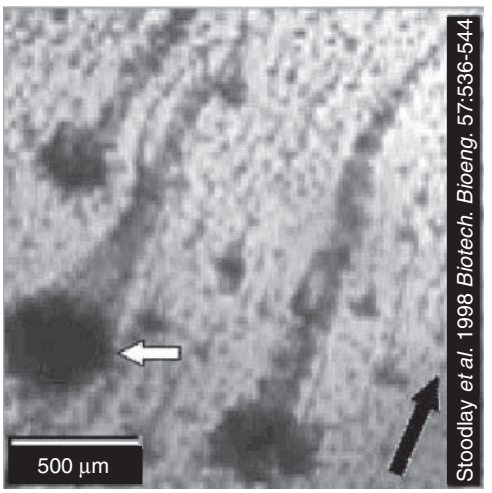

Fig. 7c. Time lapse movie showing biofilm streamers oscillating in turbulent flow. The bacterial biofilm, composed of *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, and *Klebsiella pneumoniae*, was grown on a glass observation window in a polycarbonate flow cell. The oscillation frequency of the streamers was directly proportional to the velocity of bulk liquid, suggesting that the oscillations were caused by vortex shedding of the upstream "head" (white arrow) of the streamer (Stoodley et al., 1998). Black arrow indicates flow direction; scale bar = 500 µm. For the Fig. 7c, see the online version of *The Prokaryotes*.

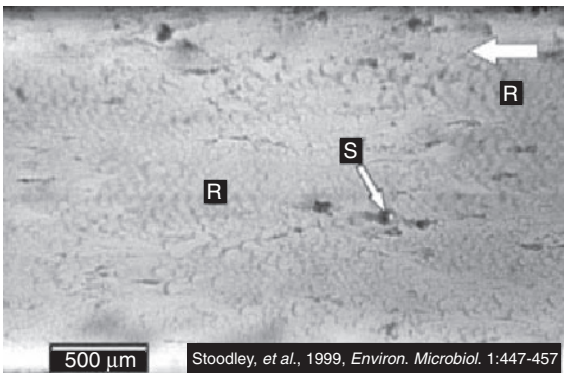

Fig. 8. Time lapse movie showing the migration of biofilm ripple-like structures across a glass surface. The mixed species biofilm was composed of *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, *Stenatrophomonas maltophilia*, and *Klebsiella pneumoniae* (Stoodley et al., 1999d). Ripple patches are labelled "R." Elongated streamers "S" also formed in the biofilm. The streamers did not migrate across the surface, but some of them were observed to detach during the observation period (see labelled streamer "S"). The biofilm was 15 days old and grown in turbulent pipe flow at a bulk liquid flow velocity of 1 $m \cdot s^{-1}$ (Re = 3600). The flow direction is indicated by the arrow. Frames were captured at 1-h intervals over 15-h. Scale bar = 500 µm. For the Fig. 8, see the online version of *The Prokaryotes*.

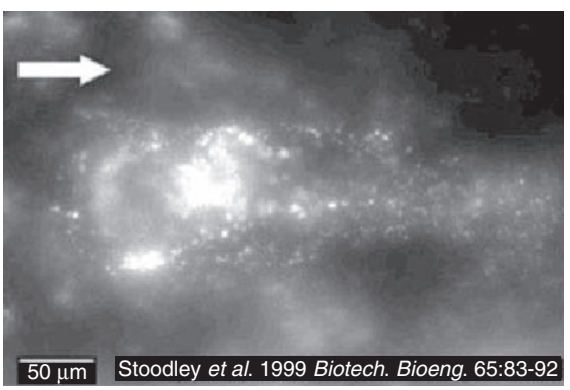

Fig. 9. Time-lapse movie showing the influence of fluid shear on biofilm structure (Stoodley et al., 1999c). The biofilm streamer was stained with fluorescent beads, which appear as bright dots and were used as fiducial points to monitor structural changes. The sequence of images shows the changes to structure as the fluid shear was increased stepwise from 0 to 10.11 Pa and then reduced stepwise back to 0. When the load was removed, the biofilm "sprang" back, clearly demonstrating an elastic response. Arrow indicates flow direction. Scale bar = 50 µm. For the Fig. 9, see the online version of *The Prokaryotes*.

form relatively flat biofilms or spherical aggregates; faster (heterotrophic) growth results in formation of more heterogeneous biofilms with cell clusters and streamers. Characklis (1990a) has demonstrated the relative contributions of nutrient loading and flow velocity on biofilm thickness. At low loading rates (0.1 g carbon $\cdot m^{-2} \cdot h^{-1}$) biofilm thickness (ca. 50 µm) was nutrient-limited and relatively independent of liquid flow velocity. However, at higher loading rates (2.4 g carbon $\cdot m^{-2} \cdot h^{-1}$), the biofilm thickness was approximately 1000 µm at a liquid flow velocity of 1.5 $m \cdot s^{-1}$ but was reduced to 200 µm when the biofilm was grown at a liquid flow velocity of 3 $m \cdot s^{-1}$. In this case, the biofilm thickness was presumably limited by shear-induced detachment as the flow rate was increased. It is well established that generally thinner biofilms form (and less biofilm biomass accumulates) under low nutrient conditions, and it has been proposed that biofilm accumulation may be limited by removing nutrients under controlled conditions in an upstream biofilter (Griebe and Flemming, 1998). However, there is less information on the influence nutrients have on the structure of biofilms. Møller et al. (1997) reported that the structure of a mixed microbial community grown under laminar flow changed in response to a switch in substrate (while maintaining a constant labile carbon loading rate) (Møller et al., 1997). When grown on 2,4,6-trichlorobenzoic acid, the biofilm consisted of mounds of cells separated by void areas. However, when the substrate was switched to trypticase soy broth, the biofilm became thicker, and growth

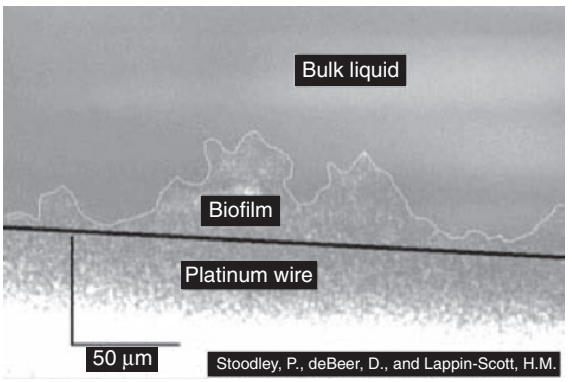

Fig. 10. Time lapse movie sequence showing the expansion and contraction of a mixed-species biofilm growing on a platinum wire (Stoodley et al., 1997). The biofilm expanded when the wire was cathodic but contracted when it was anodic. The biofilm could fully expand and contract at a maximum frequency of approximately 5 Hz. At higher frequencies the biofilm appeared to fibrillate. Similar contractions and expansions could be induced by pH alone. The edge of the wire is indicated by the black line. The edge of the biofilm has been outlined in white for clarity. Scale bar = 50 µm. For the Fig. 10, see the online version of *The Prokaryotes*.

in the void areas resulted in a less heterogeneous structure. Also, a change in nutrient concentration can cause a change in the structure of an established biofilm as well as changes in thickness and surface coverage. Stoodley et al. (1999a) reported that the structure of a 21-day mixed-species biofilm growing in turbulent flow initially consisted of ripples and streamers (see Fig. 8) but changed to large cell clusters (ca. 500 µm in length) when the carbon and nitrogen concentration was increased by a factor of 10. The biofilm also significantly increased in thickness and surface coverage. When C and N concentrations were reduced to their original levels, there was a loss of biomass and the ripples and streamers reappeared. We speculate that cell surface properties, in particular hydrophobicity or hydrophilicity, also can determine the biofilm structure. Cell surface hydrophobicity results in minimization of the contact surface between liquid and biofilm and thus in planar biofilms or spherical aggregates. Hydrophilic cells will more easily form protrusions like streamers and cell clusters. Typically, dividing cells (Allison et al., 1990) and many (facultative) aerobic heterotrophs (Daffonchio et al., 1995) are hydrophilic. Heterotrophic conditions thus result in heterogeneous biofilms. Examples of hydrophobic microorganisms are benthic cyanobacteria (Fattom and Shilo, 1984), methanogens, syntrophic bacteria, and to a lesser extent, sulfate reducers (Daffonchio et al., 1995). Indeed cyanobacterial mats and methanogenic biofilms are usually relatively flat; however, detailed observations on mat structure and heterogeneity have not been conducted to the same extent as on bacterial biofilms.

Cell-Cell Signaling Finally, cell-cell communication must be considered as a morphogenetic mechanism. By sensing cell-produced compounds, e.g., *N*-acyl-homoserine lactones where the acyl group determines action or strain specificity, cells recognize the local cell density (therefore called "quorum sensing") and react by switching on or off certain sets of functional genes. Quorum sensing regulates the expression of the LUX genes in the bioluminescent bacterium *Vibrio fisheri* and the release of virulence genes in pathogens like *Pseudomonas aeruginosa*, and it plays a role in the symbiotic host association of *Rhizobium leguminosarum* in root nodules. Genes for quorum sensing have been found in ca. 25 different bacterial species, and this communication mechanism is believed to be common among Gram-negative bacteria (Greenberg, 1997). Quorum sensing also determines the structure of *P. aeruginosa* biofilms (Davies, personal communication): the presence of *N*-3-oxododecanoyl-L-homoserine lactone enhances the production of polyuronic acids, which are important components of bacterial EPS. The lactone concentration is increased, due to restricted out-diffusion, at higher cell densities or after adhesion to a surface, thereby enhancing biofilm formation. At higher concentrations (as can occur in dense and thick biofilms), the same compound induces production of *N*-butyryl-L-homoserine lactone, which then induces the production of alginate lyase that can dissolve EPS and lead to rapid cell mobilization and formation of voids in the biofilm matrix. Mutants of *P. aeruginosa*, defective in quorum–sensing, form flat and homogeneous biofilms, while the wild-type organism forms heterogeneous biofilms (Davies et al., 1998). If these mutants are grown with *N*-3-oxododecanoyl-L-homoserine lactone added to the medium, a patchy biofilm resembling the wild-type biofilm is formed. Two counteracting lactones, one stimulating cell aggregation (biofilm formation) and one stimulating biofilm dissolution, can thus regulate biofilm structure. Halogenated furanones, produced by marine algae, interfere with the cell-cell signaling mechanism, resulting in strongly decreased biofilm accumulation (Maximilien et al., 1998). It can be expected that the newly found mechanism of cell-cell signaling will be very important in future biofilm studies. This will lead to an explanation of many

biofilm characteristics and to more ways to manipulate biofilms.

Mass Transfer and Microbial Activity

Substrates for biofilm growth usually are supplied by the water phase, and metabolic products are eventually released into the water phase. The rates of exchange between the biofilm and the water phase are determined by the mass transfer processes of diffusion and advection. Microbial conversions in biofilms are, therefore, dependent and often limited by mass transfer. The process rates should be determined in situ. Activity determinations on biofilm samples cannot give reliable data as the microenvironment cannot be accurately replicated in vitro. Conversions are related mostly to cell growth and division, and the development of reliable methods to determine growth rates of single cells in situ has proved difficult. However, the combination of two photon confocal microscopy with fluorescent gene activity reporters should remove much of the ambiguity associated with current techniques.

Mass Transfer in Biofilms

A common property of microbial mats, biofilms, flocs, and aggregates is the occurrence of mass transfer resistance. This is due to the limited water flow inside the matrix and the presence of a hydrodynamic boundary layer between the matrix and the surrounding water phase (Jørgensen and Revsbech, 1985; Jørgensen, 1994; Lewandowski et al., 1993; De Beer et al., 1993; De Beer et al., 1994; De Beer and Stoodley, 1995; Ploug and Jørgensen, 1998). Transport of solutes is thought to be primarily by diffusion inside the biofilm matrix and in the boundary layer adjacent to the solid surface. Consequently, when the internal chemical composition (substrates and products) differs from bulk water conditions, steep gradients develop. This has strong effects on the type and rates of microbial conversions. Mass transfer resistance often limits conversion rates. However, many processes can occur only inside biofilms because of special prevailing conditions. For example, anaerobic conversions like denitrification, sulfate reduction, and methanogenesis primarily take place in anoxic environments found in the deeper zones of biofilms and mats. However, recent studies showed that anaerobic processes also can occur in the oxic part of sediments and mats, indicating that anaerobic bacteria have special physiological adaptations or that anaerobic micro-niches may exist in the oxic zone (Canfield and Des Marais, 1991; Frund and Cohen, 1992; Krekeler et al., 1997). A characterization of the microenvironments and their interaction with mass transfer processes is needed to understand conversions inside biofilms.

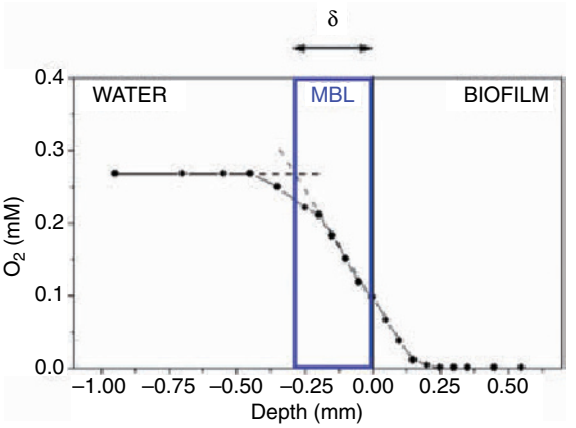

Fig. 11. Oxygen profile measured in a moderately active biofilm. The crosspoint of the dashed lines indicates the upper boundary of the hypothetical mass boundary layer (MBL), having a thickness δ. The image shows that a significant part of the mass transfer resistance can be situated outside the biofilm.

The simplest biofilm concept is a planar geometry, with microbial activity distributed homogeneously and all transport parameters constant regardless of depth. Adjacent to the biofilm is a mass boundary layer (MBL) in which the transport gradually changes from diffusional to advective in the mixed bulk liquid. This is illustrated in Fig. 11, showing an O_2 microprofile in and above a respiring biofilm. The strength of this concept is its simplicity, which facilitates mathematical modeling of transport, conversion and growth (Wanner and Gujer, 1986; Rittmann and Manem, 1992; Wanner and Reichert, 1996).

The mass-transfer resistances can be separated into external, in the MBL, and internal, in the matrix itself. The resistance in the MBL is proportional to its thickness, which depends mainly on the flow velocity of the liquid (Jørgensen and Des Marais, 1990). The mass transport coefficient, k_s, and the thickness of the MBL, δ, can be calculated from the liquid flow velocity ($_u\exists$). For example (Shaw and Hanratty, 1977):

$$k_s = 0.0889 u_\infty Sc^{-0.704} \quad (1)$$

with Sc as the Schmidt mumber,

$$Sc = \frac{\eta\rho}{D_{eff}} \quad (2)$$

with η as the dynamic viscosity, ρ as the density of the water phase, and

$$\delta = \frac{D_{eff}}{k_s} \quad (3)$$

Ultimately, the effective diffusion coefficient (D_{eff}) and the penetration depth (ρ; diffusion distance) of the limiting substrate determine the mass transfer resistance (η) in the matrix.

The relative importance of the MBL and intra-matrix resistance for conversion rates has been described for flat geometry with first- and zero-order kinetics (De Beer, 1998). Qualitatively expressed, the greater is the microbial activity of the matrix, the smaller is the penetration depth of the limiting substrate. Consequently, the relative contribution of the mass transfer resistance inside the matrix decreases. Therefore, the higher the microbial activity, the more important the MBL is for the regulation of microbial activity. The penetration depth of O_2, often the limiting substrate, is typically 100 μm in active biofilms, while the thickness of the MBL is in the range of 50–300 μm. Consequently, external mass transfer, and thus flow velocity (see Eq.), often determines the activity of biofilms.

Internal mass transfer is usually considered to be diffusional and, consequently, frequently described using a single effective diffusion coefficient (D_{eff}). The flux of a compound, therefore, depends both on its diffusion coefficient and the slope of the concentration profile:

$$J = D_{eff} = \frac{dc}{dx} \quad (4)$$

where J is the flux ($mol \cdot m^{-2} \cdot s^{-1}$), D_{eff} is the effective diffusion coefficient in the biofilm, and dc/dx is the concentration gradient.

Both diffusion and advection of solutes are important in biofilms. The biofilm matrix hinders both phenomena; obviously the matrix is an effective barrier not only for water movement (advection) but also for the random movement of solutes (diffusion). The effective diffusion coefficient (D_{eff}) is proportional to the biofilm porosity (θ) and inversely proportional to the square of the diffusional distance, the average path length (φ):

$$D_{eff} = \frac{D_w \theta}{\varphi^2} \quad (5)$$

Diffusion is the only transport mechanism when there is no flow inside the biofilm, while advection usually becomes the dominant mechanism when the matrix is sufficiently permeable to allow liquid flow. Contrary to advectional transport, diffusion becomes rapidly less effective with increasing distance. A simple calculation example demonstrates this; the root-mean-square displacement (x) due to diffusion is described by Berg, 1983:

$$\langle x^2 \rangle^{1/2} = \sqrt{2Dt} \quad (6)$$

where t = time.

From this equation, it is evident that displacement due to diffusion is time-dependent: for a diffusion coefficient with a representative value of $1 \times 10^{-9}\ m^2 \cdot s^{-1}$, the average displacement due

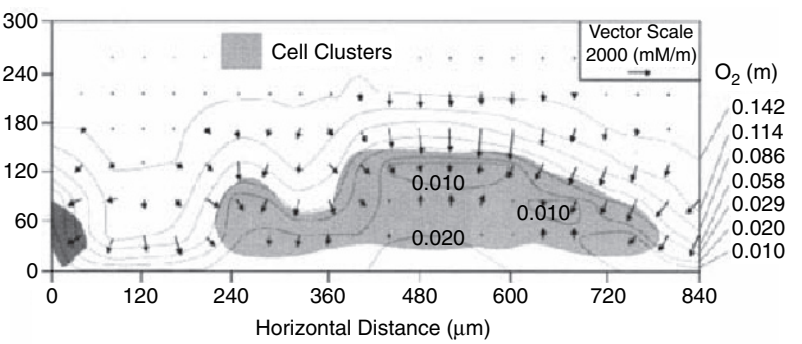

Fig. 12. Cross section through a heterogeneous biofilm showing dissolved oxygen (DO) contours associated with the cell clusters (shaded) and surrounding water channels. Twenty two adjacent DO profiles were measured by microelectrode to give a 2D array of DO measurements. The microelectrode was guided by micromanipulator and confocal microscopy was used to locate the positions of the clusters and channels. In this particular biofilm the cell clusters were held away from the flow cell wall (located toward the bottom of the figure) by "stalk-like" structures. Since this cross section did not intersect any of these stalks the biofilm cluster appears to be "floating" above the wall of the flow cell. The arrows are the calculated DO fluxes and the length of the arrow is proportional to the magnitude of the flux. Note the penetration of DO into the biofilm channel which is centered at 120 micron on the x-axis. Also note that in the center of the large cell cluster the flux arrows are pointing upwards, indicating that DO was being supplied from underneath the cell cluster. In this case the anaerobic region occurred in the center of the cell cluster, approximately 100 microns away from the substratum, and not in a layer adjacent to the wall as would be predicted for a flat biofilm. The vertical distance in microns is shown on the left Y-axis.

to diffusion is 100 μm in 5 s, 1 mm in 10 min, 1 cm in 14 hours, and 1 dm in 2 months. Diffusion is a very effective transport process for short distances (the size of bacterial cells), but it is much slower over longer distances (the thickness of biofilms). Solute transport due to advection equals the velocity of the liquid, and even if it is in the order of 1 $\mu m \cdot s^{-1}$, advection will be as important as diffusion for biofilms, which typically range from a few hundred μm to several mm thick. Microscopic observations have showed that biofilms can be highly porous, thus the common assumption that diffusion is the sole transport mechanism must be treated with care. Indeed it was shown that water can flow between the cell clusters as described in the heterogeneity section. Fluorescent beads quickly penetrated the voids, and their movement, followed by confocal microscopy, showed that water can flow through the channel-like structures (De Beer, 1994; Stoodley, 1994; 1997). With oxygen microsensors it was further demonstrated that the oxygen concentration inside the voids is much higher than that in the adjacent cell-clusters, thus diffusion will occur in and a horizontal direction or even from voids at the base of the biofilms in an upwards direction into the cell clusters (Fig. 12; De Beer, 1994). It was calculated that in such heterogeneous biofilms the interfacial oxygen flux is 2–3 times higher than that for a flat biofilm. At low flow velocity this effect disappears and a 1-D model can be applied (De Beer, 1995). Upon injecting a fluorescent dye in the voids of a biofilm an elongated plume developed, while injection inside the pores resulted in a spherical plume (De Beer, 1995). Therefore it was concluded that in voids flow occurs and induces advective transport at higher flow velocities, but in cell clusters diffusion is the only transport mechanism.

Numerous studies reporting measurements of the D_{eff} of various compounds in biofilms and microbial aggregates have been reviewed (Christensen and Characklis, 1990; Libicki et al., 1988; Siegrist and Gujer, 1985). Literature values show a wide range of variation, D_{eff} being 1–900% of the diffusion coefficient in water (D_w), reflecting the variety of biofilms studied as well as the different measurement methods. The D_{eff}/D_w ratios for substrates with small molecular weights, such as oxygen, glucose, ammonium, and nitrate, in spontaneously growing biofilms and microbial aggregates are assumed to be around 0.9 (Christensen and Characklis, 1990). Diffusion of macromolecules such as DNA, dextrans, and proteins may be more strongly impeded by biofilm matrices, resulting in decreased D_e/D_w ratios. Diffusion experiments with such molecules have been reported only for gel matrices; however, biofilms have been considered to be highly hydrated gels (Christensen and Characklis, 1990). An extensive review on diffusion phenomena in gels is given by Westrin (1991). It has been shown that the D_e/D_w of proteins diffusing through agarose gels is inversely correlated with their molecular weight (Boyer and Hsu, 1992; Arnold et al., 1985). This is due to gel-matrix polymers obstructing diffusion (Rodbard and Chranbach, 1970) as well as to hydrodynamic drag at the matrix polymer-solvent interface (Brenner and Gaydos, 1977). The impeded diffusion of large molecules in gels is strongly influenced by the microstructure of the gel matrices; consequently, information about the microstructure of the biofilm matrix may be derived from diffusion data.

Diffusivities in biofilms have been estimated by measuring transient or steady state fluxes through biofilms in diffusion chambers or in uptake experiments (Libicki et al., 1988). If the experiments are performed with a nonreacting compound or with killed biofilms, D_{eff} can be calculated by fitting the measured fluxes with a diffusion model. In the case of a reacting compound, a reaction-diffusion model is necessary.

The determination of diffusivities by these methods assumes a homogeneous and flat biofilm. It was, however, shown that biofilms are not always flat but may contain streamers, cell clusters, voids, pores and channels that may affect strongly the transport properties of the biofilm. Thus the diffusivity may be overestimated from advective transport through the pores. This may explain why D_e higher than D_w values have been reported (Libicki et al., 1988; Siegrist and Gujer, 1985).

To describe transport inside biofilms, transport in the voids (advection and diffusion) and in the base film and cell clusters (diffusion only) must be distinguished. For this, measuring techniques with high spatial resolution are needed. A powerful technique for determinating local diffusional properties of biofilms is the Fluorescence Recovery After Photobleaching (FRAP) method (Axelrod et al., 1976). Application of optical techniques is limited to transparent structures. First, a biofilm is soaked with fluorescently labelled compounds. The FRAP method measures the diffusion of fluorescent molecules into a small area in which all molecules are bleached by a high intensity laser beam. After that volume is depleted of fluorescent molecules by the laser flash, other molecules diffuse in from the surrounding area. By quantitatively monitoring this diffusion using CSLM and by fitting these data using a mathematical model, the diffusion coefficient of the compound can be calculated. The spatial resolution of the method is ca. 30 μm. It was found that the diffusion of small molecules (MW 300) was not significantly impeded by

biomass. Large molecules, such as dextrans, proteins, and DNA, were impeded (ca. 30% of that in water for large proteins, MW 200,000, and 20% for DNA, MW 3×10^6; Bryers and Drummond, 1996).

A conceptually related technique is based on microinjection of a fluorescent tracer and on monitoring the expansion of the fluorescent plume by CSLM (De Beer et al., 1997). Instead of diffusion into a depleted area (FRAP), the out-diffusion is followed into the surrounding area. The distribution pattern of the dye is fitted with an implicit equation to obtain a local value for D, the diffusion coefficient. A refinement of this technique is to detect the fluorescence with an optical fiber connected to the microinjection capillary (De Beer et al., 1997; Kühl and Revsbech, 1998). This microsensor can be used in thick nontransparent biofilms. With this technique, similar observations were obtained as with FRAP: the diffusion coefficient of small molecules (MW 300) is close to that in water, while the mobility of large molecules (MW 240,000) is decreased to ca. 30%.

Both FRAP and microinjection are non steady state methods of measuring the diffusivity at a particular location in the biofilm. The value obtained is the molecular diffusivity, corrected for the tortuosity of the matrix (D_w) but not the porosity (Libicki et al., 1988). For determination of D_{eff} (D_w/j), flux measurements during steady-state transport are needed.

Recently, two microsensor approaches were developed to determine local diffusivity (D_{eff}) with high spatial resolution. A microsensor method to determine local diffusivities or local mass transfer properties (Yang and Lewandowski, 1995; Rasmussen and Lewandowski, 1998) is based on measuring the limiting current during the reduction of Fe^{3+}. A strong inhibition of Fe^{3+} transport was measured in biofilms, especially in deeper parts of the cell clusters, with values lower than 10% of that in water. These findings contradict others that concluded small molecules are not impeded in their motility (Bryers and Drummond, 1996; De Beer et al., 1997). Possibly, because of the measuring conditions employed (0.5 M KCl and 25 mM $K_3Fe(CN)_6$), the viscosity in the biofilm was increased by cell lysis or weakening of the EPS bonds, thus decreasing the diffusivity. Recently, a diffusion microsensor was developed, based on out-diffusing of a tracer gas from a needle-type capillary, with a tip size of 140 µm. The concentration of the tracer (H_2 or C_2H_2) in the tip of the capillary is measured using a normal microelectrode incorporated into the capillary. The signal is governed by the diffusional resistance in a sphere around the tip of the sensor, and thus is proportional to the local diffusion coefficient (Revsbech et al., 1998). With this sensor the D_{eff} in methanogenic aggregates was estimated at 50% of that in water (Santegoeds, 1999a).

In a recent study using NMR imaging, D_{eff} was determined in microbial mats, which were stratified; their diffusivity values ranged from 30–60% of that in water (Wieland, 1999). These measurements were confirmed with the gas-diffusion sensor (Revsbech et al., 1998).

In conclusion, data on the diffusion coefficient in biofilms are highly variable. This may be partially due not only to differences in the techniques used but also to the possibility of large variations within individual biofilms and between different types of biofilms.

Stratification (e-donor) and Internal Cycling

In sediments, a stratification into zones with different microbial conversions is well documented (Berner, 1981). Sediments are subjected to a continuous or intermittent influx of organic matter, which is mineralized in several steps. Therefore, a wide diversity of conversions takes place, and as a consequence several profiles develop. The deeper regions are more anoxic and reduced than the top, which is usually aerobic. The organics are degraded and oxidized by bacteria using electron acceptors in the characteristic sequence O_2, NO_3^-, MnO_2, Fe^{3+}, SO_4^{2-}, and CO_2 (Reeburgh, 1983). This sequence coincides with the standard free energy changes of the reactions involved, and it is assumed that the larger the energy yield of a conversion, the greater the likelihood it will dominate other competing reactions. The mineralization processes involved are aerobic mineralization, denitrification, iron reduction, sulfate reduction, and methanogenesis. Since electron acceptors are usually supplied from the water phase, the different processes will occur adjacent to each other, going from surface to deeper zones, in the same characteristic sequence mentioned. The stratification is not necessarily strict, and processes do not necessarily exclude each other, e.g., there is no thermodynamic argument why methanogenesis does not occur under aerobic conditions. Inhibition and regulation on the cell level are strong determinants for the stratification. Denitrification is inhibited usually by oxygen, although an exception was reported (Robertson, 1983). Consequently, denitrification is located directly adjacent to the aerobic zone, with some possible overlap in the microaerobic zone (Lorenzen, 1998; De Beer and Sweerts, 1989; Robertson, 1995). Sulfate reducers were thought to be very sensitive to oxygen, and thus restricted to anoxic zones. However, recently sulfate reducers were found in oxic zones of biofilms, sediments, and microbial mats (Dilling, 1990; Krekeler et al.,

1997). Furthermore, there is evidence that sulfate reducers can be sulfidogenically active under aerobic conditions (Canfield and Des Marais, 1991). Even more confusing was the finding of sulfate reducers that oxidize sulfide aerobically (Fuseler, 1996). Sediments are not fundamentally different from biofilms, and both can be considered as matrices with localized (evidence suggests that cells are not immobilized but can swim around inside the cell clusters) microorganisms. All these processes may occur in biofilms as well, although in the relatively thin and heterogeneous biofilms, a stratification of processes and organisms may not be as pronounced and may be more difficult to study.

Owing to the short distances in biofilms, the different conversion processes can be tightly coupled and internal cycling occurs. Organic matter is subjected to hydrolysis and fermentation, producing volatile fatty acids and hydrogen. These products and the original organic matter serve as e-donors for anaerobic- and aerobic respiration and methanogenesis. In the oxic zone, products from anaerobic redox processes like sulfide, methane, and Fe^{2+} are oxidized. Thus internal cycles are possible, which can not be quantified from interfacial fluxes. Such sequences of processes can only be detected by invasive techniques with high spatial resolution, i.e., by microsensors.

An important internal cycle in biofilms is sulfate reduction coupled to sulfide oxidation. It is well known that sulfate reduction contributes considerably to the mineralization process in marine sediments (Jørgensen, 1977, 1985; Jørgensen and Des Marais, 1990; Thamdrup, 1996). Because of re-oxidation by aerobic and anaerobic processes, sulfide does not reach the top of the sediment. The importance of sulfate reduction in marine environments is usually explained by the high sulfate concentrations in seawater. However, also in freshwater systems, the sulfur cycle can be important. In aerobic wastewater biofilms, a significant part of the mineralization occurs by sulfate reducers. It was demonstrated with microsensors for S^{2-} that 50% of the oxygen was used for sulfide oxidation, implying that 50% of the mineralization of organic matter is degraded by sulfate reduction (Kühl and Jørgensen, 1992). In similar biofilms, a combination of molecular techniques and microsensor techniques was used to relate microbial activity with microbial population distributions (Ramsing et al., 1993). A good correlation was found with the distribution of sulfate reducers and sulfide production in these biofilms, which were both confined to the anoxic zones. However, owing to the metabolic versatility of sulfate reducers and their resistance to oxygen, such a good correlation between microbial populations and microbial conversions is not obvious. Recently, the development of sulfate reduction in an aerobic biofilm was studied with microsensor and molecular analyses (Santegoeds et al., 1998). It was found that sulfate reduction coupled to sulfide oxidation began only after 6 weeks, although anoxic zones were present by the first week. Once started, this process became of major importance, resulting in up to 70% of the mineralization in the biofilm. Thus sulfate reduction can be an important process even in thin biofilms that are exposed to oxygen.

In the absence of nitrate, sulfide is oxidized by oxygen, and thus the oxygen and sulfide profiles overlap. Upon addition of nitrate, a separation between the sulfide and oxygen profile occurs, because nitrate penetrates beyond the oxic layer and becomes the e-acceptor for sulfide oxidation (Kühl and Jørgensen, 1992). Furthermore, iron and manganese form important shuttles for redox equivalents in marine sediments (Canfield, 1991). Their role in biofilms is not known.

When illuminated, photosynthesizing biofilms are found. In such communities, a most complex internal cycling exists as these biofilms are in principle self-supporting. In the photic zone, CO_2 is bound in the biomass and O_2 produced. In the aerobic and anaerobic zones, the biomass is degraded to CO_2. In such systems, a large array of microbial processes can be found. Especially in microbial mats from extreme environments, such as hot springs or hypersaline lakes, undisturbed stratification of the different processes occurs. Microbial mats are actually complete ecosystems, where primary production is balanced by aerobic and anaerobic respiratory processes. Such communities are therefore highly interesting model systems. For further information on these systems, we refer to reviews (Pearl, 1996; Stal, 1994).

The main processes in the nitrogen cycle are ammonification due to degradation of organic matter, nitrification, and denitrification. Since the product of denitrification is N_2 gas, the nitrogen cycle in biofilms is not closed but depends on input of nitrogen compounds. Since nitrification is an aerobic process and denitrification proceeds primarily in the absence of oxygen, a clear stratification can be expected. Indeed, using microsensors, it could be confirmed that nitrate is formed in the oxic and consumed in the anoxic zone (Schramm and Amann, 1999; Schramm et al., 1996; De Beer, 1998; De Beer et al., 1997b). Nitrification is usually limited by oxygen penetration and confined to an outer layer of ca. 100-μm thick (De Beer et al., 1993; Schramm, 1998a). The intermediate nitrite can be found in a narrow zone near the oxic-anoxic interface, where it is formed by either incomplete nitrification or denitrification (De Beer et al., 1997b). In

biofilms, denitrification is regulated by oxygen in several ways: firstly by inhibition, secondly by nitrification in the oxic zone, and finally by transport. Denitrification takes place adjacent to the oxic zone. At higher oxygen levels, the thicker oxic zone forms a transport resistance for nitrate from the water phase.

The competition between sulfate reduction and methanogenesis for e-donors has been investigated intensively. Sulfate reduction has more favorable thermodynamics than methanogenesis (Widdel, 1988). Thus methanogenesis is typically a more important process in low-sulfate environments (freshwater), and sulfate reduction dominates in marine sediments. Anaerobic reactors are usually designed for methane production, while sulfide production is an unwanted process because of odor and corrosion problems. In practice both processes are active, resulting in biogas that is polluted with sulfide. Based on modelling, it was concluded that, under sulfate-limiting conditions, the outer layers of anaerobic biofilms or aggregates would be sulfidogenic, leaving a microniche for methanogens in the center (Overmeire et al., 1994). Such a division was indeed found: methane and sulfide microprofiles showed that sulfate reduction is confined to the outer 100 μm, while methanogenesis occurs in the center (Santegoeds, 1999a). This was also observed in aggregates preincubated for months in excess sulfate and e-donor, i.e., where sulfate reducers were expected to be present in the center as well. It was hypothesized that methanogens are needed for initial aggregate formation, while sulfate reduction develops subsequently. However, it is strange that sulfate-reducing bacteria (SRB) do not eventually colonize the aggregate center.

From the previously reviewed literature, it can be concluded that the sequence of e-acceptor use found in sediments is also present in biofilms. This was almost comprehensively demonstrated with microsensors in wastewater biofilms (De Beer, 1999). First O_2 is used by heterotrophic and autotrophic processes (nitrification and sulfide oxidation). Then NO_2^- and NO_3^-, formed by nitrification or originating from the water phase, are consumed in the zone directly adjacent to the oxic layer. Denitrification can be coupled to sulfide oxidation. Sulfate reduction is found below the denitrifying zone. Methanogenesis is also spatially separated from sulfate reduction and occurs in the deepest zones of the biofilms.

Special Physiology of Biofilm Cells?

Since biofilms function differently in many aspects from planktonic cells, it has often been speculated that a special biofilm physiology exists (Cochran et al., 2000). Biofilms usually have a lower specific conversion rate, high resistance towards biocides and antibiotics, and less sensitivity to temperature changes. It has been argued that all these phenomena can be explained by mass transfer resistance (van Loosdrecht et al., 1990). Mass transfer resistance reduces the transport of substrates and biocides to the cells, even if they form only a monolayer. Due to mass-transfer resistance, only a partial penetration of substrate occurs; but under conditions of reduced cellular activity (e.g., by cooling) a larger part of the biofilm gets penetrated with substrate, which counteracts the reduced specific conversion rates in each cell. Two other explanations for the reduced efficacy of biocides and antibiotics are: the relatively low growth rates of biofilm cells, which make them less susceptible (Brown and Gilbert, 1993), and the reduced penetration either by binding of compounds to the biofilm matrix or, in case of reactive biocides, by deactivation in the outer layers of the biofilm (Stewart et al., 1996). It appears that rather than a special biofilm physiology, the growth and activity of the cells within the biofilm may be governed by the physiochemical conditions that prevail in the biofilm microenvironment.

However, more and more evidence indicates that cells recognize and respond to the presence of other cells and surfaces in their environment. It has been shown that after attachment certain genes required for EPS synthesis are activated (Davies and Geesey, 1995) and that the production of pheromones (homoserine lactones) induces biofilm formation (Davies et al., 1998). Thus the development of a mature biofilm involves the same compounds involved in quorum sensing (Greenberg, 1997). It was carefully hypothesized that cell-cell signalling might be involved in the resistance of biofilms to biocides (Costerton et al., 1999). See further in the paragraph on "Morphogenetic factors."

Microbial Populations

Previously, microbial population analysis was based on enrichment and cultivation techniques. It has become clear that plate counts very often do not represent the true microbial community, as many strains are resistant to cultivation. Microbial analysis has become much more reliable (and easier) due to the development of noncultivation techniques. Owing to the relative ease of molecular techniques, many data are collected from a wide variety of microbial communities; however, the role of the detected populations is often not known. This can be attributed to the difficulty of functional analysis of complex communities: the conversions of a

community can be measured, but it is difficult and often impossible to assign the conversion to certain populations. However, there are some exceptions. Some microbial populations can be analyzed with a combination of microsensor and molecular techniques. Then, it is possible to determine the location of certain microbial processes (with microsensors) and to determine the location of certain microbial populations (with fluorescent in situ hybridization, FISH). Comparing these data can lead to estimations of activities and kinetics of populations in situ.

The combination of molecular and microsensor techniques was first used in a biofilm from a trickling filter (Ramsing et al., 1993). Sulfide profiles were measured with AgS microsensors from which the distribution of sulfate reduction and sulfide oxidation was determined. With oligonucleotide probes (SRB385) the distribution of SRB was determined, although it is now known that the probe is not targetting SRB exclusively. Once a reasonable agreement between the distribution of SRB and sulfate-reducing zones was found, the in situ activity could be estimated. However, SRB were also found in the oxic zones. Although 50% of the mineralization was done by sulfate reduction, only 10^8–10^9 SRB per ml were found, which was probably less than 1% of the total number of cells.

In a more detailed study, the development of the number and distribution of SRB as well as that of sulfate reduction was followed in a biofilm developing in a wastewater treatment plant. Although anoxic conditions were present from the first week on, no sulfate reduction could be detected until the sixth week. More surprisingly, SRB were present also in the initial biofilm as shown with various molecular techniques (DGGE, denaturing gradient gel electrophoresis; FISH; Santegoeds et al., 1998). A better correlation between molecular and functional analysis was found when comparing the presence of the functional gene for bisulfite reductase (DSR) and sulfate reduction (Santegoeds, 1999a), as the start of the sulfate reduction coincided with a strong increase of the signal for DSR. Thus, the presence of a functional gene in a complex microbial community seems more predictive for its behavior than a population analysis. However, in activated sludge DSR could be clearly demonstrated, but sulfate reduction was absent, even upon exposure to anoxia in the presence of a suitable cocktail of e-donor (Schramm and Amann, 1999). This points again to the fact that observed populations and biodiversity do not necessarily reflect the behavior of the community at the time of sampling. Many ecosystems and microbial communities are open and thus exchange of strains is occurring frequently. For example, wastewater treatment systems, which are the subject of many diversity studies, have an enormous input of microorganisms that are collected from a wide area or are grown in the sewer system. It is likely that the observed sulfate reducers in activated sludge originate from the input and the SRB populations need time to adapt to the conditions in the wastewater treatment plant.

In methanogenic aggregates a good correlation was found between the distribution of SRB and sulfate reduction, as well as between the distribution of methanogenic bacteria (MB) and methanogenesis. SRB were mostly found on the outside, while MB form the core of the aggregates. In between was a layer of syntrophic bacteria, which were found to supply both the SRB and MB with H_2 and acetate. In aggregates from a reactor optimized for sulfate reduction, few MB and little methanogenesis were found. In aggregates from a reactor optimized for methanogenesis, no SRB or sulfate reduction was detected (Santegoeds, 1999a). The difference between anaerobic aggregates and the previously studied biofilms and activated sludge is age: while the biofilms and flocs had a life-cycle of months or weeks, anaerobic aggregates develop over years. Probably, the SRB populations found in flocs and biofilms originated from outside the biofilms and flocs, and since they did not reduce sulfate, they were not adapted to the environment inside the studied communities. Thus, population analysis based on nucleic acid analysis must be regarded with care. It can be concluded that although certain physiological groups may be present, they may not necessarily be active. The presence of a population will only reflect the functioning of a microbial community if the community is mature and its populations well adapted to its environment.

A good correlation between activity and presence of populations is often found in nitrifying biofilms. In a high-loaded biofilm reactor from a fish hatchery, nitrate microprofiles showed nitrification in the aerobic surface layer and denitrification in the deeper anoxic zone. With FISH, populations of ammonium- and nitrite-oxidizing *Nitrosomonas* and *Nitrobacter* strains were found predominantly in this outer zone (Schramm et al., 1996). Nitrification is generally thought to be mediated mainly by *Nitrosomonas* and *Nitrobacter* strains, because these are the main species that can be isolated from environmental samples. However, with molecular techniques these strains are seldomly detectable in environmental samples. In aggregates from a rather low-loaded, fluidized bed reactor, intense nitrification was measured, but no nitrifying populations were found with the probes for *Nitrosomonas* and *Nitrobacter*. DNA was extracted, 16S-RNA coding fragments amplified

with PCR and sequenced, and after comparison with the databases, new probes were designed. The nitrifiers that were found were new *Nitrosospira* and *Nitrospira* strains, which could not be grown in culture. With FISH and by using these probes, quantification of the different populations was possible, and from the microprofiles, local activities were obtained. Thus, nitrifying activities could be estimated under different well-chosen conditions, even allowing in situ determination of Monod parameters (Schramm et al., 1998b) of up-to-now uncultured strains. The newly found strains had much lower specific activity and K_s than the known Nitrosomonas and Nitrobacter, implying a different survival strategy. In biofilms, they were found mainly in areas with low oxygen concentrations (Schramm, 1998a). *Nitrosospira* and *Nitrospira* strains are adapted to low nutrient and oxygen concentrations (K-strategy), while *Nitrosomonas* and *Nitrobacter* can compete with their much higher conversion (and probably growth) rates at high nutrient and oxygen concentrations (G-strategy).

Previously described in in situ studies, activity of populations was determined using a combination of FISH and microautoradiography, but activity determinations of single cells are also possible (Nielsen et al., 1998). Populations of filamentous bacteria from activated sludge were identified with probes for type 021N (strain identification according to Eikelboom key) and for *Thiotrix*. Uptake of six different organic substrates (^{14}C- or ^{3}H-labelled) under aerobic conditions revealed that no filaments took up all substrates and that strains, indistinguishable by morphology and molecular probes, showed differences in uptake patterns. This means again that great care must be taken when interpretating population structure of a complex community from the way its components function (Okabe, 1997).

Biofilm Control

Biofouling is the detrimental development of biofilms in engineered systems, such as industrial process equipment, drinking water distribution systems, and ship hulls. Biofilms can decrease heat transfer in heat exchangers, increase the pressure drop in pipelines, enhance corrosion, and may be a source of bacterial contamination of drinking water (McCoy, 1987; Camper, 1994; Characklis, 1990b). Biofilms are a nuisance in these systems and control of their development may be necessary to maintain process efficiency and safety. Biofilm control is often performed with biocides, of which the most commonly used is chlorine, a strong oxidizing agent and disinfectant. Biocides are much less effective against biofilms than suspended cells (Chen et al., 1993; Nichols, 1988; LeChevallier et al., 1988). Cells in biofilms are protected from biocide action and are killed only at biocide concentrations orders of magnitude higher than those necessary to kill suspended cells. It has been speculated that the lower sensitivity of biofilm cells to biocides is the result of physiological differences associated with lower growth rate (Brown and Gilbert, 1993). Alternatively, biocide may not reach the cells due to diffusional resistance of the biofilm matrix or to neutralization of biocide inside the matrix (Stewart et al., 1996). There is evidence for both theories.

Using a microsensor for chlorine it was shown that chlorine penetrates very slowly in biofilms (De Beer et al., 1994). The shape of the chlorine profiles, the long equilibration times, and the dependence on the bulk chlorine concentration showed that the penetration was a function of simultaneous reaction and diffusion of chlorine in the biofilm matrix. Frozen cross-sections of biofilms, stained with metabolic stain 5-cyano-2,3-ditolyl tetrazolium chloride (CTC; a redox dye), showed that the chlorine penetration overlapped with non-respiring zones near the biofilm-bulk fluid interface. Thus, chlorine was reduced effectively at the surface of the biofilm, which prevented its penetration to the cells in the deeper layers and thereby protected them. See further information in the section on "cell-cell signaling."

Methods for Studying Biofilms

Cultivation

Laboratory-Scale Cultivation All reactors used for cultivation of biofilms must be designed so that a selective advantage exists for cells to grow in biofilms and not in suspension. It must be kept in mind that cells in biofilms have a transport limitation not shared by suspended cells, which gives suspended cells in a reactor a selective advantage. In general, growth of suspended cells will interfere with biofilm behavior and thus complicate the interpretation of the experiment. Suspended cells can more efficiently compete for the limiting substrates, leaving little available for biofilms attached to the reactor surface. Consequently, in biofilm experiments suspended growth must be suppressed. Alternatively, certain selective pressures may favor biofilm formation. For example, biofilm formation may protect cells within the biofilm from the action of biocides or grazing predators (Costerton et al., 1994; Stewart et al., 1996). When biofilm growth is to be studied under controlled conditions, e.g., pure or defined mixed

cultures and constant conditions, ideally reactor conditions should be chosen so that the residence time of the liquid is shorter than the generation time of the cells. Then the suspended cells will be washed out and the substrate is available for biofilm growth. This was nicely demonstrated by experiments that stepwise decreased the residence time of a culture (Beeftink, 1987a). When the residence time became shorter than the generation time of the cells, wash-out occurred accompanied by a temporary increase of the substrate concentration. Subsequently, attached cell mass proliferated and the substrate concentration decreased again.

The particular design of a reactor system depends on the type of experiment, i.e., the type of process, conditions desired, and monitoring techniques applied. Besides the residence time of the medium, also the hydrodynamic regime and the microenvironment in the reactor, i.e., axial gradients, should be considered. The presence of stagnant zones must be avoided. The hydrodynamics should be predictable, and sudden expansions or contractions or sharp bends should be avoided where possible. For the medium supply, one can choose a once through system, in which fresh, sterile medium is pumped through the biofilm compartment. This ensures good control over the substrate concentrations. However, to obtain a sufficiently high flow rate to avoid axial gradients and stagnant zones, large amounts of medium are needed. Most reactor systems are operated with a continuous supply of medium, sufficient to ensure that the residence time of the medium is shorter than the generation time of the cultures, and a recycle allowing reconditioning of the medium (e.g., aeration and pH control) and control over the hydrodynamics of the biofilm. The design is often a compromise dictated by common sense. If experiments are to be done on pure cultures, a simple system that can be sterilized is preferred. Certain accomodations must be made for specific measurements, e.g., observation windows for in situ microscopy, removable slides for biofilm sampling, openings for the introduction of microsensors, and so forth.

Flow Cells One of the most widely used reactors for biofilm study is the flow cell. The system can be very simple, made of two microscopic slides and a spacer (Caldwell and Lawrence, 1988; Wolfaardt et al., 1995; Lawrence et al., 1991), which is ideal for microscopic monitoring of biofilms. The volume is small, therefore, a one-way medium supply can be used. It can easily be sterilized and so be used for pure cultures. A more complicated flow cell is needed when the biofilm is monitored with microsensors. Either a closed flow cell with openings for introduction of the sensors (De Beer et al., 1994) or an open flow cell is used (Horn and Hempel, 1997). Since these flow cells are larger, a recycle is needed to obtain good mixing of the water phase. A special type of flow cell is the Robbins device (Whiteley et al., 1997; Sly et al., 1990), essentially a pipe with sample holders, with the surface flush with the lining of the pipe. The sample holders are removable, allowing multiple biofilm sampling. Also, flow cells with observation windows for microscopy have been equipped with pressure- and flowmeters to study the interaction of hydrodynamics and biofilm accumulation (Stoodley et al., 1998).

A special flow cell was developed for immobilization of marine snow flocs (Ploug and Jørgensen, 1998). The device (called net-jet) consists of a cylinder with a fine stocking separating the top and bottom part. The hydrodynamics are not well understood, but this simple device allows fixation of flocs in an upward water stream. The flocs can be penetrated by microsensors under settling conditions, resembling the normal hydraulic regime. In this flow cell, also activated sludge flocs with a diameter of 0.2–1.5 mm were investigated (De Beer, 1998). If flow cells are well designed, the hydrodynamics can be well characterized (in contrast with many other types of bioreactor), allowing the influence of fluid shear and mass transfer on biofilm processes such as adhesion, detachment and biotransformation rates.

Annular Biofilm Reactor The annular reactor is essentially a chemostat consisting of a cylinder rotating in an outer cylinder with the reactor content between the outer and inner cylinder (Characklis, 1988). The outer cylinder can be equipped with removable sample plates that are flush with the surface. The inner cylinder rotates at variable speed, thus allowing adjustment of the hydraulic regime over a wide range, independent of the residence time of the medium. With this device, many studies have been done on initial biofilm formation (Escher and Characklis, 1990), the effect of biofilms on shear stress (Characklis, 1990), and the effect of hydraulics on biofilm formation (Gjaltema et al., 1994). It is difficult to maintain a pure culture in these reactors. The hydraulics are not well-described and not uniform (Gjaltema et al., 1994). Therefore, it now is recognized that this device cannot easily be used for quantitative studies.

Fowler Cell Hydrodynamics are important for the attachment of cells and development of biofilm. The Fowler cell (Fowler, 1988) is a radial flow cell, consisting of two plates mounted parallel to each other. The inlet is mounted in the

center so that flow occurs radially, from the center to the periphery. The flow velocity is the highest in the center and decreases with increasing radial distance. The shear forces can be calculated assuming a flat geometry.

The Modified Robbins Device (MRD) The MRD consists of a square or rectangular channel in a polycarbonate block in which 25 sampling-port studs are inserted along the length of the MRD (Hall-Stoodley et al., 1999). The studs can be fitted with different materials to investigate biofilm formation on different surfaces. The MRD is usually sterilized with ethylene oxide and the studs can be removed aseptically. The advantage of the system is that several samples can be taken simultaneously at different times to study biofilm development. Quantification, such as viable and total cell counts, total protein, and carbohydrate content, is possible on scraped samples. Although it is not possible to observe the biofilms in situ, microscopic analysis is possible using conventional staining techniques of slide-mounted samples or by electron microscopy of the colonized surfaces. The MRD is also relatively inexpensive. It can be used in both batch recirculating and once-through culture systems or can be connected to a chemostat. The major disadvantages of the MRD are the inability to directly observe the biofilm, the possible formation of significant nutrient gradients along the length of the device, and possible eddy generation around the sampling studs.

Constant-Depth Fermenter Biofilms actually never reach a steady state, in which cell growth is balanced by decay and abrasion. Instead, biofilm development is characterized by colonization, growth and sloughing events, and then by regrowth. A special type of biofilm reactor is designed in which the top of the biofilm is constantly (a few times per minute) scraped off and a constant thickness is maintained (Peters and Wimpenny, 1988). Biofilms are grown in plugged holes in a plate, over which a plastic scraper rotates. In this model system, flat biofilms were obtained, which have several advantages including: ease of microprofile interpretation, facilitated determination of D, multiple sampling (30 biofilm surfaces per plate), mass balances throughout the reactor accurately related to the biofilm surface, successional population changes to a steady-state situation followed, and spatial heterogeneity of populations determined (Wimpenny, 1996). The obvious disadvantage of this approach is that the control of the biofilm thickness is very artificial. While in normal conditions an irregular surface develops, perfectly flat biofilms are formed in this model system.

Reactors for Biofilms on Carriers A step in the direction of applied biofilm reactors is to downscale them to laboratory-size systems. Most applied biofilm reactor systems are based on biofilms on carrier-aggregated biomass, such as gas-lift reactors (GLR), fluid-bed reactors (FBR) and upflow anaerobic sludge blanket (UASB) reactors. Gas-lift reactors are attractive laboratory systems as the behavior is almost scale-independent (Beeftink, 1987b), facilitating good comparison with full-scale systems. Moreover, they are well mixed and the amount of samples that can be taken without disturbing the reactor is large. The GLR consist of two reactor compartments, a riser and a downcomer. Gas is pumped in the riser, resulting in an upflow of the water-gas-aggregate mixture. At the top of the riser the gas is separated and the water-aggregate mixture goes down in the reactor through the downcomer. In aerobic GLR, the gas is used for efficient aeration and mixing (Van Houten et al., 1994; van Loosdrecht et al., 1997; Gjaltema et al., 1997); in an anaerobic GLR oxygen-free gas is recycled for mixing only (Beeftink and Staugaard, 1986; Van Houten et al., 1994). The advantage of mixing with gas over mechanical devices (impellers) is the relatively low power input and thus low shear forces. The reactor is completed with an internal or external settler to separate aggregates from the effluent stream.

The FBR is based on suspending aggregates on an upwardly directed liquid flow. This reactor is less well mixed and axial substrate and product gradients develop. This may be a disadvantage for practial use, but for microbial ecology studies such gradient systems can be very useful (Csikor et al., 1994; Buffiere et al., 1995; Shieh and Hsu, 1996; Schramm, 1998a; De Beer et al., 1993).

The UASBs are used commonly for anaerobic treatment of concentrated wastewater. In these reactors, the hydrodynamic regime is so quiet that the aggregates are constantly settling in a sludge layer at the bottom (Hulshoff Pol, 1989; Lettinga, 1995). Laboratory-scale UASB with a volume of 1–3 liter have been used to study methanogenic and sulfidogenic consortia (Thaveeshi et al., 1995; Harada et al., 1994; Koster, 1989) as well as start-up phenomena of methanogenic biofilm reactors (Hulshoff Pol, 1989).

Microscopic and Staining Methods

Microscopy Scanning electron microscopy (SEM), transmission electron microscopy (TEM), normal light microscopy (LM), fluorescence microscopy (FM) and confocal scanning laser microscopy (CSLM) all have been used to study biofilms (Surman et al., 1996). Most microscopic methods involve some preparation of the

sample, including staining, fixation, freezing, dehydration, embedding, and sectioning. For this reason, it is important to realize that biofilms are soft and mostly consist of water (>95%) (Christensen and Characklis, 1990). Preparations for microscopy may significantly change the matrix structure by shrinking and deformation (Stewart et al., 1995), and the resulting artifacts have influenced the concept of biofilm structure for years. Most relevant is the underestimation of the spatial heterogeneity, as several steps in the preparation may level the soft biofilm structures. Then, EPS appears as strands connecting the cells. EPS morphology changes by dehydration: diffuse polymeric matter is condensed to strands, leading to overestimation of the pore-size. From SEM images the pore-size appears to be in the order of 1 μm. Good TEM preparations show a pore size of ca. 100 nm (Beeftink and Staugaard, 1986).

Images acquired by ESEM (Little et al., 1991) and atomic force microscopy (AFM; Bremer et al., 1992) with sub-μm resolution (no dehydration) do not show these strands, but rather a smooth smear. A possible artifact from ESEM is the filling of recesses by water, "drowning" the roughness elements of the surface. The sensor needle of the AFM might disturb the surrounding water, causing the polymers to move and resulting in a blurred image (Bremer et al., 1992). Samples examined by LM, FM, AFM, ESEM and CSLM can be unfixed. The recent application of CSLM has been especially instrumental in changing our concepts of biofilm structure (Lawrence et al., 1991; Massol-Deya et al., 1995; De Beer et al., 1994). With the CSL microscope, living transparent tissues can be sectioned optically, under growth conditions. In as much as out-of-focus fluorescence is effectively removed by the pinhole, the images are much sharper than standard microscopic images. Lawrence et al. (1991) published an excellent description of confocal microscopy techniques for biofilm research. Scanning electron microscopy, ESEM and AFM can be used for surface scanning, while the other techniques to some extent allow observation below the surface.

Staining Specific staining is an important tool to unravel the spatial distribution of different biofilm components, most importantly in cells, EPS and voids (Table 5). For viewing cells, stains nonspecific for DNA, such as acridine orange, diamidino-phenylindole (DAPI), ethidium bromide, and hexidium iodide are most useful. These dyes can be combined with confocal microscopy, thus giving an image of cell distributions in undisturbed biofilms or mats. Species-specific staining by oligonucleotide probes or antibodies will be treated elsewhere.

Much less attention has been paid to visualization of EPS. Staining of EPS for fluorescent microscopy or CSLM is possible for proteins (fluorescein isothiocyanate), polyuronic acids and polysaccharides (lectin conjugates, calcofluor). Calcofluor stains most polysaccharides (attaching to β-1,4 and β-1,3 polysaccharides; Haigler et al., 1980), while lectins are more specific. Also, EPS dyes will stain cells that become visible as discrete points, whereas EPS appears as a continuous sheet. *The Handbook of Fluorescent Probes and Research Chemicals* (a catalogue of molecular probes) is a highly valuable source of information about dyes and staining techniques (Haugland, 1996). Also, EPS can be stained by ruthenium red for TEM or observed directly by SEM. Voids can be made visible with negative staining using fluorescein that is quenched by the presence of biomass. Using CSLM, voids appear as bright fluorescent areas, while biomass remains dark (see Fig. 4a, De Beer et al., 1994; Lawrence et al., 1991). Also fluorescent microbeads can be used that penetrate the voids but not the cell clusters (Stoodley, 1998).

In conclusion, several new microscopic techniques now make it possible to get a much more detailed view of biofilm structure.

Microbial Activity

As biofilms consist of thin but often dense layers of cells, many trophic interactions between different populations may occur on a small scale. Examples are nitrification and denitrification, sulfate reduction and sulfide oxidation, photosynthesis and respiration. Few methods are suitable to measure in situ these coupled processes on such a small scale. Activity tests on subsamples give at best an impression of the distribution of potential activities, but do not reflect the actual rates (Okabe et al., 1996). Analysis based on in situ detection of mRNA is not developed as yet for complex communities, and its value as a quantitative method is doubtful. With autoradiography, it was possible to detect substrate use on a cell level (Andreasen and Nielsen, 1997); however, this method does not give local rates. Microsensor techniques are probably the most suitable for unraveling processes in thin complex communities. The local net consumption or production rates can be calculated from microprofiles with a spatial resolution of 25–50 micron. The main prerequisite is that the different processes must be spatially separated, with a distance of some tens of microns (with the exception of coupled photosynthesis and respiration).

Microsensors Depending on growth conditions and age, the thickness of biofilms, aggregates and

Table 5. Dyes for structural analysis of biofilms and microbial mats.

Structure	Dye	Microscopy	Staining
Cells	Classical stains (crystal violet, Gram, etc.)	LM	All cells
	Acridine orange DAPI	FM and CSLM	All cells
	Ethidium bromide	FM and CSLM	Dead cells
	Eropidium iodide		
	Hexidium iodide	FM	Living cells
	CTC, formamide	FM and CSLM	Respiratory active cells
Voids and channels	Dextran conjugate	FM	Voids
	Beads	FM and CSLM	Voids
	Fluorescein	CSLM	Voids
EPS	Alcian blue	LM	EPS (carbohydrates)
	Lectins	FM and CSLM	EPS (carbohydrates)
	Calcofluor	FM and CSLM	EPS (carbohydrates)
	FITC	FM and CSLM	EPS (proteins)
	Heavy metals	TEM	Cells, EPS

Abbreviations as stated in Table 4; DAPI, 4′,6-diamidino-2-phenylindole; and CTC, cyanoditolyl tetrazolium chloride.

flocs can reach from μm to cm, and the structural heterogeneity can be pronounced. The active zones are typically on the order of a few mm or less. This requires experimental techniques with a high spatial resolution, and here microsensors have proven highly useful tools to study the biofilm and mat microenvironments and microbial activities in immobilized cell systems (including sediments). Microsensors are needle-shaped devices with a tip size of 1–20 μm and can measure the concentration of a specific compound. Owing to the small sensing tip, highly localized measurements are possible. Although the technique is invasive, the small tips do not influence structures or processes significantly. With microsensors the spatial distribution of substrates and products can be determined, and from this, the distribution of microbial activity can be inferred.

Niels-Peter Revsbech introduced microsensors in microbial ecology (Revsbech, 1983) and also constructed the first reliable O_2 microsensors for profiling sediments and biofilms (Revsbech, 1989). Other microsensors relevant for microbial ecology were developed and used, such as for N_2O (Revsbech et al., 1988), pH (Hinke, 1969; Lee and De Beer, 1995), NH_4^+ (De Beer and van den Heuvel, 1988), NO_3^- (De Beer and Sweerts, 1989; Larsen et al., 1996), S^{2-} (Revsbech, 1983), H_2S (Jeroschewski, 1996), NO_2^- (De Beer et al., 1997), CH_4 (Damgaard and Revsbech, 1997; Damgaard, 1995), CO_2 (De Beer et al., 1997), and HClO (De Beer et al., 1994) determination. Reviews have been published on construction and use of microsensors and on interpretation of results (Thomas, 1978; Revsbech, 1986; Kühl and Revsbech, 1998; De Beer, 1998; De Beer, 1999). Here only a brief summary is given. Microsensors are based on amperometric, potentiometric or optical principles.

Amperometric sensors are based on current measurements induced by the electrochemical reduction or oxidation of the substrate in the tip, with a rate proportional (usually linearly) to its concentration. Useful O_2, N_2O, H_2S and HClO sensors are based on this principle. Many research groups have used O_2 microsensors for study of photosynthesis and respiration. Such studies are done in biofilms (De Beer et al., 1994; Kühl and Jørgensen, 1992; Lewandowski, 1991; Zhang, 1994; Harmer and Bishop, 1992; Zhang, 1996), activated sludge flocs (Schramm, 1998a; Lens et al., 1995), and marine snow (Ploug et al., 1997). The N_2O sensor has been used for denitrification studies in biofilms and microbial mats (Revsbech et al., 1988); the development of nitrate sensors has made this sensor obsolete for this purpose. The new H_2S sensor is used to study sulfate reduction and sulfide oxidation in biofilms (Santegoeds et al., 1998) and activated sludge (Schramm et al., 1998b). The HClO microsensor is used in biofilm disinfection studies (De Beer et al., 1994; Xu et al., 1995).

The variety of measurable substrates has been expanded by applying enzymes or bacteria as catalysts for the formation or consumption of redox-active compounds in the sensor. Glucose oxidase has been used for glucose sensors (Cronenberg et al., 1991), cultures of methane oxidizers in methane sensors (Damgaard and Revsbech, 1997) and pure cultures of incomplete denitrifiers in nitrate and nitrite sensors (Larsen et al., 1997; Larsen et al., 1996).

Potentiometric microsensors measure electrical potential generated at the tip by charge separation. The oldest potentiometric microsensor is the full glass pH sensor (Hinke, 1969). It is versatile (Revsbech, 1986), has a low spatial resolution owing to its 100-μm long tip, and has an ca. 30-second response time. The AgS-membrane S^{2-} electrode has been very useful in studies of

the sulfur cycle in microbial mats and biofilms (Kühl and Jørgensen, 1992; Revsbech, 1983), but it must be used with care and in absence of oxygen. The H_2S sensor has no such problems and can be used for the same research. The H_2S sensor is most suitable for environments with low pH (>8), whereas the S^{2-} sensor may still be necessary in environments with high pH. The liquid membrane ion-exchanging (LIX) microsensor technique was developed by cell physiologists for intracellular measurements (mostly of CO_3^{2-}, Mg^{2+}, Li^+, Na^+ and K^+). These sensors can be very small (with a tip diameter of less that 1 μm, the size of a bacterial cell) and are used to measure NH_4^+ (De Beer and van den Heuvel, 1988), NO_3^- (De Beer and Sweerts, 1989; Jensen, 1993), NO_2^- (De Beer et al., 1997), H^+ (Schulthess et al., 1981), CO_2 (De Beer et al., 1997) or CO_3^- (Müller et al., 1998). The NH_4^+, NO_3^- and NO_2^- sensors are used to study the nitrogen cycle in biofilms and in sediments from freshwater environments (De Beer et al., 1991; Sweerts and De Beer, 1989; Jensen, 1993; De Beer et al., 1997), and the H^+ and CO_2 sensors are used for studies on photosynthesis and respiration in algal mats.

Ion-selective microsensors have some disadvantages. Often their selectivity is not very high. Because of interference by Na^+ or Cl^- ions, measurements cannot be made in marine environments, with the exception of pH, S^{2-} and Ca^{2+}. However, their value for studies in freshwater environments is high, and no alternative exists for NH_4^+, NO_2^-, and NO_3^- microsensors. They last only ca. 1 day; however, they are easy to construct. Finally, these sensors have behaved unpredictably in some circumstances, readings drifting radically, for example, upon penetration of the biofilm. Most likely this is caused by dissolution of hydrophobic biofilm compounds in the LIX membrane. The microsensor can be protected from this phenomenon with a hydrophilic protein layer (De Beer et al., 1997).

Micro-optodes are based on the change of optical properties (fluorescence intensity or fluorescence lifetime) of a layer covering an optical microfiber. Microsensors are developed for O_2, pH and temperature. The presence of the substrate induces quenching of the fluorescence intensity or decrease of the fluorescence lifetime. Klimant et al. (1997) gave a description of the theory and practice of this technique. Advantages of optical sensors are their ease of manufacture, insensitivity to noise, stability of calibration, and mechanical strength. Disadvantages include their size (ca. 20 μm), limited types of sensors available, and cost of the opto-electronics.

Typical experiments measure transient concentration changes at a fixed position and concentration profiles. Transient concentration changes are measured during photosynthesis with the fast light-dark shift (Revsbech, 1983) or for the in situ determination of diffusion coefficients (Cronenberg, 1994a; Cronenberg, 1994b). For these types of experiments we refer to the literature; the interpretation of profiles will be discussed below.

Interpretation of Profiles Profiles give information on microbial activity as well as insight into the microenvironments in biofilms. Microprofiles depend on mass transfer and microbial conversions. Consequently, if the transport processes are known, information on the distribution of microbial activity can be derived from the measured profiles. Because of microbial conversion and mass transfer resistance effects, substrate and product profiles develop inside biofilms. If the biofilm is impermeable, diffusion is the only transport mechanism inside the matrix. The turbulent bulk liquid is usually well mixed by advective transport (transport by liquid flow). Adjacent to the matrix is a viscous boundary layer in which the mixing and flow velocity gradually decrease as the surface is approached. Consequently, the mode of transport changes gradually from advectional in the bulk liquid to diffusional in the laminar boundary layer. Diffusional transport is driven by the concentration differences as expressed in Fick's law:

$$J = D\frac{dc}{dx} \tag{1}$$

where J is the flux ($mol \cdot m^{-2} \cdot s^{-1}$), D is the diffusion coefficient ($m^2 \cdot s^{-1}$), dc is the change in concentration (in mols) over the distance dx (in meters); dc/dx is the concentration gradient. In steady state, local conversion rates are equal to transport rates. Assuming a constant D, the mass balance becomes for a planar geometry:

$$D\frac{d^2c}{dx^2} = r \tag{2}$$

where r is the conversion rate. With Eq. 2 the concentration profiles can be calculated for zero- and first-order kinetics, assuming a homogeneous activity distribution. In reality, the assumptions are often too simple: conversions are of mixed-order kinetics (Monod) and the distribution of activity is varying with depth. Then only with iterative computer modeling, concentration profiles can be calculated. By fitting calculated with measured profiles, a good estimation can be made of the distribution of microbial activity (Revsbech, 1986; Berg, 1998). The executable code of the procedure from Berg et al. (1998) is available by e-mailing the author (pb8n@virginia.edu). A more direct approach is

to derive the local activities from the profiles. Assuming a measured profile consisting of three measured points (a, b, and c), the flux between a and b and b and c can be calculated from Eq. 1:

$$J_{ab} = D_{ab}\frac{(c_a - c_b)}{(x_a - x_b)} \quad \text{and} \quad J_{bc} = D_{bc}\frac{(c_b - c_c)}{(x_b - x_c)}$$

This gives the best estimate for the fluxes through the intermediate points between the measurements, $0.5(x_a + x_b)$ and $0.5(x_b + x_c)$. If the system is in steady state, then the difference in fluxes through these points is equal to the local conversion in point b, which is approximated by:

$$r_b = \frac{J_{ab} - J_{bc}}{0.5(x_a + x_b) - 0.5(x_b + x_c)} \qquad (3)$$

If D is constant with depth and we measure with constant depth intervals, δx, then

$$r_b = D\frac{c_a - 2c_b + c_c}{\Delta x^2} \qquad (4)$$

This approach needs high spatial resolution microprofile measurements. Since noise is magnified, a smoothing procedure is recommended. Alternatively, the profiles can be fitted with a polynome. Then the local fluxes are given by the product of the derivative of that polynomial function and D. The local activities are calculated by the product of the second derivative of the function and D.

When D_{eff} is varying with depth, the local fluxes must be calculated with the local D_{eff}, using Eq. 1, and local activities calculated with Eq. 3. All these calculations can be conveniently done with a spreadsheet.

An example of such an analysis is given in Fig. 12. In a biofilm, profiles of O_2, NO_2^-, NO_3^-, and H_2S were measured. From these profiles the aerobic respiration, nitrate consumption (denitrification), and sulfate reduction rates could be calculated. The analysis shows nicely the stratification of processes, i.e., the sequence of used e-acceptors.

Although activity profiles are valuable, combining these data with bacterial population distribution allows a more complete analysis of the microbial activities in biofilms. By aligning population and activity distributions, it can be determined which microorganisms are responsible for certain conversions (Ramsing et al., 1993; Santegoeds et al., 1998). The use of molecular techniques, techniques for population analysis (e.g., DGGE) and population distribution (using fluorescent in situ hybridization, FISH) has resulted in discovery of new species and their distribution within biofilms. With microsensor analysis and FISH, the ecological niche and kinetic data could be determined from these up-to-now uncultivable species (Schramm, 1998a; Schramm et al., 1998b).

Population Analysis

Cultivation Techniques: Microslicing, Most Probable Number (MPN) Technique, Plate Counting The classical microbial approach for population analysis is based on cultivation techniques, such as plate counting and MPN. However, it has become clear that these techniques select for certain organisms and thus do not give quantitative data (Staley and Konopka, 1985). Subpopulations of environmental samples cannot be cultivated and thus do not appear in MPN or platecounts (Torsvik et al., 1990; Wayne et al., 1987). Even key players of a community may not be identified (Wagner et al., 1993; Wagner et al., 1994; Schramm et al., 1998b). Consequently, cultivation techniques give a strongly biased picture of complex microbial communities in biofilms. Moreover, assessment of microscale distribution of microorganisms is very difficult. Okabe et al. analyzed the distribution of heterotrophic and nitrifying organisms by slicing living biofilms horizontally in 100–250 μm thick sections and enumerating organisms by MPN and plate counting (Okabe et al., 1996a; 1996b). However, since active zones in biofilms are often in the order of 50–100 μm, even this fine-scale technique is too coarse. To avoid these limitations, techniques were developed for identification and counting without cultivation steps.

Molecular Techniques Species-specific detection of strains is possible with antibodies and analysis of nucleic acids. Both techniques have been used on preparations of dispersed communities (fingerprinting) and on intact biofilms or preparations in which the integrity is maintained (in situ detection). Fingerprinting with antibodies has been described for nitrifiers (Sanden et al., 1994; Both et al., 1992) and methanogens (Kobayashi et al., 1988). More often, in situ analyses (with fluorescently labelled antibodies) are used to detect the spatial distribution of certain microorganisms (Zellner et al., 1995; Kobayashi et al., 1988; Buswell et al., 1998; Coughlin et al., 1997; Sonne Hansen and Ahring, 1997; Zellner et al., 1997; Stewart et al., 1997; Morin et al., 1996; Roberts and Keevil, 1992; Hunik et al., 1993). Beside technical difficulties, such as nonspecific binding, the preparation of specific antibodies requires pure cultures. Consequently, the antibody technique is not really culture-independent, as only antibodies can be developed for organisms that can be cultivated.

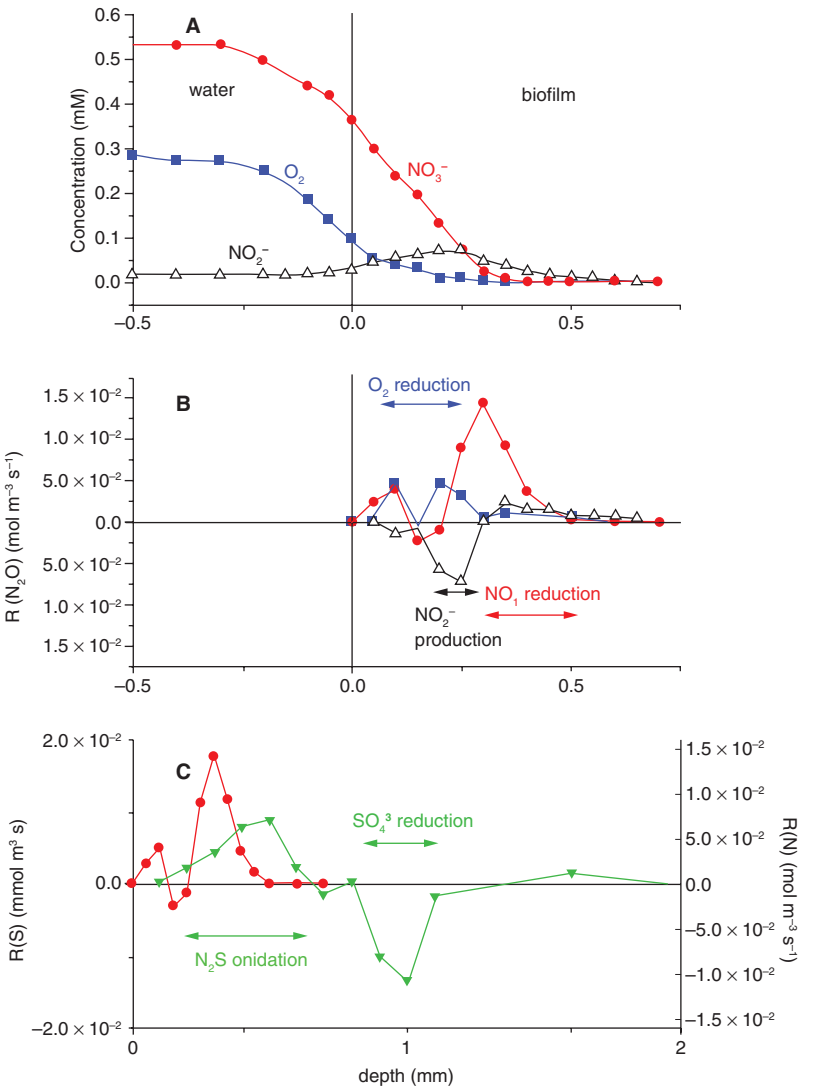

Fig. 13. Oxygen, nitrate, and nitrite profiles in a thick biofilm from a wastewater treatment plant (A) and local conversion rates calculated from these profiles (B). In (C) also the total sulfide conversion rates are plotted (sulfide profiles not shown), demonstrating that sulfide production occurs in the deep biofilm (ca. 1-mm depth) and sulfide oxidation overlaps with the denitrifying zone.

With the nucleic acid approach, population analysis is possible without cultivation. Currently, most efforts are directed to the analysis of ribosomal RNA, recently reviewed by Schramm and Amann (1999). For several reasons, 16S RNA sequence analysis is a powerful tool for the classification of microorganisms (Woese, 1987; Maidak et al., 1994). Ribosomes are present in all organisms, thus this piece of genetic material is universal. Part of the RNA molecules is identical for all microorganisms, while other regions are less well-conserved. Thus sequences can be found that are specific for different taxonomic levels, from species, genera, kingdoms and domains. Public databases contain 16S RNA sequences from many of the described bacterial species. Microbial cells contain 1,000 to 30,000 copies of 16S RNA molecules, allowing sensitive assays and identification of single cells by fluorescent oligonucleotide hybridization.

Fingerprinting techniques for populations based on 16S rDNA analysis are ARDRA (amplified ribosomal DNA restriction analysis; Heyndrickx et al., 1996), DGGE (Muyzer and De Waal, 1994) or TGGE (temperature gradient gel electrophoresis), and T-RFLP (terminal restriction fragment length polymorphism; Liu et al., 1997). These techniques all involve isolation of DNA, amplification of the genes or gene fragments encoding for 16S RNA by PCR (polymerase chain reaction).

In the procedure of ARDRA and T-RLFP, first the complete 16S RNA genes are amplified by PCR; this is followed by a digestion with restriction enzymes and size separation of the fragments by gel electrophoresis. ARDRA is used for fast screening of isolates, particularly giving information on similarities. ARDRA is less suitable for community analysis because of the complexity of resulting band patterns. T-RLFP

results in community fingerprints which can demonstrate the diversity and dynamics of microbial communities. However, different species have often similar fragment lengths, leading to an underestimation of the diversity. The more sensitive alternatives are DGGE and TGGE (Schramm and Amann, 1999).

For DGGE and TGGE only fragments are amplified (200–500 bp) and a GC-rich sequence of 40 bp is added at one end. With an increasing gradient of DNA denaturing agents, denaturation of double-stranded to single-stranded DNA fragments will occur at a position in the gel that depends on the composition of the DNA fragment (G+C content, sequence). Upon denaturation, the migration of that gene fragment stops. Consequently, fragments of the same length but with different sequences can be effectively separated, resulting in a band pattern reflecting the microbial diversity of the community. The sensitivity of DGGE is ca. 1%, meaning that bacterial populations making up 1% or more of the total community can be detected (Muyzer and Smalla, 1998). These methods (DGGE and TGGE) are very useful for detecting population changes of complex microbial communities. Bands in the gel can be further identified by hybridization analysis with specific probes (complementary fluorescently labelled DNA fragments). Also, bands can be retrieved from the gel and sequenced after amplification and cloning. Comparing the sequence with a data base allows identification or affiliation of the band within a phylogenetic tree. Although molecular methods may suffer from biases, they are probably less biased than cultivation methods. DNA has to be extracted, and not all cells may lyse. Furthermore, preferential amplification of DNA during the PCR can occur, and consequently, the band intensity in DGGE gels must not be interpreted as a quantitative measure for species abundance (Schramm et al., 1998b). Quantitative analysis is possible with hybridization, either dot-blot hybridization (Stahl et al., 1988) or in situ hybridization (Amann, 1995) with labelled oligonucleotide sequences targetting rRNA. After sequencing, it is possible to design a probe (with a fluorescent marker) targetting that sequence, and use it for FISH. Then, by a combination of FISH with microscopic analysis and cell counting, quantitative analysis is possible of uncultivated, and even uncultivable, species in environmental samples.

Fluorescent in situ hybridization (FISH) is a recently developed, very powerful tool to quantify populations within a microbial community and to determine the spatial distributions of populations on different taxonomic levels. Instead of extracting nucleic acids, the cells are gently permeabilized so that fluorescently labelled 16S RNA probes, small fragments of up to 20 bp, can enter the cells and hybridize with rRNA. Probes can be labelled with different fluorescent dyes, each with distinct excitation and emission spectra. Thus, two or more probes can be used simultaneously to detect different (up to seven) populations within one sample (Amann et al., 1996). However, the spatial distribution of populations as determined with FISH does not give information on the activity of the cells. The populations detected are there, but can be inactive or dead. Conversion rates can be derived from microprofiles determined with microsensors. At the moment, the combination of in situ techniques, i.e., molecular and microsensor techniques, gives the most accurate characterization of microbial interactions and activities in complex microbial communities.
