Preface

Each of the first two editions of *The Prokaryotes* took a bold step. The first edition, published in 1981, set out to be an encyclopedic, synoptic account of the world of the prokaryotes—a collection of monographic descriptions of the genera of bacteria. The Archaea had not yet been formalized as a group. For the second edition in 1992, the editors made the decision to organize the chapters on the basis of the molecular phylogeny championed by Carl Woese, which increasingly provided a rational, evolutionary basis for the taxonomy of the prokaryotes. In addition, the archaea had by then been recognized as a phylogenetically separate and distinguishable group of the prokaryotes. The two volumes of the first edition had by then expanded to four. The third edition was arguably the boldest step of all. We decided that the material would only be presented electronically. The advantages were obvious and persuasive. There would be essentially unlimited space. There would be no restrictions on the use of color illustrations. Film and animated descriptions could be made available. The text would be hyperlinked to external sources. Publication of chapters would be seriati—the edition would no longer have to delay publication until the last tardy author had submitted his or her chapter. Updates and modifications could be made continuously. And, most attractively, a library could place its subscribed copy on its server and make it available easily and cheaply to all in its community. One hundred and seventy chapters have thus far been presented in 16 releases over a six-year period. The virtues and advantages of the online edition have been borne out. But we failed to predict the affection that many have for holding a bound, print version of a book in their hands. Thus, this print version of the third edition shall accompany the online version.

We are now four years into the 21st century. Indulge us then while we comment on the challenges, problems and opportunities for microbiology that confront us.

Moselio Schaechter has referred to the present era of microbiology as its third golden age—the era of "integrative microbiology." Essentially all microbiologists now speak a common language. So that the boundaries that previously separated subdisciplines from each other have faded: physiology has become indistinguishable from pathogenesis; ecologists and molecular geneticists speak to each other; biochemistry is spoken by all; and—mirabile dictu!—molecular biologists are collaborating with taxonomists.

But before these molecular dissections of complex processes can be effective there must be a clear view of the organism being studied. And it is our goal that these chapters in *The Prokaryotes* provide that opportunity.

There is also yet a larger issue. Microbiology is now confronted with the need to understand increasingly complex processes. And the modus operandi that has served us so successfully for 150 years—that of the pure culture studied under standard laboratory conditions—is inadequate. We are now challenged to solve problems of multimembered populations interacting with each other and with their environment under constantly variable conditions. Carl Woese has pointed out a useful and important distinction between empirical, methodological reductionism and fundamentalist reductionism. The former has served us well; the latter stands in the way of our further understanding of complex, interacting systems. But no matter what kind of synoptic systems analysis emerges as our way of understanding host–parasite relations, ecology, or multicellular behavior, the understanding of the organism as such is sine qua non. And in that context, we are pleased to present to you the third edition of *The Prokaryotes*.

Martin Dworkin
Editor-in-Chief

Contents

Volume 2

1. Ecophysiological and Biochemical Aspects

Volume 3

A: Archaea

Volume 4

1. Firmicutes (Gram-Positive Bacteria)

1.2 Firmicutes with Low GC Content of DNA

Volume 6

Volume 7

3. Proteobacteria

3.4. Delta Subclass

3.5. Epsilon Subclass

4. Spirochetes

CHAPTER 1.1

How We Do, Don't and Should Look at Bacteria and Bacteriology

CARL R. WOESE

Background

To try to plan for the future without a sense of the past is like trying to plant cut flowers.
(Daniel Boorstein)

Microbiology today has a new-found wealth far greater than any it possessed before. The source of that wealth is the universal phylogenetic tree—the framework essential for understanding organismal relationships. The power that flows from phylogenetic ordering permeates the field. Microbiologists now accomplish with ease things that were previously impossible and approach bacteria in ways that 20 years ago were unthinkable. Microbial ecology is no longer the *faux* ecology it had been—when defining a niche in organismal terms was not an option. Today the field rests on a par with plant and animal ecology and exceeds them in importance, for it is in the microbial realm that the base and fount of the global ecosystem lie. Studying microbial diversity used to be the equivalent of hunting through antique shops for curios—which resulted in a collection of species no more connected to one another than the items in a bower bird's nest. Now all organisms sit on the well-ordered tips of branches on the universal phylogenetic tree (Woese, 1987; Olsen et al., 1994), and the study of one, far from being an isolated adventure, can contribute to the study of all. An interest in bacterial evolution used to be perceived as metaphysical and worthless. Today evolutionary relationships are the foundation and motive force behind a new and resurgent microbiology, and thence biology as a whole.

Microbial genomes can be sequenced today in their entirety, and when measured against the information gained, the cost of so doing is actually small—and that cost is continually decreasing. An exploration of a given bacterium can now start with knowledge of all of its genes. Not only are we (potentially) privy to the full range of the organism's biochemistry, but we possess a partial but very useful record of its evolutionary past. This historical record, it turns out, extends so far back into biological antiquity that the study of bacterial evolution fuses with the study of the origins of modern cells (Woese, 2002).

Unfortunately, the universal phylogenetic tree, bacteriology's essential framework, arrived rather late in the course of events. Its belated arrival adversely affected not only the development of microbiology but that of all biology (see below). Consequently, the introductory chapter to the third edition of *The Prokaryotes* is largely devoted to understanding the historical development of bacteriology, for in its twists and turns lie insights into much of what microbiology and biology are today, as well as a guide to their future development.

The editors of the second edition of *The Prokaryotes* wisely decided to give the volume phylogenetic underpinnings (as best they could at the time). In this third edition, the trend continues, and the book's phylogenetic bent is more pronounced. Bacterial taxonomy, which only two decades ago was a dry subject whose main if not only purpose was determinative classification, identification of species, has now blossomed into an intriguing, meaty study in its own right. As you use this third edition of *The Prokaryotes* realize that the book is not merely a manual for identification, cultivation, and determinative classification. Use it for what it really is, a long overdue treatise on comparative bacteriology. If you let your imaginations follow the evolutionary trails the book lays out, they will lead you to the edge of microbiology's future. Most of all, let this work by its structure open your eyes to the emerging world of bacterial evolution and the challenge that poses to all of biology. This is not the evolution that Darwin and the classical evolutionists had in mind. It is centered on physiologies rather than forms, on molecules rather than gross morphologies. And it extends the scientific reach much further into the past than was ever before possible. But to begin charting the future, we need a map of the past. As in so many walks of life, a knowledge of history is the best guide we have.

Microbiology's Halting Development

Prior to its phylogenetic liberation, microbiology had long been mired down conceptually, sinking ever deeper as twentieth century biology unfolded. This descent into innocence started long before that, however, when microbiologists failed to develop a phylogenetic, or "natural," classification system for bacteria based upon the classical characteristics available to them. As a consequence, bacteriology's development became increasingly one-sided, so much so that from an organismal perspective, the discipline developed not at all. The condition was chronic, progressing over several generations of microbiologists, and so, was scarcely felt, and to the extent that it was felt, the condition was accepted as normal.

One of the rare (if not only) times the problem was brought to the fore was in 1962 when Stanier and van Niel lamented: "... the abiding intellectual scandal of bacteriology has been the absence of a clear concept of a bacterium." Unfortunately, the authors' suggested remedy for the malaise was untenable, as we shall see, and as a consequence served to encourage the unfortunate changeover from the name "bacteriology" to "microbiology," a change that dogs microbiology to this day. A label that had denoted the study of what seemed a naturally defined grouping of organisms, "bacteriology," was replaced by one that encompassed an organismal *potpourri*. One can in principle have a biologically valid, unified concept of "bacteria," but a comparable unifying concept of the artificial grouping "microorganisms" is impossible. The semantic thimblerig involved in this name change was one of the factors that helped to push the problem of a "concept of a bacterium" off the table. From a basic scientific perspective, bacteriology in 1992 was worse off than it had been in 1962. But by 1992, bacteriology had a powerful remedy for the situation.

What Is Bacteriology?

Whatever else it is, bacteriology is first and foremost an *organismal science*, just as are zoology and botany. As such, its focus is understanding particular naturally defined groupings of organisms. A critical difference between bacteriology and the other two organismal sciences, however, is that the other two could develop as organismal sciences in the absence of molecular characterizations, whereas bacteriology could not. Bacterial morphologies are too simple and variable to have much phylogenetic significance, but phylogeny is embedded in the complex morphologies and variations on morphological themes characteristic of animal and plant life. In the bacterial world it is physiology (not morphology) that predominates and distinguishes. But, physiological characteristics have so far proven phylogenetically intractable. Whereas amongst eukaryotes, organization manifests itself predominately in structure, organization in the bacterial world occurs mainly in the shifting and subtle biochemical states of the system—something the eye cannot directly apprehend. In the absence of a knowledge of phylogenetic relationships, a concept of bacteria was unattainable.

What exactly is an organismal science? Simply put, one that seeks to understand naturally defined groups of organisms in *biological terms*. Such an understanding has four principal components: 1) structure/function—how the organisms in the group are built (organized) and how they work; 2) diversity—how many and what kinds of organisms the group comprises, and the ways in which the various kinds are similar and different; 3) ecology—how the organisms interact with their environments (including other organisms); and 4) evolution—the origins of the group and how the organisms therein are ancestrally related. This last, evolution, is what underlies and enables the development of a biological concept of a group. As Dobzhansky famously put it "... nothing in biology makes sense except in the light of evolution" (Dobzhansky, 1963). And it was the lack of this essential evolutionary framework that prevented bacteriology from developing as an organismal science.

With no understanding of phylogenetic relationships, there can be no effective study of ecology or diversity. Ecological niches cannot be defined in organismal terms, and studies in bacterial diversity amount to no more than a catalog of disconnected vignettes. It is inconceivable that a zoologist or botanist could go into the field and not be able to distinguish the animals from the plants. Yet would-be microbial ecologists were in this exact position or worse all the time: they couldn't distinguish their "animals" from their "plants" or (with a few exceptions) from representatives of any others of the many kingdom-level bacterial taxa.

Blocked from developing into a full-fledged organismal science throughout most of the twentieth century, bacteriology wandered aimlessly, not knowing what it was, where it came from, or what it should become. The field was driven by the winds of scientific fad and other outside influences. Any development our science did undergo was confined to its structure/function aspect and its applied side. With exceptions too rare to impact, twentieth century microbiologists (and biologists in general) remained unaware of microbiology's "identity crisis."

Dumbing Down

What more than anything served to obscure bacteriology's structural problem was the molecular perspective dominating twentieth century biology. Molecular biology embodies a reductionist fundamentalism that rules out any holistic perspective. The paradigm assumed that the age-old problem of biological organization would be automatically solved when comprehensive molecular parts-lists for cells were generated. Yet even with the parts-lists now in hand, the problem remains with us, awaiting a fresh, constructive, and holistic outlook. The molecular perspective took evolution for granted, found it intellectually wanting, and dismissed its study as trivial. In such a fundamentalist milieu, the organism *per se* has only a secondary existence, shadowy and temporal. For molecular biology, the organism lies essentially in its collective parts (which molecular biologists felt no compulsion to reassemble into a whole). Little wonder that under the molecular aegis, bacteriology felt no need to develop into an organismal science, even if it *could* have done so. Instead, microbiology followed molecular biology's lead and slipped into a mechanistic reductionism.

Much of the important biochemistry of the last century was done in bacterial systems. Bacteria—with their enormous population numbers, rapid growth rates, and general ease of handling—also proved well suited to many of the contemporary studies in genetics and molecular biology. In one sense, great progress occurred in microbiology over the last five or so decades. None of it, however, contributed to the development of a concept of bacteria.

Bacteriology's Wandering Course

It is difficult to know where you are going if you don't know where you came from. And if you don't know where you are going, the saying goes, any path will take you there. The future course of bacteriology (microbiology) is not something that can be left to the vagaries of chance and necessity. How bacteriology now develops is a matter of utmost concern. *The future of all biology turns upon it.*

Although Leeuwenhoek discovered the microbial world during the time of Newton, microbiology did not emerge as an effective science until two centuries later. In the last half of the nineteenth century the works of scientists like Cohn, Koch, and Pasteur laid the groundwork. And with the next generation of microbiologists, the Beijerincks, Winogradskys, and Orla-Jensens, the study of microorganisms began in earnest. The grouping of microbiologists that grew around Beijerinck and then Kluyver, known as the Delft School, became the dominant influence in microbiology for most of the twentieth century. Among the School's members, one finds articulate spokesmen with an overview of their discipline. So, it is to the Delft School that we mainly turn to learn the early history of microbiology.

Martinus Beijerinck is the actual founder of the Delft School, although Leeuwenhoek, who had lived in Delft, is portrayed as its spiritual father (van Niel, 1949). Beijerinck is credited, along with Winogradsky, with the development of enrichment culturing, through which methodology microbiologists could begin a major exploration of the nature and scope of the microbial world. Beijerinck's contributions were many and varied (van Iterson et al., 1940): he added greatly to the understanding of bacterial physiology and diversity. Through his studies on iron bacteria and the like, he was one of the first to appreciate the intimate role bacteria play in geologic processes. He was keenly aware of developments in genetics (in the higher forms) and was perhaps first to suggest that some of the variation seen in the microbial world was of mutational origin. His discovery of a filterable factor associated with tobacco mosaic disease made him a pioneer in virology. And he was keenly aware of Darwin. How did this enlightened Dutch scientist view the study of microorganisms? On the occasion of his being awarded the Leeuwenhoek Medal (microbiology's highest and his most prized honor), Beijerinck addressed the question:

> [M]icrobial ecology . . . is the most necessary and fruitful direction to guide us in organizing our knowledge of that part of nature which deals with the lowest limits of the organic world, and which constantly keeps before our minds the profound problem of the origin of life itself (Beijerinck, 1905; van Iterson et al., 1940; translated by van Niel, 1949).

This is a sophisticated view of microbiology. The importance of the microbe-environment relationship is foremost, with (microbial) evolution constantly in the background, shaping and deepening the outlook. To me, Beijerinck's concept of the microbial world seems deeper and more holistic than any that followed until the present day, when the realities of genomics are bringing us once more to a similarly broad and inspiring perspective on bacteria and their world.

In this quote (and in his studies), Beijerinck did not (to my knowledge) speak to the importance of determining the natural relationships among microorganisms. It is possible he did not believe (as others of his day did not) that bacteria evolved in a Darwinian fashion, as animals and plants do. I would prefer to believe, however—especially given his familiarity with Darwin's writings (van Iterson et al., 1940)—that

Beijerinck saw no way to determine these relationships given the primitive state of bacteriology in his day. Only with the later accumulation of large numbers of bacterial species (mainly through enrichment culturing) would the problem of their classification become a choking one, and only then, when traditional taxonomic approaches failed to yield a satisfactory (natural) classification system, would the problem become genuinely acute (Stanier and van Niel, 1962).

Beijerinck's successor at Delft was Albert Jan Kluyver. A brilliant and sophisticated scientist, Kluyver was by training a biochemist, not a microbiologist. Only upon assuming Beijerinck's chair did he transform himself into the latter (Kamp et al., 1959). It is in Kluyver that I see the beginning of bacteriology's drift away from striving to become an organismal discipline. Kluyver is noted, and rightly so, for his fundamental, unifying contributions to biochemistry (Kluyver and Donker, 1926; Kluyver, 1931). He pioneered what he called "comparative biochemistry," a field he envisioned as "... benefit[ing] biochemistry in a manner similar to that in which the concept of 'comparative anatomy' had helped to bring order into [anatomy]" (Kluyver, 1931; van Niel, 1949). Yet in one way, the analogy deceives. Comparative anatomy is basically an organismal, evolutionary pursuit. Comparative biochemistry is not. The latter is simply a way to bring some chemical order to the plethora of biochemistries that abound in nature. Kluyver's simile here veils the important distinction between the organism and its parts. My assertion that Kluyver represented (or came to represent) the biochemical dissection of bacteria rather than an organismal comprehension thereof finds indirect support in van Niel's historical account of the Delft School, which details Kluyver's contributions to biochemistry while failing once to mention Kluyver's (and his own) concerns with developing a natural bacterial classification (van Niel, 1949).

The Gordian Knot of Bacterial Classification

The Linnean system had proven extremely useful in structuring our knowledge of zoology and botany, making both into respectable organismal sciences even before Darwin's time. Darwin's theory did not change the Linnean classification of animals and plants all that much; it merely provided it theoretical justification (Darwin, 1859).

Early microbiologists were aware of the benefits of "natural" classification. Yet I have never satisfied myself as to the degree of their commitment to or the depth of their appreciation of evolution. Was a natural system merely the most useful classification, or were bacteria given the evolutionary significance Beijerinck (quoted above) seemed to accord them? Clearly, most microbiologists of the time simply wanted some kind, any kind, of useful pigeonholing system. *Bergey's Manual*, a (much criticized though popular) determinative system, provided precisely that (Stanier and van Niel, 1941).

Kluyver and van Niel's classic paper of 1936 on bacterial classification represents the Delft School outlook. The paper was a reasoned discussion of the problems faced in contemporary bacterial classification, in the context of which the authors then proposed a system of their own, which they hoped would overcome some of the problems and, so, move bacteriology closer to a genuine natural bacterial system. At the time, classifications were largely morphological and their purpose for the most part utilitarian. A salient exception to these approaches had been the system of Orla-Jensen (see Kluyver and van Niel, 1936), which was based on an evolutionary conjecture, namely that the first organisms to evolve were necessarily autotrophs (Oparin and his ocean had yet to enter the picture). Like Beijerinck, Orla-Jensen appeared to believe that microorganisms held the key to understanding life's origin, and he constructed a classification that hopefully would help to bring out the origin of metabolism. At this time, Kluyver and van Niel seemed to share Beijerinck's belief in the importance of bacteria as evolutionary beacons; at least they said: "A true reconstruction of the course of evolution is the ideal of every taxonomist" (Kluyver and van Niel, 1936).

In the Kluyver-van Niel article, one readily senses bacteriology's ongoing struggle regarding the bases upon which to develop bacterial classification. Because zoological and botanical classifications are morphologically based, a strong precedent existed for putting bacterial classification on a similar footing—despite the fact that microbiologists intuitively knew that bacteria are as fundamentally physiological as animals and plants are morphological. On what levels, to what extent, in what ways, then, are the morphological and various physiological properties of bacteria taxonomically significant? In the following, we see Kluyver and van Niel worry the problem (Kluyver and van Niel, 1936, pp. 370, 371):

> The question then arises in which [bacterial] characters phylogeny expresses itself. There is no doubt that in this respect morphology remains the first and most reliable guide ... [although] the indispensability of physiological characters for the purpose of classification has also been generally accepted. ...
>
> A lack of insight in the fundamentals of metabolism has thus far been the great stumbling-block for a rational application of physiological characteristics in taxonomy and it also explains the horror with which many systematicians have

witnessed their ever increasing use. . . . The fundamental nature of the energy providing processes justifies the view that they should be rated first amongst the physiological characters suitable for classification. . . .

Because the classification sought was a natural one, the kinds of choices Kluyver and van Niel were entertaining required the answers to certain evolutionary questions. But there were no *a priori* answers—even hints of them. Natural classification then had to rest on a foundation of conjecture—bolstered by the hope that if the scheme were anywhere near phylogenetically valid, it could bootstrap itself into a true natural classification. (Only today is knowledge of evolutionary relationships independent of [and so can precede the construction of] a taxonomy rather than follow from it.)

There is little point in detailing Kluyver and van Niel's attempt at a natural classification. But since the tenor of their thinking is so instructive as to the microbiological gestalt of their day, it is worth sampling a bit more. After debating the relative significance and utility of morphological and physiological characteristics in bacterial classification, the authors (tentatively) opt for ". . . the use of morphological criteria as [the] main guiding principle . . . above the rank of genera" (Kluyver and van Niel, 1936).

It is basic to biological thought that the complex tends to evolve from the simple, and given the presumed primitive nature of bacteria, Kluyver and van Niel carried this notion to the extreme:

> It seems acceptable that the diversity of bacterial forms is the outcome of various independent morphological evolutions which have had their starting-point in the simplest form both existent and conceivable: the sphere (Kluyver and van Niel, 1936, p. 387).

From this starting assumption they picture the aboriginal spherical bacterium as (somehow) giving rise to four basic morphological types: 1) coccoid (the Micrococcaceae), 2) cells with polar flagella (Pseudomonadaceae), 3) cells with peritrichous flagella (Bacteriaceae), and 4) a nonmotile line whose beginnings are streptococci. Each of the four primary lineages in turn evolves in a quasi-ontogenetic fashion through stages of increasing complexity to some "highest stage of development," e.g., the coccoid forms giving rise to sarcinae (packets of cocci), and thence sarcinae that form spores, or the "streptococcal" lineage developing through short Gram-positive rods to mycobacteria and ultimately the complex actinomycetes (Kluyver and van Niel, 1936).

Within each main line of morphological descent, morphology increasingly gives way to physiological characters in defining the lower taxonomic levels (Kluyver and van Niel, 1936). In retrospect, unfortunately, bacterial classification in the early twentieth century comes to be little more than a tapestry of *Just So Stories*.

The Beginning of the End

We need to consider one final attempt to devise a natural bacterial system, which was proposed by Stanier and van Niel five years after the Kluyver and van Niel system (Stanier and van Niel, 1941). Again our reason for doing so does not lie in the system itself but in the discussion that accompanied it. Theirs was the last blush of enthusiasm among microbiologists for developing a comprehensive natural bacterial classification, and the last time that having an evolutionary overview of the bacteria of any kind was vigorously defended (Stanier and van Niel, 1941).

Bacterial taxonomists had long been split into two camps: the *idealists*, represented especially by members of the Delft School, and the *realists*, represented by the majority of other bacteriologists, e.g., the board of *Bergey's Manual* (Breed, 1939; Stanier and van Niel, 1941). The overarching perspective of the idealists recognized the importance to the discipline's future of a phylogenetically based taxonomy. The realists' practical perspective was content with the intellectual pauper's gruel provided by a taxonomy merely enabling species identification and a convenient pigeon-holing system. Stanier and van Niel deplored this mercantile mentality (Stanier and van Niel, 1941):

> In most biological fields it is considered a truism to state that the only satisfactory basis for the construction of a rational system of classification is the phylogenetic one. Nevertheless, "realistic" bacteriologists show a curious aversion to the attempted use of phylogeny in bacterial systematics. . . . To what may we ascribe this distrust of phylogeny? In part it is undoubtedly due to the unsatisfactory nature of certain systems, purportedly based on phylogeny, which have been proposed in the past. However, the mere fact that a particular phylogenetic scheme has been shown to be unsound by later work is not a valid reason for total rejection of the phylogenetic approach.

The authors then turn to the drawbacks of the alternative:

> . . . There is good reason to prefer an admittedly imperfect natural system to a purely empirical one. A phylogenetic system has at least a rational basis, and can be altered and improved as new facts come to light; its very weaknesses will suggest the type of experimental work necessary for improvement. On the other hand, an empirical system is largely unmodifiable because the differential characters employed are arbitrarily chosen and usually cannot be altered to any great extent without disrupting the whole system. . . . [When the] wide separation of closely related groups caused by the use of arbitrary differential characters . . . makes it impossible to tell with certainty in what order a given organism belongs, an empirical system loses its value. . . .

This is incisive commentary! But unfortunately, it is just about the last one hears the idealist perspective, the last time the attitude "if it can't be solved today, then we will try anew tomorrow," is expressed.

That final time seems to be 1946, when van Niel gave a major address concerning bacterial classification at that year's memorable post-war Cold Spring Harbor Symposium. In the address, he analyzed in detail the failures of current and past attempts at natural bacterial classification. He pointed out the difference between the successful use of morphological characters in plant and animal classification, and their lack of utility in the bacterial case (as mentioned above). He detailed the frustrations bacteriologists had experienced in trying to use physiological characteristics for classificatory purposes, concluding that there is no way one can determine natural relationships in the bacterial world as things then stood (van Niel, 1946). But at the end of this depressing critique, van Niel held firm to the idealist position: "[Thus, since] the morphology of a bacterium is of no more use in [classification] than is its physiology . . . the search for a basis upon which a 'natural system' can be constructed must continue" (van Niel, 1946, p. 290).

Where To Play? The Sand Castles Have All Washed Away

The year was 1955 when van Niel returned for the last time (to my knowledge) to the subject of natural bacterial classification (van Niel, 1955). By that time biochemists, following Kluyver's pioneering synthesis of microbial biochemistry, had turned their attentions in earnest to bacterial systems; sexual recombination had been discovered in bacteria by Lederberg and Tatum (1946), and geneticists were poised to take advantage, and (as mentioned) molecular biologists too were finding bacterial systems highly suitable for their studies. The emphasis in bacteriology was definitely shifting strongly in the reductionist structure/function direction. And van Niel returned to his topic, with a changed, jaded outlook.

Van Niel's still hopeful (and scientifically proper) perspective of 1946—"it hasn't been done yet, so we must continue"—had now become the pessimistic (and scientifically unacceptable)—"it hasn't been done yet, so it can't be done," which he expressed this way:

> What made Winogradsky . . . grant that the systematics of plants and animals on the basis of the Linnean system is defensible, while contending that a similar classification of bacteria is out of the question? The answer must be obvious to those who recognize in the former an increasingly successful attempt at reconstructing a phylogenetic history of the higher plants and animals . . . and who feel that comparable efforts in the realm of the bacteria (and bluegreen algae) are doomed to failure because it does not appear likely that criteria of truly phylogenetic significance can be devised for these organisms (van Niel, 1955, pp. 101–102).

The idealists were now in full retreat, and in the process took an untenable fallback position, namely that the concept of a bacterium could be developed *without* resort to phylogenetic relationships. It could be developed simply by knowing the structure/function differences between eukaryotes and "prokaryotes." A little thought shows the folly in this. As emphasized above, an organismal science *must* be founded on evolutionary relationships. Yet, that is far from what the next generation of microbiologists were taught. In *The Microbial World* first edition, 1957:

> An eminent contemporary bacteriologist, van Niel, who is noted for his taxonomic studies on several groups of bacteria, has expressed the opinion that it is a waste of time to attempt a natural system of classification for bacteria, and that bacteriologists should concentrate instead on the more humble practical task of devising *determinative keys* (Stanier et al., 1957, p. 296).

In *Archives of Microbiology*, 1962:

> It is now clear that among organisms there are two different organizational patterns of cells . . . the eucaryotic and procaryotic type. *The distinctive property of bacteria and bluegreen algae is the procaryotic nature of their cells*. . . . The remaining pages of this essay will be devoted to a discussion of the essential differences between these two cell types, upon which rests our only hope of more clearly formulating a "concept of a bacterium" (Stanier and van Niel, 1962, pp. 20–21).

In *The Microbial World* second edition, 1963:

> All [bacteria] share the distinctive structural properties associated with the procaryotic cell, and we can therefore safely infer a common origin for the whole group in the remote evolutionary past; we can also discern four principal sub-groups, blue-green algae, myxobacteria, spirochetes, and eubacteria, which seem to be distinct from one another. . . . Beyond this point, however, any systematic attempt to construct a detailed scheme of natural relationships becomes the purest speculation, completely unsupported by any sort of evidence. The only possible conclusion is, accordingly, that *the ultimate scientific goal of biological classification cannot be achieved in the case of bacteria* (Stanier et al., 1963, p. 409).

A similarly dark and contrived picture was painted in the third, 1970, edition of *The Microbial World* and carried through essentially unchanged into the fourth (Stanier et al., 1970b; Stanier et al., 1976).

Here Comes the (Molecular) Cavalry

The sad irony in all this is that while the idealist position was in retreat, with defeat masquerading as victory, and while new recruits were taught

not to look back, as the importance of a "concept of a bacterium" (and with it any interest in bacterial evolution) slipped from view, the ground for a genuine phylogeny of bacteria, which could transform the discipline, was simultaneously being prepared. In the early 1950s, Sanger had sequenced the first proteins (Sanger and Tuppy, 1951; Sanger and Thompson, 1953), and the notion that molecular sequence comparisons were a rich source of evolutionary information was beginning to take hold:

> Biologists should realize that before long we shall have a subject which might be called "protein taxonomy"—the study of amino acid sequences of proteins of an organism and the comparison of them between species. It can be argued that these sequences are the most delicate expression possible of the phenotype of an organism and that vast amounts of evolutionary information may be hidden away within them (Crick, 1958, p. 142).

However, among microbiologists Crick's prescience fell on deafened ears. The molecular and bacteriology paradigms were somehow on different conceptual planes. However, some "macrobiologists" did see the new molecular royal road to phylogeny (Zuckerkandl and Pauling, 1965), and a cottage industry arose around confirming and (slightly) extending the classical phylogenetic tree through sequence comparisons of cytochrome *c*s and of a few other molecules (Fitch and Margoliash, 1967). Yet the record shows that even among these first generation molecular evolutionists there was no recognition of the importance of the larger and far more important problem of using molecular sequence comparisons to infer *bacterial* phylogenies, which would have opened the door to the universal phylogenetic tree.

Microbiologists did get on the molecular evolution bandwagon, but belatedly and halfheartedly. In the main, their efforts relied upon simple and relatively uninformative methods, such as nucleic acid hybridization (Gillespie and Spiegelman, 1965), and their interests were confined largely to weeding out misclassified species from genera and in properly grouping genera into families. A few protein sequences were attempted and superficially analyzed, but those responsible saw nothing of evolutionary value in the comparisons (Ambler et al., 1979a; Ambler et al., 1979b; Meyer et al., 1986)! The compelling vision of the idealists, the overriding concern with building a concept of bacteria on a comprehensive natural bacterial taxonomy, was gone. (Two prominent exceptions to the above characterization of microbiologists' attitudes toward bacterial taxonomy appear to be expressed by the Europeans J. De Ley and O. Kandler, in whose works and writings the candle of hope still flickered for a broad reaching, if not comprehensive, natural bacterial system [Heberlein et al., 1967; Schleifer and Kandler, 1972].)

Cleaving the Gordian Knot It was only a matter of time before the sleeping giant of bacterial phylogeny would be roused by a dose of molecular medicine. By the mid-1960s Sanger's "oligonucleotide cataloging" method had come along (Sanger et al., 1965). By 1970, my laboratory was using it on ribosomal RNAs (Sogin et al., 1971; Woese et al., 1974). The universal distribution of rRNA, its large size, its high degree of sequence conservation, and a presumed refractoriness of rDNA to horizontal gene displacement argued that the molecule could be used to derive a universal phylogeny (Fox et al., 1977b; Woese, 1987). By 1975, we had characterized about 30 rRNAs (mainly bacterial) by the method (Woese et al., 1975), a number that approached a hundred by the end of the decade. With the 1980s, newer and faster methods permitted effectively full sequencing of an rRNA molecule (Lane et al., 1985), which significantly sharpened branching orders in the universal tree. Today the sequencing of rRNA (or rDNA) has become trivial, and the collection of rRNA sequences now numbers in the tens of thousands (Maidak et al., 2001).

The most important findings to come out of this new and revolutionary approach to bacterial taxonomy (and taxonomy in general) were that, yes, phylogenetic relationships among bacteria (distant or not) could be determined, and so, developing a clear concept of a bacterium was now feasible, second in importance only to the determining of the universal phylogenetic tree itself (Fox et al., 1980)—one of the great problems that the nineteenth century in biology bequeathed to the twentieth. As Darwin had said (Burkhardt and Smith, 1990): "The time will come I believe, though I shall not live to see it, when we shall have very fairly true genealogical trees of each great kingdom of nature" (Darwin Corresp. 6:456). The discovery of the Archaea (Fox et al., 1977a; Woese and Fox, 1977b) once and for all exploded the prokaryote/eukaryote phylogenetic myth. The universal tree shows prokaryotes to comprise not one, but two, unrelated major organismal groups (primary lines of descent), the Archaea and the Eubacteria. The new perception of microbial diversity that came out of the universal tree, in addition to the unexpected discovery of a third highest level grouping of organisms, found biology organizationally unprepared. Academic department structures, their organization and courses, did not and still do not reflect the new reality. Most textbooks do not do so adequately even today. And the funding priorities for governmental supported biol-

ogy remain structured in a way that recognizes a bipartite, not tripartite, division of life.

Reaching into the Unknown While rRNA phylogenies put bacteriology on the road to becoming a full fledged organismal discipline, they alone did not completely resolve bacterial ecology's core problem: a phylogenetic framework is a necessary but not sufficient condition for developing bacterial ecology. To identify a species, the bacterial ecologist has first to detect and isolate it. Proper identification of a bacterial species was firmly believed to require its cultivation (in pure culture) in the laboratory. Yet the vast majority of bacterial species in the typical niche go undetected, and among those that can be detected, most defy laboratory (pure) culture. (Just how severe a problem this was did not become apparent until relatively recently, well after the fact.)

But, contrary to established belief, isolation of bacteria in laboratory culture is not an absolute requirement for bacterial identification and classification. Since bacteria can now be identified and related merely through the sequence of one molecule, rRNA, only that molecule needs to be isolated from the environment to detect, identify, and classify organisms. This realization seems first to have occurred to Norman Pace, in the early 1980s. Over the next several years, he and his coworkers published a series of articles pointing out in principle and demonstrating in practice the new molecular sequence-based approach to microbial ecology (Stahl et al., 1985; Olsen et al., 1986). The crippling limitations that organismal detection and laboratory isolation had previously imposed on microbial ecology had vanished!

Pace and coworkers went further, showing that for certain purposes it was not even necessary to *isolate* a molecule (or its gene) from the environment: "phylogenetic stains" (sets of fluorescent nucleic acid probes for rRNA) could be developed to identify individual cells microscopically *in situ by species, genus, family, etc.* (DeLong et al., 1989). Using this powerful new methodology, a microbiologist could identify any and virtually all microbial species in a given niche in terms of phylogenetic relationships and morphology (and that, obviously, is only the beginning for such a methodology). At last a genuine bacterial ecology is emerging! It is impossible to overestimate the importance of phylogeny and direct detection of genes to bacterial ecology's development.

Perspective

Throughout its history molecular biology has been guided in one way or another by "the problem of the gene," which basically defined twentieth century biology. What would molecular biology have been like had the gene not been its focus? I ask this simply to provide perspective in posing a second question: what would bacteriology have been like if developing "a concept of a bacterium" *had* been its central focus, and it had succeeded in doing so—allowing bacteriology to become a full fledged organismal science?

Early on, microbiologists were not averse to asking evolutionary questions: are all bacteria at base specifically related to one another? Did bacterial evolution follow a course primarily laid out by morphological or physiological development? Were the first bacteria heterotrophs or autotrophs? Were they mesophiles or thermophiles? Are all photosynthetic bacteria related to one another to the exclusion of nonphotosynthetic species? How did the many diverse bacterial metabolisms come into being? How many times did this or that phenotypic feature evolve? Does this or that common feature signify relationship or convergent evolution? Unfortunately, all such questions (necessarily) were answered only by (untestable) conjectures—not a very reliable foundation upon which to base a concept of bacteria. A fabric of conjecture soon comes to be viewed as metascience (Stanier, 1970a), and this has the effect (most unfortunate in microbiology's case) of squelching inquiry. In this way, bacteriology came to abandon its evolutionary curiosity—much to its and biology's detriment.

Just as unsubstantiated conjecture leads to stifling curiosity, phylogenetic knowledge does the opposite. Fairly reliable responses to the early microbiologists' evolutionary musings would have led to the asking of new, more detailed questions. Had a reasonable natural bacterial classification come on the scene early enough, the spirit of evolutionary inquiry would not have withered but intensified, and a genuine concept of bacteria would naturally have followed. The development of all twentieth century biology would have been different, retaining to some extent a focus on the organism as a whole and its evolution. Ah well. . . .

Archaea and Eubacteria

As discussed above, the character of a prokaryotic type of cell is expressed far more in physiology (dynamic pattern) than in morphology (static pattern), which underlies why bacterial morphologies and the like are so uninformative (even deceiving) phylogenetically. It also accounts for why the two prokaryotic cell types appear so similar upon superficial analysis. At

the molecular level, however, this impression of kinship between the two quickly evaporates. In their histories, the two prokaryotic types have followed very different paths that from time to time have crossed, leading to the occasional transfer of genes (especially early on), which accounts for much of the similarity often taken to signify specific relationship at the organismal level. Yet in looking at the core functionality of the cell, the enormous gulf between archaea and eubacteria leaps out.

Metabolism, Membranes and Walls

Let us begin a comparison of the two types with their metabolisms, wherein the differences are relatively few, but still significant. The eubacteria are far and away the most metabolically diverse and versatile group of organisms on the planet. The metabolic uniqueness of the archaea is most prominently displayed in methanogenesis, a metabolism confined to the Euryarchaeota. The most interesting thing about archaeal metabolism may be the unique set of cofactors it employs (mainly in methanogenesis). To mention some: the C-1 carriers, coenzyme M, methanofuran, and methanopterin; F_{420}, an electron carrier analogous to NAD; F_{430}, a nickel-containing porphyrin akin to heme, vitamin B_{12}, and chlorophyll; and methanophenazine, a membrane-bound carrier that functions like a quinone (Wolfe, 1992; Beifuss et al., 2000). Viewed metabolically these cofactors are interesting but not all that unusual in the reaction types they catalyze. What is unusual and intriguing, however, are their biosyntheses (the study of which is still in its beginning phases). While the pathways in archaeal cofactor synthesis themselves tend to be fairly standard in a chemical sense, the enzymes catalyzing the reactions more often than not have no homologs outside of the archaea. As suggested by Graham and White (2002), the unity of biochemistry we have known since the time of Kluyver may be as much a matter of evolutionary convergence on common biochemical themes as it is retention of ancestral metabolic ways.

Archaeal membrane structure is unique as well. It is based upon ether-linked branched-chain lipids, whereas in the eubacterial and eukaryotic cases, straight-chain ester-linked lipids predominate (Kates, 1964; Kates et al., 1968; Torrnabene and Langworthy, 1979). Cell wall structures differ too. The eubacterial wall characteristically comprises murein (peptidoglycan), while archaeal walls are most often proteinaceous (Kandler and Hippe, 1977; Kandler and König, 1985). In Methanobacteriales species, however, walls comprise pseudomurein, a compound that, as the name suggests, resembles eubacterial murein (König and Kandler, 1979). Yet the sugars from which murein and pseudomurein are built are largely different, and when the biosynthetic mechanisms involved in wall formation are considered, it is clear that murein and pseudomurein are another example of biochemical convergence (Hartmann and König, 1990).

Translation

It is in information processing that the differences between eubacterial and archaeal cell designs appear in their full glory. Of the three main information processing systems (translation, transcription, and genome replication), translation exhibits the most universality in its componentry, the most homology between archaea and eubacteria (and eukaryotes). Ribosomal RNAs, elongation factors, ribosomal proteins, aminoacyl-tRNA synthetases are all basically universal. However, among these universal protein components, a clear distinction exists between the eubacterial and archaeal versions. The distinction is characteristically so blatant that it tends to stand out even upon gross inspection of a sequence alignment (Woese et al., 2000). (For example, the eubacterial versions of a given sequence often contain moderate to large blocks of amino acids [located terminally or in the interior of the molecule] not seen in the archaeal versions and *vice versa*. In addition, for those columns in an alignment where composition is highly conserved, one often sees that the characteristic eubacterial composition differs from that characteristic of the archaea.) This nearly qualitative distinction between archaeal and eubacterial versions of a sequence, this difference in genre between the two, has been called the "canonical phylogenetic pattern" (Woese et al., 2000). Differences this extreme are never encountered among the various eubacterial taxa or among different archaeal taxa (although in each case there have been three billion years or so, most of this planet's history, in which such differences could have arisen). When eubacterial and archaeal sequences show these differences in genre, their eukaryotic counterparts are almost always of the archaeal genre (Woese et al., 2000).

A minority of ribosomal proteins, however, are not universally distributed. A relatively small cadre are characteristic of and found only in eubacteria, while a somewhat larger set is common and confined to the archaea and eukaryotes, with yet a few others being found only in eukaryotic ribosomes. Overall, though, translation gives the impression of a system that existed in basically modern form at the root of the phylogenetic tree.

Transcription

Transcription presents a similar evolutionary picture, but with more, and more pronounced, exceptions to universality (Langer and Zillig, 1995). The two largest (the catalytic) subunits of the DNA-dependent RNA polymerase, β and β′ in eubacterial nomenclature, are clearly universal and show the canonical pattern (with again eukaryotic sequences being of the archaeal genre). But that's about it for homology. For the remaining main subunit of the eubacterial RNA polymerase (α), homology between the eubacterial and archaeal versions is only partial. Eubacterial α occurs in two copies in the holoenzyme, whereas its archaeal counterpart (found also in eukaryotes) comprises two separate proteins of very different size, each present in single copy in the holoenzyme, with parts of each showing homology to (somewhat) different parts of eubacterial α (Langer and Zillig, 1995). The archaeal transcription polymerase has a number of additional (smaller) subunits, all of which occur in the eukaryotic enzyme(s), but not in the eubacterial. And as in the case of translation, the eukaryotic version(s) of the transcription polymerase contain a few additional subunits specific to themselves (Tjian, 1996). When it comes to transcription initiation, one sees no homology between the eubacteria and the archaea: the two mechanisms are different and use different componentry (Bell and Jackson, 2001). Once again the eukaryotes possess an embellished archaeal version.

Genome Replication

Genome replication is the extreme example of archaeal/eubacterial difference. The closely related archaeal and eukaryotic systems are to a first approximation totally distinct from their eubacterial counterpart (Olsen and Woese, 1996). And, as now might be expected, the mechanism of initiation of chromosome replication in the eubacteria is fundamentally different from that basically common to the archaea and eukaryotes (Kelman, 2000). In the past it was common to draw phylogenetic significance (i.e., specific relationship) from the fact that archaea and eubacteria both have circular chromosomes, in distinction to eukaryotic chromosomes, which are linear. In light of the similarity between the archaea and eukaryotes in both chromosome replication and the initiation thereof, that conclusion needs revisiting.

It is also of interest that both the eukaryotic and archaeal (euryarchaeal) chromosomes show nucleosome organization—the single archaeal histone responsible being a homolog of the four (related) histones that structure the eukaryotic nucleosome (Reeve et al., 1997). This is an example of a theme that repeatedly occurs in the chromosome replication mechanism and elsewhere, namely: a job is done by a particular multimeric protein complex. The many subunits therein, however, represent only one or a few gene families. In the eukaryotic case, a number of different members of a family tend to be represented in the complex, each present in *single* copy. In the archaeal case, there tends to be only one member of the corresponding family, and that present in *multiple* copies.

Comparisons between the information processing systems of Archaea and Eukarya are what give rise to the strong impression of fundamental relationship between the two. However, that specific relationship is reflected in relatively few molecules other than those involved in information processing, one example being HSP-60. Overall, the relationships among the three basic cell types present a complex, fascinating conundrum—a delightful challenge.

The close resemblance between archaeal and eukaryotic versions of the three information processing systems has been the source of much speculation as to the origin of the eukaryotic cell, speculation that usually takes the form of invoking a fusion of a particular bacterial cell (such as an α proteobacterium) with a particular archaeal cell (say, a methanogen; Martin and Mueller, 1998) or sees some hypothetical ancient "protoeukaryotic" cell as horizontally acquiring certain metabolic capabilities from the eubacteria and information processing capabilities from the archaea (Hartman, 1984). I do not like either type of explanation. The first type gives the eukaryotic cell no character of its own before it emerges from the fusion of the two prokaryotic types. In the second, the protoeukaryotic cell suddenly acquires information processing systems that it has never before encountered, and its basic cellular design is suddenly altered. All such models miss the essential point in cellular evolution: the core machinery of the three primary cell types evolved and became established in each case well before any cells achieved their "modern" type of organization (Woese, 2002). Evolution does not proceed by suddenly and drastically altering a given cell design (at least a fairly advanced one). These models ignore the possibility (likelihood) that a cell design is stable, homeostatic, in an evolutionary sense.

Horizontal Gene Transfer: How Cells Evolved

It might seem that horizontal gene transfer (HGT) would be a complicating factor in understanding how the various major cell types

evolved. Yet, far from being a complicating factor, HGT turns out to be the essence of the process (Woese, 2000). As is now well known, HGT appears to have had (at certain times in evolution) the potential not only to introduce entirely new functions into cells, but to displace any constituent (gene) in the cell with an alien equivalent. What effect has HGT had on the genetic record of organismal descent? What is its relationship to canonical pattern? Understanding here pivots on what the characteristics of HGT are and what factors determine them.

The interested reader will find a more extensive and useful discussion of the major problem of evolving cellular organization and its relevance to the universal phylogenetic tree structure in Woese (Woese, 2000; Woese, 2002).

The most obvious thing about HGT is its extreme variability, in both frequency and phylogenetic range, from one gene to another, from one major taxon to another, and *likely* from one evolutionary stage to another (Woese et al., 2000). It turns out that the dominant factor shaping HGT is the organization (design) of the potential recipient cell (Woese, 2002). The various components of a cell are in one way or another, to one extent or another, interconnected, variously integrated into the cell's "design fabric." Some of them are weakly and simply integrated into the fabric, others tightly and complexly so (Woese and Fox, 1977a; Woese et al., 2000). Components of the first type are in effect modular: functionally and structurally they are pretty much self-contained and self-defining, i.e., their interactions with the rest of the cell componentry are minimal. It stands to reason that such a modular, loosely coupled, component is far more likely to undergo horizontal gene displacement by some alien equivalent than is highly and idiosyncratically integrated componentry.

An ideal system for assessing the character of HGT is the translation apparatus, for while most of its componentry, e.g., the ribosomal proteins and elongation factors, are tightly coupled into the rest of the mechanism (and hence the cell fabric), the tRNA charging enzymes (aminoacyl-tRNA synthetases) are not; the latter are modular, are loosely coupled into the cellular fabric. And as might then be expected, the ribosomal proteins and elongation factors have been largely unaffected by HGT, whereas the aminoacyl-tRNA synthetases have been quite highly buffeted by it, both in terms of the frequency with which HGT has affected them and the (broad) phylogenetic range of many of the alien displacements that have occurred (Woese, 2000). It is common, for example, to see the archaeal genre of a given aminoacyl-tRNA synthetase in one or a few eubacterial lineages (Woese et al., 2000).

A detailed phylogenetic analysis of the 20-odd aminoacyl-tRNA synthetases (Woese et al., 2000) shows: 1) that about two thirds of the tRNA charging enzymes exhibit the canonical pattern typical of the other components of the cellular information processing systems; and 2) that in all these cases the canonical pattern has to one extent or another been eroded by HGT; but 3) that the degree to which and the ways in which that pattern has been eroded are idiosyncratic, qualitatively different for each of the enzymes. From these facts it was concluded that the canonical phylogenetic pattern itself was not produced by HGT, but reflects some earlier evolutionary dynamic (Woese et al., 2000). Thus, the canonical pattern represents a (partial) genetic record of organismal histories that extends back to the root of the universal tree. In other words, while HGT has been a powerful, pervasive, and shaping force in organismal evolution (especially early on), it has not completely obliterated the ancestral organismal trace that the universal tree represents.

As the reader can see, I cannot discuss similarities and differences among the major organismal types without the discussion shifting into an evolutionary framework. This, however, is no peculiarity of mine, but rather the fact that such matters cannot be productively discussed in any other context. So, like it or not, microbiology is going to be in the center of evolutionary study in the future—and *vice versa*.

Microbiology on the Move

A great deal has happened in bacteriology in the last decade or so. The four pillars upon which a true bacteriology must be built are now in place, and the long sought "concept of bacteria" is beginning to take shape. Bacteria are now routinely seen in terms of their natural (phylogenetic) relationships; discussions often turn on various aspects of their evolution. The sleeping giant of microbial ecology has finally awakened and we are beginning to see the microbial base of the biosphere. Geomicrobiology, which increasingly ties bacteria to geological processes, is a burgeoning field. Marine microbial ecology is bringing to the fore the important role that bacteria play in determining the character of the oceans. Genomic microbiology is beginning to tackle some of the knotty problems associated with bacterial evolution, adaptation to environments, and the evolution of the global ecosystem itself. These and similar developments are the potential building blocks of a new microbiology. But the concrescence of twenty-first century microbiology will not occur unless we, its practitioners, understand *what bacteriology is and, thus, what its future goals are*.

To me, microbiology today resembles a peasant who has suddenly become wealthy. The chains of poverty are gone, but the cobwebs that are the habits of poverty remain and hold him fast. Obviously there are no longer scientific barriers to bacteriology's becoming the organismal discipline it should long ago have become. But, who cares anymore? The idealists among us, whose crucial role it had been to define and develop the character of bacteriology, to keep the discipline on track, are long gone. The character of bacteriology (like that of the peasant) is essentially defined by overlords, external circumstances, be they scientific or practical (societal). Contrast bacteriology to disciplines such as genetics and molecular biology, disciplines that once were strong in being defined from within—disciplines whose paradigms embodied major scientific goals, disciplines that had a grand vision. Microbiology was never that. Today's microbiologists are, unfortunately, the realists of yesteryear. The field is without overview, without a concept of itself, and its goals remain shaped by practical considerations and influences from the stronger disciplines. Only an agonizing awareness of the situation will change that.

Where Is Our Essence?

It is time to take stock. Microbiology today is not the discipline microbiologists knew 30 years ago. Everything is new—the technology, the problems that the discipline faces, our training, our conceptual framework, and the way microbiology is perceived by the other sciences. Only the organisms remain the same. But is this last even true? The organisms *per se* may be the same, but our perception of them surely isn't. What is a bacterium to us except a synthesis of the various ways in which we experience it? That surely has changed, dramatically so. (Is one's concept of bacteroides and cytophagas, for example, the same as it previously was once one knows that these two phenotypically dissimilar types are actually specifically related to one another? What are *Deinococcus* and *Thermus* doing in the same stable? Are the myxobacteria that we know today as members of the δ-proteobacteria the same as the classical myxobacteria, which if they had any affiliation at all, it was to the cyanobacteria?) The only things that remain at all constant are the prejudices we have inherited from our intellectual forbears. Time to clear the table!

There are two fundamental challenges that microbiology faces today, challenges deep and basic enough that they speak to the whole of biology. First is the age-old question "where do we come from," which can now be addressed in the form of how cellular organization evolved. The other is the problem of the biosphere: what is this incredibly complex yet smooth functioning web of interactions among this incredibly diverse collection of organisms—this coherent, self-sustaining, overarching state of the whole? Actually these two problems are at base the same. And the understanding of both lies in the microbial world, in its diversity, in the (functional) structure of microbial communities, in the organization of microbial cells, in evolutionary and other adaptive responses of microorganisms to environmental perturbations, and in the incredible interconnectedness of microbial life in general. In a way, twenty-first century microbiology is a return to microbiology's roots, a rediscovered and development of the grand view of microorganisms that Beijerinck and other early microbiologists shared.

The View from the Top (see The Phylogeny of the Prokaryotes: A Living Tree in Volume 2)

We have discussed above the major features that distinguish the Archaea and Eubacteria. What remains to be done is provide an organismal overview of the individual domains. We will go about this in a top down fashion, starting with the major eubacterial and archaeal taxa, leaving the details and definitions of the lower, subordinate taxa to you and the next generation of microbiologists. I do not claim that these high level taxa as currently defined are entirely correct (are genuine naturally defined groupings) in all cases, but most of them surely are, and, therefore, our discussing them at this point is useful. Let us start with:

The Organismal Structure of the Archaea

As we have seen above (and elsewhere), the Archaea represent a unique cell design (Graham et al., 2000). In their cellular organization they stand apart from the Eubacteria and, of course, the Eukarya. The Archaea are also unique in their overall phylogenetic structure: the domain comprises two characterized kingdoms, the Euryarchaeota and the Crenarchaeota—with the possibility of a third kingdom, the "Korarchaeota," lurking among the unwashed masses of species that have been identified only through direct isolation of rRNA genes from the environment (Barns et al., 1996). Even a fourth archaeal kingdom is suggested by the recent discovery of a bizarre nano-sized exosymbiont associated with particular ones of the Crenarchaeota (Huber et al., 2002). What makes archaeal phylogeny stand apart from that of the Eubacteria and Eukarya is the pronounced phenotypic and

genotypic distinction between the kingdoms Euryarchaeota and Crenarchaeota—the depth of their phylogenetic split, the genomic differences between them. Interkingdom differences of this magnitude are not seen in the other two domains.

The euryarchaeota appear phenotypically constituted (designed) around a methanogenic metabolism. They are also characteristically thermophilic and show relatively high intracellular concentrations of monovalent ions. To our present knowledge, the kingdom has spawned four main methanogenic branches (phyla), the *Methanococcales,* the *Methanobacteriales,* the *Methanomicrobiales,* and the *Methanopyrales* (Olsen et al., 1994; see Methanococcales, Methanobacteriales and Methanopyrales and Methanomicrobiales in Volume 3).

The euryarchaeal kingdom also harbors other, non-methanogenic, phenotypes. Interestingly, all but one of these are offshoots of the lineage that gives rise to the Methanomicrobiales. The non-methanogenic phenotypes in question are the extreme halophiles, the sulfate reducing archaea (Archaeoglobales) and the Thermoplasmatales. The lone non-methanogen group not stemming from this lineage is the Thermococcales (which comprises the genera *Thermococcus* and *Pyrococcus*); see The Order Halobacteriales, Archaeoglobus, Thermoplasmatales and The Order Thermococcales in Volume 3.

The extreme halophiles are facultative aerobes that grow in highly saline environments and have been known to microbiologists for ages: they are known for putrefying salted fish among other things. The extreme halophiles are also notable for the reddish pigment(s) they produce, which are in part responsible for the striking red color in salt evaporation ponds. Among these pigments is bacterial (now archaeal) rhodopsin, which provides them a photochemistry. Archaeal rhodopsin is central to a light driven transmembrane pump, by means of which the extreme halophiles can derive energy; see The Order Halobacteriales in Volume 3.

Beyond their extremely high (5M) intracellular potassium ion levels and their photochemical ability (unique among cultured bacteria), the extreme halophiles offer little of interest, unless it be the fact that as an organismal group they are phylogenetically very tightly clustered—and so, of relatively recent origin.

One naturally assumes, given the specific (though somewhat distant) phylogenetic relationship to the Methanomicrobiales, that the metabolism of the halophiles is probably a derived, degenerate form of the metabolism characteristic of the Methanomicrobiales. But, the halophile genome shows something different. It is rife with bacterial genes and others that have no relationships functionally or phylogenetically to methanogens and methanogenesis.

The second grouping in the Methanomicrobiales cluster comprises the anaerobic sulfate reducing organisms of the family Archaeoglobales—see Archaeoglobus in Volume 3. Iron reduction is seen in the genus *Ferroglobus* (Hafenbradl et al., 1996). The members of this order, though anaerobic, produce no methane, except for a trickle thereof. The biochemical reason is obvious: the gene for the terminal enzyme in the methanogenic pathway, methyl CoM reductase, is missing from their genomes. Yet the rest of the methanogenic pathway appears intact in these organisms. However, *Archaeoglobus sp*. run the pathway backward (oxidatively), producing carbon dioxide as the end product. The Archaeoglobales are highly thermophilic, with no known exceptions, which distinguishes them from their sister lineages, the Methanomicrobiales and extreme halophiles, lineages that do not appear to harbor hard-core thermophiles.

The final aberrant phenotype within the Methanomicrobiales segment of the euryarchaeal tree is the Thermoplasmatales—see Thermoplasmatales in Volume 3. They are ostensibly wall-less thermophiles (unique among the archaea), whose thermoacidophilic phenotype superficially resembles that of the crenarchaeota. And again iron metabolism surfaces in the genus Ferroplasma (Golyshina et al., 2000). Direct environmental sampling for rRNA genes reveals that the Thermoplasmales also encompass a low temperature marine grouping (DeLong, 1992)—whose phenotype is otherwise unknown. In their genomic makeup these organisms are the most phylogenetically cosmopolitan of all the archaea.

I find it intriguing that among all euryarchaeota, it is only the Methanomicrobiales (and their ancestral lineage) that have proven so evolutionarily inventive. In addition to spawning the above-described aberrant phenotypes, the Methanomicrobiales proper have been inventive in terms of methanogenesis itself. These are the only methanogens that utilize certain carbon sources other than carbon dioxide (e.g., acetate) in methanogenesis. And they seem to be able to utilize the methanogenesis pathway in both directions—which they do in metabolizing acetate (e.g., see The Order Methanomicrobiales in Volume 3). Interestingly, their genomes are quite large by archaeal standards (Deppenmeier et al., 2002; Galagan et al., 2002)—and they contain a number of non-archaeal genes!

Among the euryarchaeotes one finds both autotrophic and heterotrophic organisms (which is typical of large organismal groupings, of course). In the present case, the phylogenetic arrangement and genomic analysis of species

strongly suggest that the heterotrophs are derived from the autotrophs, not the reverse.

The Crenarchaeota, the other of the (classically recognized) archaeal kingdoms, cannot be usefully characterized at this point in time. The reason is two-fold. For one, the group has been relatively poorly studied in the laboratory. For another, the crenarchaeal species isolated in laboratory culture form only a phylogenetically restricted and nonrepresentative subset of the kingdom as a whole: direct environmental gene probing has shown that the crenarchaeal tree contains many branchings that are far more deeply placed than those of the cultured crenarchaeal species (DeLong, 1992; Barns et al., 1994). I will leave you with this impression: crenarchaeota are basically thermophilic organisms whose metabolisms somehow feature sulfur prominently. They are basically anaerobic, though they can be facultatively aerobic in some cases. And, as an evolutionist might expect, mesophilic (even psychrophilic) phenotypes also exist. Indeed, one of the major phenotypes in the oceans—the largest biotope on the planet—represents one particular crenarchaeal group, the Order Cenarchaeales, which abounds throughout the breadth and depth of the oceans, being remarkably in evidence in Antarctic waters (DeLong, 1997).

I have one closing thought concerning the archaea. The depth of the phylogenetic split between the two archaeal kingdoms seems the tip of an evolutionary iceberg. We have much to learn evolutionarily from this group of organisms. It saddens me to see how little interest goes into studying the archaea as an organismal group. And the fact that there exists an entire archaeal kingdom, the Korarchaeota, not a single representative of which has been isolated, is doubly distressing.

The Organismal Structure of the Eubacteria

The eubacteria are the consummate metabolists: sheer metabolic power and versatility. They are the masters of metabolic theme and variation—just as eukaryotes are masters of structural theme and variation. Some day we will understand just how eubacteria could have acquired such a varied metabolic repertoire. Their versatility is the more interesting when one realizes (from genomic analysis) that much of the more limited metabolic repertoire of the Archaea beyond that characteristic of the methanogens and methanogenesis is (as alluded to above) the product of metabolic capabilities (enzymes and pathways) imported from the eubacterial world.

The phylogenetic structure of the Eubacteria is rather different from the archaeal one just discussed. Viewed from afar, the main eubacterial lineages appear to radiate out from a "crown group," with a few atavistic forerunners branching from the eubacterial stem slightly earlier (examples being the Aquificales and the Thermotogales). (It is the crown radiation that spawns the phenotypic richness we characteristically associate with the Eubacteria.)

Among the major (kingdom level) eubacterial taxa—those dominant by virtue of numbers, phylogenetic diversity, and ecological impact—there exist several kingdoms and phyla about which we know next to nothing. Only a few, if any, cultured species represent them, their evolutionary breadth and ecological prominence being demonstrated by the large numbers of environmentally derived rRNA sequences from the various groupings (Pace, 1997). The lesson that has yet to sink in is that microbiologists *know relatively little about the bacterial world*. We clearly have no useful idea of what some of the major environmentally important bacterial groups are and are doing. You would think that a great deal of work would now be going into remedying this situation. This is not the case, however. Ask yourselves: do microbiologists have better things to do?

Let us begin with the major (most significant) eubacterial kingdoms and phyla, and then, when appropriate, extend to their subordinate classes. I more or less lump kingdoms and phyla here, because—until the proper genomic criteria have been developed to define taxonomic rank on the basis of the properties of naturally defined organismal groups—it is not in some cases possible to distinguish the two.

THE PROTEOBACTERIA One of the most, if not the most, ecologically dominant eubacterial kingdoms is the Proteobacteria (see Introduction to the Proteobacteria in Volume 5). The kingdom comprises five phyla, distinguished by the Greek letters αε. The α, β, and γ phyla obviously cluster, which easily emerges by any number of different phylogenetic analyses, while δ and ε, which may be specifically related, stand apart—but still within the proteobacterial kingdom. The β-phylum is actually a major branching within γ. I still consider β to be of phylum rank because of the apparent phenotypic diversity within it and its branching from a section of the γ-tree which, except for the β-branch, contains no photosynthetic representatives. (A taxonomic precedent for such a ranking is given by the class of mammals arising from within the class of reptiles.)

The α-phylum (see The Phototrophic Alpha-Proteobacteria in Volume 5) to a first approximation comprises (purple) photosynthetic lineages, nonphotosynthetic derivatives thereof, and a variety of pathogenic groups, mainly intra-

cellular pathogens. The most notable of the latter is the rickettsial group (see The Order Rickettsiales in Volume 5) (which comprises the genera *Rickettsia*, *Wolbachia*, *Ehrlichia*, *Anaplasma*, and *Cowdria* [see Introduction to the Rickettsiales and Other Intracellular Prokaryotes; The Genus *Wolbachia*; The Order Rickettsides; and The Genus *Bartonella* all in Volume 5]). What seem to be free-living relatives of these pathogens have been detected by rRNA analyses from marine habitats, although none have been cultured.

While the closely related agrobacteria and rhizobacteria, which play such important roles in the plant kingdom, are not members of the rickettsial group proper, the mitochondria are (Gray et al., 2001). At this point I'm going to leave further exploration of this interesting eubacterial phylum to the tastes of the reader—but not without first mentioning an evolutionary peculiarity of the α-proteobacteria. The α-phylum appears (anecdotally) to be (to have been) more prone to the horizontal import of genes than are most or all other proteobacterial phyla, as judged by the number of archaeal genre aminoacyl-tRNA synthetase genes they contain (Woese et al., 2000). A systematic study of HGT in the α-phylum is definitely called for, especially an accounting of when in the phylum's evolutionary history the bulk of these transfers occurred.

Little more needs be said than already has been about the β-phylum (see The Phototrophic Betaproteobacteria in Volume 5). The photosynthetic phenotype therein (represented in several lineages) is unlike the photosynthesis found in the γ-phylum (the latter are the purple sulfur bacteria), but akin to the purple non-sulfur types seen in the α-phylum. The β-phylum is again a haven for pathogens (e.g., chapters on *Burkholderia* [see The Genus *Burkholderia* in Volume 5], *Neisseria* [see The Genus *Neisseria* in Volume 5], and *Bordetella* [see The Genus *Bordetella* in Volume 5]) but also for a varied collection of metabolisms (e.g., chapters on the lithotrophic ammonia and nitrite oxidizers [see The Lithoautotrophic Ammonia-Oxidizing Bacteria and Nitrate-Oxidizing Bacteria in Volume 5], *Thiobacillus* [see The Genus *Thiobacillus* in Volume 5], and the dinitrogen-fixing *Derxia* [see The Genus *Derxia* also in Volume 5]). I am inclined to believe, on the basis of the relative uniqueness of the characteristic β-rRNA sequence, that the grouping may have begun as a rapidly evolving off-shoot of the γ-lineage.

The γ-proteobacteria do live up to the implication of the designation "proteo-"; a great deal of morphological and other phenotypic variation is housed therein. Thus, one can make few generalizations about the phylum as a whole. The purple photosynthesis characteristic of the γ-phylum is, as just mentioned, biochemically unique, and the lineages harboring it, the genera *Chromatium* (see The Chromatiaceae in Volume 6), *Ectothiorhodospira* (see The Family Ectothiorhodospiraceae in Volume 6), and closely related kin branch early from the γ-stem. These photosynthetic γ-proteobacteria deserve far more genomic attention than they have been given to date. I stress this because if photosynthesis is ancestral to the proteobacteria, at least to the α-β-γ cluster therein, then a genomic understanding of the photosynthetic representatives of the kingdom should prove key in the longer term to an understanding of the group's evolution.

This leaves the δ- and -phyla of the proteobacteria. Again a lack of significant genomic coverage of this assemblage—except, of course, for a notable preoccupation with the pathogenic helicobacteria—leaves little to be said. Perhaps the most significant phenotypic characteristic of the group is a lack of photosynthetic representatives. The reduction of sulfur compounds is a predominant theme among the δ-lineages. One would like to see a representative genomic sweep of the δ-phylum and some genomic emphasis on the nonpathogenic members of the -phylum, such as *Wolinella* (see The Genus *Wolinella* in Volume 7) and *Thiovulum*.

Mention must be made, of course, of the myxobacteria (see The Myxobacteria in Volume 7), which are one of the four major classically recognized bacterial groups (see quote from *The Microbial World* second edition, above). Under molecular scrutiny, however, the myxobacteria turn out to be subordinate to, a lineage within, the δ-proteobacteria. Yet, their complex and beautiful morphologies and complicated life cycles give cause to wonder. How could such morphologically rich and metabolically versatile entities phylogenetically reside among the otherwise morphologically drab δ-proteobacteria? The genomes of the myxobacteria are inordinately large, much larger than other δ-proteobacteria. Within their excess DNA must lie the answer.

The Gram-Positive Eubacteria This ecologically and phylogenetically major eubacterial kingdom (see The Genus *Eubacteria* in Volume 4) is one of the few classical eubacterial groupings to survive relatively unscathed the molecular phylogenetic assault on bacterial taxonomy. A fair bit of taxonomic reorganization has occurred within the kingdom, and some new members that do not possess typical Gram-positive walls have been added. But the two classical traits, endospore formation and Gram-positive wall, turn out to be phylogenetically

valid characteristics. The only real taxonomic surprise has been the addition of the photosynthetic heliobacteria to the group (Woese et al., 1985a; see The Family Heliobacteriaceae in Volume 4).

The main phylogenetic split among the Gram-positive eubacteria separates the "high G+C" group (the actinomycetes [see Introduction to the Classification of the Actinomyces in Volume 3], mycobacteria [see The Genus Mycobacterium–Medical and Non-Pathogenic Mycobacteria in Volume 3], and a number of others) from the "low G+C" group. The phylogenetic split between the two is great enough that their specific relationship might be questioned. While the coherence of the entire kingdom was apparent in phylogenetic analyses of the small subunit rRNAs (Olsen et al., 1994), it cannot be reliably demonstrated in my experience using the large subunit rRNAs. What is called for here is an appropriate test of the coherence of this kingdom based upon genomic analysis of the proper Gram-positive genomes—key ones of which have yet to be sequenced, however.

While most eubacterial genomes are sequenced for medical reasons—and this is surely true in the Gram-positive kingdom—one would still not single out the kingdom as an evolutionary training ground for pathogens. Metabolic versatility is its hallmark. The clostridia (not a genus or family, but a phylogenetically widely dispersed agglomerate of many different low G+C Gram-positive lineages) are classically notorious for the variety of degradative biochemistries of which they are collectively capable. Several clostridial genomes have now been sequenced, but many more are needed, and I would hope chosen in a systematic, phylogenetically comprehensive manner.

The Cyanobacterial Kingdom This grouping (see Cyanobacteria–Isolation, Purification, and Identification in Volume 4 and Cyanobacteria: Ecology, Physiology, and Molecular Genetics also in Volume 4) is one of the very few high-level eubacterial taxa that are anywhere near phenotypically uniform. Morphological variety abounds (as expected for a high-level taxon), but chlorophyll-based photosynthesis appears a constant metabolic theme in all. Classically isolated cyanobacteria contained only chlorophyll *a*, whereas the chloroplasts of plants, which are domesticated cyanobacteria, contain both chlorophylls *a* and *b*. Cyanobacteria that contain both chlorophylls have more recently been found (Lewin, 1984). Although the chloroplast lineage(s) traces to the general cyanobacterial cluster, no lineage representing a free-living cyanobacterium shows a specific relationship to the chloroplast lineage. Indeed the cyanobacterial phylogenetic tree has a remarkably bushy appearance. Why this is so is again the type of question that an evolutionarily oriented bacteriology finds interesting. Did the invention of oxygenic photosynthesis in the ancestor of the whole group kick off a major evolutionary radiation, open a vast new evolutionary world for exploration?

It should be noted that chlorophyll *g*, characteristic of the Gram-positive photosynthetic heliobacteria, is the closest in structure to the cyanobacterial chlorophylls of all the eubacterial chlorophylls. Tantalizing molecular clues have also suggested a specific relationship between the Gram-positive eubacteria and the cyanobacteria—none as yet convincing, however.

The Chlorobium-Cytophaga Kingdom This grouping and the drawing together of the cytophaga-bacteroides phylum (by whatever name) (see The Family Chlorobiaceae; The Order Cytophagales; and the Medically Important Bacteroides ssp. in Health and Disease all in Volume 7) is one of the more significant triumphs of rRNA-based molecular phylogeny of the bacteria. As one can infer from the glut of generic names that constitute the phylum (*Cytophaga*, *Flexibacter*, *Flavobacterium*, *Microscilla*, *Bacteroides*, and a host of lesser known genera), the grouping lay in separate taxonomic pieces before the advent of this molecular approach. The bringing together of the aerobic cytophagas and their ilk with the anaerobic bacteroides was an impressive join. Interestingly, the phylum does not comprise two major classes, split along aerobic/anaerobic lines. The bacteroides cluster forms a rather superficial branching from the main stem of the phylum, and has close specific relatives having a cytophaga phenotype. (None of the latter have piqued the interest of genome sequencers yet.) I would note that the rRNA analysis reveals the coherence of this phylum very clearly: the members of the group exhibit a clean rRNA signature (Woese et al., 1985b).

The specific relationship between cytophagas and the green photosynthetic *Chlorobium* species (the latter an unexpectedly tight phylogenetic cluster for a phylum) was only weakly suggested by the small-subunit rRNA comparisons. To demonstrate the relationship convincingly, we had to resort to sequencing the large subunit rRNA (Burggraf et al., 1991). And although expected, it is most reassuring to see the coherence of the kingdom spelled out in full genomic detail by the comparison of the genome of a *Chlorobium* species (Eisen et al., 2002) with that of *Porphyromonas*, a member of the bacteroides contingent (Paster et al., 1994). In its entirety this kingdom, with its spectacular admixture of phenotypes, demands some sort of

evolutionary rationalization. So, as you might by now expect, I would encourage a concerted, systematic genomic assault on the problem.

THE SPIROCHETES Since bacteriology's beginnings, this kingdom has been recognized as a major taxon (again see above quote from the second edition of *The Microbial World*). The unusual morphology of these organisms together with their unique mode of locomotion makes them stand out among all bacteria. The kingdom is phenotypically (morphologically) pure, monolithic—with one minor exception, an organism originally described as mycoplasma-like, but otherwise uncharacterized (K. Stetter, unpublished observation) except for an rRNA sequence that places it clearly among the spirochetes (Maidak et al., 2001). See Free Living Saccharolytic Spirochetes: The Genus *Spirochaeta* in Volume 7.

The spirochete grouping is deeply split phylogenetically into two major lineages, phyla. The one encompasses the more typical spirochetes such as *Spirochaeta halophila* (and houses the spirochete pathogens to which so much genomic attention has been paid, i.e., *Borrelia* and *Treponema* [see The Genus *Borrelia* and The Genus *Treponema* both in Volume 7]). The other is basically a lineage of aerobic spirochetes, the leptospiras (see The Genus *Leptospira* in Volume 7) and their relatives (some pathogenic).

At some early point in the evolutionary history of the spirochete kingdom (exactly how early cannot be pinned down yet, because genome sequences are not available for the leptospira lineages), the spirochetes experienced a considerable amount of HGT. This assertion, however, is based on a very small sampling of genes, namely the aminoacyl-tRNA synthetases. The spirochetes have replaced more of their ancestral aminoacyl-tRNA synthetases by synthetases of the archaeal genre than has any other eubacterial group (Woese et al., 2000).

THE PLANCTOMYCETES, CHLAMYDIAE, AND VERRUCOMICROBIA These three phenotypically disparate and phylogenetic distant groupings are combined here because fragmentary (unpublished) evidence suggests that they may well turn out to be specifically related to one another (at the kingdom level) when the appropriate genomes are available. Only the chlamydiae have been given significant attention to date (again for reasons of their pathogenicity). The reader is invited to peruse this third edition of *The Prokaryotes* for evidence of this relationship (see The Order Planctomycetales; The Genus *Chlamydia*–Medical; and The Phylum Verrucomicrobia all in Volume 7).

As their name suggests, the *Planctomyces* were originally thought to be eukaryotic. Their walls, as are the walls of chlamydiae and verrucomicrobia, are not typically eubacterial. It is unfortunate that so few examples of the verrucomicrobia exist in culture, for in nature they are clearly a major and ecologically important group of organisms. The planctomyces and relatives also appear to be playing a significant environmental role(s), although perhaps not at the level of the verrucomicrobia.

It has recently been discovered that the *Prosthecobacterium* subgroup of the verrucomicrobia carries two tubulin genes, the only known bacterial sources of these molecules, heretofore considered unique and essential components of the eukaryote cytoskeleton (Jenkins et al., 2002).

THE DEINOCOCCUS-THERMUS AND CHLOROFLEXUS GROUP Here again are two phylum level taxa that, I feel, will some day be united into a eubacterial kingdom. The phylogenetic grouping of Deinococcus and Thermus (see The Genus Thermus and Relatives in Volume 7), two disparate phenotypes in their own right, is another triumph of molecular (rRNA-based) phylogenetics (Weisberg et al., 1989). And the genomic sequence data now available more than confirm the relationship. The *Chloroflexus* grouping (see The Family Chloroflexaceae in Volume 7) likewise was pulled together through rRNA analysis (Olsen et al., 1994). A specific relationship between the two phyla, however, is not convincingly demonstrated on this level, merely vaguely suggested. So far, a lack of sufficient genomic sequence data prevents the hypothesis being put to critical test—but early results from the genomic front are encouraging, however (R. Overbeek, personal communication).

The ecological significance of these two phyla is still being explored (by default as it were, because no one knows *a priori* what will be uncovered when new niches are probed by Pace's methodology). Environmental sampling of rRNA sequences shows there to exist additional major lineages in both the Deinococcus-Thermus and the Chloroflexus phyla, none as yet with isolated representatives (N. Pace, personal communication).

THE REMAINING EUBACTERIAL KINGDOMS AND PHYLA With the above, I have come nowhere near to covering the full range of eubacterial kingdoms and phyla. However, those that remain fall into one or both of two categories: 1) demonstrated to be ecologically and phylogenetically major groupings by direct rRNA analyses of niches, but not represented by any (or very few) cultivated examples, and 2) represented by

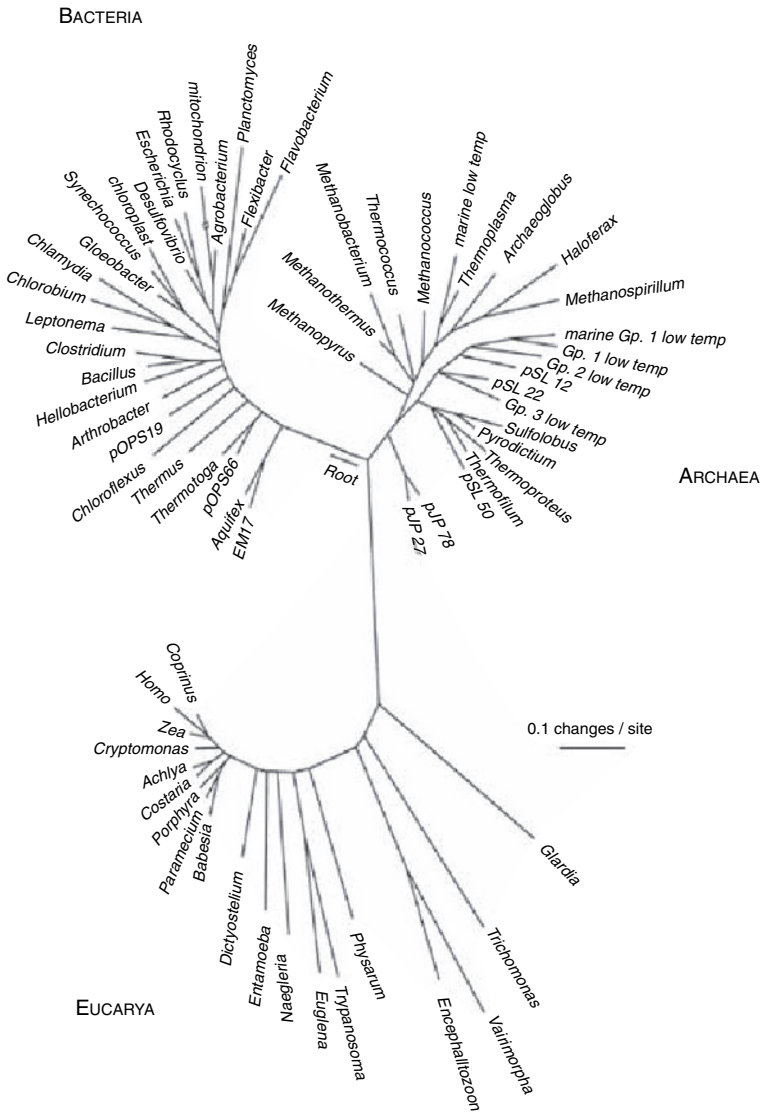

Fig. 1. Universal phylogenetic tree based on small subunit (SSU) rRNA sequence. Sixty-four rRNA sequences representative of all known phylogenetic domains were aligned and a tree was produced using FASTD NAML. That tree was modified, resulting in the composite one shown, by trimming lineages and adjusting branch points to incorporate results of other analyses. The scale bar corresponds to 0.1 changes per nucleotide.

few directly isolated rRNA clones and no or few cultivated species. These bear little comment at this point in time. A phylogenetic tree (Fig. 1) generated by N. Pace and colleagues gives some idea of the overall scope of the major eubacterial lineages (Pace et al., 1997).

I would end this brief, incomplete survey of the major organismal groupings by mentioning two eubacterial kingdoms that have rather limited ecological distribution, but are represented by genome sequences. Both are among the deepest branching eubacterial lineages (see Fig. 1). The first is represented by *Aquifex* (Huber et al., 1992; Deckert et al., 1998; see Aquificales in Volume 7). The second comprises what are now called the *Thermotogales* (Huber et al., 1986; Nelson et al., 1999). The number of generic names in the group, *Thermotoga*, *Geotoga*, *Petrotoga* and so on, does suggest a somewhat varied ecological distribution for the various members of the kingdom (see Thermotogales in Volume 7).

Now, on to the feast that awaits you in the rest of this third edition of *The Prokaryotes*.

CHAPTER 1.2

Databases

WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER AND ERKO STACKEBRANDT

Introduction

Computerization of microbiological data was first introduced by Sneath (1957) to handle the enormous amount of phenetic data collected to analyze the numerical phenetic taxonomy (NT) of the genus *Chromobacterium* (105 characters of 45 operational taxonomic units [OTUs]). This work paralleled the work of Sokal and Michener (1958), who used electric tabulating machinery and an electric mechanical desk calculator to generate a classification of bees of the *Hoplitis* complex (122 characters of 97 species). Sokal and Sneath joined forces to develop the *Principles of Numerical Taxonomy* (Sokal and Sneath, 1963) and they, together with Florek et al. (1951), Cain and Harrison (1958), and Rogers and Tanimoto (1960), were the first to develop and apply clustering methods (such as single and average-linkage clustering), probabilistic distance coefficients in NT, Jaccard's coefficient, scaling of multistate characters, parallelism and convergence, and equal weighting. Many of these algorithms and their modifications are still used today to analyze DNA and RNA electrophoretic patterns (Riboprint, denaturing gradient gel electrophoresis [DGGE], thermal gradient gel electrophoresis [TGGE], amplified fragment length polymorphism [AFLP], restriction fragment length polymorphism [RFLP], and the like), protein patterns, fatty acid methyl ester patterns, and evaluation of ecological parameters, to name a few. As mentioned by Sokal (1985), most larger universities acquired their first computer in 1956, but it took another 15–20 years before PCs were provided to biologists.

The present easy accessibility of public databases of biological resources and their sequences of nucleic acids and proteins let us forget how cumbersome comparative sequence analysis was 30 years ago. Similarities were determined from sequences, scattered in the literature, which had to be searched for, copied, and aligned by hand. By the late 1970s, dozens of short oligonucleotides that constituted a 16S rRNA catalogue (Uchida et al., 1974; Fox et al., 1977) were compared using a simple average linkage cluster analysis. For those of us who had no access to a personal computer, the calculation of similarities was done on paper. Nevertheless, as long as the fragments to be compared were short and the number of organisms analyzed were small (<20), it was the sequence analysis, not the determination of similarity coefficients (S_{AB}), that constituted the bottleneck of the approach. The discoveries of the phylogenetic uniqueness of the Archaea that led to the recognition of the three primary kingdoms (Woese and Fox, 1977) and thus revolutionized many fields in biology were achieved without the use of PCs and sophisticated treeing algorithms. Though hypotheses of phylogeny were derived mainly from similarity (phenetic) comparisons of rRNA catalogues and the extent of the homoplasy (parallelisms and reversals) was underestimated, most of the general findings from the 1970s and 1980s were proven right when analysis of more complete genes and genome fragments was evaluated by more sophisticated evolutionary models.

Public Databases

From the late 1970s on, availability of the genome sequences of the bacteriophages PhiX 174 and G4 required computers to store and analyze the data (McCallum and Smith, 1977; Staden, 1977; Staden, 1978; Godson et al., 1978). The strategy of shotgun cloning used computers to design the sequencing strategy (Staden, 1982). Tools used routinely these days (such as functions for alignment, edit, search, contig assembly, database comparison, folding, homologies, and translation functions) were developed. The increasing number of sequences in the literature required a coordinated storing and retrieving system. In 1980 the European Molecular Biology Laboratory (EMBL) Data Library was founded—the first central depository of nucleotide sequence data in the world (precursor to

EMBL's European Bioinformatics Institute [EBI] Outstation). But at that time it was not essential to deposit sequences, and the older literature still contains sequences that have not yet been transferred to an electronic platform. In 1982, *Nucleic Acids Research* devoted a whole issue to the use of computers in the analysis of nucleic acid sequences (Söll and Roberts, 1982). The role of this journal continues to inform scientists about the development of established databases and the availability of the rapidly proliferating new databases on individual markers (e.g., bacterial virulence factors, protein families, and pathways), individual species (e.g., *Pseudomonas aeruginosa* and *Candida albicans*), and specific groups of organisms (e.g., Yeast and *Caenorhabditis*). The journal also gives an overview of molecular biology database collections in the first issue of each volume (http://nar.jour nals.org/cgi/content/full/33/suppl_1/D5), listing more than 700 entries, ordered according to determination and application. Three of the major databases constitute an international nucleic acid sequence database cooperative: DDBJ (http://www.ddbj.nig.ac.jp/), Japan; EMBL (http://www.ebi.ac.uk), Europe; and GenBank (http://www.ncbi.nlm.nih.gov/Genbank/index.html), United States. They are regularly exchanging new additions.

The Swiss-Prot (now UniProt; http://www.expasy.uniprot.org/) database plays a crucial role in that it provides the user with integrated databases (nucleic acid sequences, protein sequences, protein tertiary structure, and specialized databases). Besides a high level of integration, UniProt allows a high level of annotation on functions of proteins (secondary to quaternary structure, modifications, and domain sites) and a low level of redundancy, indicating conflicting entries which occur in multiple databases. The UniProt/TrEMBL database (http://www.uniprot.org/entry/P99999, http://www. expasy.uniprot.org/index.shtml) complements the UniProt database by providing translations of all open reading frames of nucleic acid sequences provided by the three major databases indicated above.

Another entry to information retrieval is via the Entrez browser, giving access to major databases. These may be broad databases such as GenBank and protein sequence database, complete genomes, three dimensional structures, single nucleotide polymorphism, and population study data sets to chemical structures of small molecules and bioactive chemical substances. Entrez is known best as the gate to PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi). The pendant at the EBI data library is the sequence retrieval system (SRS; http://srs.ebi. ac.uk).

Ribosomal RNA Databases

Ribosomal rRNA sequence data still provide a solid basis for microbial taxonomy and identification. Three major projects are maintaining databases of processed rRNA primary structure data.

The Ribosomal Database Project (RDP) II initially founded by Carl Woese and coworkers in 1992 is now maintained at the Center for Microbial Ecology at Michigan State University (http://rdp.cme.msu.edu). The RDP maintains databases of aligned large and small subunit rRNA sequences. The alignments in RDP databases are optimized by specialists taking into account higher structure features and can be used as guides for the alignment of user provided data. The data can be accessed by the browsing of databases (http://rdp.cme.msu.edu/hierarchy/hb_intro.jsp) according to RDP's or National Center for Biotechnology Information (NCBI)'s taxonomic hierarchy. The RDP hierarchy is based upon that proposed in the recent edition of *Bergey's Manual of Systematic Bacteriology.* The databases or user defined subsets can be downloaded as compressed files in GenBank (*.gb.bz2) or FASTA (*.fasta.bx2) format and either as aligned or non-aligned datasets on (http://rdp.cme.msu.edu/misc/resources.jsp). The RDP also provides facilities for on-line sequence checking of user-provided sequences and database entries such as searching most similar primary structures, preliminary alignment and phylogenetic analysis, chimera checking, and oligonucleotide (probe) matching. Additional databases are indicated in Tables 1 and 2.

The European Ribosomal RNA Database located at the University of Ghent (Belgium; http://www.psb.ugent.be/rRNA/) maintains small and large subunit rRNA sequences in aligned format. The alignment takes into account secondary structure prediction based upon comparative analysis of the database sequences. Data selection and download can be done by using a query interface or a taxonomy browser. An rRNA BLAST service and some stand alone software for primary and secondary structure editing are available at or from this site.

The two major tasks of the ARB Project (*arbor*, Latin: tree; http://www.arb-home.de) initiated in 1992 at the Technical University of Munich are 1) the maintenance of a structured integrative database combining processed primary structures and any type of additional data assigned to the individual sequence entries and 2) a comprehensive selection of software tools (controlled via a common graphical interface) directly interacting with one another and the central database (Ludwig et al., 2004). Initially designed for rRNA data, the ARB software

package can also be applied to DNA, protein and full genome sequences. ARB software and databases are accessible to the public (http://www.arb-home.de) and have to be installed locally. The ARB project provides databases for large and small subunit rRNA, a selection of evolutionarily conserved protein genes such as the genes for elongation and initiation factors, ATPase subunits, recA, RNA polymerases, DNA gyrases, heat shock proteins, and amino acyl tRNA synthases as well as full genome sequences. The primary structures representing organisms, genes or gene products are stored in individual database fields. The primary data are processed with respect to alignment, higher order structure prediction, conservation profiles, and other criteria. According to the ARB concept of an integrative database, any type of additional data can be stored within user defined database fields assigned to the respective sequence. It is either stored in the local database or linked to it via local networks or the internet. The database is hierarchically structured and highly compressed. The data can be imported and exported in a variety of commonly used formats. Easy data access is possible via powerful search and retrieval tools or by mouse click at the nodes of graphically visualized (phylogenetic) trees. The ARB software package comprises a comprehensive set of cooperating tools for database maintenance and analysis. Among these tools are powerful primary and secondary editors as well a 3-D structure tool allowing visualization of any type of

sequence-associated information such as search strings, probe and primer sites, any type of profiles, in situ accessibility maps, position filters, and functional sites by user defined background colors (Kumar et al., 2005). Further important coordinated software tools concern automated and user supported sequence alignment, a selection of alternative treeing methods, and phylogenetic probe design and evaluation. ARB-genome is designed for functional genomics. The integrated database allows the user to assign experimental parameters as well as results from proteomics and transcriptomics to the respective organism and gene data. The interacting software tools allow comparative genome as well as experimental data visualization and analysis.

rRNA Targeted Probe Databases

Taxon specific probe technologies nowadays are central tools in microbial identification, taxon specific enrichment, and ecological studies. Against the background of many examples of redundant, ineffective, and incorrect probe design, databases for evaluated taxon specific probes are urgently needed.

ProbeBase (http://www.microbial-ecology.de/probebase/index.html) was an initiative of the microbial ecolog group at the Lehrstuhl für Mikrobiologie of the Technical University of Munich (http://www.mikro.biologie.tu-muenchen.de) and is now located at the University of Vienna. It contains published rRNA-targeted oligonucleotide probe sequences, DNA microarray layouts, and associated information. The probes were not only evaluated in silico using the ARB program package and databases (http://www.arb-home.de) but also experimentally tested.

The Roscoff database maintains experimentally evaluated rRNA targeted probes specific for eukaryotes, protists (mostly photosynthetic), and cyanobacteria at the Station Biologique de Roscoff. The data are accessible at (http://www.sb-roscoff.fr/Phyto/Databases/RNA_probes_introduction.php).

The ARB probe library gives access to all possible phylogenetic probes against the full background of the current ARB databases. A platform-independent client which can be downloaded from (http://www.mikro.biologie.tu-muenchen.de) visualizes a phylogenetic tree. This tree provides mouse click access to any potential node or subtree specific probe target and additional descriptive information. Users have to be aware that the potential probe targets are designed and evaluated in silico but not tested in vitro.

Concluding Remarks

Despite the progress in bioinformatics and genomics as well as the collaboration of some of the databases, the concept of integrative databases—the assignment of any information (be it primary data of expression studies, physiological pathways, or conventional descriptive data such as a picture of the habitats or recordings of the voices of higher organisms) to the sequence data—is not yet optimally implemented. As with data-bases, a similar situation is seen with respect to interoperability of the vast number of software tools. The ARB concept is an attempt to combine direct interaction of various tools and databases with a maximum of accepted interventions by the individual user.

CHAPTER 1.3

Defining Taxonomic Ranks

ERKO STACKEBRANDT

Systematics and Classification

"Well, in *our* country," said Alice, still panting a little, "you'd generally get to somewhere else—if you ran very fast for a long time, as we've been doing."

"A slow sort of country!" said the Queen, "Now, *here*, you see, it takes all the running *you* can do, to keep in the same place. If you want to get somewhere else, you must run at least twice as fast as that!"

—Lewis Carroll, *Through the Looking Glass*, (1872)

Those who have chosen systematics, classification, and taxonomy as research topics have learned to consider the complexities as exciting and important. For others, these topics are mainly boring and through changes in names of microbial taxa, may cause confusion. Indeed, the problem of changing names of taxa is inherent. Classification is motivated by the desire of taxonomists to provide the user with a system that in their opinion optimally reflects the natural relatedness between the taxa. Now finally, the determination of phylogenetic relationships is achievable (Stackebrandt, 1992). Looking back in the history of microbiology, the lack of interest in classification can be traced to the enormous difficulty of past generations of systematists to put in order the phenotypic and genotypic properties of the steadily growing numbers of bacterial strains. The user of taxonomy was confronted with constantly changing classification concepts and systems, taxonomic rearrangements, and synonymy of names. Problems also arose from the terminology: while some regard systematics and taxonomy as synonymous, others define taxonomy as the theory and practice of classifying organisms and systematics as broader, including the evolutionary and phylogenetic components. For many researchers, nomenclature is their only contact with taxonomy, and the contact occurs only when they are confronted with name changes. However, systematics includes more than naming of organisms (Stackebrandt et al., 1999).

Classification is done by generating as much data on the properties of novel isolates as possible and by the process of identification, e.g., comparing the data with the database of previously classified organisms and by affiliating the isolate with a previously described or a new species. Classification includes the theory and process of ordering the characterized organisms into one or more systems. Nomenclature is the naming of the appropriate taxon within a classification system, and it includes subjective changes that occur whenever novel insights alter the taxonomic weight of characters, and thereby the rank of taxa.

As outlined (Stackebrandt et al., 1992), several classification systems exist in parallel and no classification system can claim predominance. No two systems of clustering need to match. As long as a system succeeds in doing what it sets out to do, it cannot be described as wrong or in error.

There are systems that group microorganisms on the basis of their increasing degrees of risk to humans, animals and plants. Here, organisms are artificially, pragmatically classified into risk groups according to degree of pathogenicity or risk potential, and this system serves no other purpose (Table 1).

Another system focuses on the rapid and reliable identification of bacteria for which knowledge about phylogenetic relatedness is not mandatory (Table 2). In such a diagnostic system, used in the past, affiliation of an isolate to a genus and species was based on Gram-stain reaction, oxygen requirement and morphology, chemotaxonomy, numerical phenetic analyses, usage of rapid diagnostic kits (e.g., API, Merieux, and BIOLOG), and combinations of selected physiological tests. (API System, La Balme les Grottes, 38390 Montalieu Vercieu, France. BIOLOG, Biolog, Inc., 3989 Trust Way, Hayward, CA, 94545 USA.)

Yet another system considers similarities in homologous molecules. Organisms are grouped according to their phylogenetic relatedness, which is then circumscribed by a wide range of genomic and epigenetic characteristics. This

Table 1. Examples of prokaryotic species classified by risk.

Genus	Risk group 1	Risk group 2	Risk group 3
Chlamydia	not known	*C. trachomatis*	*C. psittaci*
Bacillus	*B. circulans*	*B. cereus*	*B. anthracis*
Burkholderia	*Bu. cocovenenans*	*Bu. Cepacia*	*Bu. mallei*
	Bu. antropogonis	*Bu. Vietnamensis*	*Bu. pseudomallei*
Francisella	not known	*F. tularensis* subsp. *mediasiatica*	*F. tularensis* subsp. *tularensis*
Mycobacterium	*M. asiaticum*	*M. avium*	*M. leprae*
	M. fallax	*M. chelonae*	*M. tuberculosis*

Table 2. Examples of Bacteroidaceae classified by phenotypic properties.

Family	Genera	Main diagnostic differences
Bacteroidaceae[a]	*Bacteroides*	Peritrichous straight rod; produces a mixture of fermentation products from carbohydrate and peptone; butyrate not a major product
	Fusobacterium	Nonmotile straight rod; butyrate is a major product
	Leptotrichia	Nonmotile straight rod; lactate is the sole major fermentation product
	Butyrivibrio	Motile, not peritrichous, curved rod; butyric acid is the major fermentation product
	Succinimonas	Short, motile rod or coccobacilli; single polar flagellum; succinate and acetate are major fermentation products
	Succinivibrio	Motile helical or spiral-shaped cell; single polar flagellum; succinate and acetate are major fermentation products
	Anaerobiospirillum	Motile helical or spiral-shaped cell; bipolar tufts of flagella; succinate and acetate are major fermentation products
	Wolinella	Motile, helical to curved, or straight rod, single polar flagellum; either hydrogen or formate as electron donor for reduction of fumarate to succinate; carbohydrates not fermented
	Selenomonas	Motile, crescent-shaped cell, tufts of flagella on concave side; fermentation products are propionate and acetate
	Anaerovibrio	Motile curved cells, single polar flagellum, lipolytic; fermentation products are propionate and acetate
	Pectinatus	Motile curved cells, lateral flagella aligned on concave side; fermentation products are propionate and acetate

[a]Members of the family Bacteroidaceae are described as Gram-negative, fermentative anaerobic organisms (Holt et al., 1994).

genealogically based classification system is the most comprehensive one in overall understanding of the biology of the organisms, including the evolution of core processes of genetics, biochemistry, and physiology. This approach, which was outlined two decades ago, is applied by the vast majority of microbiologists.

Thus, classification in bacteriology is based on the principle of degree of relatedness. The grouping of organisms, whether or not they are formally designated taxa (e.g., genera, phyla, domains, groups, clusters, etc.), generally brings together those organisms on the basis of shared properties. Of the many systems that have been described in the past, the one that is based on genealogical relatedness offers the greatest potential, as it explains the widest range of genetic and biochemical properties. Genealogy derived from gene sequence similarity has the added advantage of working with a reliable, objective and stable basis for identification and classification. The dramatic changes that occurred in the classification of species of *Bacteroides*, lumped together in the past on the basis of a few superficial properties, are an excellent example of a shift to the concept that regards phylogenetic relatedness as the most reliable basis for classification (Table 3). The reclassification of a species requires redefinition of its properties. Analysis of the natural relatedness of a species will provide information on its phylogenetic position, i.e., its nearest neighbor(s). However, in many cases the position will not provide information on other properties needed to decide whether this species can be considered a species of a known genus or the nucleus of a novel genus. These conclusions depend upon the results of a wide array of phenotypic and genomic properties.

This chapter introduces the importance of gene and gene product sequence homology as a basis for an objective framework in which to order lineages of prokaryotic organisms. It then describes the (subjective) decision-making by which bacteriologists, on the basis of a phylogenetic framework, define the ranks of species and genera, and it deals with the problem of delineating ranks above the genus level. Special emphasis is placed here on the pragmatic definition of the species. An example of the process of

Table 3. Changes in higher classification as exemplified by the fate of some species of Bacteroides (see Table 2) after phylogenetic-polyphasic taxonomic analysis (Shah and Collins, 1989).

Traditional classification	Phylogenetic classification	Affiliation to higher taxon
Bacteroides furcosus	*Anaerorhabdus furcosus*	Bacteroidaceae
Bacteroides bivius	*Prevotella bivia*	Bacteroidaceae
Bacteroides endodentalis	*Porphyromonas endodentalis*	Bacteroidaceae
Bacteroides microfuscus	*Rikenella microfuscus*	Bacteroidaceae
Bacteroides amylophilus	*Ruminobacter amylophilus*	Gamma subclass of Proteobacteria
Bacteroides gracilis	*Campylobacter gracilis*	Epsilon subclass of Proteobacteria
Bacteroides hypermegas	*Megamonas hypermegas*	N.D.
Bacteroides nodosus	*Dichelobacter nodosus*	Beta subclass of Proteobacteria
Bacteroides termitidis	*Sebaldella termitidis*	N.D.
Bacteroides succinogenes	*Fibrobacter succinogenes*	Phylum Fibrobacter

Abbreviation: N.D. not determined.

modern classification is given for actinomycete taxa. This chapter should be studied in conjunction with the one by Wolfgang Ludwig (Ludwig, 1999), as many examples of lineages defined by 16S rDNA analysis, of the phylogenetic coherence or incoherence of taxa, and the delineation of higher taxa, can be judged best by having the phylogenetic tree available.

Past Classification Attempts

Ranks or taxa have been introduced in the classification of biological specimens to facilitate communication among men and to arrange living matter by morphological, physiological, ecological and genomic features. The basis of any system is the species and the genus, and according to the binomial system (Linnaeus, 1753), the description of a type species is not possible without describing a genus, and a genus cannot be described without a species. This simplicity explains why the binomial system is still used for the naming of organisms within the three domains Archaea, Bacteria and Eucarya (Woese, 1987). Moreno (1997) states: "The wisdom of Linnaeus was not only to create a comprehensive classification system, but more importantly, a useful one." The definition of a species has been debated extensively since the publication of the key work—*On the Origin of Species* (Darwin, 1859). At that time, the debate centered on animals and plants but excluded the prokaryotes mainly because they had no evolutionary record.

Bacterial classification as a science began with the contribution of Cohn (1872, 1875), who was the first to ask if bacteria, like plants and animals, can be arranged in species and genera. He presented a classification scheme composed of six genera that were distinguished on the basis of morphological criteria. However, he clearly pointed out that morphological properties are insufficient, inasmuch as similarly shaped bacteria may have different physiological characters. Cohn regarded the genera as natural entities but the species he described as largely provisional. With hindsight, it is possible to conclude that early microbial systematists were in no position to judge the importance of such simple properties in evolutionary terms. It was not known until the late 1970s that taxa defined by superficial properties such as morphology did not necessarily match taxa defined by traits that arise in the course of long evolutionary processes.

In the early twentieth century, the number of determinable properties expanded dramatically and, consequently, the number of species increased. New strains of medical importance were described as new taxa and the classification systems placed emphasis on these organisms and their identification. New systems were proposed in which the accent shifted from morphology to physiology, metabolism, pigments, and pathogenicity (Migula, 1900; Orla-Jensen, 1909; Pringsheim, 1923; Prévot, 1938; Kluyver and van Niel, 1936; Stanier and van Niel, 1941). To incorporate the wealth of information and to integrate the different prokaryote systems with those of higher animals and plants, a single unified formal system of bacterial classification was established by Buchanan (Buchanan, 1916, 1918). This system provided the basis for *Bergey's Manual of Determinative Bacteriology*, which, in the many editions that followed, presented better than any other source the most useful references for identification but retained a nomenclature that connoted phylogenetic relationships, in the tradition of Buchanan's system. Attempts to construct another single formal classification system or to work with several systems in parallel were criticized. Kluyver and van Niel (1936) suggested that rather than searching for a natural system, taxonomists should develop determinative keys to provide the easiest possible identification of species and genera. However, because the choice of characters used to establish the system was subjective, it was recognized that empirical sys-

tems would be largely unmodifiable. Consequently, the whole system was disrupted when novel characters were taken as the basis for the establishment of a new classification system. The main advantage of the empirical system was its immediate practical utility, but even this advantage disappeared when differential characters were not actually mutually exclusive. The period during which the importance of developing a natural classification system was recognized (Stanier and van Niel, 1941) but considered unachievable lasted until 1975. The question then remains why past generations of microbiologists could not develop a phylogenetic framework for prokaryotes. In hindsight, the answer is quite easy: Early attempts were prone to failure because scientists lacked fundamental genetic information, understanding of mechanisms of heredity, and the technical ability to find out the structure of genes and chromosomes.

Phylogeny Is Based on Homology

Phylogenetic systematics seeks congruence between the lines of descent evolved over time and the supraspecific taxa described by taxonomists. Prerequisite for the description of a taxon of any rank in a phylogenetic system is the recognition that all members originate from one ancestral form and that homologous traits of the ancestral form are found also in their descendants. The question then remained which of the several thousand semantides in a prokaryotic cell are useful for phylogenetic studies. The establishment of a system which is set up to subsume all species must include phylogenetic markers that are ubiquitously distributed, functionally equivalent, and homologous housekeeping molecules. These markers should be homologous apomorphic characters that evolved only once (synapomorphy) but not by convergence. Homology is the sharing by two taxa of a property derived from the same or equivalent property of the nearest common ancestor. Deciding whether a property is homologous or the product of convergence has been the greatest problem, and one that could have been solved only by comparing the course of evolution of each property as laid down in the fossil record. It is obvious that lack of a substantial fossil record and thus the inability to use that record to draw conclusions on genomic and phenotypic properties have prevented the inductive derivation of genealogical lines. Furthermore, morphological complexity and comparative anatomy, extremely useful properties of eukaryotes for determining homologies, are absent in the morphologically and developmentally simple prokaryotes. As a consequence, a phylogenetic classification system only became available after the theoretical and methodological basis had been laid about 30 years ago.

One of the main intellectual breakthroughs that helped microbiologists solve the problems of phylogeny was provided by Zuckerkandl and Pauling (1965), who recognized that organisms are the products of historical events and that all cellular structures reflect their evolutionary history. These scientists also commented that in the case of microorganisms, early evolutionary events can be documented only at the primary structural level of homologous and phylogenetically informative molecules. When comparing organisms, the number and composition of sequence differences between corresponding proteins and genes coding for rRNA reflect phylogenies and consequently allow the recognition of pairs or groups of organisms that originated from a common ancestor. Determining relatedness is based on sequence analysis of genes or their transcripts, also known as the semantides.

There are three categories: primary (DNA), secondary (RNA), and tertiary (proteins) semantides. Sequences of these molecules are molecular chronometers, records of evolution, as they indirectly measure the time lapsed since their origin, and the comparative analysis of primary structures is a powerful tool to measure evolutionary relationships. Episemantic molecules to be used in comparative studies are synthesized under the control of tertiary semantides, and above all it is the chemical composition of cell constituents that have received considerable attention (Schleifer and Kandler, 1972). Asemantic molecules (e.g., exogenous vitamins, phosphate ions, oxygen, viruses) are not produced by the organisms themselves and do not express any of the historic information that organisms contain.

Zuckerkandl and Pauling state that "at any level of integration, the amount of history preserved will be the greater, the greater the complexity of the elements at that level and the smaller the parts of elements that have to be affected to bring about a significant change. Under favorable conditions of this kind, a recognition of many differences between two elements does not preclude the recognition of their similarity." The correctness of this hypothesis was demonstrated by the impressive phylogenetic trees of gene and protein sequences. Episemantic molecules were not considered useful for deriving evolutionary conclusions because enzymes with different primary structures can lead to the synthesis of identical episemantic or similar molecules in different organisms as long as the active enzymatic sites are similar.

The Main Phylogenetic Parameters for Classification

The two main tools [sequence analysis of the semantides DNA, RNA and proteins (Zuckerkandl and Pauling, 1965) and hybridization of genomes] for determining phylogenetic relationships in prokaryotes were developed in the mid-1960s. Historically, the molecular approaches used were sequence analyses of proteins, such as cytochrome C, fibrinopeptides, and ferrodoxins, as well as immunological approaches, such as immunodiffusion and microcomplement fixation. However, the latter methods as well as protein sequencing became less significant with the availability of rapid sequencing techniques for DNA. The branching patterns based upon 16S rRNA and 16S rDNA sequences were surprising, mainly because these patterns showed that characters used traditionally to cluster organisms have in reality restricted phylogenetic meaning. Prominent examples of phenotypic characteristics shown not to circumscribe higher taxa in the past are now examples of characteristics whose evolutionary development has recently been or is soon to be unraveled. These are cell walls (Kandler and König, 1985; Stackebrandt et al., 1985; Schleifer et al., 1990), aerobic metabolism (Fox et al., 1980; Seewaldt et al., 1982), spore formation (Ash et al., 1991; Collins et al., 1994; Stackebrandt and Rainey, 1997), biosynthetic pathways (Balch et al., 1979; Fowler et al., 1986; Stackebrandt et al., 1989), and photosynthesis (Gibson et al., 1985; Woese et al., 1985a; Stackebrandt et al., 1988; Imhoff et al., 1998a; Imhoff et al., 1998b). Today, sequencing of 16S rDNA in bacteriology is so widely accepted that it is considered a classical approach. The sequencing and analysis strategies and their bearing on evolution, phylogeny, classification and identification are now textbook knowledge.

16S rDNA Analysis

Though the importance of rDNA sequencing, alignment, and data analysis is covered extensively in chapter 1 (Ludwig, 1999), the main points are repeated here. The primary structure of the rDNA molecules spans an enormous geological period, almost 3.6 Gy. Why especially has this molecule been selected for phylogenetic analysis? Both the gene and its product are ubiquitous and have functional constancy, common ancestry, genetic stability, appropriate size, and independently evolving domains within the molecule.

Sequence analysis of rRNA or other phylogenetically meaningful genes (Schleifer and Ludwig, 1989) has become a rapid standard technique, and the sequences generated have a very low error rate. The restriction in the use of this molecule as a phylogenetic marker springs from certain intrinsic properties: considering the billions of years that have passed since their origin, the number of informative positions within sequences is small. To maintain function, a reasonable percentage of the positions must remain invariant or be highly conserved, and many of the remaining characters cannot be changed independently. As a consequence, the majority of evolutionary events will remain undiscovered. Another restriction is that most prokaryotic organisms have 2–14 copies of the multigenic rRNA operon in the genome (Farrelly et al., 1995). PCR amplification will mask possible intracistronic microheterogeneities, which consequently may obscure elucidation of small differences between closely related organisms. Sequence analysis of individually cloned operons will unravel these heterogeneities but these few changes must be regarded as "noise" and hence without phylogenetic implications.

Higher order structures of rDNA and rRNA molecules facilitate sequence alignment which can easily be done manually. Several algorithms are available for phylogenetic analyses (Ludwig, 1999). Once a phylogenetic tree or a dendrogram is generated, the taxonomist must judge whether the branching order of the phylogenetic tree is reliable. Numerous factors can influence the topology of a branching pattern, which is a dynamic construct that changes with any new sequence included, or region selected, for analysis. Nevertheless, the topology of trees, which are generated on the basis of genes subjected to the same fate in evolution (e.g., common horizontal or vertical gene transfer), are rather stable and robust constructs. Results of comparative analyses of other conservative molecules responsible for central functions such as the β–subunit of ATP synthases, elongation factors, phosphoglycerate kinase, and DNA-directed polymerase demonstrate this point. Thus, trees based on rDNAs and rRNAs reflect not only the evolution of these molecules but also, most likely, the evolution of a major portion of the genome. In principle, the primary structure of the most widely analyzed 16S rRNA gene must be regarded as a miniaturized version of a major part of the genome, and, though due to its size of only 1,540 bases, as having much less power to resolve.

DNA-DNA Hybridization

This method was the first molecular approach used routinely for measuring degrees of relatedness and the first phylogenetic one to be generally accepted for improving bacterial clas-

sification. It is still the most rapid and inexpensive of all phylogenetic methods for measuring an average nucleotide similarity of the entire genome; however, it gives no indication of which genes contribute to or detract from the similarity. Also, this technique reveals why neighboring species show somewhat lower similarity values. Though unclear and unsatisfactory, the information found in a genome, containing a range of highly to less conserved genes, has the advantages over information obtained by comparison of individual genes or gene products only. Several hybridization techniques have been thoroughly tested to determine the influence of various experimental parameters and compared to determine reproducibility and limitations (Grimont et al., 1980; Huss et al., 1983; Baumann et al., 1983; De Ley, 1970; De Ley, 1970; Schleifer and Stackebrandt, 1983). DNA-DNA pairing studies, comparing the same strains by different techniques, were in good agreement (see Schleifer and Stackebrandt, 1983 for examples). Some novel techniques and variations of established methods have been introduced such as hybridization in microdilution wells (Ezaki et al., 1989; Hara et al., 1991; Kaznowski, 1995), the random-primed labeling and signal amplification system (Amersham Life Science, Piscataway, NJ), or detection of double-stranded, digoxigenin-(DIG) labeled DNA with anti-DIG antibodies conjugated with alkaline phosphatase (Lind and Ursing, 1986; Ziemke et al., 1998). Some of these novel methods have not been compared with the established ones (S1-, renaturation- and filter methods), but others such as the microplate technique (Ezaki et al., 1989) and the renaturation technique correlated very well (Goris et al., 1999).

Relationships are usually expressed in terms of DNA similarities. It should be noted that because the underlying processes of renaturation are still unknown, the expression "DNA homology" should not be used in connection with DNA reassociation techniques. Wayne and colleagues (1987) recommended use of a second parameter, the Tm(e) value (Tm(e) is the melting point of DNA formed originally by the reassociation process of two single stranded DNA molecules; (e) stands for eluted labeled single stranded DNA which is released by heating up the double stranded DNA), especially in those cases where, under optimal hybridization conditions, DNA similarities fail to discriminate between fine details in relationships. The inverse linear correlation between Tm(e) and DNA similarity makes determination of both parameters somewhat redundant (Grimont et al., 1980; Baumann et al., 1983), and hence Tm(e) values is usually not included in DNA-DNA reassociation studies.

Greater reproducibility and small sampling error (Sneath, 1989) are obvious advantages of DNA hybridization. The disadvantages are the unavailability of equipment, i.e., a thermocontrolled spectrophotometer, and lack of DNA in sufficient quantity and purity, as exists with many archaea and lithoautotrophic bacteria. The limited resolving power of DNA hybridization has been recognized from the very first experiments. It has been calculated that for reassociation under optimal hybridization conditions (25°C below the Tm(e) of the DNA), the two DNA strands must exhibit at least 80% sequence complementarity. Depending on the sequence similarity of the reassociating single strands, a difference of about 20% is then spread between 0% (no hybridization) and 100% (as defined by maximal reassociation obtained with the homologous DNA strands). It is therefore obvious that a given DNA homology value does not reflect the actual degree of sequence similarity of the primary DNA structure. As measured with experimentally introduced mispairings, thermal stabilities have been estimated to decrease from 1 to 2.2% for each percent mispairing (Bautz and Bautz, 1964; Britten and Kohne, 1968; Ullman and McCarthy, 1973). Although these experiments have been performed on short stretches and not on complete genomes, one can nevertheless argue that organisms that share 70% DNA similarities share at least 96% DNA sequence identity (Johnson, 1973). If the number of bases in the genome of E. coli is approximately 4×10^6, then 4% differences or 1.6×10^5 nucleotides are different (not taking into account the possibility that genome rearrangement is a source of decrease in DNA similarity). This divergence could easily account for the significant differences in phenotype observed between strains of some species, e.g., *E. coli* (Brenner, 1991).

Correlation of Individual Phylogenetic Parameters

It is generally accepted that if two organisms have highly similar DNA, they are closely related genetically. The parameters measured by different methods have shown excellent agreement when closely related organisms are compared. However, when parameters from more distantly related organisms are measured, the data are difficult to reconcile (Huss et al., 1983; Grimont et al., 1980). Numerous studies have shown that phenotypic and genetic similarities agree only if the borderline of 70% similarity is obtained under optimal hybridization conditions. Therefore, this borderline has been recommended for species differentiation (Wayne et al., 1987). Values from 30 to 70% reflect a moderate degree of relationship, whereas values become

increasingly unreliable (and taxonomic conclusions should be avoided) once these values fall below the 30% level. One has, however, to consider that this recommendation was derived mainly from experience of working with numerous strains of enterobacterial species (Steigerwalt et al., 1976; Brenner, 1991). Thus, transferring the situation found for a phylogenetically very shallow group of mainly eukaryote-associated organisms to two ancient, highly structured, and enormously diverse prokaryotic domains grossly underestimates the different mechanisms as well as the mode and tempo by which organisms evolve. But then one has to remember that the delimitation value (of 70%) is artificial and used to structure the bacterial world at the level of species.

For highly related organisms, there is very good congruence in general between DNA-DNA and DNA-rRNA hybridizations (De Smedt and De Ley, 1977; De Vos and de Ley, 1983; Johnson and Francis, 1975). The Tm(e)s for strains of species exhibiting more than 60% DNA homology differ by less than 2°C. However, the DNA-rRNA hybridization technique has been superseded first by 16S rDNA cataloguing and then by sequence analysis of 16S rDNA. Values on DNA-rRNA hybridization are found in the literature before 1995. Likewise, similarity coefficients of the 16S rRNA cataloguing approach (S_{AB} values), the predecessor technique of 16S rDNA similarity determination, are found in the literature before 1990. For the same reasons as for total 16S rDNA, correlation between DNA pairing values and S_{AB} values is only marginal (Stackebrandt, 1992). Only of historic value are the correlation blots between rRNA homology and S_{AB} values (Schleifer and Stackebrandt, 1983) and the correlation between S_{AB} values and actual almost complete 16S rRNA sequence homologies (Woese, 1987).

The correlation blot, determined for the two most widely used approaches for discovering prokaryotic phylogeny, justified continuing the use of the DNA-DNA reassociation technique. Let us assume the unlikely case that the plot showed linear correlation between intraspecies DNA similarities of above 70% and 16S rDNA sequence similarities above 97.5%. The DNA hybridization method would have disappeared overnight. Unfortunately (for those who are using the reassociation technique) the situation is different. The 16S rDNA is not a miniaturized mirror image of the genome but is too constrained by its function to change as quickly as less conserved molecules. As a consequence, there is a curvilinear relation between the two parameters (DNA-DNA reassociation and rDNA similarities; Amann et al., 1992; Fox et al., 1992; Stackebrandt and Goebel, 1994). Each approach is strong in those relationship areas that other methods are weak in. Sequence analysis has proven to be a reliable way to distinguish the phylogeny of organisms of different domains (with 55–60% similarity) from moderately related species (around 97% similarity). Above 97% 16S rDNA hybridization values can be as low as 55% or as high as 100%. Several organisms, which are known to share 99.8% or even 100% rDNA similarity, belong to different species because the DNA reassociation values are below the 70% threshold value. Even if one considers that the DNA reassociation values originated from different laboratories using different reassociation methods, the evidence is strong enough to state that the sensitivity of DNA-DNA reassociation is significantly greater than that of 16S rDNA sequencing. When a 16S rDNA similarity value of less than 97% was found to correspond to a DNA-DNA reassociation value of not more than 60%, Stackebrandt and Goebel (1994) recommended that DNA pairing studies did not have to be performed at this and lower levels of sequence similarity. These levels indicated that the strains concerned are not members of the same species.

The correlation blot of 16S rDNA and DNA-DNA similarity values obtained for some species described in 1998 and their nearest phylogenetic neighbors (Fig. 1) demonstrates that the recom-

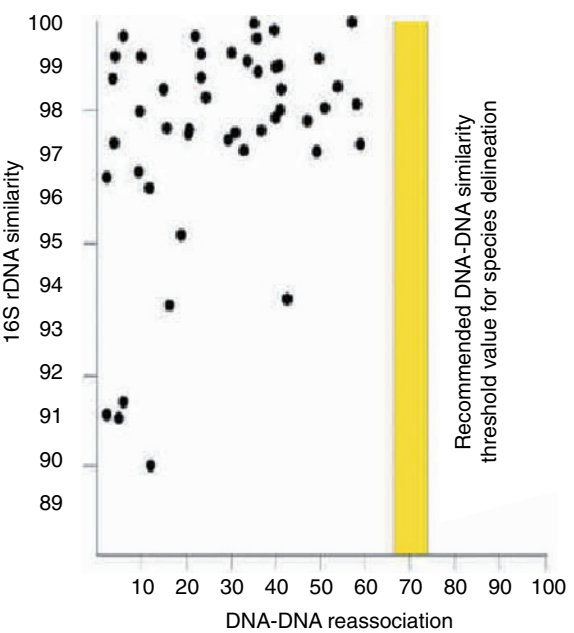

Fig. 1. Correlation blot between 16S rDNA and DNA-DNA reassociation similarities, indicating for several phylogenetically highly related species (as determined by 16S rDNA values of >98%) that DNA-DNA similarities are clearly below the threshold value of 70% recommended for species delineation. Values are taken from volume 48 of the *International Journal of Systematic Bacteriology* (1998).

mendation of Wayne et al. (1987) has been accepted by taxonomists. Except for a single case, all strains of a species share higher than 70% DNA-DNA similarity, while they share less than 70% DNA-DNA similarity with their nearest neighboring species. The one exception refers to *Pelistoga europaea*, which have four genomovars that are related at the 40% DNA similarity level. The authors (Vandamme et al., 1998), however, clearly state that the lack of phenotypic evidence presently excludes the description of four individual species, a step that may be necessary once these differentiating characteristics become available.

Comparison of Phylogenetic Patterns of 16S rDNA

The increasing number of dendrograms and phylogenetic trees in the literature reflects the common notion that the 16S rDNA sequencing method is a "traditional" method. Many trees are not comparable as they were generated from partial sequences and different treeing methods (summarized by Felsenstein, 1982, 1988) and are therefore of historic interest only (Stackebrandt, 1988, 1992). Today nearly complete sequences are compared using a few treeing algorithms of proven resolving power and statistical significance (Ludwig, 1999). But some problems remain. First, the parts of the sequence judged to be of less phylogenetic importance are subjectively omitted. Second, computer programs cannot handle the enormous amount of data in a reasonable time without omitting either the number of reference organisms or sequence information. However, one must differentiate between goals; this determines the number of sequences used. For taxonomic studies, e.g., questions about the intrageneric relationships, the number of sequences is mostly restricted to those of type strains and a few others. In this case the complete sequence information, including that of the variable regions, can be compared. The branching pattern obtained will change if this small dataset is embedded in a larger one composed of sequences of members of families, orders, classes, and so on. At each level, information will be lost by either removal of variable regions or trimming of stem and loop structures to the minimum length common to all members of the dataset and by omission of those regions for which ambiguous sequence information is provided. Each of these steps will most likely lead to changes in the branching pattern of any lineage. Thus, the picture created from the inclusion of thousands of sequences in a single dataset is not more than an approximation of the phylogeny. The literature is full of examples that demonstrate changes of phylogenetic relatedness within genera and families through the influence of new entries in the database. Most of the branching patterns are supported by high bootstrap values that for a given tree indicate that the statistical analysis supports the order of lineages. But this statistical analysis is per se no indication that the pattern reflects the natural relationship with a similar degree of confidence.

If an algorithm does not exist that could provide a tree more closely reflecting the evolution of prokaryotes, then we must accept the pattern that appears to be the most plausible one. It may be the one showing the highest degree of topographic similarity to patterns derived from different informative molecules, although it should be noted that these similarities are not per se proof of phylogenetic "truth." The phylogenetic framework referred to as the most convincing one for the bacterial and archaeal kingdoms is today classified as domains Bacteria and Archaea (Woese, 1987; Olsen et al., 1994).

The Prokaryotic Species: A Natural Entity or a Taxonomic Myth

The evolutionary record as a basis for phylogenetic studies can now be found in the extensive database of molecular sequences, which have placed the bacterial world into the framework of the evolutionary process. But this information alone does not help describe a species or how a species has to be defined. Rather, it puts the prokaryotes on the same level with animals and higher plants in the debate about species as a general unit for biodiversity, evolution and taxonomy. Does this mean that biologists can now define the category species as a comparable biological entity for every organism? The problem is that biologists themselves are not clear about the definition of "species," a concept that lacks a theoretical basis (Bachmann, 1998). The concepts of phylogenetic species (Cracraft, 1983), taxonomic species (Staley and Krieg, 1984), biological species (Dobzhansky, 1937; Istock et al., 1996), which disregards asexual reproduction entirely, and ecological species (Istock et al., 1996) have strengths and weaknesses, and each of them stresses different aspects of biology and evolution. In his dictionary of microbial taxonomic usage, Cowan (1968) even states bluntly that the species is not a natural entity. Surprising perhaps to microbiologists, there are some zoologists (Hull, 1997) and botanists (Bachmann, 1998) who suggest the possibility that the species is not an objective basic unit of taxonomy. The nonexistence of species as an objective category and as a product of natural selection, which after sufficient study is identifiable by the taxonomist, has been recognized by microbiologists for more

than 20 years. Bacteriologists in particular follow guidelines and recommendations to provide stability, reproducibility, and coherence in taxonomy—although in the final analysis, species description is still subjective. This concept does not include the role of reproductive isolation, i.e., the barriers to horizontal gene transfer over large phylogenetic distances; it does not even try to explain the mode of speciation. One may be amused by such a naïve approach—but once you decide that a species can not be recognized as a natural entity, the only alternative is a compromise of a working definition. In that, the fundament of a species can be found in genealogical relatedness of its members (Wayne et al., 1987; Stackebrandt and Goebel, 1994). This strategy has facilitated the practice of taxonomy—a strategy also used by protozoologists, mycologists and algologists. As Bachmann (1998) points out, the most useful general species definition would be the one that allowed "the largest number of individual organisms to be unequivocally assigned to species so that some basic conditions are satisfied." These conditions are: 1) strains are assigned to only one species and never to none; 2) all lines of descent within a species are members of that species; 3) members of a species should be phylogenetically related; and 4) the species (so defined) should apply to taxa that coincide more or less with the intuitively recognized species. Most obviously, conditions 1) to 3) are already in effect in bacteriology, while condition 4) has failed significantly in the past because of inability to classify a prokaryotic species by intuition.

There is no recognized concept of a prokaryotic species, though Istock et al. (1996) defines nine different mechanisms for their evolution. Nevertheless, the pragmatic definition is well accepted among bacteriologists. The combination of phylogenetic grouping based on sequence comparisons with taxonomic classification is a very powerful approach. This polyphasic approach is the only accepted strategy, which does not mean that certain components of the approach are not criticized. The process of revision and constant adaptation appears necessary as not only new insights into cell structure and cell function should be incorporated but also the microbiologists' perception. As Staley and Krieg (1984) phrased it: "A classification that is of little use to the microbiologist, no matter how fine a scheme or who devised it, will be ignored or significantly modified." This is true for each level within a hierarchical system, and the history of microbiology is marked by many examples of rejected systems. The higher ranks are almost completely defined by subjective arguments—to the point where the importance of working with taxa above the rank of genera is considered trivial (O'Hara, 1994). The importance of any hierarchical system goes beyond the main function of classification and identification. Based on knowledge available at the time of its establishment, a hierarchical system should explain and increase understanding of the evolution of organisms and their groupings. In bacteriology, time has seen various hierarchical systems and various proposed phylogenetic paths fail because they were not based upon the natural relationships but rather on properties believed to express natural relationships such as morphology (Cohn, 1872; Stanier and van Niel, 1936), pigmentation, physiology (Orla-Jensen, 1909; Margulis, 1981), and cell constituents (Schleifer and Kandler, 1972). Some of these attempts were important contributions in their time because the classification system based upon them actually reflects phylogenetic divergence (e.g., peptidoglycan structure, lipids, fatty acids). This strategy has changed now, as the order of phylogenetic lineages guides the bacteriologists to the two basic units, the genus and species, without the need for a superimposed system. Actually there is no immediate need to work with a hierarchical system, but it is tempting to do so to comprehensively classify similarities, differences and evolutionary traits. Time and the recognition of the semantic character of the macromolecules DNA, RNA and proteins have shown that this basis was lacking (Zuckerkandl and Pauling, 1965). Today, we see the emergence of higher taxa along the phylogenetic structure and, like in systems of plants and animals, taxa of the same rank are not necessarily comparable units or describable in a coherent way. Also, we must be aware that only a small fraction of prokaryotic species are described, and new entries will not only change the description of the higher ranks but may change the composition of taxa as well. However, the advantage of a rational hierarchical structure, i.e., based on the organisms' evolutionary history, makes it highly likely that changes within the system will occur only within ranks of a common genealogical lineage and not, as in the past, affect and possibly change remotely related taxa.

The species definition applied today does not incorporate the modus of grouping entities into named "natural" species. Several factors that contribute to the evolution of the genome have been identified through intensive multilocus enzyme electrophoreses and sequence typing of housekeeping genes (Maiden et al., 1996) and of random amplified polymorphic DNAs and multilocus enzyme electrophoreses (Selander et al., 1994; Istock et al., 1996). Some organisms, e.g., *Neisseria* and *Rhizobium* species, as well as enterobacterial species (Guttmann and Dykhuizen, 1994), are subjected to reticulate events or

panmixis (Maynart-Smith, 1993; Istock et al., 1996) in which clonal relationships, due to mutational events and vertically transmitted accessoric genetic elements, are disturbed by horizontal genetic transfer, e.g., conjugation, phage transduction DNA transformation (Achtman, 1998). Other strains that are mostly endosymbionts and obligate pathogens, such as members of the genera *Bartonella*, *Brucella*, and *Rickettsia*, are mainly clonal because they are subject only rarely to horizontal gene transfer. In some species the recombination is more frequent among strains of different than of the same species (e.g., the enterobacteria), which leads to the homogenization of the gene pool of the interacting organisms (Guttmann and Dykhuizen, 1994). An attempt to formulate a biological species definition for bacteria takes the following observations into account (Dykhuizen and Green, 1991): 1. Phylogenetic trees from different genes from members of a single species should be different (shown for three genes from *E. coli*). 2. Phylogenetic trees from different genes from members of different species should be the same (as shown for two genes from seven species of *Neisseria*). Without questioning the validity of this approach, it is obvious that this strategy is far beyond the capability of routine sequence analysis methods, especially inasmuch as several strains of a single species must be investigated, and although worth discussing, this approach cannot immediately replace the present pragmatic species definition.

The current pragmatic species definition also does not account for the ecological niche, although the source of the isolate is part of a species description. This site is the strain's actual place in the ecosystem provided the strain is dependent on its environment, e.g., the rhizoplane, rhizosphere, and host in endosymbiotic and pathogenic relationships. The terms (marine water, fresh water, mud, sediment, soil, rumen, skin and so on) are too superficial to describe the exact niche from which complex environmental samples are taken. Knowing about the site of speciation and the environmental selection of members in a clonal population may help explain the path of evolution and the mode of speciation, but this information does not help define the level at which a subpopulation may be regarded as an individual species.

The Pragmatic Species: Definition

The definition of a prokaryotic species has a phylogenetic component given by Cracraft (1983) as "the smallest diagnosable cluster of individual organisms within which there is a parental pattern of ancestry and descendents" and a taxonomic component given by Colwell (1970) as "a group of related organisms that is distinguished from similar groups by a constellation of significant genotypic, phenotypic, and ecological characteristics." This definition combines descriptions of geno-, or genomospecies, taxospecies, and phenospecies, which reflect the different concepts of species upheld in the past decades. From a pragmatic point of view, all these facets have been incorporated into a single definition, though the terms are still in use. An "optimal" species is one that simultaneously represents a phylogenetically, phenotypically, and naturally occurring group, but except for many strains of pathogenic species, the species' ecological niche is either not known or the number of isolated strains is too small to identify their original habitat. It should be remembered, that from the broad diversity of prokaryotic organisms, which may reflect a genetic and epigenetic continuum, a single strain is chosen as the type strain. Strains that are sufficiently similar, i.e., by mainly DNA-DNA reassociation used today in prokaryotic taxonomy, are considered members of this species. This concept of selecting species has been described as the arbitrary species concept (Staley, 1997). The combination of arbitrary selection and artificial species delineation is admittedly arguable and open to discussion, especially when taxonomists covering different fields of biology meet. When compared with the phylogenetic diversity of a prokaryotic species, the phylogenetic diversity of *Homo sapiens* and its closest relatives, the higher evolved apes (all species from man to lemurs, comprising about 200 species, which are related by higher than 75% DNA reassociation; Sibley et al., 1990), would be within the 70% threshold value. Obviously, the species definition of prokaryotes cannot be applied to eukaryotic organisms. For prokaryotic organisms the pragmatic approach to the species definition has been extremely useful and its success is measured by its widespread acceptance.

Delineating a Species

In the daily routine a new isolate runs through an identification process, which may be different from laboratory to laboratory and from taxon to taxon. Many scientists, however, are not interested in a fine resolution of relationship, or they are not in a position to go through the laborious identification process. Some initial superficial tests are performed, like determination of colony morphology and pigmentation, shape, spore formation, Gram stain and relationship to oxygen. The aim of the study is to define the identification procedures to follow—but it can be

expected that phylogenetic diversity in many similar-looking organisms remains undetected. The classification process starts when the isolate does not fit the description of one of the 4,200 validly described species.

Let us assume the laboratory is equipped with facilities to generate a 16S rDNA sequence. It is recommended to start any survey with this molecule, as the database of prokaryotic strains is enormous, covering more than 95% of described species. To search for the closest relative using available 16S rDNA sequence data, taxonomists are offered electronic help by the BLAST system (blast.help@ncbi.nlm.hih.gov), the Ribosomal Database Project (http://www.cme.msu.edu/RDP), or updates of the ARB program (http://www.arb-home.de). The taxonomic browser will guide the user to a phylogenetic arrangement of taxa. The search in RDP and ARB will show the phylogenetic distance to the isolates' nearest neighbor(s), but the quality of the search depends upon the completeness of the 16S rDNA database. The sequences available, species analyzed, and whether comparison is based on short stretches or on almost complete sequences, may vary. Once the approximate nearest phylogenetic neighbor has been identified, a search of the public databases for recent entries is recommended.

The result of the analysis will affect future strategy. Let us assume that the 16S rDNA similarity to its nearest neighbor has values higher than 97–98%. Many scientists will be satisfied knowing the approximate phylogenetic position and will not continue the identification process. Others, however, will be eager to determine the more precise affiliation of the isolate. The way to proceed depends upon the number of species in the phylogenetic vicinity of the isolate.

1. In case the isolate falls within the boundaries of a genus, the description of this genus will be a guide to the few key properties needed to place the isolate in this genus. If the species within this genus are separated by distinct phenotypic properties (which one should assume but which is not always the case), these should be sought in the isolate and, if present, the isolate has been identified. If not, DNA-DNA reassociation studies are recommended to determine whether the isolate is the nucleus of a new species. In case DNA similarities are lower than about 70% DNA-DNA reassociation, the isolate should be described thoroughly, providing evidence for the genus characteristics and those properties that distinguish the new species from the established ones.

Examples are found frequently in the literature and a few of them are shown here:

The most widely encountered situation is the description of a new species which shows less than 70% DNA-DNA reassociation with those species to which it is closely related by 16S rDNA similarity: Hybridization values for the type strain of the new species and that of the closest relative usually range between close to 70% and almost zero percent. To give two examples, *Kocuria rhizophila* is separated from *Kocuria varians* by a similarity value of 52.6% (Kovacs et al., 1999), while the DNA-DNA relationship between the type strains of *Methanococcus infernus* and *Methanococcus jannaschii* was less than 10% (Jeanthon et al., 1998).

In those cases where the DNA-DNA reassociation value between an isolate and a described species is ≥70%, this information will usually not be recorded, unless the new strain leads to the description of a subspecies or to an emendation of the species description. Many examples exist in the literature that demonstrate the intraspecies genomic homogeneity.

DNA-DNA reassociation reveals that the type species of two different species are actually strains of the same species: The species *Kocuria erythromyxa* was reclassified as *Kocuria rosea* on the basis of 95% DNA-DNA reassociation and similar phenotypic differences (Schumann et al., 1999).

Species are separated at the threshold value of around 70% DNA-DNA similarities on the basis of differences at the epigenetic level. For example, the separation of the type strains of *Desulfurella acetivorans* from *Desulfurella multipotens*, sharing 69% DNA-DNA similarity, was based on the ability of the latter strain to use butyrate as growth substrate and to grow chemolithoautotrophically on mineral medium containing molecular hydrogen, CO_2 and elemental sulfur (Miroshnichenko et al., 1994).

The recommendations (Wayne et al., 1987) to delineate species in genomic terms at a threshold value of around 70% DNA-DNA reassociation are guidelines but should not be applied as fixed rules. Though the majority of species are actually described as suggested, there are a few exceptions:

One example refers to the lack of any phenotypic differences in the two putative species that are separated by higher than 70% DNA-DNA reassociation. In practice, it would be impossible to affiliate other strains to either species and to distinguish between the two species without performing DNA-DNA reassociation studies (Vandamme et al., 1998). One should, however, consider that the primary structure of a 16S rRNA, like that of other genes, is a linear compilation of phenetic characters, whose composition at a defined position should be treated as a phenetic property. For example, ornithine at position 3 of the peptidoglycan subunit is treated as a different taxonomic marker than the pres-

ence of diaminopimelic acid or lysine at the same position in a different organism. Thus the differences in nucleotides involved in compensatory base exchange in the 16S rDNA nucleotide sequences that occur between two closely related species distinguishable by DNA-DNA reassociation should be accepted as characters with discriminating power. Using this strategy, a new species of *Sulfitobacter mediterraneus* has been described which by the profile of its metabolic properties could not be distinguished from *Sulfitobacter pontiacus* (Pukall et al., 1999). Whether to consider other gene sequences, significant differences in the patterns of whole cell proteins, or restricted or amplified nucleic acids should be decided case by case.

The other examples refer to medically important organisms. Strains of *Escherichia coli* and *Shigella dysenteriae* are extremely closely related and exhibit DNA hybridization values as high as 89% (Brenner, 1973). Nevertheless, for epidemiological purposes the two taxa are not considered strains of the same species but are presently allocated to two different genera. On the other hand, certain strains of *Clostridium botulinum* are remotely related only by 16S rDNA analysis, they share less then 10% DNA-DNA similarity as measured by hybridization, and they are more closely related to other *Clostridium* species than they are related among themselves. However, as all of them express a botulinum toxin, which immediately guides the physician in the therapy of botulism, no attempts have been made to alter the classification of these strains (Fig. 2).

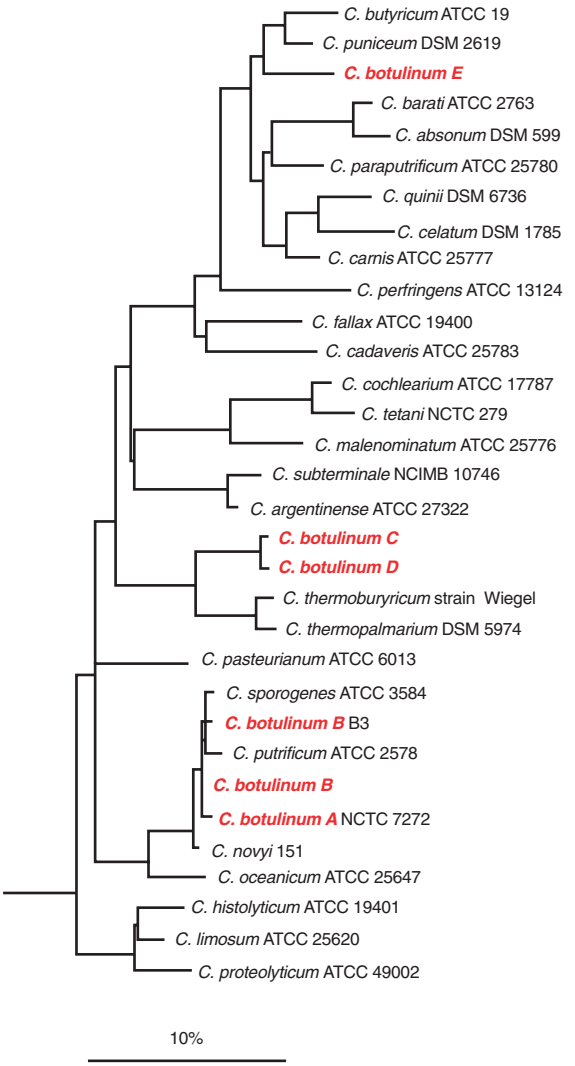

Fig. 2. The phylogenentic relatedness of *Clostridium botulinum* strains exhibiting different serotypes among strains of different *Clostridium* species of group I (Collins et al., 1994). The 16S rDNA dendrogram is a detail of the ARB tree. The scale bar corresponds to 10 nucleotide substitutions per 100 sequence positions.

1. Despite the recommended value of 70% DNA similarity, taxonomists working with some defined prokaryotic groups have altered this value to come to a better correlation between phenotypic and genotypic similarities. Within the family Pasteurellaceae, a DNA-DNA reassociation value of and above 85% describes a species (Mutters et al., 1985). Similar values have been found for the interspecies relatedness of *Blastomonas pertussis*, *Blastomonas parapertussisi* and *Blastomonas bronchiseptica* (Kloos et al., 1981) and between members of the spotted fever group of *Rickettsia* (Walker, 1989). Another well-known example in the literature is the fate of the members of the genus *Brucella* (Moreno, 1997). This genus contains six species (Meyer, 1990), in spite of the fact that DNA-DNA reassociation values separate these species above 98% similarity (Verger et al., 1985). For the workers in the field, the presence of individual DNA restriction patterns, phenotypic and antigenic properties, and, above all, the distinct biological behavior of the species, e.g., host range and pathogenicity, are more indicative than the strict application of the general rule of separating species.

2. In the case of 16S rDNA, if similarity values indicate an approximately equidistant relationship to members of different genera, the diagnostic properties given for these genera must be tested for the isolate. Such highly related genera have been described in the order Actinomycetales, α and γ subclasses of Proteobacteria, and the *Bacillus* line of descent. If the properties match those of one of the genera, the identification process will be restricted to members of this genus and one has to proceed as indicated under 1. If the analysis of the genus-

specific properties reveals no match with any of the genera, it is likely that the isolate represents yet another closely related genus of this genus cluster and the description of the new species and the new genus will go hand in hand. Well-known examples are the closely related species of the genus *Rhizobium*. Nevertheless, at this high level of 16S rDNA relationship, the analysis also will have to include the only technique recommended for the elucidation of intragenus relationships, i.e., the determination of DNA-DNA reassociation values between the species of the new genus and the species of the neighboring genera. Another example has been described for the genera *Blastomonas* and *Erythromonas* in the alpha subclass of Proteobacteria (Yurkov et al., 1997). The type strain of *E. ursincola* shares 99.2% 16S rDNA similarity with the type strain of *B. natatoria*. Based upon the presence of bacteriochlorophyll a in *E. ursincola* and its absence in *B. natatoria*, it was concluded that these organisms represent different genera. The DNA-DNA reassociation value of about 40% for these two strains (Tindall, pers. comm.) supported the taxonomic separateness of the two species. If, however, future studies show that the presence of bacteriochlorophyll a is not a unifying property of *E. ursincola* strains, or if bacteriochlorophyll is found in strains of *B. natatoria*, the taxonomic rationale for having two genera will diminish.

3. If the new isolate shares less than 97% sequence similarity with the nearest phylogenetic neighbor, then as many taxonomists now recommend (Stackebrandt and Goebel, 1994) DNA-DNA reassociation studies are unnecessary, because the latter values will range clearly below the 70% reassociation borderline value recommended for species definition. Indeed, a survey of articles of volume 48 of the *International Journal of Systematic Bacteriology* indicates that for about 30% of all newly described species sharing less than 97.5% 16S rDNA sequence similarity with their closest neighbor, DNA-DNA reassociation has not been determined. In those cases in which DNA-DNA reassociation values were provided, the values are clearly below the 70% threshold (Fig. 1).

Several genes other than the one coding for 16S rDNA have been sequenced recently to test the discriminating power of 16S rRNA genes. Interestingly, in *Shewanella* species, genes coding for gyrB were found to have a less conservative primary structure (Venkateswaran et al., 1998) than those coding for 16S rRNA and thus appear to be better suited for the elucidation of close relationships. In *Pseudomonas*, results of gyrB analysis matched those of 16S rDNA analysis, but only when the highly variable regions were omitted from the latter molecule (Yamamoto and Harayama, 1998; Yamamoto et al., 1999). Other genes used were the chaperonin GroRL (Viale et al., 1994), heat shock protein (hsp65) for strains of the *Mycobacterium avium* complex (Swanson et al., 1997), a gene (sodA) coding for a manganese-dependent superoxide dismutase in streptococci (Poyart et al., 1998), the ompA gene of Rickettsiae (Fournier et al., 1998), the mba gene fragments of *Ureaplasma* (Knox et al., 1998), or the RNAse P in Actinobacteria (Cho et al., 1998).

Increasingly, the spacer regions (ITS) separating the genes coding for the 16S rRNA and the 23S rRNA are used to determine inter- and intraspecies relatedness (Barry et al., 1991; Gü and Stanisich, 1996; Leblond-Bourget et al., 1996). Though this approach is currently used mainly for differentiation but not for the delineation of species, this and other molecular techniques such as chromosomal DNA fingerprinting (RFLP, restriction fragment length polymorphism; AP-PCR, arbitrarily primed PCR; ERIC-PCR, enterobacterial repetitive intergenic consensus PCR), gene fingerprinting (rDNA-RFLP analysis; Vaneechoutte, 1996), or ribotyping (Grimont and Grimont, 1986; Webster et al., 1994) can be useful in revealing the homo- or heterogeneity of strains of a species.

The Phenotypic Circumscription of a Species

In contrast to the rather stringent genomic definition of a "species," the phenotypic characterization of a new species is very variable. The properties to be investigated depend upon those indicated as being specific for the genus and on the set of characters already indicated for discriminating between species described for the genus.

Extensive morphological and ultrastructural characterization must be presented, especially for species of novel genera. Records on enrichment and isolation, motility, colony characterization, optimal growth conditions, growth requirement and substrates, and on base composition of DNA are parts of a set of characterizing features. Analysis of special features is required for certain taxa, such as antigenic characterization for *Leptospira* and mycoplasmas. Many of the properties to be provided for the description of a species are listed either in the descriptions of minimal standards, which are available for species of some genera, or they are compiled in *Bergey's Manual of Systematic Bacteriology*. Information about the phylogenetic position of a putative new type strain facilitates the selection

of such features and guides the search for taxonomically relevant properties.

Delineation of the Genus

The definition of a genus given by Cowan (1968) has not been changed by the input of molecular data. Cowan states that genus is "... one of the basic ranks in the hierarchical systems used in biology, and probably the highest rank with any significance in microbiology. In position between FAMILY and SPECIES, it is best considered as a collection of species with many characters in common; unfortunately no one has indicated the extent of this sharing of characters, and it is purely a matter of personal judgement ... as to what constitutes a genus. Like the SPECIES, the genus is a subjective concept without any foundation in fact."

A significant finding of the analysis of rRNA, rDNA and DNA-DNA reassociation studies was to point out the genetic heterogeneity of many phenotypically defined genera. Since genus and species are those ranks for which proper descriptions are needed most urgently, the new results were both confusing and encouraging (Stackebrandt and Woese, 1984): confusing in a sense in that in many cases, the working basis (the genus) had to be redefined after genera described on traditional grounds were found to be phylogenetically incoherent or after the type species was found to actually be a member of a different genus. Examples have been described for *Methanobacterium*, *Azospirillum*, *Pseudomonas*, *Bacillus*, *Clostridium*, *Streptococcus*, *Flavobacterium*, *Bacteroides*, *Arthrobacter*, *Micrococcus*, *Brevibacterium*, *Nocardia* and several genera of phototrophic organisms, but it should be stressed that almost each genus was involved in the reclassification process to a varying degree. Some examples are listed in Table 4.

The results of the reclassification process, i.e. the elimination of misclassified strains, not only resulted in the description of genomically and phenotypically homogeneous genera, but also led to the reduction of species number per genus (Table 4).

A new genus has to be described when a strain or a strain cluster is shown to branch outside the radiation of a validly described genus and the isolated phylogenetic position is accompanied by distinct phenotypic properties not found among the neighboring genera. On the other hand, the placement of a new taxon with a novel pattern of phenetic properties within the radiation of a genus may point towards its taxonomic heterogeneity, which consequently may lead to the dissection of the genus. The decision about which phenotypic properties to use for the circumscription of a novel genus is up to the taxonomist but depends to some extent upon the description of the neighboring genera. The genus-specific characteristics must be present in each species of the genus. The following is a short list of examples of highly to moderately related genera and their discriminating properties:

Chemotaxonomic properties: In the order Actinomycetales for example the high degree of chemical diversity in the peptidoglycan, fatty acids, polar lipids, menaquinones, whole cell sugars or teichoic acid offers superb diversity at the epigenetic level to delineate genera. The correlation with phylogenetic analysis is so high that the finding of a new combination of such patterns indicates a new genus (Embley and Stackebrandt, 1994).

Morphological, chemotaxonomic and growth properties: The main basis for the division of the former genus *Bacillus* into eight genera has been the extensive phylogenetic analysis of its species (Stackebrandt et al., 1986; Ash et al., 1991; Rainey et al., 1993). The separation into several genera is based mainly upon the chemical structure of peptidoglycan, cell shape, spore shape, anaerobic growth, optimum pH, growth in 10% NaCl, and cellular fatty acids. As compared with the actinomycete genera, the importance of chemotaxonomic properties is low. The most species-rich genus, *Bacillus* (>60 species) itself, is heterogeneous with respect to amino acid composition of peptidoglycan, spore shape, anaerobic growth, presence of swollen sporangium and other features, and it can be expected that this genus will be subject of even further dissection.

Biochemical properties: The genus *Rhizobium* has been dissected into *Sinorhizobium*, *Azorhizobium*, and *Mezorhizobium* and these genera, together with *Allorhizobium*, *Mycoplana*, *Phyllobacterium*, *Agrobacterium*, *Bartonella bacilliformis* and *Blastobacter aggregatus* constitute a highly related group of mainly plant-associated bacteria (>92% 16S rDNA similarity). Phylogenetic analysis indicates that members of *Rhizobium* do not form a coherent genus but some members are more closely related to *Allorhizobium* (de Lajudie et al., 1998). The discriminative features between *Rhizobium* species and members of morphologically similar genera are predominantly results of carbon assimilation tests.

Morphological, physiological and growth properties: The number of genera within the family Chromatiaceae has recently been significantly enlarged, following the dissection of *Cromatium* into six genera and the reclassification of two *Thiocapsa* species as the type species of two novel genera (Imhoff et al., 1998b). This move was due to the phylogenetic heterogeneity of the genera involved though no novel phenotypic data were found that would clearly support the

Table 4. Some examples for the dissection of phenetically defined genera by transfer of species into phylogenetically coherent genera.

Phenetic definition	Number of species: Before	Number of species: Transferred reclassification	Emerging phylogenetically coherent genera	Higher order affiliation
Bacillus	124	36	*Bacillus*	
		3	*Alicyclobacillus*	
		19	*Paenibacillus*	
		10	*Brevibacillus*	Bacillaceae
		3	*Aneurinibacillus*	
		1	*Virgibacillus*	
Bacteroides	65	40	*Bacteroides*	Bacteroidaceae
		1	*Ruminobacter*	Succinivibrionaceae, γ-subclass of Proteobacteria
		7	*Porphyromonas*	Bacteroidaceae
		21	*Prevotella*	Bacteroidaceae
		1	*Anaerorhabdus*	Cytophagales
		1	*Megamonas*	not known
		1	*Rikenella*	Cytophagales
		1	*Mitsuokella*	Sporomusa subbranch of Clostridium group
		1	*Dichelobacter*	γ-subclass of Proteobacteria
		1	*Fibrobacter*	Fibrobacter line of descent
		1	*Sebaldella*	Fusobacterium line of descent
		1	*Dialister*	Sporomusa subbranch of Clostridium group
		1	*Campylobacter*	ε-subclass of Proteobacteria
		1	*Capnocytophaga*	Cytophagales
		1	*Tissierella*	Clostridium group
Brevibacterium	26	16	*Brevibacterium*	Brevibacteriaceae, Actinomycetales
		4	*Curtobacterium*	Microbacteriaceae, Actinomycetales
		3	*Corynebacterium*	Corynebacteriaceae, Actinomycetales
		2	*Cellulomonas*	Cellulomonadaceae, Actinomycetales
		4	*Microbacterium*	Microbacteriaceae, Actinomycetales
		1	*Arthrobacter*	Micrococcaceae, Actinomycetales
		1	*Desemzia*	Camobacterium group, Enterococcaceae
		1	*Exiguobacterium*	Bacillaceae
Clostridium	143	14	*Clostridium*	Clostridium subline of Gram-positive bacteria, Clostridiaceae
		1	*Oxalophagus*	Bacillaceae
		1	*Paenibacillus*	Bacillaceae
		1	*Eubacterium*	Clostridiaceae
		1	*Syntrophospora*	Clostridiaceae
		1	*Oxobacter*	Clostridiaceae
		2	*Moorella*	Clostridiaceae
		2	*Thermoanaerobacter*	Clostridiaceae
		2	*Thermoanaerobacterium*	Bacillaceae
		1	*Caloramator*	Bacillaceae
		1	*Filifactor*	Clostridiaceae
		1	*Sporohalobacter*	Haloanaerobiales
Flavobacterium	40	21	*Flavobacterium*	Flavobacteriaceae
		1	*Empedobacter*	Flavobacteriaceae
		2	*Sphingomonas*	Zymononas-group, α-subclass of Proteobacteria
		2	*Microbacterium*	Microbacteriaceae, Actinomycetales
		1	*Halomonas*	Halomonadaceae, γ-subclass of Proteobacteria
		1	*Myroides*	Flavobacteriaceae
		1	*Planococcus*	Bacillaceae
		1	*Cytophaga*	Cytophagales
		1	*Vogesella*	β-subclass of Proteobacteria
		1	*Telluria*	β-subclass of Proteobacteria
		1	*Marinobacter*	γ-subclass of Proteobacteria

reclassification process. Consequently, the traditional taxonomic markers (motility, presence of gas vesicles, morphology, salinity and temperature optimum, vitamin requirement, base composition of DNA, and chemoautotrophy) were reassessed and new patterns of differential characteristics were proposed to describe the 14 genera of Chromatiaceae.

End products of carbohydrate fermentation, morphology and chemotaxonomy: The genus *Bacteroides* has been a dumping ground for many phylogenetically misclassified strains, the extent of which was only unraveled by 16S rDNA analysis. As Table 3 shows, 12 new genera have been established for former *Bacteroides* species, some of which are related to members of the Proteobacteria.

The availability of a most comprehensive phylogenetic framework, covering the majority of described species, leads to the recognition of genus boundaries and, consequently, to the establishment of phylogenetically homogeneous genera. Genera in which species are described following their phylogenetic analyses are also mostly homogeneous, e.g. genera *Campylobacter*, *Helicobacter* and *Arcobacter* (Fig. 3). Nevertheless, in some areas of the phylogenetic tree the reclassification process did not parallel the progress in the recognition of relatedness. The prime examples are the deeply branching lineages of the *Clostridium-Bacillus* subline of Gram-positive bacteria, e.g., *Clostridium*, *Eubacterium*, *Ruminococcus*, *Peptococcus*, and species of other genera that are phylogenetically heterogeneous. Another example is the family Pasteurellaceae, in which members of the genera *Pasteurella*, *Haemophilus* and *Actinobacillus* are not yet reclassified to match their phylogenetic relatedness (Fig. 4). The phylogenetic branching clearly indicates the inappropriateness of some classical taxonomic properties to define genera, but novel discriminating characteristics to circumscribe the new emerging genera have not yet been found. The features identified as being of little taxonomic value are the combination of: 1) Gram-positive staining, rod-shaped morphology, spore formation, anaerobic metabolism lacking sulfur reduction (*Clostridium*); and 2) Gram-positive staining behavior, morphology, lack of spore formation and anaerobic metabolism (*Peptococcus*, *Ruminococcus*, *Eubacterium*). The situation is complicated even more by the branching of the spherical, spore-forming *Sarcina* species within the radiation of the

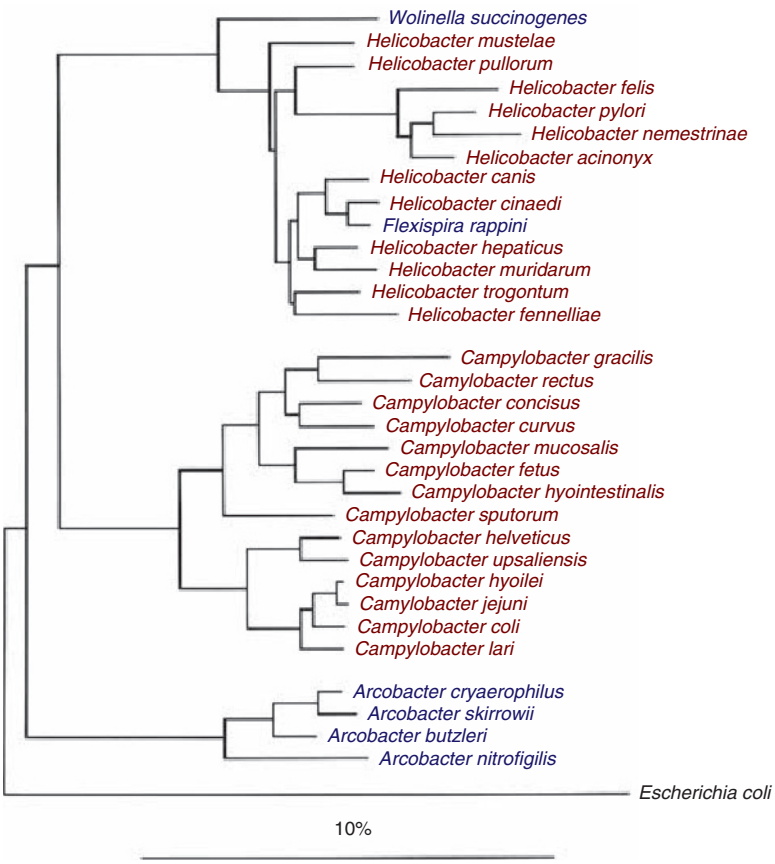

Fig. 3. 16S rDNA dendrogram of the *Campylobacter-Helicobacter-Arcobacter* line of descent, classified as the ε-subclass of Proteobacteria. The intrageneric structure of the genera is taxonomically coherent. The scale bar corresponds to 10 nucleotide substitutions per 100 sequence positions. The dendrogram was generated by the neighbor-joining algorithm (Felsenstein, 1993).

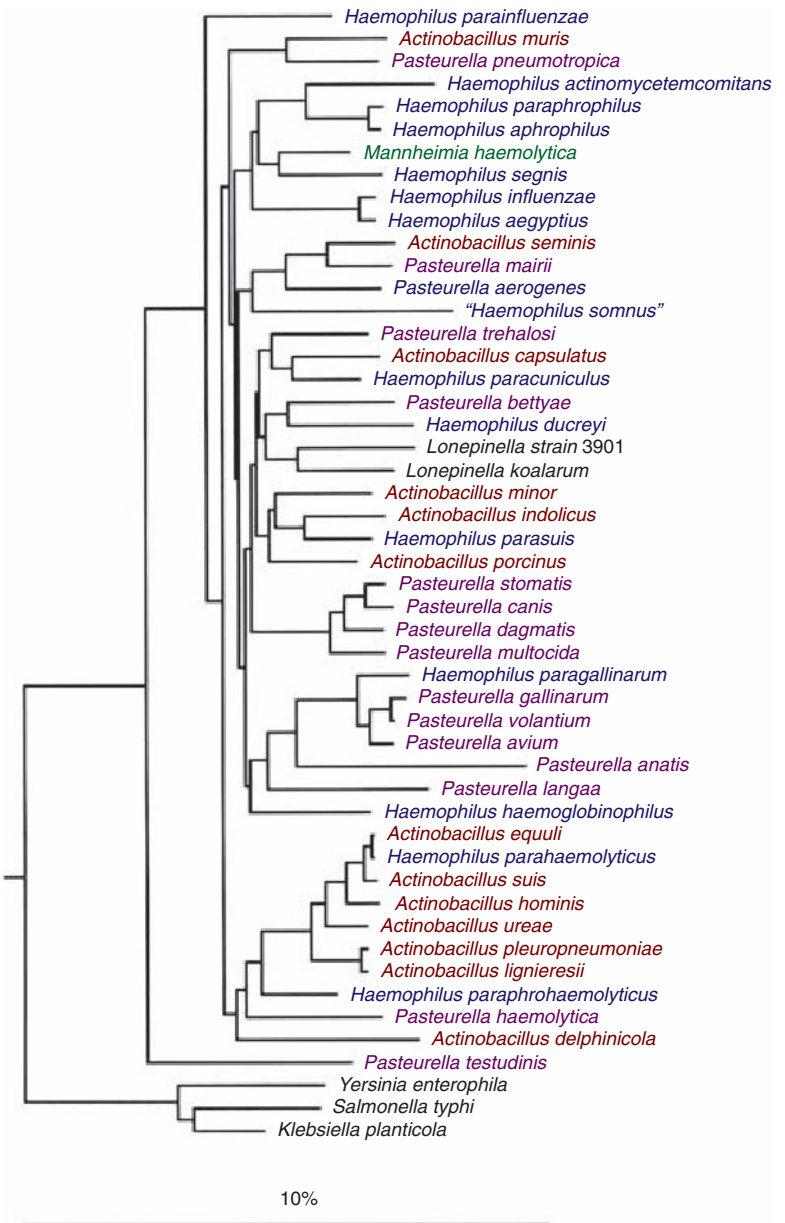

Fig. 4. 16S rDNA dendrogram of the Pasteurellaceae, a member of the γ-subclass of Proteobacteria. Due to the lack of discriminating phenotypic characteristics the intrageneric structure of the genera is taxonomically very incoherent. The scale bar corresponds to 10 nucleotide substitutions per 100 sequence positions. The dendrogram was generated by the neighbor-joining algorithm (Felsenstein, 1993).

Clostridium cluster I (according to Collins et al., 1994) that contains the type species and through the intermixing of Gram-negative species (Cluster IX) with Gram-positive *Clostridium*-type organisms (Schleifer et al., 1990; Stackebrandt and Rainey, 1997). As most of the genera defined by Gram-negative species are phylogenetically coherent taxa, such as *Sporomusa*, *Selenomonas* and *Pectinatus*, the misclassified non-type species of *Clostridium*, *Eubacterium* and some other genera must be reclassified, provided phenotypic properties are available that would support the reclassification. This information, however, is missing for most of the lineages prone to reclassification, except for a few examples in which new genera have been described, e.g., *Moorella*, *Filifactor*, *Thermoanaerobacter* and *Thermoanaerobium*.

Genera May Have Different Phylogenetic Depth

Individual genera that are phylogenetically coherent and have been properly described phenotypically may vary significantly in their phylogenetic depth, i.e., the relative time that passed after the two most unrelated members of a genus separated from a common ancestor. It has been noted (Stackebrandt, 1992) that in contrast to phylogenetically defined taxa, those based on

phenotypic description in the past have no depth per se, as nonmolecular properties are not able to measure relative evolutionary time. Genera can either have few or many species, but as long as secondary or tertiary semantides are analyzed, nothing can be said about when the common ancestor of the respective taxon evolved. The definition of a genus assumes that the phenotypic properties of its species are uniformly distributed among the species while the underlying structure of those genes used for phylogenetic analysis (and probably of other genes as well) may vary dramatically. Actually, for 16S rRNA genes, the degree of sequence variation between members of a genus may range from small (for instance, above 97% for *Micrococcus*), to moderate (92% for *Streptococcus*), to significant (about 79% for *Spirochaeta*) (97, 92, and 79% are all sequence similarity values.) Except for some recently evolved eukaryote-associated symbionts, it is still impossible to correlate sequence divergence of a given gene with a time scale, but it is possible to determine the relative age of a taxon from a comparison of 16S rDNA similarity values of the most unrelated species of a genus. For practical reasons, three categories named "age groups" have been described (Stackebrandt, 1988). These "groups" are hypothetical entities not clearly delineated in the hierarchical tree.

Members of the first "age group" were assumed to have evolved during the anaerobic phase of evolution. Species of such genera are in most cases well separated, which explains why DNA-DNA hybridization fails to relate them. Representative genera are found in the several families of methanogenic bacteria, as well as in *Bacteroides*, *Spirochaeta*, and *Clostridium* (senso strictu, i.e., cluster I) and their several phylogenetically related lineages, which need to be reclassified or have already been reclassified. The subjective selection of genus-specific phenotypic traits has not permitted determination of the actual phylogenetic depth of these taxa. It is of interest to note that certain phenotypic traits of taxonomic significance, including morphology, spore formation, proteins of the photosynthetic apparatus, and biochemical properties, appear to have remained constant over billions of years. The dramatic differences between the molecular and the phenotypic level appear to be rooted in mechanisms that cause a disjunction between the evolution of genotype and phenotype. This problem has been discussed by Nanney (1984), who suggested that the highly conserved morphological characteristics of eukaryotic species are the result of a compounding of molecular properties that may themselves be very divergent. As a consequence, divergent structure-forming components may interact in a way that conserves the resulting morphological structure, as well as biochemical pathways and physiological properties, in the case of prokaryotes.

Members of the second "age group" are those genera whose ancestors evolved during the transition period when the earth passed from an anaerobic to an aerobic environment. Descendants of this group are either facultatively anaerobic or aerobic. Most species are moderately related, but groups of closely related species exist. Their existence may be viewed as a more recent speciation event, causing strains of certain species to evolve faster than others. The reasons for this are not known, but changes in the evolutionary rate caused by changes in the environment may play a dominant role. Examples are found in *Bacillus*, *Streptococcus*, *Lactobacillus*, and *Corynebacterium*.

Members of genera belonging to the third "age group" probably evolved during the aerobic phase of evolution. Genera are very shallow phylogenetic taxa, since even the most distant species are still highly related. Most of these genera can be separated easily from closely related taxa by a combination of chemotaxonomic markers. The presence of different phenotypes in closely related genera is an indication of rapid evolution at the overall DNA level. This is seen not only in many actinomycete genera, e.g., *Streptomyces*, *Actinomadura*, *Staphylococcus*, *Listeria*, but also in many Gram-negative genera, e.g., *Vibrio*, *Shewanella*, *Rhizobium*, *Hyphomicrobium* and most genera of the Enterobacteriaceae. Genes coding for ribosomal RNA, on the other hand, are so conserved in their primary structure that changes at the level of the overall chromosome do not manifest within a short period. It is therefore obvious that DNA-DNA reassociation studies will reflect the actual relatedness between the species most closely, whereas comparison of complete rDNA sequences often fails to reliably determine the intrageneric structure of these taxa.

The presence of groups with varying phylogenetic depth explains why initial attempts have failed to delineate taxa by a purely phylogenetic—and inflexible—approach. The following example demonstrates this impracticability. For the methanogenic bacteria (Balch et al., 1979), a lower range of S_{AB} values of 0.55 to 0.65 was set for species differentiation (S_{AB} values are now replaced by rDNA similarity values, and S_{AB} values of 0.55 to 0.65 correlate with about 88 to 91 % similarities). If this same range were applied to the bacterial genus *Staphylococcus*, all of its members would have to be reduced to a single species. Application of the phylogenetic genus definition to the methanogens on the branching pattern of the order actinomycetes would have

even more dramatic consequences in that all genera would be united in a single genus (Fox and Stackebrandt, 1987). Using operational definitions as the sole criteria for taxon delineation, most of the existing phenotypically well defined and phylogenetically coherent genera would have to be considered invalid. Individual genera would have to be dissected to form several new genera with identical properties (that were once used to combine its members), or different genera, whose members exhibit such a wide variety of phenotypes that the classification would be of little practical value, would have to be united. The effects of the different delineation strategies on the classification of actinomycetes have been demonstrated schematically (Fox and Stackebrandt, 1987).

It must, however, be remembered that the delineation of a genus in bacteriology does not have to follow the historical record at all but depends upon the availability of phenotypic data coupled with the opinion of the taxonomists (Cowan, 1968). The availability of a phylogenetic framework has initiated a trend that led to the description of genera as phylogenetically shallower than genera based solely upon phenotypic properties. This is most dramatically seen in the dissection of some former species-rich genera, e.g., *Micrococcus*, *Brevibacterium*, *Pseudomonas*, and *Bacteroides* that has led to the description of many monospecific genera.

Classification Is a Dynamic Process (Stackebrandt, 1991)

Microbiologists are aware that the available phylogenetic branching patterns, although sensational and revolutionary because of their new potential, only very incompletely reflect the actual situation in nature. Phylogenetic reconstructions are based on inferred homologies but, unless witnessed by the evolutionary history of taxa, i.e., by fossil data, cannot be considered definitive (Rothschild et al., 1986). Furthermore, the tree mirrors the presence of certain categories, e.g., the spirochaetes, the planctomycetes, and the thermotogas, that may be self-defining since they are emerging constantly, no matter which molecule and method are used. However, the isolated position of these groups, well defined by genotype and phenotype today, may disappear tomorrow when more organisms are investigated. Thus, whenever new information—either within established taxa or in neighboring groups—requires corrections, flexibility is called for and changes have to be made for the benefit of a better agreement between phylogeny and taxonomy. The main advantages of the phylogenetic system lie in its stability: only the rank (either vertical or horizontal) but not its place within the hierarchical structure will be changed—as happened in past systems (a comparison of *Bergey's Manual of Determinative Bacteriology* from the first through eighth edition is instructive).

Even the most convincing tree is always in a dynamic state; this forces taxonomists to stay flexible to adjust not only established ranks but also nomenclature according to new insights. One problem still remains: the original advantage of the tree—its objectivity (in so far as is possible)—is weakened by subjective (variable emphasis on characters) clustering of organisms. As in previous decades, the most practicable system (or parts thereof) will succeed against competing systems with less persuasive arguments. The ultimate goal is to establish a hierarchical system where all taxa show phylogenetic coherency and, at least for ranks below the family level, a great deal of phenotypic coherency as well. On the other hand, sufficient differences need to be known to distinguish taxa from each other by stable and easily determined characters. While phylogenetic coherency is easy to define, the term "phenotypic coherency" varies according to the taxonomist. Again, practical considerations must come before petty splitting or lumping.

Profound knowledge about the phylogenetic clustering of members of the taxa in search is prerequisite. An optimal survey would work with coded, unnamed organisms to judge the resulting branching pattern without prejudice. The study should include the type strain of the type species and, if any information is already available, the type strain of the most unrelated representatives of the taxon. Depending on numbers of strains investigated, degree of relationships, and cost effectiveness, studies will include DNA-DNA pairing. The resulting pattern depicts the relative branching order, that, depending on the size of the database and the selection of reference organism, will immediately yield information about the phylogenetic homogeneity of a group of isolates. In the second step, the branching pattern is superimposed with phenotypic data to delineate clusters of organisms which are phylogenetically coherent and easy to recognize by phenotypic characters. This is prerequisite not only for identification, but also to decide which of the several possible branching patterns best reflects phylogeny most closely. It should be mentioned in this context that in the presence of varying evolutionary rates, species with the greatest nucleic acid sequence similarity are not necessarily the most closely related; while programs that optimize branch length take care of this problem, numerical phenetic analyses in fact

would cluster these species as neighbors. The combination of taxon-describing characters will not be predictable in most cases and the search will have to be extended to features not previously considered of taxonomic significance. Still many phylogenetically coherent taxa exist for which appropriate characters have not been found as yet.

The Higher Taxa

Analysis of sequences of rDNA and genes coding for proteins are routine some 10 years after the introduction of the PCR technology and the automated sequencing process. Large-scale genome sequencing projects are underway and the availability of an enormous number of sequences of homologous genes will one day allow a much more precise measurement of the branching order of lineages. However, with new lineages emerging from pure culture studies and analysis of complex microbial communities, the main topic of discussion is presently not the definition of higher taxa but very early evolutionary events, such as those that led to the formation of the eukaryotic cell, and the data discussed are sequence analyses of genes such as hsp70 (chaperone protein), glutamate dehydrogenase, glutamine synthase, aspartate aminotransferase and others (Gupta and Golding, 1993; Gogarten et al., 1989). Lateral gene transfer effects must not be neglected when phylogenetic trees based upon heat shock proteins (hsp70) are interpreted (Gribaldo et al., 1999; Philippe et al., 1999). The question whether or not the Gram-positive bacteria are more closely related to the Archaea than to the Gram-negative bacteria (Gupta and Golding, 1996) is a problem that can not be resolved on the basis of a few signature stretches of the gene and the amino acid sequence derived therefrom. The problem awaits a better understanding of the fate of the molecule in early evolution and greater ability to interpret the sequence data from a single gene in context of the overall biology of the organism.

According to Woese and colleagues (Woese et al., 1990), extant organisms are grouped within one of three major lines of descent, for which the domain has been proposed. The term "taxon domain" has replaced the term "primary kingdom" (Woese and Fox, 1977) originally given for the three main lines of descent which, based upon 16S rRNA analyses, are as unrelated to each other as each of them is related to the eukaryotic line. With the higher resolution provided by complete sequences of small-subunit rRNAs and other homologous marker molecules, this picture has been confirmed. The archaeal lineage is clearly separated from the other prokaryotic lineage, the Bacteria, forming a sister group of the Eucarya.

The main issue discussed at the end of the 1970s was whether the tripartition of extant species is accompanied by phenotypic properties that would support the phylogenetic finding. These properties were believed to exist because molecular analyses revealed the presence of evolutionary ancient groupings. While characters shared between members of two of the three domains are of no use for placing strains in the phylogenetically correct kingdom, certain characters are indeed exclusive for a particular primary domain and hence of diagnostic value. However, one can not exclude the possibility that nonhomologous phenotypes occur among members of different domains that mirror common evolutionary origin. On the other hand, homologous properties may actually be found exclusively among members of two domains, but this distribution is not due to common ancestry but to horizontal gene transfer.

Besides the structure and nucleotide composition of the 16S rRNA, several epigenetic properties were unique to Archaea and supported the validity of the description of this domain. Above all they were the lack of a typical peptidoglycan (replaced by a pseudomurein, a proteinaceous wall, or a heteropolysaccharide; Kandler, 1982), the presence of ether-linked isoprene units, and the complex modification pattern of ribosomal RNAs. In addition, certain archaeal taxa exhibit unique properties, which are absent in other taxa of this domain and in any bacterial or eukaryal taxon. The most well recognized ones are the coenzymes involved in methanogenesis; the energy-generating bacteriorhodopsin, halorhodopsin, and other sensory rhodopsins contained in the purple membranes of halophiles; survival under hyperthermophilic conditions; and singular physiological features such as the presence of a modified Entner-Doudoroff pathway. Other features will be discovered through the comparative analyses of fully sequenced archaeal genomes.

Since publication of the last edition of the Prokaryotes (Balows et al., 1991), new main lines of descent have been shown to exist in the domains Archaea and Bacteria, and most lineages have been significantly extended by studies on pure cultures and analysis of environmental samples. Ranks above the genus level have been described for several of these main lineages and for some of their sub-branches. What has been stated about the unreliability of standardized sequence similarity values of a single molecule to define a genus is also true for all higher ranks from family to kingdom. Consequently, a coherent hierarchical system of prokaryote taxa does not exist. While for one lineage a fully hierarchical

structure has been provided (Stackebrandt et al., 1997), there is no consensus about the level of the highest rank of a lineage. Lineages that are approximately equivalent in phylogenetic depth (i.e., the 16S rDNA similarity value that separates the most remotely related members of that lineage) are called kingdom (within the domain Archaea), phylum (some of the lineages originally defined by Woese et al., 1985, e.g., *Chloroflexus*, *Chlorobium*, *Deinococcus*, *Thermus*, *Bacteroides*, *Clostridium-Bacillus*), class (Actinobacteria, Proteobacteria), or order (Aquificales, Thermotogales, Spirochaetales, Verrucomicrobiales, Chlamydiales, Planctomycetales).

The phylogenetically defined higher taxa stand side by side with higher taxa established in the pre-phylogeny era. Some taxa were found to match the phylogenetic circumscription, e.g., the class Mollicutes, the orders Spirochaetales, Chlamydiales, and Myxobacteriales and the family Enterobacteriaceae, while others had to be emended or redefined on the basis of 16S rDNA sequence data to fit into a phylogeny-based hierarchical system, e.g., Micrococcaceae and Pseudomonadaceae. Yet other higher taxa such as the Bacillales and Clostridiales are still awaiting a formal revision, as phylogenetic evidence strongly points towards their dissection.

The Archaea

Concerning the phylogeny-based description of higher taxa, the domain Archaea has received considerable attention, primarily because of research activity in the laboratories of Ralph Wolfe and Carl Woese at the University of Illinois at Urbana-Champaign. Shortly after archaebacteria (as these organisms were named in 1979) were recognized, Balch et al. (1979) provided a comprehensive hierarchical system based on the assumption that the rate of 16S rRNA evolution in these organisms was similar. Consequently, species, genera, families and orders were delineated by ranges of S_{AB} values of 16S rRNA,which were 0.55–0.65, 0.46–0.51, 0.34–0.36 and 0.22–0.28, respectively. Later it became obvious that different bacterial species not only evolve a different mode and at a different rate (Woese et al., 1985c), but also their rRNA and rDNA may have different G+C content (Woese et al., 1991; Rainey et al., 1993; Liesack et al., 1992). The result was artificial misplacement of bacterial species in the phylogenetic dendrogram. The suggestion not to use a rather inflexible range of phylogenetic distances for the delineation of any taxon (Fox and Stackebrandt, 1987; Stackebrandt, 1992) has been accepted and applied to more recent descriptions of higher taxa in the domain (Burggraf et al., 1997).

When higher taxa were proposed for the second archaeal kingdom, the Crenarchaeota, only a few species had been described. It is therefore not surprising that the phenetic descriptions of the orders Thermoproteales (Zillig et al., 1981), Sulfolobales (Stetter, 1989), as well as those of the families Thermoproteaceae (Zillig et al., 1981) and Desulfurococcaceae (Zillig et al., 1982), Pyrodictiaceae and Thermofilaceae (Burggraf et al., 1997), are virtually the same as the genera they encompass. The inclusion of more organisms in a higher taxon, e.g., Thermoproteales and Thermoproteaceae (Burggraf et al., 1997) broadens the phenetic description.

The Bacteria

A similar situation is encountered among the deeply branching lineages of the domain Bacteria. Encouraged by the ease at which higher taxa were described for archaeal lineages, orders and families were almost simultaneously described with the recognition of a new genus or a cluster of neighboring genera. Examples are the order Aquificales, embracing the family Aquifexaceae, and the genera *Aquifex*, *Calderobacterium*, *Hydrogenobacter*, and *Thermocrinis*, as well as the order Thermotogales, embracing the family Thermotogaceae and several genera, e.g., *Thermotoga*, *Geotoga* and *Petrotoga*.

These examples demonstrate that the description of a higher taxon for a phylogenetic lineage is facilitated by the small number of organisms and by the isolated position of the lineages. The situation is different in the four main bacterial lineages, which show a complex phylogenetic structure: the Gram-positive bacteria (division Firmicutes), the class Proteobacteria, the Bacteroidaceae-Cytophagales line of descent, and the cyanobacteria phylum. Within the cyanobacterial lineage, higher taxa have been described on the basis of morphology and, within the Prochlorophytales, of pigment composition. Analysis of 16S rDNA clearly demonstrates that the present affiliation of genera into the orders Chroococcales, Nostocales, Oscillatoriales, Pleurocapsales and Stigonematales is not always supported from a phylogenetic point of view.

One of the most unexpected relationships that emerged from the analyses of rRNA, rDNA, and certain genes coding for proteins was the specific grouping of the *Bacteroides* and *Cytophaga-Flavobacterium* lines of descent. No higher taxon has been proposed as yet for the lineage comprising the phylogenetic assemblage of genera but, with the exception of the phylogenetically coherent family Sphingobacteriaceae (Steyn et al.,

1998), organisms are related to the traditional higher taxa Cytophagales and Bacteroidaceae.

The Higher Taxa of the Gram-Positive Bacteria

The Gram-positive bacteria constitute the division Firmicutes (Gibbons and Murray, 1978), which, with the exception of members of *Deinococcus*, appears to form a phylogenetically coherent taxon. The common ancestry of the two major sublines, however, one embracing the actinomycetes, the other containing the clostridia, bacilli and their relatives, has not been convincingly demonstrated by rDNA analyses. If, for the time being, it is assumed that these organisms indeed share a common ancestry, then the deep separation between organisms with a DNA base composition of less than about 50 mol% G+C (the *Clostridium-Bacillus* lineage) and those with a higher G+C content (the Actinobacteria) may facilitate resolution of their hierarchical structure.

A hierarchical classification system has been described for the actinomycetes and their relatives (Stackebrandt et al., 1997). The rationale for doing so was based on the fact that nearly all type strains of validly described species were characterized phylogenetically and that the genera constituted phylogenetically and phenetically coherent taxa. The decision to classify phylogenetically neighboring genera into families, neighboring families into suborders, and to continue up to the level of the class Actinobacteria was done irrespective of phenetic properties on which higher classification of these genera was based in the past. Rather than focusing on characteristics such as morphological, physiological and chemotaxonomic traits, which, except for the presence of mycolic acids, have no or only restricted phylogenetic meaning above the genus level, ranks were defined on the basis of emerging phylogenetic clusters and the presence of taxon-specific rDNA signature nucleotides. As a consequence the actinomycete proper has been classified into 5 subclasses, 6 orders, 10 suborders, and 35 families. Each taxon is characterized by a set of 16S rDNA signature nucleotides which were present in all or at least in the vast majority of members of a taxon at the time of its description. This way of circumscribing taxa is similar to the traditional, phenotype-based classification in that new members may have properties that differ to some extent from those of other members of the taxon. Consequently, the deviation may lead to an emendation of the taxon or, where the deviation is significant, to a dissection of the taxon. Any deviation from the signature pattern of a new member of a taxon may cause the taxonomist to revise the description of this taxon. In contrast to the past, lumping or splitting of taxa will not dramatically change the classification system, although the transfer of a taxon into the neighboring taxon of the same level may occur in those cases where the branch points of taxa in the phylogenetic tree are not well resolved. Within the second major lineage of the Firmicutes, the situation is more complicated. This phylogenetic cluster contains several higher taxa described by phenetic characteristics, e.g., the orders Bacillales and Clostridiales as well as the families Bacillaceae, Clostridiaceae, and Peptococcaceae, but the phylogenetic structure of such taxa does not correlate at all with the phylogenetic suprageneric classification. The situation is even more complicated by the present inability to define a genus *Clostridium*, needed to start a comprehensive phylogenetic classification process. The only higher taxon phylogenetically described so far within the *Clostridium* lineage is the order Haloanaerobiales, containing the families Haloanaerobiaceae (Oren et al., 1984) and Halobacteroidaceae containing Gram-negative, fermentative, halophilic and anaerobic bacteria (Rainey et al., 1995). The phenetic order Bacillales, developed from an ancestor of the Clostridiales, embraces the phylogenetically and phenetically coherent class Mycoplasmatales and the families Streptococcaceae and Lactobacillaceae, next to other higher taxa to be described. It is obvious that any attempt to create a fully comprehensive phylogeny-based hierarchical classification system for the *Clostridium-Bacillus* lineage has to await a thorough reclassification of the majority of genera contained in the lineage. This process has started with the dissection of the genus *Bacillus* and the establishment of new genera but will continue at a slower pace than in other lineages because of the significant degree of discord between phenetic classification and the phylogenetic position of species.

The Higher Taxa of the Proteobacteria

Members of the Proteobacteria are distributed into five subclasses. From the beginning of the molecular era of taxonomy, many of the Gram-negative taxa were investigated in parallel by 16S rRNA cataloging and determination of 16S rDNA similarities (Fox et al., 1977; Palleroni et al., 1973), and the agreement of the branching patterns was convincing. Almost complete 16S rDNA sequences have been generated for these and other organisms now seen to be members of the Proteobacteria. The phylogenetic clustering of organisms of quite different phenotypes initially surprised traditional microbiologists and gave the first indication that conventional classification does not reflect natural relationships.

Phototrophic bacteria were found to be neighbors of nitrite-oxidizing and carbon-monoxide-oxidizing forms, and organisms associated with eukaryotic cells were more closely related than originally believed (e.g., *Agrobacterium*, *Rhizobium*, *Brucella*, *Rochalimea*). But most unexpectedly, almost all of the more general characters used so far in classification lost their significance as taxon-describing features, e.g., photosynthesis (Stackebrandt et al., 1988a), carbon monoxide oxidation (Auling et al., 1988), methane- and methanol oxidation (Bowman et al., 1993), as well as all kinds of cell shapes, such as helical (Woese et al., 1982), budding (Stackebrandt et al., 1988b), or prosthecate (Schlesner et al., 1989). Stimulated by the phylogenetic data, supporting evidence has subsequently become available from chemotaxonomic studies. Among these criteria are polyamine patterns (Busse and Auling, 1988), ubiquinone types (Urakami et al., 1989), fatty acid compositions (Urakami and Komagata, 1987; Sittig and Schlesner, 1993), chemical compositions of lipid A, and the core region of lipopolysaccharides (Weckesser and Mayer, 1988).

The process of transforming phylogenetic evidence into the description of higher taxa is slow. This is not only true for a formal description of the subclasses but especially for the groupings within the subclasses. The reasons are obvious: 1) emphasis is placed on the generation of phylogenetically coherent genera; 2) neighboring genera may differ from each other significantly in phenotypic properties, which excludes the provision of phenetically coherent higher taxa; 3) the phylogenetic distances separating groups of genera from each other are small and the order is most likely distorted by new sequence entries; and 4) many new proteobacterial genera are presently described that may result in emendations and changes in the order of higher taxa.

The richest family structure is present in the γ-subclass in which a large number of genera, which are not necessarily phylogenetically coherent (e.g., *Pasteurella*, *Haemophilus*, *Serratia*, *Enterobacter*), are members of phylogenetically coherent families such as *Pasteurellaceae* and *Enterobacteriaceae*. Other well-defined families are Vibrionaceae, Aeromonadaceae, Legionellaceae and other families shown in Fig. 5. The only family that seems to be phylogenetically incoherent is Methylococcaceae. While the majority of genera of this family are positioned as shown in Fig. 4, the genus *Methylococcus* branches adjacent to the family Chromatiaceae. The other subclasses are less formally structured. Among the α-subclass, the Acetobacterceae, Rhizobiaceae, and the Rickettsiales constitute phylogenetically rather homogeneous taxa, while in the β-subclass, which appears as a

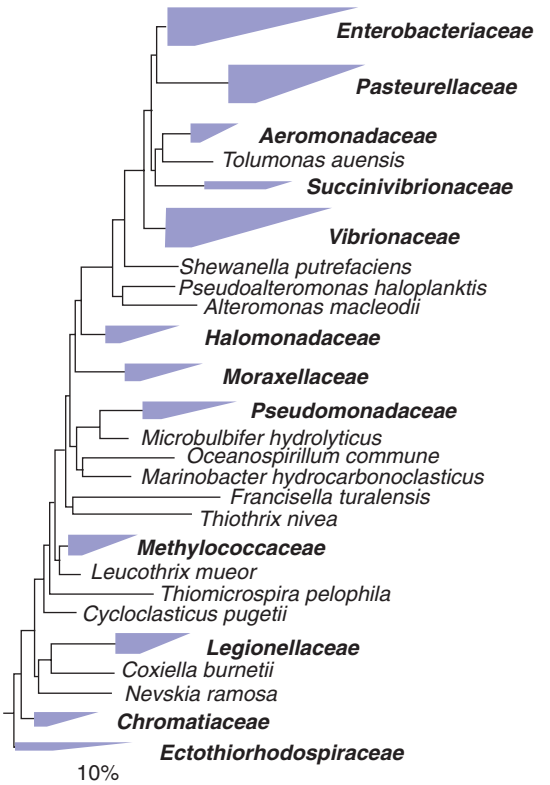

Fig. 5. 16S rDNA dendrogram of the γ-subclass of Proteobacteria, showing the position of phylogenetically coherent families. The 16S rDNA dendrogram is a detail of the (ARB tree). The scale bar corresponds to 10 nucleotide substitutions per 100 sequence positions.

subgroup of the γ-subclass, this refers to *Comamonadaceae* and *Neisseriaceae*. Within the δ-subclass the order *Myxobacterales* provides one of the rare examples in bacteriology in which the taxonomic structure as derived from phenotypic characterization, i.e., complex and highly ordered morphologic processes, is indeed valid indication of phylogenetic structure (Spröer et al., 1999).

Application of the Polyphasic Approach to Classification

The following is an example of the polyphasic approach to systematics (Fig. 6). First, it is assumed that the organisms abbreviated A through H have no taxonomic history but present novel isolates. In reality this is not the case because they represent well-known actinomycete genera and species (Stackebrandt et al., 1997). Analysis of 16S rDNA data leads to the placement of their sequences within the radiation of members of the class Actinobacteria, forming a sister-branch of the family Pseudonocardiaceae. As the phylogenetic depth of the new

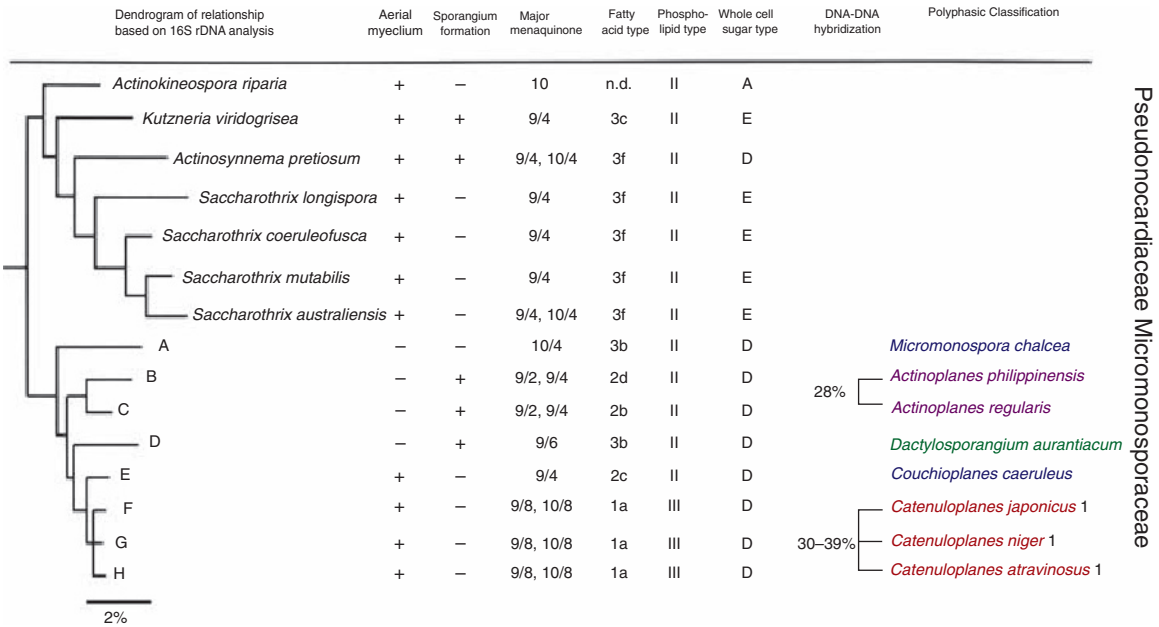

Fig. 6. Example of a polyphasic approach to bacterial taxonomy. The present classification is based on phylogenetic coherence of genera delineated from each other on the basis of morphological and chemotaxonomic properties. The selection of suitable properties depends upon the taxon under investigation. For clarity, the information on fatty acids, phospholipids, and whole cell sugars is abbreviated (*Bergey's Manual of Systematic Bacteriology*, Wilkins & Wiley, Baltimore, 1986). [1], data from Tamura et al., 1993, 1995.

lineages is comparable to that of the genus *Saccharothrix*, lineages A through H could constitute a novel genus. However, as the rate of evolution is different in members of different genera, the newly emerged phylogenetic cluster might well embrace two or more genera. Hence, the provision of a phylogenetic dendrogram alone does not a priori permit conclusions about the rank of taxa. According to the polyphasic approach, one would try to allocate as many genetically stable characters as possible to the isolates A to H to find characters that are unique to one phylogenetic cluster but different from neighboring clusters. As some characters may be shared by different genera, it is the presence of a unique pattern of characters that decides if a rank is delineated from its neighbors. Figure 6 lists some of the morphological and chemotaxonomic characters used in the polyphasic classification of actinomycetes. As derived from the example of the Pseudonocardiaceae, each genus is characterized by a unique set of morphological and chemical properties. Species of the genus *Saccharothrix* share the genus-specific pattern (but they can be distinguished from each other by physiological reactions). Patterns obtained for the (hypothetically) new organisms are novel for the actinomycetes genera and indicate five subgroups worthy of genus rank. To determine whether the isolates with identical phenetic patterns constitute individual species, DNA-DNA reassociation experiments must be performed. Isolates B and C (Stackebrandt et al., 1983), as well as isolates F, G and H (Yokota et al., 1993) represent individual species, as in each case the reassociation values are below 70%. Consequently the isolates can be classified into five new genera containing 8 new species which can be phenotypically separated (not shown).

The affiliation of the new monophyletic genera to a family on the basis of phenotypic data is not appropriate because of the great morphological and chemical diversity that would not exclude identification of other actinomycete genera as members of this family. As discussed (Stackebrandt et al., 1997), the presence of a pattern of 16S rDNA signature nucleotides common to all members of *Micromonospora* and related genera and different from those defined for other actinomycete families circumscribes the family Micromonosporaceae at the genomic level. Another set of signature nucleotides common to all monophyletic families led to the description of the order Actinomycetales, yet another set to the definition of the six actinobacterial orders of the class Actinobacteria.

CHAPTER 1.4

Prokaryote Characterization and Identification

HANS G. TRÜPER AND KARL-HEINZ SCHLEIFER

The aim of characterization (in the present context) is to obtain a complete collection of data describing the properties of a prokaryotic pure culture, i.e., to develop a description. The aim of "identification" is to equate the properties of a pure culture with those of a well-characterized and accepted species. When identification in this sense cannot be accomplished, the aim of identification must shift to characterization of a new species, i.e., to a new description.

It is clear that the amount of data required for the identification of an isolate with an established species is usually lower than the amount of data collected for characterization. And it is also clear that the final aim of characterization, as mentioned above, is never reached because continuing progress in scientific and technological methods allows the study of an ever-increasing number of characters or properties of a species. Although this continuous progress results in a higher reliability in identification, the practical aim of identification is to base it upon the smallest possible number of characteristics. Therefore, identification in many cases (especially with pathogenic organisms) is a compromise between accuracy and speed. The selected characteristics used for identification usually are weighted and are those that have proved to be significant in distinguishing one organism from another.

Prokaryote Systematics

Definitions

We may define systematics as the scientific study of organisms with the ultimate object of characterizing and arranging them in an orderly manner. Systematics also might be defined as "the study of organismal diversity and interrelationships." Following Cowan (1968), systematics includes taxonomy (with its subdivisions, see below) and includes aspects of ecology, biochemistry, genetics, pathology, molecular biology, and microscopy.

Taxonomy is often used as a synonym for systematics. Stanier et al. (1986) define taxonomy as "the art of biological classification," while Simpson (1961) defines it as the theoretical study of classification, including its bases, principles, and rules. Cowan (1968) states that taxonomy consists of:

1. *Classification*, which means the orderly arrangement of units into groups.
2. *Nomenclature*, which means the labeling of units defined by classification.
3. *Identification* of unknowns with the units defined by classification and labeled by nomenclature (i.e., identification is the practical application of the arts of classification and nomenclature).

Classification is often confused with identification, because identification may be understood either transitively (identification of unknowns with units defined by classification) or intransitively (to describe the identity of a species as such and use it as a basis for classification). Thus Stanier et al. (1986) consider the two functions of taxonomy to be: 1) to identify and describe the basic taxonomic units or species; and 2) to devise an appropriate way of arranging and cataloging these units. The interrelations between these items are depicted in a flow diagram in Fig. 1.

Nomenclature of Bacteria

Since most microbiologists are not primarily involved in taxonomic work, a short introduction to the International Code of Nomenclature of Bacteria will be presented in the following discussion.

The 1975 revision of the International Code of Nomenclature of Bacteria (Lapage et al., 1975) became valid 1 January 1976. It consists of 7 General Considerations, 9 Principles, 65 Rules (some being supplemented by Recommendations which do not have the force of Rules), 10 Appendices, the Statutes of the International Committee on Systematic Bacteriology, and the Statutes of the International Union of Microbiological Societies (IUMS).

The International Code of Nomenclature of Bacteria is designed to guarantee the correct names of taxa. It contains rules about the rank of taxa; naming of taxa; nomenclatural types and their designation; priority and publication of names; citation of authors and names; changes in names of taxa as a result of transference, union, or change in rank; rules about illegitimate names

This chapter was taken unchanged from the second edition.

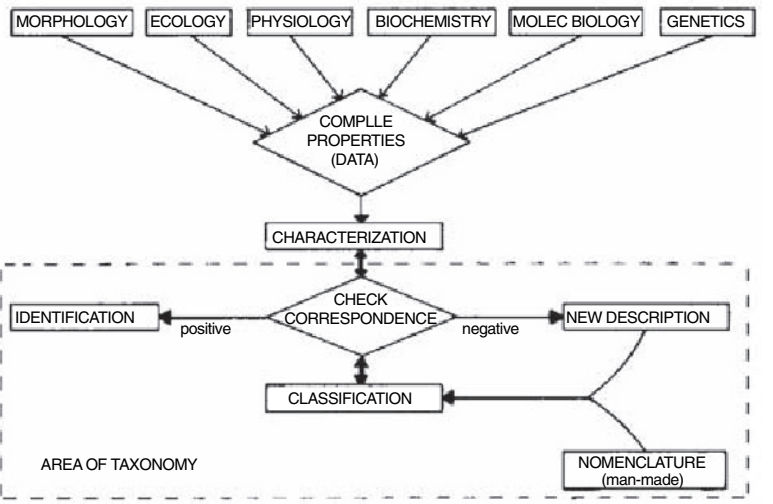

Fig. 1. Information flow diagram indicating the relationships between the characterization and the classification of a bacterial strain. The two important working steps (indicated by diamond-shaped boxes) are compiling properties and checking for correspondence between characterization and classification.

and epithets; replacement, rejection, and conservation of names and epithets. Also, a number of rules and Appendix 9 pertain to the correct usage of Latin orthography.

Appendix 4 of the International Code of Nomenclature of Bacteria is especially important because it contains the conserved and rejected names of bacterial taxa. The Opinions of the Judicial Commission of the International Committee on Systematic Bacteriology are contained in Appendix 5. These opinions have the same force as the rules. New Opinions are published in the *International Journal of Systematic Bacteriology.*

The Rules of the International Code of Nomenclature of Bacteria are designed to make effective the Principles. They are internationally accepted and must be obeyed in bacterial nomenclature, even retrospectively. Bacterial nomenclature is not completely independent; for practical reasons, bacteria may not bear names that are validly used for algae, fungi, protozoa, or viruses (Principle 2).

In the Code, the word "taxon" (plural "taxa") is used for any taxonomic group of organisms (General Consideration 7). The correct name of a taxon (Principle 6) is based upon:

1. Valid publication. Since 1976, this means publication of the name in the *International Journal of Systematic Bacteriology.* The publication of the name in this journal must be accompanied by a description of the taxon or by a reference to a previous effectively published (see below) description of the taxon (Appendix 7). A type must be designated for the new taxon or combination (Rule 27).

2. Legitimacy. Names must be in accordance with the Rules.

a) Priority of publication. Each taxon above species (up to and including order) can bear only one correct name, the earliest that is in accordance with the Rules of the International Code of Nomenclature of Bacteria (Rule 23a). The name of a species is a binary combination of generic name and specific epithet (Rule 12a). Within a genus, a species can only bear one correct epithet, the earliest given in accordance with the Rules of the International Code of Nomenclature of Bacteria (see also below: *Approved Lists of Bacterial Names*).

b) Effective publication. "Effective" publication means to make printed material generally available, by sale or distribution, to the scientific community, for the purpose of providing a permanent record (Rule 25). New names presented at meetings, in minutes or abstracts of meetings, in collection catalogs, newsletters, newspapers, nonscientific periodicals, patents, or distributed on microfilms or microcards, etc., are not considered effectively published by the International Code of Nomenclature of Bacteria.

A taxon consists of one or more elements. For each named taxon of the various taxonomic categories (Table 1), there shall be designated a nomenclatural "type" that is the element of the taxon to which the name is permanently associated.

The taxonomic categories form a hierarchy which is depicted in Table 1. In general, little use is made of subcategories, such as "suborder" and "subfamily," or of the category "tribe."

The basis of the taxonomic hierarchy is essentially the species. The definition of a prokaryote species has often given rise to discussions and arguments among biologists. Cowan (1968) humorously summarized a species as "a group of organisms defined more or less subjectively by the criteria chosen by the taxonomist to show to best advantage as far as possible and putting into practice his individual concept of what a species is."

Table 1. Taxonomic categories, examples, and types.

Taxonomic category	Latin suffix	Example[a]	Type (definition)	Type (example)
Division[a]	Not fixed	Gracilicutes		
Class		Photobacteria	One of the contained orders	
Subclass		Anoxyphotobacteria		
Order	-ales	Rhodospirillales	Genus, on whose name the name of the higher taxon is based	*Rhodospirillum*
Suborder	-ineae	Rhodospirillineae		
Family	-aceae	Rhodospirillaceae		
Subfamily	-oideae	Rhodospirilloideae		
Tribe	-eae	Rhodospirilleae		
Subtribe	-inae	Rhodospirillinae		
Genus	Not fixed	*Rhodospirillum*	Designated species	*R. rubrum*
Subgenus		—		
Species		*R. rubrum*	Designated strain	Strain ATCC 11170
Subspecies		—		

The examples given are classical and should be changed during further development of a phylogeny-based taxonomy, as follows: Above order: proposal of Gibbons and Murray (1978); the class was changed to Proteobacteria by Stackebrandt et al. (1988). Below subclass: from Pfennig and Trüper (1971), where subcategories were not mentioned.

The textbook written by Stanier et al. (1986) states: "... a species consists of an assemblage of individuals (or, in microorganisms, of clonal populations) that share a high degree of phenotypic similarity, coupled with an appreciable dissimilarity from other assemblages of the same general kind."

The modern phylogenetic definition of a species (Wayne et al., 1987) is based on DNA-DNA hybridization procedures and generally would include all strains with approximately 70% or greater DNA-DNA relatedness and with 5°C or less ΔTm. Both values must be considered. Phenotypic characteristics should agree with this definition and would be allowed to override the phylogenetic concept of species only in a few exceptional cases.

It is recommended that a distinct genospecies (i.e., a species discernible only by nucleic acid comparisons) that cannot be differentiated from another genospecies on the basis of any known phenotypic property not be named until some phenotypic differentiating property is found (Wayne et al., 1987).

When a new species is described, the type must be indicated. Whenever possible the type should be a pure culture designated as type strain. For a species described from impure cultures, a description, a preserved specimen, or an illustration may serve as the type (Rule 18a). If such an organism is brought into pure culture later on, it may be designated as the type strain and replace the original type (Rule 18h).

Before publication of the name of a new species, a culture of the type strain should be deposited in at least one of the permanently established culture collections from which it is readily available. The strain number given by the culture collection should be quoted in the published description (Recommendation 30a).

Subspecies designations can be used for genetically close organisms that diverge in phenotype. There is some evidence, based on frequency distribution of ΔTm values in DNA hybridization, that the subspecies concept is phylogenetically valid and can be distinguished from the infrasubspecific variety concept, which is based solely upon selected "utility" attributes, but not demonstrable by DNA reassociation (Wayne et al., 1987).

Appendix 10 of the International Code of Nomenclature of Bacteria deals with infrasubspecific subdivisions. An infrasubspecific taxon is one strain or a set of strains showing the same or similar properties and treated as a taxonomic group. An infrasubspecific term is used to refer to the kind of taxa below subspecies.

The terms commonly used for such subdivisions usually contain the suffixes -type, -var, or -form. Appendix 10 recommends the use of the suffix -var in order to avoid confusion with the strict use of the term "type" for the nomenclatural type (Rule 15). The following terms are recommended (with the terms that should be avoided in parentheses): biovar (biotype, physiological type); chemovar; chemoform (chemotype); cultivar; forma specialis (special form); morphovar (morphotype); pathovar (pathotype); phagovar (phagotype, lysotype); phase; serovar (serotype); state.

"Biovar" pertains to biochemical or physiological properties, "chemovar" to production of a particular chemical, "chemoform" to chemical constitution, "cultivar" to special cultivation properties, "forma specialis" to a parasitic, symbiotic, or commensal bacterium distinguished primarily by adaptation to a particular host or habitat (it should be named preferably by the scientific name of the host in the genitive). "Morphovar" pertains to morphological characteris-

tics, "pathovar" to pathogenic reactions in one or more hosts, "phagovar" to reactions to bacteriophage, "serovar" to antigenic characteristics. The term "phase" should be restricted to well-defined stages of naturally occurring alternating variations. "State" is used for colonial variants—e.g., rough, smooth, mucoid—which may be defined antigenically and then considered as serovars.

An alphabetical compilation of all names that have been used in bacteriology (except for the cyanobacteria), including the evaluation of their legitimacy and valid and effective publication, is contained in the Index Bergeyana (Buchanan, Holt, and Lessel, 1966), with three addenda prepared up to 1969 (Hatt and Zvirbulis, 1967; Zvirbulis and Hatt, 1969a, 1969b). For the language of taxonomy and nomenclature, we recommend the *Dictionary of Microbial Taxonomy* (Cowan, 1978), where helpful and sometimes humorous instructions are provided.

Approved Lists of Bacterial Names

Since 1 January 1980, priority of bacterial names is—by international agreement—based upon the *Approved Lists of Bacterial Names* (Skerman, McGowan, and Sneath, 1980). Names that were not included in the *Approved Lists* lost standing in bacterial nomenclature, but are, however, available for reuse (Rule 24a).

Since 1 January 1980, valid publication of new names and new nomenclatural combinations can only be obtained by publication in the *International Journal of Systematic Bacteriology*, either of an original article or in the "Validation Lists" regularly appearing in that journal.

These lists constitute validation of the publication of new names and new combinations that were previously effectively published outside the *International Journal of Systematic Bacteriology.* Up to the end of 1989, 31 such validation lists have been published in the *International Journal of Systematic Bacteriology.*

Towards a Modern Taxonomy

Prokaryote taxonomy began when Ferdinand Cohn (1872) grouped the bacteria—according to their overall morphological appearance—into cocci, short rods, elongate rods, and spirals. Cohn (1875) also perceived the high degree of relationship between the "common bacteria" and the cyanobacteria (then called blue-green algae) and grouped them together as the Schizophyta.

Although the purely morphological approach soon proved to be insufficient, morphology and, increasingly, ultrastructure, still play an important role in identification.

A new era in bacterial taxonomy, dominated by physiology, began with the classification system of Orla-Jensen (1909). Numerous physiological properties of bacterial cultures were determined for characterization and predominantly used for identification. Later, enzymes were studied and metabolic pathways elucidated.

Orla-Jensen 1909 and later Kluyver and van Niel (1936) as well as Stanier and van Niel (1941) proposed taxonomic systems based on the presumed evolutionary relationships of bacteria. Van Niel (1946) himself, however, pointed out the shortcomings of the deductive phylogenetic approach to bacterial classification. The shortcomings were mainly seen in the lack of suitable parameters that clearly allow differentiation between "relationship" and mere "resemblance," not to mention the general lack of paleontological evidence. Stanier (1971) pointed out that the question of relatedness can be probed at two slightly different levels: 1) the strictly genetic level where general organization and base sequence homologies of the deoxyribonucleic acids of different organisms are compared; and 2) the epigenetic level (a term coined by Stanier), where properties are compared that are expressed at the level of translation (or, less commonly, of transcription).

Since then the study of microbial phylogeny has attracted increasing attention, and the taxonomy of prokaryotes undoubtedly will eventually reflect phylogeny. The work of C. R. Woese (for details, see Prokaryote Systematics: The Evolution of a Science in this Volume) has especially been a "milestone" in this respect. It has been recommended (Wayne et al., 1987) that DNA-DNA hybridization should be the standard arbiter for the designation of species (see also above).

Phylogenetic relationships have been assessed at all taxonomic levels by analysis of rRNA and/or the gene that encodes it. Current analyses involve the application of DNA/rRNA hybridization and comparative sequencing of 5S rRNA, 16S rRNA and 23S rRNA. Other macromolecules besides rRNAs, e.g. elongation factor Tu and β-subunit of ATP-synthase, can also be used as phylogenetic markers (Schleifer and Ludwig, 1989). Data obtained from comparative sequence analyses provide the best basis at the present time for phylogenetic relationships among all bacteria. However, differences in evolutionary rates in various groups of organisms and other considerations mentioned below prevent the use of phylogenetic parameters alone in delineating taxa. Therefore, the integrated use of phylogenetic and phenotypic characteristics, called polyphasic taxonomy (Colwell, 1970) is necessary for the delineation of taxa at all levels from kingdom to genus (Murray et al., 1990).

For such analyses to be accurate and universally applicable, it is essential to start with a typical strain which is designated the type strain of the type species for the genus or genera under study. To determine the phylogenetic range of a genus, one must use type strains of the two most divergent species, which should be selected by DNA-DNA hybridization or other appropriate phylogenetic measure, and/or by consideration of phenotypic characteristics. It is frequently essential and always advantageous to use additional, authentic, well-characterized reference strains when they are available.

Because a polyphasic approach, including phenotypic and phylogenetic data, is essential for designating taxa, descriptions of new genera should, whenever possible, include either sequencing or hybridization data. The optimal methods for determining phylogenetic relationships above the species level are DNA-rRNA hybridization and 16S rRNA sequencing of 1,000 or more bases. 23S rRNA may provide greater sensitivity for some applications but need not be done routinely. Sequencing of 5S rRNA can also be useful (Erdman et al., 1985) but because of the small size of the macromolecule, less information is provided. When comparing results to published sequences, scientists should be aware of data from strains other than the type. In the absence of a type strain sequence, a strain authenticated to be at the same species level to the type strain by DNA-DNA relatedness should be satisfactory (Wayne et al., 1987).

All sequences from which phylogenetic and taxonomic conclusions have been derived should be published or made available through data banks. This must be done not only for the organisms under investigation, but also for the reference strains used in tree construction. Failure to do so has resulted in the inability to test the proposed phylogenetic conclusions and prevents building a database available to all scientists. Restriction of sequence information to small fragments allows recognition of taxa and may be useful for identification, but is of questionable value in deriving phylogenetic conclusions.

Phylogenetic relations have been assessed at all taxonomic levels by analysis of rRNA or rRNA genes. Chemotaxonomic markers and genetic transformation are unevenly distributed but rarely give information on the hierarchic rank of the taxa studied. There is, however, good evidence in bacterial systematics of congruence between the distribution of specific chemical markers and the relative position of species in phylogenetic trees. The use of chemotaxonomic markers can be expected to help in delimiting groups of related species (Murray et al., 1990).

As a taxonomic consequence, the first step in the identification of bacteria is to try to assign organisms to genera. Therefore, the greatest clarity in circumscription and utility in the choice of characters must be accorded to the generic level. It is completely impracticable to define genera solely on the basis of phylogenetic data. Genera need to be characterized using phenotypic properties even if the choice of phenotypic markers might change as a result of the development of better tests. A degree of flexibility is necessary in the definition of genera. In cases where there is disparity between phylogenetic and phenotypic data, priority should be provisionally given to the latter. In such instances, further detailed comparative studies of the phenotype should be encouraged to resolve the apparent disparity so that classification reflects phylogenetic relationships (Murray et al., 1990).

Numerical Taxonomy

A well-established means for the assessment and evaluation of phenotypic data is numerical taxonomy (Goodfellow, 1977; Sneath, 1971; Sneath and Sokal, 1973; Sokal and Sneath, 1963; Hill, 1974). For numerical studies, the results are tabulated in a table of t organisms versus n characters. The term OTU (operational taxonomic unit) is used for an individual strain. The characters should be independent and should come about equally from the various different categories of properties (morphology, physiology, biochemistry, serology, etc.). For statistical reasons, the total number of characters should be above 60. Whereas in conventional taxonomy so-called characteristic tests and differentiating media are in use (with special importance for identification), numerical taxonomy principally allots the same weight to each character, because there is no logical alternative that would allow independence from the personal opinion of the scientist. This principle was introduced into (plant) taxonomy by Adanson (1763).

The number of common characters is considered as a quantitative measure for the taxonomic relationship (not phylogenetic "relatedness"). As an important consequence, not all members (species) of a group must have one special property in common. Similarities are quantitatively expressed by the matching coefficient of Sokal and Michener (Skerman, 1967), usually expressed in percent:

$$S_{SM} = \frac{\text{sum of positive and negative matches}}{\text{total number of tests}}$$

The similarities between each OTU and every other OTU under study are set out in tables in the form of a triangular similarity matrix (also called a Sneath diagram). By forming linkage groups and performing cluster analyses, the

numerical taxonomist finally arrives at a rearranged matrix that depicts linkage clusters. Another way to express relations between OTUs after an analysis is by the use of dendrograms. Kaneko (1979) introduced the correlative similarity coefficient as a new criterion for forming dendrograms. Other coefficients for numerical taxonomy have been evaluated by Austin and Colwell (1977). Detailed information about the use of computer analysis in numerical taxonomy can be obtained from Sneath (1972, 1977, 1979a, 1979b, 1979c, 1980a, 1980b, 1980c). Computer-aided identification systems have also been described, e.g., by Edwards (1978), Kellogg (1979), Schindler, Duben, and Lysenko (1979), Beers and Lockhard (1962), Gyllenberg (1965), Holmes and Hill (1985), Lapage et al. (1970, 1973).

Assessment of Morphological and Ultrastructural Characters

Microscopic Characters

Cell Shape The shape of cells, although of general importance in bacteriology, plays a special role in the identification of stalked, budding, or sheathed bacteria, as well as within the physiological group of the phototrophic bacteria, especially the cyanobacteria. In medical microbiology, cell shape is especially important for the identification of fusiform bacteria, coryneform bacteria, spirochetes, spirilla, and vibrios. Where conspicuous cell aggregates are formed, they are a very useful tool for identification, as is the formation of fruiting bodies by the myxobacteria (see The Myxobacteria in Volume 7) and the formation of mycelia by actinomycetes (see Introduction to the Taxonomy of Actinobacteria and The Families Dietziaceae, Gordoniaceae, and Tsukamurellaceae Nocardiaceae in Volume 3). Cocci occur as diplococci, sarcina packets, chains (*Streptococcus*), and clumps (*Staphylococcus*). In the Chromatiaceae and Chlorobiaceae, there exist such typical forms as *Thiopedia* (platelets), *Thiocapsa* (tetrads), and *Thiodictyon* and *Pelodictyon* (nets).

The disease "Vincent's angina" is diagnosed in many laboratories only by microscopic demonstration of a marked overgrowth of the microflora normally present in the oral cavity and pharynx by fusiform and spirochetal bacteria. The variability in size and shape can be a help in identifying a species; cells of a club-shaped *Corynebacterium diphtheriae* are pleomorphic, whereas cells of diphtheroids are more uniform in shape. The demonstration of a large number of Gram-positive cocci in feces may indicate an enterocolitis caused by *Staphylococcus aureus*, and the appearance of Gram-negative diplococci in cerebrospinal fluid suggests a meningitis with *Neisseria menigitidis* as the etiological agent.

Cell Size The diameter (thickness) of cells is used to differentiate between species in genera such as *Chromatium* and *Beggiatoa*. Due to the reproductive patterns of bacteria, in most cases the diameter of a cell is a more stable property than its length.

Cellular Motility Motility of cells may not be a generally stable character, although it is important in the identification of the various groups of gliding bacteria: e.g., The Myxobacteria in Volume 7, flexibacteria The Order Cytophagales in Volume 7, The Family Chloroflexaceae in Volume 7, gliding Cyanobacteria—Ecology, Physiology, and Molecular Genetics in Volume 4, and Beggiatoaceae (The Genus *Beggiatoa* and *Thioploca* in Volume 6).

Since great variability in motility occurs within the Enterobacteriaceae, motility is of comparatively little importance there (see New Members of the Family Enterobacteriaceae in Volume 6).

In medical microbiology, direct inspection for motility is used in a few cases. Venereal lesions can be examined by very experienced personnel for the typical movement of *Treponema pallidum*. Most members of the *Proteus* group are very actively motile. Starting from one colony on nutrient agar, these strains spread over the surface of the agar plate, a phenomenon known as swarming.

Care should be taken not to confuse the terms "immotile" and "nonmotile." A species (or strain) may be called nonmotile only if it is permanently so and has no means of locomotion (flagella or gliding) at all. On the other hand, "immotile" is a temporary status of a cell.

Flagellation The type of flagellation, i.e., position and number of flagella, is often used in the definition of genera and even higher taxa. However, flagellation is not always a constant characteristic. For example, although it is a generally accepted opinion that pseudomonads and vibrios possess polar flagella, certain marine *Vibrio* species (formerly in the genus *Beneckea*) have polar flagella only in liquid media; on solid media, they develop lateral flagellation (Allen and Baumann, 1971; Reichelt and Baumann, 1973). The peritrichously flagellated hydrogen oxidizing bacterium, *Alcaligenes eutrophus* (formerly *Hydrogenomonas*), is closely related to a genus that also contains polarly flagellated, hydrogen oxidizing bacteria, such as *Pseudomonas facilis* (formerly *Hydrogenomonas*).

These examples may demonstrate the relative value of type of flagellation for the identification

of bacteria. For further details, we recommend the review by Rhodes (1965) on flagellation as a criterion for the classification of bacteria.

Sporulation The presence of spores or the ability to form spores under limited nutrient conditions is of great importance since positive endospore formation aids in rapid identification.

The only endosporeforming bacteria that have clinical importance belong to the genera *Bacillus* and *Clostridium*. The ability to form endospores has, therefore, a great distinguishing value. Since sporulation of human pathogens is not common in original clinical material or in media used for the isolation of the bacteria, subculture in special sporeforming media is often helpful for demonstrating the spores. The endospores can be detected by a specific spore stain, but usually the Gram stain or direct examination with a phase contrast microscope is sufficient because the endospores are highly refractive and do not take up dyes of the Gram stain. Not only the presence but also the position of the spore within the cell may be of great diagnostic value, e.g., for the identification of *Clostridium tetani* and *C. botulinum*.

For the identification of actinomycetes, the shape and color of their conidiospores are of great importance.

Cellular Inclusions Microscopically visible cellular inclusions other than spores may be used in identification procedures for certain bacteria. Globules of elemental sulfur inside the cells are used in differentiation of phototrophic sulfur bacteria (The Family Ectothiorhodospiraceae in Volume 6). A protein crystal will help to identify *Bacillus thuringiensis*. The highly refractile gas vacuoles found in phototrophic and other bacteria are usually specific taxonomic criteria.

The demonstration of polymetaphosphate (volutin granules) may be a help for the presumptive identification of *Corynebacterium diphtheriae* and for distinguishing *C. diphtheriae* from diphtheroids. In clinical specimens and in organisms grown on media without potassium tellurite, these inclusions were found typically in most cells of *C. diphtheriae*, morphovar *mitis*, as polar bodies, whereas diphtheroids produce these granules usually only in a few cells or not at all. Because the basophilic volutin granules appear reddish when stained with toluidine blue, such storage materials are also called metachromatic granules. Common procedures for the staining of volutin granules in cells of corynebacteria are Albert's and Neisser's stain: after staining, the polymetaphosphate bodies appear blue-black and the cytoplasm appears light brown.

Color The color of single cells studied under the microscope may reveal whether a purple sulfur bacterium contains the conspicuous purple-red carotenoid okenone, thus allowing quick allocation in the family Chromatiaceae.

The color of cell suspensions is of far greater importance. In many cases of pigment-containing bacteria, an experienced microbiologist will be able to judge from typical colors without recording absorption spectra of the respective suspensions. For safe identification, however, an absorption spectrum is indispensable, e.g., for the identification of phototrophic bacteria (see The Phototrophic Way of Life in Volume 2).

Whereas the color of single cells or cell suspensions may not always give the decisive clue, the color of colonies—either in deep agar-shake cultures or on agar surfaces—may help in identification. This is the case with *Serratia marcescens* within the Enterobacteriaceae, with *Halobacterium* (to distinguish it from other extremely halophilic bacteria), and with the phototrophic bacteria.

Colonial Morphology The morphology of a bacterial colony will vary greatly with the temperature, pH, atmosphere, age, and medium on which it is grown. Therefore, colonial morphology is merely a helpful character in identification when standardized media and growth conditions are used. In this case, the colonial pigmentation, surface, size, shape, production of slime, elevation, odor, opacity, swarming behavior, consistency, and changing color of the medium are important parameters for the characterization of new organisms. In some cases these parameters are also of importance for the identification of clinical isolates. For example, tiny, opaque to transparent colonies of about 0.5 mm in diameter on blood agar with a clear zone around the colonies (beta hemolysis), sliding entirely across the agar when touched with a wire loop, are likely to be *Streptococcus pyogenes*. In contrast, colonies of *Streptococcus pneumoniae* on blood agar are mucoid, about 1 mm in diameter, surrounded by a zone of discoloration (alpha hemolysis), and often umbilicated, which means that the autolyzed flat center of the colony is surrounded by an elevated rim.

Often, species such as *Staphylococcus aureus* can be preliminarily identified because of the golden-yellow pigmentation of the butyrous colonies, which are 2–3 mm in diameter and often surrounded by a small zone of β hemolysis. Strain variation may occur in colonial morphology. Wild-type strains of *Shigella sonnei* form convex colonies with a circular shape and a smooth surface, whereas colonies of mutants of *S. sonnei* that have lost the ability to synthesize

specific components of the outer cell wall are flat with a rough surface and an irregular shape. In addition to staining behavior and biochemical activity, the colonial appearance is an important characteristic for the separation of *C. diphtheriae* into the morphovars *gravis*, *mitis*, and *intermedius*. Agar-dissolving bacteria are quickly identified by the holes they form in agar surfaces. Liquefaction of gelatinous solid media is used in medical diagnostic bacteriology, as well as for the identification of *Rhodocyclus gelatinosus*.

Ultrastructural Characters

The fine structure of cells studied by electron microscopy provides several characters that have turned out to be useful in identification. The decision of whether a cell is Gram positive or negative may be derived from electron micrographs, but other cell wall layers (Glauert and Thornley, 1969: the "topography" of cell walls) and very typical intracytoplasmic membrane systems also become visible. The latter are especially important for the identification of phototrophic (cyanobacteria and purple bacteria), methylotrophic, and chemolithoautotrophic (thiobacilli and nitrifiers) bacteria. Special organelles, the chlorosomes (Staehelin et al., 1978), characterize the Chlorobiaceae, and the phycobilisomes characterize the cyanobacteria. Carboxysomes, a polymerized form of the enzyme ribulose-bisphosphate carboxylase, appear as conspicuous polyhedral bodies in autotrophic bacteria only (Shively, 1974).

Gram-Staining Behavior

The ultra-structural and chemical differences between Gram-negative and Gram-positive bacterial cell walls are well substantiated. The Gram stain remains an indispensable method, especially in clinical and food microbiology, though there are examples of staining variability due to age and other factors. Some species react Gram-positive in the exponential growth phase, but become Gram-negative in the stationary phase. The methanogenic bacteria, none of which so far contains a peptidoglycan cell wall, in part stain Gram-negative, in part Gram-positive (Kandler and Hippe, 1977; Kandler and König, 1978). In the halobacteria, which also lack peptidoglycan, while *Halobacterium* reacts Gram-negative, *Halococcus* reacts Gram-positive.

Chemical Composition of Cell Constituents

Our increasing knowledge of the chemical composition of cell constituents has considerably improved the classification and identification of prokaryotes. Chemotaxonomic methods are now widely used, in particular, for those groups of prokaryotes where morphological and physiological characters have largely failed or have not been sufficient to provide a satisfactory classification. Simple and rapid qualitative analyses of cell walls or even of cells can be used to discriminate among groups of bacteria. However, when applying chemotaxonomic markers, microbiologists should be aware that sometimes one criterion, such as identical DNA base ratio or, less frequently, identical cell wall or lipid composition, can occur in quite different organisms. If this occurs, it is more prudent to rely on chemotaxonomic differences to exclude an organism from a taxon than to use a similarity as the sole criterion for inclusion.

DNA Base Composition

The usefulness and the taxonomic implications of the GC content of the DNA base have been reviewed by Mandel (1969). The DNA composition is one of the required characteristics of the minimum list of data for a description of a new species. By far the most used technique is the determination of the thermal denaturation temperature, but the determination of buoyant density in CsCl can also be used. Other methods, including chromatographic determinations and spectrophotometric approximations from absorbancy ratio, play only a minor role (Schleifer and Stackebrandt, 1983; Johnson, 1986).

As already pointed out by Mandel (1969), the GC content is only an exclusionary determinant in the classification of bacteria, in that two strains differing in more than 5 mol% should not be allocated to the same species, whereas on the other hand, a similar DNA base composition does not necessarily imply that the two strains are closely related.

Phylogenetic studies on the primary structure of the 16S rRNA (Woese, 1987) have demonstrated that the GC content of the DNA is not a phylogenetic marker per se. Only in the classification of Gram-positive eubacteria does the GC content allow the allocation of a strain into one of the two major lines of descent, one of them embracing high GC-content organisms, the other embracing those with low GC values. The situation is different among the Gram-negative eubacteria, which embrace several major lines of descent, to which organisms cannot be allocated according to their gross GC content.

Organisms whose DNA base compositions differ by more than 10 mol% ordinarily should not be considered members of the same genus. However, this raises the question of whether or not taxonomists should set fixed boundaries for the

range in the GC content for taxa above the species level. There are examples of phylogenetically coherent genera such as *Lactobacillus* and *Spirochaeta* with a GC content differing by more than 10 mol%. In practice, however, DNA base composition, in combination with other chemotaxonomic markers, has proved to be a valuable character in resolving taxonomic problems and in supporting results from phylogenetic studies.

Membrane Composition

Besides representing a selective barrier, the cytoplasmic membrane assumes many functions attributable to specialized organelles in eukaryotic cells. Prokaryotes show a greater variety in their membrane composition than eukaryotes do. The composition of the membrane is an important character for the identification of prokaryotes.

Polar Ester Lipids of Eubacteria Polar lipids are amphipathic molecules and can be extracted readily from bacterial cells with chloroform-methanol mixtures. Phospholipids are the most common polar lipids. They are derivatives of phosphatidic acid (phosphoglycerides) and, in most eubacteria, are quite uniform with regard to their overall pattern. Therefore, they are not of great value as chemotaxonomic markers. Glycolipids are not as widespread as phospholipids and are found predominantly, although not exclusively, in Gram-positive bacteria (Shaw, 1975). Diglycosyl diglyceride is usually the major glycolipid. Members of the same genus normally contain the same glycolipid, e.g., α-diglucosyl diglyceride is found in streptococci, whereas galactosylglucosyl diglyceride is present in lactobacilli. The presence of diacylinositol mannoside appears to be typical for members of the genus *Propionibacterium*. However, the same glycolipid may also occur in quite distantly related organisms. For example, *Acholeplasma laidlawii* contains the same diglucosyl diglyceride as found in some streptococci.

Fatty Acids Fatty acid composition of lipids can be helpful in the classification of eubacteria. The majority of all fatty acids are found in the membrane as acyl substitutes of glycerol, sugar, or amino compounds. Gram-negative eubacteria also contain fatty acids in their cell wall as constituents of lipopolysaccharides, phospholipids, and lipoprotein. The fatty acyl ester lipids of eukaryotic and prokaryotic membranes are replaced by ether lipids in archae-bacteria.

Most fatty acids of eubacteria are in the range of C_{12} to C_{20}. There are branched fatty acids, hydroxy fatty acids, cyclopropane fatty acids, and saturated and unsaturated ones. They may have even-numbered or odd-numbered carbon chains. Differences in the fatty acid composition can be used for the rapid identification of various eubacteria (Tornabene, 1985; Miller, 1982). Fatty acid patterns can be determined rather easily and quickly, and automatic identification is even possible (Eerola and Lehtonen, 1988). However, the bacteria have to be cultivated under carefully controlled conditions since fatty acid patterns may alter in response to exogenous and endogenous parameters, such as growth temperature, composition pH of medium, or age of the culture.

Hopanoids Prokaryotes do not normally synthesize sterols. There are only two genuine exceptions, namely *Methylococcus capsulatus* and *Nannocystis exedens* (Tornabene, 1985). However, in recent years, hopanoids and other polyterpenoids have been discovered in prokaryotes (Ourisson et al., 1987), which can be considered as sterol surrogates. Hopanoids have been found in various eubacteria. For instance, they are present in most cyanobacteria, methylotrophs, Rhodospirillaceae, acetic acid bacteria, and various other Gram-negative and Gram-positive eubacteria. They have not been found in archaebacteria, purple sulfur bacteria, or Enterobacteriaceae. Although archaebacteria do not contain hopanoids, they have phytanyl and bisphytanyl ethers that are also polyterpenoids.

Ether Lipids There are two different types of ether lipids: plasmalogens, which contain a vinyl ether bound to glycerol, and alkyl ethers, which represent the condensation of fatty alcohols to glycerol. Plasmalogens are found in anaerobic eubacteria. Membranes of archaebacteria contain alkyl glycerol ether lipids (Goldfine and Langworthy, 1988). The alkyl chains usually consist of phytanyl residues. Diethers containing two C_{20} phytanyl chains are characteristic membrane components of all archaebacteria. Tetraethers containing two C_{40} phytanyl chains are present in thermophilic and many of the methanogenic archaebacteria, but not in halobacteria.

Aliphatic Hydrocarbons The occurrence of aliphatic hydrocarbons can be used to separate micrococci from staphylococci. Micrococci contain long-chain (C_{22}–C_{32}), methyl-branched monoolefins which are also helpful in differentiating species of this genus. Such hydrocarbons can also be found in some coryneform bacteria and in *Pseudomonas maltophilia*, but not in any other pseudomonad (Tornabene, 1985).

Isoprenoid Quinones Isoprenoid quinones play an important role in electron transport and active transport. Different bacteria not only syn-

thesize different quinone types (ubiquinone, menaquinone, demethylmeraquinones), but in particular the length and the degree of saturation of polyprenyl side chains are of considerable value in classification (Collins and Jones, 1981). The cyanobacteria contain neither ubiquinones nor menaquinones but phylloquinones and plastoquinones, which are normally associated with green plants. Most strictly aerobic, Gram-negative eubacteria produce only ubiquinones, whereas facultatively anaerobic, Gram-negative eubacteria contain in addition menaquinones and/or demethylmenaquinones. Aerobic and facultatively anaerobic, Gram-positive eubacteria produce only menaquinones. Strictly anaerobic eubacteria lack isoprenoid quinones or contain only menaquinones. Menaquinones are also found in archaebacteria.

Bacteriochlorophylls The occurrence of different bacteriochlorophylls can be helpful in the classification of phototrophic bacteria (Oelze, 1985). The majority of the species of the Rhodospirillaceae, Ectothiorhodospiraceae, and Chromatiaceae contain bchl *a* only. However, some of them possess bchl *b* instead.

In Chlorobiaceae and Chloroflexaceae, bchl *c, d,* and *e* are the main pigments. They are always accompanied by small amounts of bchl *a.* Bchl *a* is also found in *Erythrobacter*, whereas *Heliobacterium chlorum* contains bchl *g.*

Cytochromes Bacterial cytochromes are involved in a wide variety of redox processes such as aerobic and anaerobic respiration and photosynthetic electron transfer. Most cytochromes are associated with the cytoplasmic membrane. However, there are some *c*-type cytochromes and various oxygenases located within either the cytoplasm or the periplasmic space. Cytochrome patterns of bacteria can be used as a valuable chemotaxonomic character since, unlike the mitochondrial respiratory chains of eukaryotes, bacterial respiratory chains contain a greater variation of different cytochromes (Jones and Poole, 1985). Conventional difference spectrophotometry, preferably at low temperatures, is sufficient to determine the cytochrome pattern (Faller et al., 1980). It has been reported that the cytochrome pattern $bcaa_3$ and *o* occurs predominantly in Gram-positive bacteria and the pattern *bcdo* and a_1 is often found in Gram-negative bacteria (Jones and Poole, 1985). However, other studies have revealed that cytochrome *d* is also present in some Gram-positive bacteria, in particular in micrococci and coryneform bacteria (Faller et al., 1980; Faller and Schleifer, 1981). Cytochrome *c* is often absent in both Gram-negative and Gram-positive bacteria, and enterobacteria can be easily separated from pseudomonads since the former do not contain cytochrome *c* and are therefore oxidase negative.

When cytochrome patterns are used for taxonomic studies, it has to be taken into account that growth conditions (nutrition, growth phase) can influence quantitatively and, to a lesser extent, qualitatively the cytochrome content of a bacterial culture (Faller et al., 1980; Faller and Schleifer, 1981). To assess the cytochrome-synthesizing capacity of a strain, cells from both the exponential and the stationary growth phase (as a minimum) have to be examined.

Cell Wall Ultrastructure and Composition

Most prokaryotic cells are surrounded by a cell wall that maintains their shape and preserves the plasma membrane against osmotic disruption. These cell walls consist of several classes of unique heteropolymers whose existence helps not only to distinguish prokaryotic from eukaryotic organisms but also to separate the eubacteria into distinct groups, such as the Gram-positive and the Gram-negative bacteria. The phylogenetic difference between Gram-positive and Gram-negative eubacteria is well established (Woese, 1987). The Gram-positive eubacteria are distinguished from the Gram-negative ones by their ability to retain iodine-fixed crystal violet in the presence of alcohol. However, the Gram reaction is quantitative rather than qualitative, and some eubacteria are Gram-variable. A positive Gram reaction may depend on the length of alcohol treatment and/or on the growth phase. A clear separation of Gram-positive and Gram-negative bacteria can be obtained by the differences in the ultra-structure and chemical composition of their cell walls.

In the electron microscope, the cell wall profiles of these eubacteria are quite distinct (Beveridge, 1981). The cell wall of Gram-positive eubacteria reveals in profile one thick (30–80 nm) and more or less homogeneous layer, whereas Gram-negative eubacteria have a thinner, distinctly layered cell wall with an outer membrane resembling the typical trilaminar cytoplasmic membrane in profile. The polymers found in the cell walls of these two groups of bacteria are chemically quite different. The walls of Gram-negative cells are mainly composed of lipopolysaccharide, phospholipid, protein, lipoprotein, and relatively little peptidoglycan (usually less than 10% of the total cell wall). The Gram-positive cells contain as major components peptidoglycan (usually more than 30% of the total cell wall), polysaccharides or teichoic acid (or both), or teichuronic acid. Thus, in contrast to the Gram-negative, the Gram-positive eubacteria contain hardly any lipids in their cell

walls. There is, however, one exception: acid-fast bacteria. They are resistant to decolorization with acidic ethanol after staining with fuchsin (Ziehl-Nielsen staining). These acid-fast bacteria (*Mycobacterium*, *Norcardia*, and *Corynebacterium sensu stricto*) are Gram-positive eubacteria which contain large amounts of lipids in their cell walls—in particular, mycolic acids (Minnikin and Goodfellow, 1980). The results of a study by Goren et al. (1978) indicate that the lipid barrier of the cell wall mycolyl-arabinogalactan hinders the penetration of the bleaching acid.

Peptidoglycan (murein, mucopeptide) is the only cell wall polymer found in both Gram-positive and Gram-negative eubacteria. It is also present in cell walls of cyanobacteria (Weckesser et al., 1979). The fine structure and the chemical composition of the cell walls of cyanobacteria are similar to those of Gram-negative eubacteria. However, in cyanobacteria, the peptidoglycan layer is thicker and its degree of cross-linkage is higher than in Gram-negative eubacteria (Woitzik et al., 1988). Moreover, polysaccharides can be covalently linked to the peptidoglycan of unicellular cyanobacteria. There are only a few prokaryotes, such as the mycoplasma group (Mollicutes) and the Archaebacteria, which lack peptidoglycan.

Enterobacterial Common Antigen Enterobacterial common antigen (ECA) is a surface antigen typical for all members of the family Enterobacteriaceae (Kuhn et al., 1988). It is located in the outer membrane and can easily be detected in nonencapsulated strains by passive hemagglutination or colony immunoblotting (Meier-Dieter et al., 1989). It is composed of a linear polysaccharide chain containing three different amino sugars. The sugar chain can be linked to a diglyceride through phosphodiester linkage or, in a few rough mutants, it can also be bound to the lipopolysaccharide. Unlike other common antigens, e.g., the outer membrane proteins, it is restricted to the Enterobacteriaceae and shows strong cross-reaction between all species studied so far. Common antigens may also exist for Bacteroidaceae (Marx et al., 1982) and *Pseudomonas aeruginosa* (Sawada et al., 1985).

Lipopolysaccharides Lipopolysaccharides are known to contain the endotoxic principle of Gram-negative eubacteria and are the chemical basis for the O antigens, also called surface antigens (Wilkinson, 1977). The side chain carries the determinants of O-antigenic specificity and is the most important one of the three cell-surface antigens for the serological classification of Enterobacteriaceae at an infrasubspecific level. The other two antigens are H (bacterial flagellum) and K (capsule). The O-specific side chains consist of up to 30 repeating units, each containing three to six sugar residues. The variety, substitution, and linkage of these sugars are responsible for the antigenic diversity (Jann and Westphal, 1975). Besides common hexoses, also 6-deoxyhexoses, 3,6-dideoxyhexoses, and *O*-methyl sugars are found as constituents of the cell surface antigens. *O*-methylated sugars are characteristic for lipopolysaccharides from purple bacteria and cyanobacteria (Weckesser et al., 1979).

The core region of the lipopolysaccharide is composed of a short, acidic heterooligosaccharide that in most Enterobacteriaceae consists of phosphorylated 2-keto-3-deoxyoctonate (KDO), phosphorylated L-glycero-D-mannoheptose, D-glucose, D-galactose, and *N*-acetylglucosamine. The composition of the core structure is much more conserved within the Gram-negative bacteria than the O-specific chains (Wilkinson, 1977). It is essentially the same in all S-form lipopolysaccharides from *Salmonella*. In general, KDO and aldoheptose are the most distinctive components of bacterial lipopolysaccharides. Although KDO is a generally reliable marker for most lipopolysaccharides, the absence of such a sugar in some of them and the detection of a KDO-polymer in *Escherichia coli* (Taylor, 1974) indicate some limitations to its use as a diagnostic tool. Moreover, the determination of small amounts of KDO with the usual thiobarbituric acid method is rather difficult (Hofstad, 1974).

Lipid A carries the endotoxic activity of lipopolysaccharide and is the most conservative structural part (Lüderitz et al., 1978). The backbone of lipid A consists of a β-1,6-linked D-glucosamine disaccharide which carries phosphate residues in positions 1 and 4. Long-chain fatty acids, which make up the bulk of lipid A fractions, are linked to both the amino and hydroxyl groups of glucosamine. The *N*-acyl residue is characteristically a 3-hydroxyalkanoic acid, e.g., β-hydroxymyristic acid in enterobacterial lipopolysaccharides. However, some Gram-negative bacteria contain a form of lipid A which exhibits a different backbone composition. Thus, in the lipid A of *Pseudomonas diminuta*, *Rhodopseudomonas viridis*, and *R. palustris*, glucosamine is replaced by 2,3-diamino-2,3-dideoxy-D-glucose. Phosphate is absent in the lipid A of some bacteria and cyanobacteria (Weckesser et al., 1979). Some types of lipid A contain, in addition to glucosamine, other saccharide components.

Chemotyping (qualitative composition of the polysaccharide moiety) and serotyping of the O-specific chains should be, as in the case of Enterobacteriaceae, suitable for further differentiation within a species (infrasubspecific taxon). However, the complete serological cross-

reaction of O antigens of certain strains of *Salmonella* and *E. coli* suggests a need for greater diagnostic caution. The structure of the polysaccharide core can be used in some cases to separate at the genus level (*Salmonella*, *Shigella*). On the other hand, cores of different structure are found within the genus *Escherichia* (Nikaido, 1970). A limited number of studies with Rhodospirillaceae indicate that lipid A may be a valuable chemotaxonomic marker (Weckesser et al., 1979).

Cell Wall Polysaccharides of Gram-Positive Eubacteria In addition to peptidoglycan, Gram-positive bacteria contain polysaccharides and/or teichoic acids in their cell walls.

Polysaccharides In contrast to the thoroughly studied lipopolysaccharides, little is known about the cell wall polysaccharides of Gram-positive eubacteria. The only cell wall polysaccharides which have been intensively studied are those of streptococci. They form the basis for the serological grouping of streptococci. Supraspecific, specific, and infrasubspecific taxa can be distinguished by the serological specificity of these cell wall polysaccharides (Schleifer and Kilpper-Bälz, 1987).

Other well-characterized polysaccharides are arabinogalactan and arabinomannan, which are linked to mycolic acids and found in acid fast and related bacteria (Lederer et al., 1975). The presence of arabinose, galactose, and *meso*-diaminopimelic acid in a cell wall hydrolysate is characteristic for the *Corynebacterium-Mycobacterium-Nocardia* group of bacteria (Keddie and Bousfield, 1980).

Teichoic Acids Cell wall teichoic acids are covalently linked to peptidoglycan. They usually consist of polyols (glycerol, ribitol, mannitol) which in most cases are connected through phosphodiester bridges and substituted by sugars, amino sugars, or D-alanine residues (Archibald, 1974; Anderton and Wilkinson, 1985). There are also teichoic acids lacking polyols. In rare cases, *N*-acetylamino sugar residues are linked through phosphodiester bridges and form an integral part of the polymer chain (Endl et al., 1983). Cell wall teichoic acids are found only in a limited number of Gram-positive eubacteria, such as various actinomycetes, bacilli, brevibacteria, certain lactobacilli, listeria, and staphylococci.

The chemical composition, structure, and serological specificity of this cell wall polymer have proven to be of value in the classification of Gram-positive eubacteria. A well-known example consists of the wall teichoic acids of staphylococci (Endl et al., 1983, 1984). The presence of teichoic acid is a characteristic marker in the separation of staphylococci from micrococci which lack this polymer. Cell wall teichoic acids are also a valuable tool in the classification of *Brevibacterium linens* and related strains (Fiedler et al., 1981) of certain lactobacilli (Sharpe, 1970; Knox and Wicken, 1973) and actinomycetes (Naumova, 1988).

Mycolic Acids Mycolic acids are high-molecular-weight, 3-hydroxy acids with a long alkyl branch in position 2. They are restricted to members of the genera *Caseobacter*, *Corynebacterium*, *Mycobacterium*, *Nocardia*, and *Rhodococcus*. Differences in their structure have proved to be a valuable chemotaxonomic marker in the classification and identification of these taxa (Minnikin and Goodfellow, 1980; Dobson et al., 1985).

Peptidoglycan Peptidoglycan (sometimes called murein) is a heteropolymer consisting of glycan strands that are cross-linked through short peptides. The glycan strand is made up of alternating β-1,4-linked residues of *N*-acetylglucosamine and *N*-acetylmuramic acid, a derivative of glucosamine and unique constituent of peptidoglycan. The peptide moiety is linked to *N*-acetylmuramic acid and contains both L- and D-amino acids. The peptidoglycan of Gram-negative eubacteria is remarkably uniform (Schleifer and Kandler, 1972) and only a few exceptions are known (Schleifer and Stackebrandt, 1983).

Gram-positive eubacteria contain a multilayered peptidoglycan and reveal, in contrast to Gram-negative organisms, a great variation in the composition and structural arrangement of their peptidoglycans. Minor variations can be found in the glycan strand. In mycobacteria and nocardia, the *N*-acetyl group of muramic acid is oxidized to *N*-glycolyl (Lederer et al., 1975). A relatively simple procedure for detecting the presence of *N*-glycolylation of peptidoglycans has been described by Uchida and Aida (1977).

The greatest variation occurs within the peptide moiety of the peptidoglycan. Both the peptide subunit (stem peptide) and the interpeptide bridges, which cross-link the peptide subunits, can vary in their structure and composition. Based on the mode of cross-linkage, two main groups of cross-linkage, A and B, can be distinguished (Schleifer and Kandler, 1972).

A given peptidoglycan structure is a fairly stable character and fulfils the most important prerequisites of a useful taxonomic marker (Schleifer and Kandler, 1972). No single-step mutations are known so far which lead to an altered peptidoglycan structure. Phenotypic variations are also rather limited and can be easily controlled (Schleifer et al., 1976).

The determination of the primary structure of the peptidoglycan (peptidoglycan type) provides the full content of taxonomically useful information and has revealed differences between organisms which could not be detected by simple qualitative cell wall analyses (Keddie and Bousfield, 1980). However, in many cases where the peptidoglycan structure is already known, simple cell wall analysis provides a powerful tool for the primary stage of identification. In some groups of Gram-positive bacteria, such as the actinomycetes and the coryneform bacteria, the determination of the cell wall composition is usually a prerequisite for a reliable classification and identification (Keddie and Bousfield, 1980).

Cell Envelope Polymers in Archaebacteria With the exception of mycoplasma, *Planctomyces*, and *Isophaera*, the absence of peptidoglycan is a characteristic feature that distinguishes archaebacteria from eubacteria. Archaebacteria exhibit at least five different morphological types of cell envelopes. Type I shows a more or less homogeneous electron-dense layer, 10 to 200 nm in width, and consists mainly of pseudomurein (Methanobacteriales), a nonsulfated (*Methanosarcina*), or a sulfated acidic heteropolysaccharide (*Halococcus*). Most of the Gram-positive archaebacteria show this type of cell envelope (Kandler and König, 1985). Type 2 is found only in the Gram-positive *Methanothermus fervidus*. The rigid cell wall is composed of pseudomurein covered with a surface layer of protein (Stetter et al., 1981). Type 3 is widely distributed among Gram-negative archaebacteria, such as all thermoacidophiles and many methanogens and halophiles. In contrast to Gram-negative eubacteria, neither a specific sacculus nor an outer membrane is present. The cell envelope consists of only one surface layer (the S layer) composed of protein or glycoprotein subunits (Sleytr and Messner, 1983). Type 4 is a rather complex cell envelope and is found only in *Methanospirillum*. The individual cell is surrounded by an electron-dense layer (10 nm in width) probably of proteinaceous nature, and several cells are held together by a sheath consisting of protein fibrils (Sprott and McKeller, 1980). Type 5 lacks any kind of cell envelope and is found in *Thermoplasma* (Darland et al., 1970) and *Methanoplasma* (Rose and Pirt, 1981). The differences in the cell envelope of archaebacteria can be used as a chemotaxonomic tool for their identification and classification (Kandler and König, 1985).

Other Cellular Constituents

Electrophoretic Protein Patterns Whole-cell protein patterns, reviewed by Jackmann (1987) and Kersters (1985), can be used for classification and identification. The method requires considerable standardization and pattern correction in order to obtain optimum results (Albritton et al., 1988). It shows similar discrimination to DNA-DNA hybridization. More distant relationships can be measured by analysis of ribosomal proteins (Böck, 1985). In the latter example, a two-dimensional separation was applied. It is superior to one-dimensional separation since there are less superposition effects, and fewer corrections are necessary.

Electrophoretic Enzyme Patterns Multilocus enzyme electrophoresis has long been a standard method in systematics and population genetics of eukaryotes and has also been applied to prokaryotes (Selander et al., 1986). Water-soluble cellular enzymes are separated by electrophoresis and detected by enzyme-specific staining methods. Differences in the amino acid sequence can yield mobility variants of an enzyme (electromorphs) that can be directly equated with alleles at the corresponding structural gene locus. The disadvantage of this method is that numerous gels are required in order to score sufficient different enzymes in a polymorphic population.

Polyamines Polyamines function as polycations under physiological conditions and are widely distributed among prokaryotes. They stabilize nucleic acids and membranes and influence many enzymatic reactions. They represent a valuable chemotaxonomic marker in methanogenic bacteria and the Proteobacteria. A distinct polyamine pattern could be found for each of the four families of methanogenic bacteria (Scherer and Kneifel, 1983). The unusual polyamine 2-hydroxyputresceine occurs as a specific component within members of the beta subclass of the Proteobacteria, whereas in the alpha subclass, a triamine, such as spermidine or symhomospermidine, was found as the characteristic component (Busse and Auling, 1988).

Nucleic Acid Probes

Nucleic acid probes can be used for the rapid detection and identification of bacteria. They consist of fragments of single-stranded nucleic acids (mostly DNA) that bind to complementary target nucleic acids, either DNA or RNA. The lengths of the fragments range from 15 to 10,000 nucleotides. The longer ones are isolated from the nucleic acid of the target organism, the shorter ones are synthesized in the laboratory.

The nucleic acid probe technique can be divided into four steps: 1) An appropriate probe is designed and labelled with a detector group. 2) The target nucleic acid is extracted from the organism or from a specimen containing this organism. 3) The target nucleic acid is hybridized with the specific probe. 4) The amount of hybrid formed is determined. The different steps are discussed below.

Isolation or Synthesis of Specific Nucleic Acid Probes

Probes can be designed by several different approaches. The simplest way is the application of whole cell DNA. Bacterial cells are blotted onto membrane filters or microdilution plates, lysed, and hybridized with labelled genomic DNA of reference strains (Morotomi et al., 1988; Ezaki et al., 1989). The method is simple, quick, and useful for a large number of strains, but it lacks specificity and closely related species cannot be distinguished. The latter may be achieved by isolating and cloning species-specific DNA fragments (Schmidhuber et al., 1988). Unfortunately, the genetic stability of such random DNA fragments is not guaranteed. To distinguish virulent strains from avirulent ones or to detect strains or species with distinct metabolic activities, probes should be used which are complementary to genes coding for these properties (Moseley et al., 1982; Liebl et al., 1987).

Probes reacting with 16S or 23S rRNA or their genes are of special interest. These rRNA molecules are ubiquitous and contain regions of various degree of conservation (Woese, 1987; Höpfl et al., 1989). Therefore, information on the nucleotide sequence of these molecules can be used to design probes of various specificity ranging from subspecies to kingdom level. It is even possible to design a probe that will react with any cellular life form. These probes are ideal for distinguishing between phylogenetically related and unrelated groups of organisms. The use of probes with different specificity allows rapid identification of an isolate (Regensburger et al., 1988). A one-step identification may be possible by the use of "reversed hybridization," i.e., labelled target nucleic acid is hybridized to a panel of unlabelled immobilized DNA probes (Dattagupta et al., 1989).

Extraction of Target Nucleic Acid

Target nucleic acids have to be isolated from organisms or specimens before hybridization to nucleic acid probes can be performed. Release of nucleic acids can readily be achieved by treatment with detergent, alkali, lysozyme, or a combination of these reagents. The lysis of Gram-positive bacteria is more difficult. Other chemical methods, e.g., treatment with hot alkali or phenol, or even physical methods, e.g., sonication or shaking with glass beads in a ball mill, must be used to achieve sufficient lysis of cells. For colony hybridization of Gram-negative cells, the colonies are fixed to nylon or nitrocellulose membranes and lysed by simple alkali treatment (Sambrook et al., 1989).

Hybridization of Target Nucleic Acid with Nucleic Acid Probe

Specific hybridization consists of two steps: first, the binding (hybridization) of the probe to the target nucleic acid and second, the separation of specific hybrids from nonspecifically bound or unbound probe. Hybridization can be performed on solid supports or in solution. For solid-phase hybridization, denatured target nucleic acid is immobilized on nitrocellulose or nylon membranes. Unbound or nonspecifically bound probe can be readily removed from the membrane-bound hybrid by washing. The rate of hybridization in solution is considerably higher than for solid-phase hybridization, and the target nucleic acid is completely accessible for the probe. The only disadvantage of the hybridization in solution is the more complicated separation of the hybrids from the unbound probe.

A special kind of solid phase hybridization is in situ hybridization. One method uses in situ lysis of bacterial cells grown on or transferred to membrane filters (colony hybridization). It is a convenient and rapid method to detect and identify distinct groups of bacteria in mixed microbial populations (Festl et al., 1986). Another method involves single-cell hybridization with radioactively or fluorescently labelled oligonucleotide probes directed against 16S rRNA. Fixed whole cells can be made permeable to oligonucleotide probes, thus allowing a phylogenetically based identification (Giovannoni et al., 1988; DeLong et al., 1989). This technique can also be applied for a species-specific detection of bacteria in natural samples (Amann et al., 1990).

Detection of Hybrids

The nucleic acid probe has to be labelled prior to hybridization in order to detect the formed hybrids. The label can be covalently bound to the probe (direct labelling), or an unlabelled detector group can be covalently linked to the probe and detected by a labelled binding protein (indirect labelling). Various techniques used for labelling probes and detecting hybrids have been reviewed by Matthews and Kricka (1988).

Applications for Nucleic Acid Probes

Nucleic acid probes have broad applications. They can be used not only for the detection and identification of bacteria but also for the diagnosis of infectious disease, the detection of pathogenic and spoilage bacteria in food products, and for studying microbial ecosystems. Nucleic acid probes are highly specific, and their genomic targets are not affected by changing environmental or physiological conditions.

The technique is faster than conventional identification methods and can be applied in the identification of organisms grown in pure or mixed cultures. Nucleic acid probes are especially useful for the identification of slow-growing and fastidious organisms. They can also be used for the direct detection of bacteria in their natural habitat. Even bacteria that have not yet been cultivated can be detected, either through the use of reverse transcriptase sequencing of extracted rRNA (Weller and Ward, 1989) or by applying the polymerase chain reaction (Saiki et al., 1988) with oligonucleotide primers that are complementary to conserved regions of 16 or 23S rRNAs.

A major disadvantage of the nucleic acid probe technique has been its lack of sensitivity. However, this problem can now be solved since there are several ways to increase sensitivity, e.g., amplification of target nucleic acids or signals, using high copy-number target sequences or improved detector groups. Amplification of target nucleic acids with polymerase chain reaction has considerably improved the sensitivity. This technique was used to detect as few as 35 colony-forming units of L. pneumophilia in a water sample (Starnbach et al., 1989).

Physiology and Metabolism

Basic Energy Metabolism

Physiological "properties" of bacteria are expressions of metabolic pathways present in the respective species. As far as types of overall energy metabolism are concerned, the relation to oxygen and light of a given bacterium will decide whether it performs photosynthesis, fermentation, or respiration as the main energy-yielding process.

The ability to utilize light as the sole source of energy clearly separates the phototrophic bacteria (including the cyanobacteria) from all other prokaryotes. Of course, this ability requires the presence of the numerous properties that constitute a functioning photosynthetic apparatus (see The Phototrophic Way of Life in Volume 2). Strict anaerobiosis (see The Anaerobic Way of Life in Volume 2) is also linked to a unique set of properties. In addition, a large number of bacteria have the ability to grow in the absence of oxygen as well as in its presence. These facultatively anaerobic bacteria possess more than one energy-yielding system.

Nutritional and Metabolic Characters

Metabolic properties of a given bacterium are detected and determined by studying the utilization of nutrients, the production of metabolites, or the presence of typical enzymes. In diagnostic bacteriology, especially in the medical and food sectors, such specific biochemical tests are routinely performed for the identification of bacteria.

The fermentation of glucose, lactose, mannitol, or other sugars may be easily detected by the production of gas or by change in color of an indicator dye caused by the production of acids. The qualitative and quantitative analysis of acid end products is an important aid in the identification of bacteria, especially of anaerobic bacteria of the genera *Clostridium*, *Bacteroides*, *Peptococcus*, and *Peptostreptococcus*. Volatile fatty acids may be estimated in the culture suspension, in an ether extract of the culture, or in the bacterial cell directly or after derivative formation, by gas-liquid chromatography or by other techniques, such as isotachophoresis.

In addition to the acid end products, the presence in the medium of other fermentation breakdown products, such as indole and hydrogen sulfide, is characteristic for certain bacteria. Thus, the ability of an organism to produce indole by the enzymatic cleavage of the amino acid tryptophan has long been used as part of the IMViC reactions used to separate *Escherichia coli* from *Enterobacter aerogenes*.

In most treatments on identification in this book, the pattern of utilization of carbon sources plays an important role in the differentiation of species. The ability of certain microorganisms to utilize organic acids such as acetate, citrate, and malonate as sole source of carbon for metabolism has been useful, especially in the differentiation of Gram-negative rods. The alkaline reaction products present in the medium of microorganisms that utilize the carbon of these substances change the color of the pH indicator.

In thiobacilli, the utilization and formation of sulfur compounds serves in identification (see The Colorless Sulfur Bacteria in this Volume). In lactic acid bacteria, the formation of L- versus D-lactic acid is of diagnostic value.

Special Nutritional Requirements

Many bacteria of medical importance do not grow on media generally used for screening and

identification, because they need accessory growth factors. Some of these bacteria, such as members of the rickettsiae and chlamydiae, are highly fastidious in their requirements and grow only inside living cells (obligate intracellular parasites). The determination of nutritional requirements can provide diagnostic characters for some bacteria. Thus, certain species of *Haemophilus*—minute, Gram-negative, rod-shaped bacteria—are characterized by their requirement for NAD (V factor) and for the heme portion of hemoglobin (X factor) for growth on laboratory media, whereas other species of the genus require only one of these factors. These growth requirements are also responsible for a phenomenon called satellitism, which can be a help in the preliminary identification of *Haemophilus* in clinical specimens. In satellitism, members of the genus such as *Haemophilus influenzae*, which are dependent on both factors, develop significant colonies on blood-agar plates only near colonies of *Staphylococcus aureus*, which produce the required substances.

Enzymes

Enzymes used for diagnostic purpose include catalase, coagulase, β-galactosidase, urease, gelatinase, lysine decarboxylase, lecithinase, and phosphatase. As an example, the detection of lysine or ornithine decarboxylase activity is useful in the identification of organisms within the Enterobacteriaceae. The enzyme removes the carboxyl group from the amino acid, thus producing the corresponding amine with liberation of carbon dioxide and a change in color of a pH indicator in the medium.

Some bacteria produce hemolysin, i.e., enzymes that destroy red blood cells. The different types of hemolysin action observed on blood agar plates are an aid in the identification of certain species. For example, some strains produce a greenish discoloration of the medium around the colonies accompanied by the partial lysis of the red blood cells (alpha hemolysis), other strains form a clear zone by the complete lysis of the cells (beta hemolysis), and still others are found to cause no lysis at all.

Based exclusively or predominantly on physiological properties, rapid and widely automated identification procedures have been developed and are being used in clinical and food microbiology (e.g., Gyllenberg, 1976; Goodfellow et al., 1987; d'Amato et al., 1985; Bascomb, 1985).

Ecological Parameters

Since all living beings have one or more ecological niches, they have a set of optimal ecological parameters that can be used as part of their description. The optimal growth temperature and the temperature tolerance of a prokaryote culture are both of great importance for characterization and identification. Psychrophilic, thermophilic, and extremely thermophilic species are easily classified by these parameters. Pathogenic as well as rumen and intestinal bacteria usually have an optimal growth temperature near the body temperature of their hosts.

In a similar way, the optimal pH as well as the tolerated pH range are very important properties for devising media for the enrichment of bacterial strains.

Further ecological parameters, such as redox conditions, salinity (osmolarity), light intensity, and hydrostatic pressure, are of equal importance. There are extremely tolerant and highly adapted bacteria for each of these parameters and often for more than one. Often these forms are not just adapted to but have come to require extreme conditions, e.g., the halobacteria and the thermo-acidophilic bacteria.

Whereas high hydrostatic pressure may not affect autochthonous deep-sea bacteria, it slows down the metabolic rates of bacteria that inhabit surface or terrestrial habitats (Jannasch and Wirsen, 1973).

The relationship to other living beings has led to the evolution of bacterial properties that may be useful for identification. Within the nitrogen-fixing, symbiotic genus *Rhizobium*, the species are differentiated by host specificity. Many other bacteria pathogenic for plants, animals, and humans are host specific. Further details may be found in Bacterial Virulence in this Volume and Plant Pathogenic Bacteria in this Volume.

Susceptibility to Bacteriophages, Bacteriocins, and Other Antimicrobial Agents

The susceptibility of bacteria to bacteriophages depends on the presence of specific receptor structures in the surface of the cell to which the phages can adsorb. On the basis of their interaction with known phages, strains of bacteria can be classified into groups, or phagovars, and, to a lesser extent, the genus or the species can be determined. Only a few phages with specific action are used for diagnostic purposes. Thus, strains of *Vibrio cholerae* can be differentiated into classical and El Tor phagovars by phage susceptibility.

Furthermore, certain phages lyse all strains of *Yersinia pseudotuberculosis*, but not strains of *Y. pestis* and *Y. enterocolitica*.

Since a large proportion of strains of certain bacterial species are lysogenic, they may be characterized by indirect phage typing (lysogenotyp-

ing), i.e., the detection and identification of temperate phages present as prophages in bacteria. However, the method used most is the differentiation of the bacterial strains on the basis of their susceptibility to a standard set of known phages (lysotyping).

At present, phage typing is used by specialized diagnostic laboratories especially for the identification of *Salmonella typhi*, *S. paratyphi*, *S. typhimurium*, and *Staphylococcus aureus*.

Another method for differentiating strains of the same species is bacteriocin typing. Bacteriocins are high-molecular-weight bactericidal proteins which are produced by various species of bacteria and are active only against other strains of the same species or closely related species. Because different strains of a species usually produce bacteriocins with different activity patterns, strains can be subdivided by the characterization of their bacteriocin. Besides bacteriocin production, strains can be characterized by the determination of their sensitivity pattern against a standard set of known bacteriocin-producing strains, bacteriocin-containing lysates or extracts, and purified bacteriocins.

Bacteriocin typing has become a useful method for comparing strains of medical isolates such as *Shigella sonnei*, *Serratia marcescens*, other Enterobactericeae, and *Pseudomonas aeruginosa*.

In addition to phage typing and bacteriocin typing, determination of chemical and serological properties, typing by R factors, electrophoresis patterns of cell proteins, and differences in nutritional requirements for amino acids and other selected substances (auxotyping) are used either separately or together to obtain a more detailed level of differentiation within bacterial species (Bergan and Norris, 1978; Kwapinski, 1977).

Resistance and susceptibility to inhibitors such as fuchsin, bismuth sulfite, desoxycholate, tellurite, bile salts, optochine (a derivate of quinine), and higher concentrations of sodium chloride are also generally stable characters and can serve as diagnostic aids. For example, most strains of pneumococcus (*Streptococcus pneumoniae*) are characteristically susceptible to optochine, whereas most strains of related alpha-hemolytic "viridans" streptococci are resistant. Furthermore, the patterns of susceptibility to antibiotics can be useful in distinguishing between similar species as well as between strains of the same species.

Identification Keys and Diagnostic Tables

The types of characters to be tested during the identification of prokaryotes and eukaryotes are often presented in the form of dichotomous keys and diagnostic tables.

A taxonomic key consists of a steplike series of questions. If these are all of the "yes-no" kind, the key is called a dichotomous one. Dichotomous keys are ideally suited for computerization. There are few successful applications of keys to microbiology, however, as Cowan (1968) pointed out, mainly because the constructor soon runs out of known contrasts.

The first successful modern key for the identification to generic level of bacteria was that developed by Skerman (1967). Skerman also constructed the key to the genera contained in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Buchanan and Gibbons, 1974).

Keys within clearly defined groups of bacteria are much more common than general bacteriological keys. Such keys are found in *Bergey's Manual of Systematic Bacteriology*, as well as in many chapters of this handbook.

The characters used for the construction of keys must be constant characters; i.e., they must always be present in or absent from a taxon. Such properties become "key" characters. Positive "key" characters are also called "diagnostic" or "marker" characters. Since keys are usually constructed for diagnostic purposes, the characters used are weighted ones, and they form a hierarchy with the most important characters usually being listed first.

Diagnostic tables are tables of characters for the identification of taxa that are based upon the sharing of several (usually unweighted) characters. Such tables contain more information than dichotomous keys and therefore appear to be more complicated. But, in many cases, identification is easier using diagnostic tables. When several characters are variable, the diagnostic table is much more successful as a determinative aid than a key in which (if all characters of the table are included) there are too many routes leading to the same identification (Cowan, 1968).

Minimal Requirements for a Description of a New Species

Sneath (1977) has pointed out that a species can be visualized as a cluster of a very large number of strains in a character space. As an approximation, this space may be treated as roughly spherical, and it can therefore be described using sampling theory, by its center, while its radius defines an envelope that includes about 100% of the strains. When a reference description of a species is set up based on a small number of strains, one is in effect making an estimate of the true position of the center and of the true

Table 2. Minimum data required for the description of a new species.

	Required data	Desired/required data, if applicable
Cell morphology	Cell shape[a]	Color
	Cell size (diameter, length)	Flagellation type[a]
	Motility	
	Visible internal or external structures[a]	Spores[a], appendages[a], capsules[a], sheaths[a]
	Formation of typical cellular aggregate[a]	
	Occurrence of cell differentiation[a]	Life cycle[a], heterocysts[a], hormogonia[a]
	Ultrastructure (general)[b]	Ultrastructure of flagella, envelope, cell wall[b]
Colonial morphology	Appearance of cell suspensions	Color of suspension (absorption spectra)
	Appearance of colonies	Color of colonies
		Motility of colonies
		Formation of fruiting bodies[a]
		Formation of mycelia[a]
Staining behavior	Gram stain	Acid-fast stain, spore stain, flagellum stain
Cell constituent	DNA base ratio	Nucleic acid homology; rRNA sequences
	Reserve materials	Cellular pigments
		Cell wall and membrane constituents
		Typical enzymes
Physiology	Temperature range and optimum	Salinity or osmolarity requirements
	pH range and optimum	Vitamin requirements
	Modes of energy metabolism (phototrophy, chemotrophy, lithotrophy, organotrophy)	Typical metabolic products formed (acids, osmolytes, pigments, antibiotics, toxins, antigens)
	Relation to oxygen	
	List of electron acceptors	Tolerances and susceptibilities
	List of carbon sources	
	List of nitrogen sources	
	List of sulfur sources	
Ecology	Natural habitat(s)	Pathogenicity, host range
		Antigen formation
		Serology
		Phage susceptibility
		Symbiosis

[a]To be demonstrated by light microscopy.
[b]To be demonstrated by electron microscopy.

radius. A sample of only one strain cannot tell anything about the radius of the cluster and is only a poor guide for defining the position of the cluster's center. Sneath postulated that 25 strains are needed for a rather accurate definition of the center and the radius of a cluster and suggested that the minimum number is about 10 strains.

If this number were to have been internationally agreed upon for descriptions of new species (taxa), many if not most of the new prokaryote species described since the times of M. W. Beijerinck and S. N. Winogradsky could not have been described as such. In the majority of cases, new species and genera have been and still are described on the basis of only a few strains, or even only one.

Usually, a newly isolated strain is not isolated accidentally or at random. It has either been recognized microscopically by its morphology and then been sought by use of various enrichment and isolation procedures, or a special selective nutrient medium or enrichment procedure is designed first, and the predominant organism is then isolated.

If a prokaryote strain is considered as a new species, authors should at first explain why they consider this as a new species; i.e., they should carry out a thorough comparison between the "new" and the known species (and genera) of the bacterial group with which the new organism shows most similarities. If, as is usually the case, the new organism can be allotted to one of the major groups of prokaryotes, the description of a new species (and/or genus) should contain at least the information presented in Table 2. The requirements demanded and recommended by the International Code of Nomenclature of Bacteria when a new species is described were discussed in "Nomenclature."

CHAPTER 1.5

Principles of Enrichment, Isolation, Cultivation and Preservation of Prokaryotes

JÖRG OVERMANN

Introduction

Currently, a total of 4700 validly published prokaryotic species are recognized (as of July 2002; DSMZ, 2002; Euzéby, 2001; Fig. 1). In contrast, the number of bacterial species present in just one type of forest soil has been estimated to be 13,000 or even 53,000 species (Torsvik et al., 1994; Sandaa et al., 1999). In light of these more recent findings, the earlier estimate of the fraction of already cultured bacterial species of 20% (Wayne et al., 1987) appears to be much too optimistic. This view is also supported by numerous molecular investigations of 16S rRNA gene sequences in natural bacterial assemblages that indicate a significant fraction of bacteria present in the environment has not yet been recovered by cultivation-based approaches (Fuhrman et al., 1992; Ward et al., 1992; Barns et al., 1994; DeLong et al., 1994; Hiorns et al., 1997; Kuske et al., 1997; Ludwig et al., 1997; Suzuki et al., 1997; Gich et al., 2001; Béjà et al., 2002). The 16S rRNA gene libraries of natural bacterial communities usually do not match sequences of strains isolated from the same or similar samples (Hiorns et al., 1997; Suzuki et al., 1997; Hugenholtz et al., 1998). Even a large cultivation campaign during which 659 bacterial isolates were obtained from grassland soil did not yield any strain with a 16S rRNA sequence corresponding to the dominant strains in the natural community (Felske et al., 1999). In some cases, this discrepancy may simply be the result of the low number of cultivation attempts, since even conventional cultivation trials continue to yield novel phylotypes of bacteria (Pinhassi et al., 1997; Suzuki et al., 1997) and the number of recognized species continuously increases at a rate of about 190 species per year (Fig. 1).

In many instances, key reactions in biogeochemical cycles appear to be mediated not by the frequently isolated prokaryotes but rather by other prokaryotes that are phylogenetically unrelated and mostly not-yet-cultured. Examples include members of the *Nitrosospira*-group which (instead of *Nitrosomonas* spp.) catalyze nitrification in at least some environments (Hastings et al., 1998; Schramm et al., 1999), *Achromatium* spp. and coccoid magnetotactic bacteria participating in the sulfur cycle (Spring et al., 1993), archaea which apparently mediate anaerobic methane consumption (Hinrichs et al., 1999), and novel type II methanotrophic bacteria oxidizing methane at atmospheric concentrations (Holmes et al., 1999; Roslev et al., 1999). Some environments harbor whole groups of entirely unknown bacteria and archaea, which most likely are important for the biogeochemical transformations (Hugenholtz et al., 1998). These include for instance members of the green filamentous bacteria (Coolen et al., 2002) or freshwater actinobacteria (Glöckner et al., 2000). In addition, first culture-independent analyses of large genome fragments retrieved from natural samples have recently uncovered bacteria present in the natural environment that have a previously unrecognized physiology (Béjà et al., 2000). Only in a few instances could numerically important bacterial species apparently be isolated (Ferris et al., 1996; Kalmbach et al., 1997). With the aid of modern molecular methods, some information on the physiological capabilities of "not-yet-cultured prokaryotes" can now be obtained even down to the single-cell level (Ouverney and Fuhrman, 2000).

Though culture-independent techniques have improved, they still provide only limited insights into the physiology of prokaryotes. Therefore, the role of not-yet-cultured prokaryotes in the environment cannot be fully appreciated until these microorganisms are available for detailed physiological and molecular studies. So far, our present methods for the enrichment, isolation and cultivation are largely based on concepts developed first and foremost for the isolation of medically important bacteria. The failure to cultivate many of the ecologically relevant bacteria clearly indicates that there is a need for the development of novel cultivation methods.

Successful enrichment, isolation and cultivation of prokaryotes critically depend on the choice of appropriate growth media and incubation conditions. In the following chapters, the requirements of prokaryotic cells for growth in

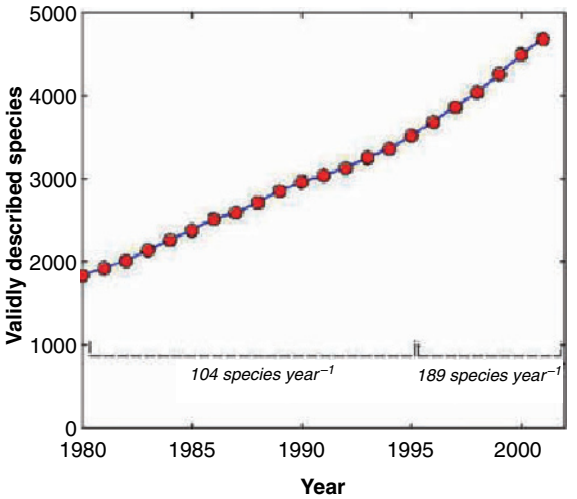

Fig. 1. Increase in validly described species since the appearance of the approved list of bacterial names in 1980. Data were taken from Euzéby (2001) and the (http://www.dsmz.de/bactnom/bactname.htm) Deutsche Sammlung für Mikroorganismen und Zellkulturen and do not include Comb. nov. and *Nomines nova*.

the laboratory and the different existing methods for their cultivation are discussed.

Historical Perspective

Girolamo Fracastoro (1478–1553) first proposed the existence of minute living bodies. He proposed that transfer of this "contagium" was the cause of infectious diseases. Prokaryotes were first made visible by Antonie van Leeuwenhoek (1632–1723), a draper and amateur lens maker living in Delft, The Netherlands. In one of his letters to the Royal Society of London published in 1676, he gave the first account of "kleine diertjes" (little animals), descriptions proving he indeed had seen bacteria. In another letter of September 17, 1683, he provided the first picture of bacteria. These now famous drawings depict cocci, rods, vibrios and spirilla that van Leeuwenhoek had observed in scrapings from his teeth. Although Robert Hooke had described cork "cells" and fossilized foraminiferan shells earlier (Hooke, 1665), he never recorded observations of bacteria, most likely because he only used dry inanimate preparations. The success of van Leeuwenhoek was based on 1) the high quality of the lenses (magnifications up to 280 times) he used and mounted in homemade single-lens microscopes (Dobell, 1932; Porter, 1976), 2) his way of mounting and viewing specimens with a kind of dark-field illumination, and 3) the time he devoted to microscopic investigation.

The work of Louis Pasteur (1822–1895), which marks the beginning of scientific microbiology, follows the scientific discussion over the next 200 years on the issue of spontaneous generation, which assumed mice, frogs, and "lower" forms of life could develop spontaneously in decaying organic matter and mud. Pasteur's experiments with his famous swan-necked flasks ruled out spontaneous generation and at the same time laid the foundations for aseptic manipulation and sterilization. Questioning the belief of eminent chemists of his time, Pasteur provided the first notion of the microbial nature of fermentation in milk (Pasteur, 1862) and of anaerobic life. Other studies revealed that fermentation of sugar to alcohol, wine to vinegar, and the putrefaction of meat all were caused by microorganisms. Each particular kind of fermentation was accompanied by the development of a specific type of microorganism.

Until 1884, the bacterial pleomorphism versus monomorphism controversy was a central issue of microbiology. The description of rust and smut fungi and their morphological changes during development had caused confusion among the early bacteriologists, and it was assumed that, depending solely on growth conditions, one and the same bacterium is able to appear in different forms (pleomorphic), can cause completely different diseases, and form totally different metabolic products. Of outstanding importance for our current thinking in microbiology is the contribution of Robert Koch (1843–1910), the founder of medical bacteriology. In his experimental work, Koch established a series of criteria, the so-called "Koch's postulates," for the identification of causative agents of infectious diseases:

1. The microorganism should be constantly present in animals suffering from the disease, but should not be present in healthy individuals
2. The microorganism must be cultivated in pure culture outside the diseased animal
3. Healthy animals infected with these pure cultures must display the characteristic disease symptoms
4. The microorganism should be reisolated from the experimental animals and shown to be the same as the original

In 1876, Koch isolated the anthrax bacillus from diseased cattle and conclusively demonstrated that the large nonmotile bacilli caused the disease. In 1873, Joseph Lister (1827–1912) had introduced the serial dilution technique to achieve pure cultures. However, this procedure did not yield pure cultures in the hands of every researcher. Pure culture techniques employing solid nutrient media containing gelatin were developed by Anton de Bary (1831–1888) and Oscar Brefeld (1839–1926) for the study of fungi (Bull and Slater, 1982). Although the latter scientists succeeded in cultivating fungi on solid

media, their techniques were not suited for the isolation and growth of bacteria for several reasons: various bacteria were found to liquefy gelatin, on hot days it melted spontaneously, and gelatin-based media could not be incubated at the temperature that most human pathogens needed to grow in a convenient time span. Subsequently, agar-solidified media (around 1881), covered culture dishes, and staining techniques were developed in the laboratory of Robert Koch and, in nearly unaltered form, have remained major tools in bacteriology and medical microbiology until today. After employing agar media, Koch announced his discovery of the tubercle bacillus as the causative agent of tuberculosis in 1882, at the time when this disease had many victims in Europe (Groeschel, 1982). Two years later, he published the discovery of the cholera bacillus.

Subsequently, microorganisms were found to be also of crucial importance for the geochemical cycles. Ferdinand Cohn was the first to realize the role of microorganisms in the transformation of organic matter and inorganic substances on earth (Cohn, 1872). The most significant contributions to the knowledge of the various types of microorganisms responsible for specific chemical transformations in nature (especially for the nitrogen and sulfur cycles) came largely from the laboratories of Sergius Winogradsky (1856–1953) and Martinus Willem Beijerinck (1851–1931). During the 1880s, Winogradsky advanced the concept of chemosynthesis on the basis of his studies of the colorless sulfur bacteria, *Thiothrix* and *Beggiatoa* (Winogradsky, 1949), concluding that these aerobic bacteria obtain their energy for autotrophic growth by oxidizing reduced sulfur compounds (such as sulfides and sulfur) to sulfate.

The work of Beijerinck, with the contributions from Winogradsky, led to the development of the enrichment culture technique. Instead of directly isolating microorganisms from nature by exposing nonselective growth media to some environment and allowing chance to dictate what grew, Beijerinck proposed a different approach. Tailoring culture conditions to favor microbes with a particular metabolic activity usually leads to a rapid enrichment of the desired organism, even if its original numbers are very low in the sample (Van Iterson et al., 1940). One of the early examples of the application of this principle was in Beijerinck's paper on sulfate reduction, which led to the discovery and isolation of *Spirillum* (*Desulfovibrio*) *desulfuricans*, described in a preliminary paper in 1894. Besides root nodule bacteria, *Lactobacillus* species, and others, Beijerinck also isolated the first pure cultures of aerobic nitrogen-fixing bacteria from a culture obtained by Winogradsky. Winogradsky applied enrichment of selective cultures for his research on sulfur bacteria and nitrifying bacteria and also used this technique to identify nitrogen-fixing bacteria in soil. In the years to come after Beijerinck, the success of the batch enrichment culture technique was demonstrated over and over again in the work of Kluyver, Van Niel, Stanier and their students and associates (Veldkamp, 1965; Van Niel, 1967; Pfennig, 1993).

At a time when the discovery of a bewildering variety of microbial forms and activities reached its height, Albert J. Kluyver (1884–1957) and H.J.L. Donker published a seminal paper on the unity in biochemistry (Kluyver and Donker, 1926). This synthetic paper was based on an integration of the ideas of Carl Neuberg, Heinrich Wieland, Otto Warburg, and A. Harden. The concept was that, in addition to a number of hydrolases, cells contained various oxidoreductases catalyzing the transfer of hydrogen from one molecule, the hydrogen (H) donor, to another, the H acceptor, along a gradient of energy. Hydrogen acceptors other than oxygen might also be used (e.g., sulfate). The first report on the view that photosynthesis can be considered as a light-dependent reaction in which different substrates, specific for the different kinds of photosynthetic organisms, serve as H donors for the reduction of carbon dioxide came from Van Niel (1930). Van Niel (1967) described a general formula of photosynthesis. His work was extended greatly by N. Pfennig and his students, who grew many of the anaerobic photosynthetic bacteria in pure culture (Pfennig, 1993).

Early attempts to devise truly anoxic culturing techniques included the use of deep-agar shake tubes gassed with hydrogen, the use of pyrogallol to remove oxygen, sealed tubes, and the isolation of colonies by picking with capillary pipettes. Still, the only anaerobes isolated until 1940 were sporeformers and several nonsporeforming bacteria of clinical importance, while identities of the majority of the anaerobic prokaryotes in sediments, soils, and the gastrointestinal tract remained unknown. This was in part due to the fact that techniques were insufficient to reach the necessary anaerobic conditions, but also to the fact that the media used were not habitat-simulating. Hungate (1950), the first student of Van Niel from the United States, developed an anoxic roll tube technique based on various approaches from the older literature and used habitat-simulating media in the isolation of cellulolytic rumen bacteria (Hungate, 1966; Hungate, 1969; Hungate, 1985). The Hungate technique was very successful and has been widely adapted by microbiologists from various other fields (dentistry, sewage and sediment microbiology).

Many soil bacteria were studied in pure culture after their discovery to examine their basic

metabolism and metabolic capacities. Winogradsky emphasized that the conclusions drawn from laboratory studies on the behavior of bacteria in the natural habitat may be misleading because laboratory strains might only be artefacts, i.e., selected by the chosen nutrient medium, temperature, aeration and agitation. Consequently, he already warned against the use of bacterial strains from culture collections as typical wild-type cells, and together with some of his students, designed methods to study bacteria in situ, within their natural habitats. Winogradsky's concepts on soil microbiology and on the differentiation between autochthonous and allochthonous populations in the soil are the basis of relevant, current research.

The majority of physiological investigations have been limited to pure laboratory cultures. According to the statement of Oscar Brefeld, work with impure cultures yields nothing but nonsense and *Penicillium glaucum* (Brefeld, 1881). However, Koch's methods may also have hindered the understanding of the microbial interactions as they occur in complex natural microbial communities, e.g., in soil (Winogradsky, 1949). In fact, interactions between microorganisms under natural conditions may lead to transformations that are unknown from pure cultures. The shortcomings of pure culture techniques are illustrated best by the interspecies hydrogen transfer described first by M.J. Wolin in 1975, as well as by the inhibition of growth of a *Micrococcus* culture by a chance *Penicillium* contaminant (Fleming, 1929), which led to the discovery of antibiotics. For an in-depth understanding of microbial physiology, microbial transformations therefore have to be studied also in natural mixed microbial communities.

Prokaryotic Growth

Parameters of Prokaryotic Growth

In media of appropriate composition and in the presence of suitable substrates, bacteria multiply. The rate of growth is dependent on substrate concentration, temperature, pH, and osmolarity and can be assessed from the increase in bacterial cell number or in bacterial biomass. This distinction has to be made since under certain conditions growth is not completely balanced, and the increase in biomass is not paralleled by an increase in cell numbers or vice versa. As an example, cells in the early stationary phase can undergo reductive division whereby cell numbers continue to increase while a constant overall biomass of the culture is maintained (Kolter et al., 1993).

Upon inoculation of bacterial cells into fresh growth medium, a period without growth is frequently observed (the so-called "lag phase") during which adaptation of the cells occurs by, e.g., synthesis of cellular enzymes. Afterwards, a phase of exponential growth occurs until cell growth is limited by substrate availability and by accumulation of toxic metabolic products or unfavorable pH (stationary phase). The stationary phase is then followed by a phase of prokaryotic biomass reduction due to lysis of cells. If changes in bacterial cell numbers N are followed during the exponential phase, the specific division rate ε and the generation time g are used for the mathematical description of growth (N_0 denoting the initial cell number, and t the time of incubation):

$$N = N_0 \cdot 2^{\nu t} \tag{1}$$

$$g = \frac{1}{\nu} \tag{2}$$

In a growing culture, the concentration of prokaryotic biomass X increases autocatalytically (a first-order reaction), that is, the instantaneous biomass changes $\mathrm{d}X/\mathrm{d}t$ are proportional to the biomass present (Lengeler et al., 1999). Here the specific growth rate μ and the doubling time t_d are used to describe prokaryotic growth:

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \mu \cdot X \tag{3}$$

and hence

$$X = X_0 \cdot e^{\mu t} \tag{4}$$

The biomass doubling time is then calculated according to

$$t_\mathrm{d} = \frac{\ln 2}{\mu} \tag{5}$$

The two parameters μ and ν are related according to

$$\mu = \nu \cdot \ln 2 \tag{6}$$

The specific growth rate is determined by the substrate concentration which, based on the theoretical consideration of Monod (Monod, 1942; Monod, 1950), can be described by

$$\mu = \mu_\mathrm{max} \cdot \left(\frac{S}{K_s + S} \right) \tag{7}$$

where μ_max is the maximum value of the specific growth rate attained at unlimiting substrate concentrations S and K_s (the saturation constant numerically equal to the substrate concentration at which $\mu = 0.5\ \mu_\mathrm{max}$).

For comparison of growth characteristics between different cultures, the K_s value has been

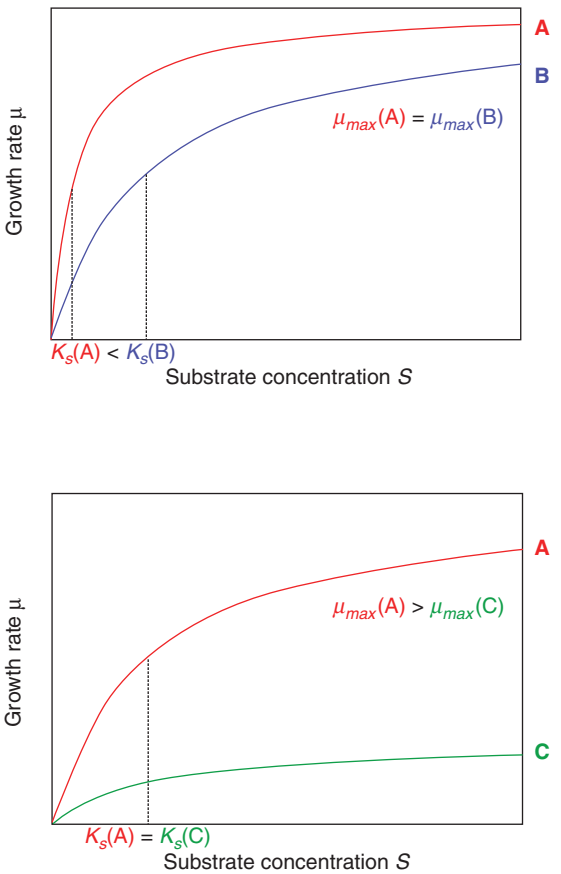

Fig. 2. Significance of the substrate affinity of growth (μ_{max}/K_s, i.e., the initial slope of the μ versus S curve) for three species A, B and C. Comparison of substrate-dependent specific growth rates for two strains A and B with the same maximum growth rate but different K_s values (upper panel), and for two strains A and C with the same K_s value but different maximum growth rates μ_{max} (bottom).

frequently invoked as a measure of affinity for a given substrate. However, prokaryotes with similar K_s values may differ substantially in their affinity (Fig. 2) since the substrate affinity of growth is not solely determined by the K_s value of the prokaryote, but rather by the ratio μ_{max}/K_s (Schut et al., 1997).

Modes of Prokaryotic Growth

One of the most pronounced differences between prokaryotes and eukaryotes is the high metabolic versatility of the former. Among the outstanding metabolic properties of prokaryotes is the use of inorganic electron donors for energy generation, anaerobic growth, and the fixation of molecular nitrogen. In eukaryotes, these properties are either restricted to a few species or completely lacking. Novel ways of energy generation continue to be uncovered (Zengler et al., 1999; Schink and Friedrich, 2000).

Table 1. Classification of microbial metabolism on the basis of energy source, the type of electron donor, and the type of carbon source.

Energy source				
Chemical:	*Chemo-*			
Light:	*Photo-*			
Electron donor				
Inorganic:		*-litho-*		
Organic:		*-organo-*		
Carbon source				
CO_2:			*-auto-*	
Organic:			*-hetero-*	
Both:			*-mixo-*	
				-troph

According to the concept of unity in biochemistry, redox reactions are central to life. Only a few exceptions exist to the rule that biological energy is produced in redox processes (Thauer et al., 1977). Such catabolic nonredox processes comprise the arginine fermentation in *Enterococcus faecalis*, xanthine fermentation in *Clostridium cylindrosporum*, and the pyruvate fermentation to acetate and formate in *Proteus rettgeri*. In these cases, substrates are metabolized by lytic rather than redox reactions, and energy is conserved by substrate level phosphorylation. Also, photophosphorylation in *Halobacterium halobium* proceeds without the participation of an electron chain.

In the case of chemotrophic prokaryotes, the energy driving cellular processes is derived from an exergonic chemical reaction (Table 1), during which an exogenously supplied substrate reduces an external electron acceptor (e.g., during respiration with oxygen, nitrate or sulfate). Alternatively, a metabolic product of the substrate reduces an electron acceptor formed intracellularly from the substrate (fermentation).

The standard free energy change of a specific type of microbial metabolism can be assessed from the difference between the standard redox potential of the electron donors (E_0'[don]) and that of the electron acceptors (E_0'[acc]; tabulated in Thauer et al., 1977), according to

$$\Delta G_0' = -n \cdot F \cdot \Delta E_0' = -n \cdot F \cdot \left[E_0'(\text{acc}) - E_0'(\text{don}) \right] \quad (8)$$

where n is the number of electrons transferred and F is the Faraday constant (96.48 $kJ \cdot V^{-1}$).

The standard free energy change of a reaction can also be calculated from the free energy of formation (G_f^0) of the products and reactants (Thauer et al., 1977) and, in case of energy-yielding reactions involving H^+, the number of protons formed (m) and the free energy of

formation of a proton at pH 7 and 25°C ($\Delta G_f'[H^+]$):

$$\Delta G_0' = \sum G_f^0(\text{products}) - \sum G_f^0(\text{reactants}) + m \cdot \Delta G_f'(H^+)$$
$$= \sum G_f^0(\text{products}) - \sum G_f^0(\text{reactants}) + m \cdot (-39.83\ \text{kJ}) \quad (9)$$

(Madigan et al., 2000a). It has been suggested that microbes can exploit a reaction for growth, if the Gibbs free energy is ≥20 kJ·(mol substrate)$^{-1}$ and hence sufficient for the translocation of one proton across the cytoplasmic membrane (Schink, 1991; Schink, 1997). However, experiments with syntrophic cultures indicate that even smaller amounts of energy may be utilized and that syntrophic associations with methanogens metabolize near thermodynamic equilibrium at values as little as $\delta G' = -4.5$ kJ·(mol substrate)$^{-1}$ (Scholten and Conrad, 2000; Jackson and McInerney, 2002). In ecological niches where available energy is at a minimum, prokaryotes are hence capable of maximizing energy conservation when thermodynamic constraints begin to limit substrate degradation. It has been suggested that the underlying mechanisms control changes in cellular phosphorylation potential or the electronmotive membrane potential of the syntrophically metabolizing bacteria and that these mechanisms may be triggered by signals from their hydrogen-scavenging partner (Jackson and McInerney, 2002).

In contrast to chemotrophs, phototrophic prokaryotes exploit electromagnetic energy for growth. During photosynthesis, light absorption converts a cellular pigment (the reaction center chlorophyll or bacteriochlorophyll) from a weak to a strong reductant. Electrons are transferred to associated electron carriers and—during cyclic electron transport (cyclic photophosphorylation)—finally returned to the oxidized reaction center pigment. As a principal difference from chemotrophic prokaryotes, phototrophic prokaryotes can convert light energy into chemical energy (a proton gradient) without the need of an external electron donor.

Clearly, organic or inorganic carbon compounds represent the most important nutrients for prokaryotic growth. Traditionally, prokaryotes have been divided into two major groups with respect to their carbon requirement, namely autotrophs and heterotrophs. Autotrophic prokaryotes assimilate carbon dioxide as the principal source of cellular carbon. It has to be noted, however, that some inorganic carbon-fixing enzymes, such as acetyl-CoA carboxylase or propionyl-CoA carboxylase (present in certain autotrophs), as well as anaplerotic enzymes such as phosphoenol pyruvate (PEP) carboxylase or biosynthetic enzymes such as carbamoyl phosphate synthetase fix bicarbonate instead of CO_2 (Neuhard and Kelln, 1996; van der Meer et al., 2001). As a rule, these microbes use light or the oxidation of inorganic compounds for the generation of metabolic energy; hence they grow as photolithoautotrophs or chemolithoautotrophs (Table 1), respectively. Facultative autotrophs can also grow at the expense of organic carbon compounds, whereas mixotrophs can utilize CO_2 and organic carbon compounds simultaneously. One and the same strain can grow chemolithoautotrophically under one set of environmental conditions, but switch to chemoorganoheterotrophic growth under different conditions. Consequently, the metabolic types listed in Table 1 are not mutually exclusive, but may occur in the same prokaryote. In the case of heterotrophic bacteria, organic carbon compounds are used not only for biomass synthesis, but also for energy generation. Approximately half of the organic carbon compounds are assimilated by aerobic microorganisms. Fermenting bacteria assimilate significantly less, typically 10–20%, while the remaining carbon substrate is required as an energy source.

The redox state of carbon in biomass (in $<C_4H_8O_2N>$, on average –0.25) is more reduced than many carbon sources utilized by prokaryotes. This situation is most pronounced in the case of autotrophic growth, but also during growth on organic carbon sources such as formate, glycollate, malate, fumarate, oxaloacetate or citrate. The substrates used in microbial metabolism therefore not only serve to generate energy in the case of chemotrophic species, but also yield reducing power for the cells to carry out a variety of reductive processes during synthesis of new cell biomass. In the classification of microbial metabolism, the (inorganic or organic) nature of the electron donor for these reductive processes is considered (Table 1).

Requirements for Prokaryotic Growth

General Composition of the Prokaryotic Cell

For the understanding of the thermodynamics of bacterial growth and as a basis for the design of appropriate growth media, knowledge of the composition of prokaryotic biomass is essential. Of the more than 100 elements that appear in the periodic table, some 35–40 are considered essential. Six nonmetals (C, O, H, N, S and P), together with four metals (K, Mg, Fe and Ca) comprise an average of 98% of the dry weight of prokaryotes.

A good first approximation of the mean composition of prokaryotic biomass is given by the formula $<C_4H_8O_2N>$, although a more elaborate formula for the composition of bacterial cells, namely $C_4H_{6.4}O_{1.5}NP_{0.09}S_{0.024}$, has been published (Battley, 1995). The total ionic constituents of the cytoplasm account for 1% of its dry weight. Consequently, the so-called "macroelements" (Table 2) are needed in relatively high concentrations in the growth medium. Most bacteria do not require Na, although many marine bacteria, certain phototrophs, and some strict anaerobes require this element. Chloride has been found to be obligatory for the growth of a variety of bacteria (Table 2). It should be noted, however, that certain gliding bacteria, e.g., the marine filamentous sulfate-reducing bacterium *Desulfonema magnum*, strictly require calcium concentrations of ≥4 mM (Widdel et al., 1983). This appears to be related to a higher Ca^{2+} requirement of gliding motility (Castenholz, 1973; Burchard, 1980).

The range of organic carbon compounds utilizable by heterotrophs is vast; virtually any compound synthesized by biological processes, as well as many xenobiotica (compounds synthesized in the laboratory which do not originate in nature), can be degraded by microbes. Different species of heterotrophic prokaryotes utilize considerably different numbers and kinds of carbon substrates. Some, such as the pseudomonads, are versatile and are known to utilize over 100 different carbon compounds as the sole source of carbon and energy. Their substrates include carbohydrates, sugar acids, polyols, fatty acids, primary alcohols, amino acids, and aromatic substances. In contrast to these versatile bacteria, several groups exist that are limited in their ability to decompose organic compounds. In this cat-

Table 2. Macroelements and their physiological functions.

Element	% dry weight	mM[a,b]	Physiological functions
C	48–59[c]		Main constituent of organic cellular material
O	13.1–23.9[c]		Organic material and cytoplasmic water
H	6.4–8[c]		Organic material and cytoplasmic water
N	13.6–14.7[c]		Proteins, nucleic acids, and coenzymes
S	0.9–1.4[c]		Cysteine, methionine in proteins, coenzymes thiamine pyrophosphate, coenzyme A, biotin, and α-lipoic acid
P	2–5.4[d]		Nucleic acids, nucleotides, phospholipids, teichoic acids, and coenzymes
K	0.03–1.4	18–800 *4500*	Predominant monovalent cation in cytoplasm, maintenance of cell osmolarity, cofactor of some enzymes (e.g., pyruvate kinase, peptidyltransferase, L-malate dehydrogenase; Walderhaug et al., 1987)
Mg	0.007–0.05	6–46[e,f]	Predominant intracellular divalent cation, cofactor of many enzymes (e.g., kinases), in phosphate esters, ribosomes, membranes, and cell wall
Ca	0.00006–0.06	0.01–9.5[g]	Present in exoenzymes (α-amylases and proteases) and in cell walls, role in transformation, Ca^{++}-dipicolinate is an important component of endospores
Na	*1.45*	*1400*	Bacterial oxaloacetate, glutaconyl-CoA, and methylmalonyl-CoA decarboxylases; NADH-quinone reductase of halophilic *Vibrio* spp. (Skulachev, 1987), transport, H_4MPT:CoM methyltransferase of methanogenic archaea
Cl	0.05	31–*1600*[f,h]	Essential for active uptake of compatible solutes and flagella formation in halophiles, e.g., *H. halophilus*
Fe	0.003–0.02[i]	1.2–7.7	Present in cytochromes, ferredoxins, and other Fe-S-proteins, cofactor in enzymes (some dehydratases)

Abbreviations: CoA, coenzyme A; NADH, reduced beta-nicotinamide adenine dinucleotide; and H_4MPT:CoM, reduced molybdopterin coenzyme M.

[a]Interconversion between % dry weight and mM was done based on the cytosolic volume of *E. coli* of 0.9 µl·(mg protein)$^{-1}$, equivalent to 0.45 µl·(mg dry mass)$^{-1}$ (Gangola and Rosen, 1987).

[b]Intracellular concentrations in halophilic archaea or bacteria are given in italics.

[d]From Damoglou and Dawes (1968) and Norland et al. (1995).

[e]From Schmidt et al. (1971); up to 60 mM in moderately halophilic eubacteria (Shindler et al., 1977).

[f]From Battley (1995).

[g]In *E. coli* depending on extracellular concentrations (Gangola and Rosen, 1987). The intracellular concentration of free Ca^{2+} is 90–700 nM.

[h]In *H. halophilus* (Roeßler and Müller, 1998). Chloride has been shown to be obligatory also for growth of *Paracoccus denitrificans*, *Aeromonas hydrophila*, *Escherichia coli*, *Proteus mirabilis*, *P. vulgaris*, *Vibrio fischeri*, *Bacillus megaterium*, *B. subtilis*, *Staphylococcus aureus*, *Corynebacterium glutamicum*, and *Thermus thermophilus* (Roeßler and Müller, 2002).

[i]Niehaus et al. (1991), calculated from their value of 1.6–6.9 µmol Fe·(g protein)$^{-1}$, and Braun (1997), based on the cellular amount of iron ions of 10^5 cell^{-1} and a cytosolic volume of 0.14 µm^3. Intracellular volume calculated from a protein content of *E. coli* of 156 fg·cell^{-1} (Neidhardt and Umbarger, 1996) and the cytosolic volume given in footnote[a].

egory are the obligate methylotrophs that only use methane, methanol, dimethyl ethers, and a few other compounds. Highly specialized species are restricted to the use of only one type of organic carbon substrate, e.g., *Bacillus fastidiosus* to uric acid. Many chemoorganotrophs still require carbon dioxide in small amounts for anaplerotic reactions, e.g., the synthesis of oxaloacetate by PEP carboxylase, PEP carboxykinase, PEP carboxytransphosphorylase, and by pyruvate carboxylase (Wood-Werkman reactions). Since carbon dioxide is produced during catabolism of organic compounds, it does not normally become a limiting nutritional factor. However, some bacteria, such as *Neisseria* and *Brucella*, require higher concentrations of carbon dioxide (up to 10%) in the atmosphere for good growth in organic media, a need that must be considered in isolating and cultivating such organisms.

Oxygen and hydrogen are derived from water and, in the case of heterotrophic bacteria, from the organic carbon source. Molecular O_2 is required in only few exceptions, where an OH group is introduced by mono- or dioxygenases during the biosynthesis of cell constituents. In cellular material, nitrogen is incorporated in the reduced form as amino groups. Many prokaryotes are capable of assimilatory nitrate reduction and therefore grow with nitrate as nitrogen source. A number of aerobic and anaerobic bacteria are capable of nitrogen fixation and thus grow in media devoid of a combined nitrogen source. Some prokaryotes, such as anoxygenic phototrophs, depend on reduced nitrogen in the form of ammonium salts. Others require amino acids or oligo- or polypeptides as a source of cellular nitrogen.

A large fraction of phosphorus is bound in RNA. As a result, phosphorus demand increases with the specific growth rate of the cells. No reduced phosphorus compounds are stable, and cellular phosphorus is in the oxidation state of phosphate. Hence inorganic phosphate is the usual source of this element for microbial nutrition. Since phosphate is frequently also used as a pH buffer, it is added in excess of the growth requirement. However, high concentrations of inorganic phosphates may be growth inhibitory to at least some aquatic bacteria (Bartscht et al., 1999). Organic phosphorus sources such as glycerophosphate are an alternative supply.

Cellular sulfur is mostly in the reduced state and present in the sulfur-containing amino acids cysteine and methionine. Many bacteria are capable of assimilatory sulfate reduction and thus can utilize sulfate to satisfy the sulfur requirements for growth. Other prokaryotes, such as about half of the strains of anoxygenic phototrophic bacteria or methanogenic archaea, require sulfur in a reduced form as either sulfide or an organic compound with a thiol group, such as cysteine.

Potassium is the principal inorganic cation in the cell and reaches a concentration of about 300 mM in the cytoplasm. Although much of it is bound in the ribosomes, it is also a cofactor of some enzymes, is required for carbohydrate metabolism, and is involved in many transport processes and osmoregulation. Usually, an inorganic potassium salt (K_2SO_4 or KH_2PO_4) is added to the growth medium to satisfy this requirement.

The magnesium requirement of bacteria is principally that of bacterial ribosomes. Magnesium also functions as an enzyme cofactor and is present in cell walls and membranes. It is usually supplied as magnesium sulfate. Iron is required at micromolar concentrations, whereas the trace elements listed in Table 3 should be present in

Table 3. Microelements: their source and physiological functions.

Element	Source	Physiological functions
Mn	Mn^{2+}	Superoxide dismutase, photosystem II, some enzymes (PEP carboxykinase and citrate synthase)
Co	Co^{2+}	Coenzyme B_{12}-containing enzymes (glutamate mutase and methylmalonyl-CoA mutase)
Cu	Cu^{2+}	Cytochrome oxidase, plastocyanin, nitrite reductase, oxygenases, and superoxide dismutases[a]
Mo	MoO_4^{2-}	Nitrate reductase, nitrogenase, xanthine dehydrogenase, and formate dehydrogenase
Zn	Zn^{2+}	Carbonic anhydrase, alcohol dehydrogenase, alkaline phosphatase, aldolase, RNA and DNA polymerase, and proteinases
Ni	Ni^{2+}	Urease, hydrogenase, and cofactor F_{430}
V	$VOSO_4$	V-dependent nitrogenase, and bromoperoxidase
Se	SeO_3^{2-}	Formate dehydrogenase, hydrogenase, and glycine reductase in clostridia
W	WO_4^{2-}	Some formate dehydrogenases
B	H_3BO_3	Formation of heterocysts, akinetes in cyanobacteria; possibly crosslinking of pyranoses in cellular envelope;[b] and AI-2 (cyclic borate diester)[c,d]

Abbreviations: PEP, phosphoenol pyruvate; V-dependent, vanadium-dependent; and AI-2, autoinducer-2.

[a]Certain cyanobacteria such as *Synechococcus* are very sensitive to Cu, which therefore has to be omitted from the respective growth media.

[b]Loomis and Durst (1992).

[c]However, boric acid acts as a bacteriostatic agent under certain circumstances (Lum and Meers, 1989).

[d]Chen et al. (2002).

growth media at concentrations between 0.01 and 1 μM. Trace elements are toxic at higher concentrations. Since divalent and trivalent metal cations tend to form insoluble hydroxides or phosphates at neutral to alkaline pH, they may become unavailable to bacteria in growth media. Concentrated stock solutions of inorganic salts therefore are often kept anoxically at acidic pH, and minimal amounts of complexing agents (ethylenediamine-N,N,N′,N′-tetraacetic acid [EDTA] and nitrilotriacetic acid [NTA]) are incorporated.

In addition, a variety of microelements (Mn, Co, Cu, Mo, Zn, Ni, V and B) is required (Table 3). Certain prokaryotes, in particular strict anaerobes, often also require selenium and tungsten.

Growth Factors

Many bacteria grow with a single carbon compound added to the medium. Additional organic compounds often stimulate the growth of microorganisms when present in small concentrations. These so-called "growth factors" represent building blocks of major cell constituents, and their addition to the medium therefore decreases the need for de novo biosynthesis in the cell, if the compounds can be transported into the cell. Generally, the growth factors recognized are 1) amino acids, 2) purines and pyrimidines, and 3) vitamins. The latter are required only in small amounts (on the order of $mg \cdot liter^{-1}$, or between 0.1 and 1 μM). The biological function of a number of vitamins is listed in Table 4. Synthetic stock solutions of vitamins should be kept dark, cold, anoxic and sterile (by filtration) and at a slightly acidic pH. They should be added to the medium after autoclaving the latter.

However, many prokaryotes obligately depend on the presence of growth factors in the medium because the cells are unable to synthesize all cell constituents from a single carbon source. In more rare cases, unusual compounds such as porphyrins (hemin in the case of *Haemophilus* spp.), short-branched fatty acids (e.g., 2-methyl-*n*-butyric acid in the case of *Methanobacterium ruminantium*) or straight-chain fatty acids, mevalonic acid, cholesterol (*Mycoplasma*), choline, betaine, and polyamines are required. Some vitamins are required only during growth on specific substrates (such as B_{12} by *Escherichia coli*). Essential growth factors may include a few vitamins, such as biotin and *p*-aminobenzoic acid in the case of *Clostridium kluyveri*, or a large variety of compounds (as in the case of lactobacilli, which grow in media supplemented with peptone, Tween 80, acetate and Mn^{2+} salts [MRS-medium]). Many lactic acid bacteria including *Leuconostoc* have a requirement for Mn^{2+} (Boyaval, 1989). However, the addition of growth factors such as yeast extract or casamino acids also clearly inhibits growth of some photolithoautotrophic or chemolithoautotrophic bacteria (Overmann and Pfennig, 1989).

Growth factors may also stimulate microbial growth in an indirect fashion. Recently, evidence has accumulated for a stimulatory role of humic substances and extracellular quinones (e.g., anthraquinone-2,6-disulfonate) in dissimilatory iron reduction (Lovley and Blunt-Harris, 1999a). In addition, organic ligands such as EDTA, NTA, *n*-methyliminodiacetic acid, ethanol diglycine, deferoxamine, or phosphates, if added to growth media, make Fe(III) more available and increase rates of microbial reduction significantly (Lovley et al., 1996b; J. Overmann et al., in preparation).

Table 4. Functions of vitamins and related compounds in prokaryotes.

Vitamin	Physiological functions
p-Aminobenzoic acid	Precursor of tetrahydrofolic acid involved in one-carbon transfer
Biotin	Carbon dioxide fixation and release
Coenzyme M	Methane formation
Folic acid	Tetrahydrofolic acid involved in one-carbon metabolism
Lipoic acid[a]	Transfer of acyl groups, e.g., prosthetic group of pyruvate dehydrogenase complex
Thiamine (B_1)	Thiamine pyrophosphate is prosthetic group of decarboxylases and transketolases
Riboflavin (B_2)	Precursor of FMN and FAD, prosthetic group of flavoproteins, and redox reactions
Pyridoxine (B_6)	Pyridoxalphosphate coenzyme of transaminases and amino acid decarboxylases
Cyanocobalamin (B_{12})	Molecular rearrangement reactions (e.g., glutamate mutase)
Pantothenic acid	Precursor of CoA, prosthetic group of acyl carrier proteins, and participant in metabolism of fatty acids
Nicotinic acid	Precursor of NAD and $NADP^+$, and found in many dehydrogenases
Vitamin K	Precursor of menaquinone, and electron carrier in respiratory chains
Hemin	Precursor of cytochromes, and involved in redox reactions

Abbreviations: FMN, flavin mononucleotide; FAD, flavin adenine dinucleotide; CoA, coenzyme A; NAD, nicotinamide adenine dinucleotide; and NADP, nicotinamide adenine dinucleotide phosphate.
[a]Dithiooctanoic acid.

pH

In natural environments, the pH value varies from below 1 in acidic springs to over 11 in soda lakes (Brock, 1978; Grant and Tindall, 1986; Madigan et al., 2000a). Prokaryotes can be isolated from these environments and are capable of growing at such pH values (Brock, 1978; Langworthy, 1978; Horikoshi and Akiba, 1982; Krulwich and Guffanti, 1989). Species with optima for growth below pH 5.5 are usually called acidophiles and can grow even at pH values of 1 (e.g., *Acidithiobacillus* and *Sulfolobus*). Prokaryotes with optima above pH 8.5 are called alkaliphiles and grow up to values of pH 11.5 (e.g., *Sporosarcina pasteurii*). Many enzymes and structural components in these extremophiles cannot function properly at the very high or low pH values found in their external environment, and the intracellular pH is kept at relatively constant values (Krulwich and Guffanti, 1983; Krulwich and Guffanti, 1989; Padan and Schuldinger, 1986; Matin, 1990). In general, the internal pH of acidophiles is regulated to a value of 6.0–7.0, and alkaliphiles maintain an internal pH 1 to 2 units lower than the external value.

The majority of natural environments possess pH values between 5 and 9, and the pH optima for the growth of most prokaryotes (neutrophiles) fall well within this range. Neutrophiles keep the internal pH slightly more alkaline than this value outside. For example, *Escherichia coli* regulates its internal pH at 7.4 to 7.8 during growth over the external pH range of 5.0 to 9.0 (Slonczewski and Foster, 1996).

During the growth of microorganisms in cultures, pronounced pH changes can occur because organic acids (especially during fermentation) and ammonia from nitrogen-containing compounds are produced. When exposed to pH values at the upper or lower end of the permissive range of growth, prokaryotes may exhibit metabolic properties not displayed at normal pH values. A well-known example is the shift towards production of nonacidic end products by fermentative bacteria (Graham and Lund, 1983; Gottwald and Gottschalk, 1985; Ferchichi et al., 1986; Huang et al., 1986; Forsberg, 1987; Hommes et al., 1989). Weak organic acids also influence the cytoplasmic pH in a direct manner since in their undissociated form they are lipophilic and therefore rapidly diffuse through cell membranes, ultimately conducting hydrogen ions along the transmembrane gradient. As a result, the intracellular pH is lowered. At low pH values, the effect of extracellular pH in microbial growth is therefore magnified in the presence of organic acids. Hence, permeant acids such as benzoic, propionic, and sorbic acids are inhibitors of microbial growth (and in fact are used as food preservatives), and their potency increases with decreasing pH (Ingraham and Marr, 1996). However, the sensitivity of bacterial cells to low pH values is less pronounced in the stationary phase (Ingraham and Marr, 1996).

In high nutrient strength complex media, the various acidic and basic functional groups of organic molecules often provide sufficient buffering capacity. In mineral media and low nutrient strength complex media, continuing acidification or alkalinization of the growth medium will rapidly lead to arrest of growth of prokaryotes. Therefore, the pH has to be maintained within the permissive range for growth using appropriate organic or inorganic buffer systems (Table 5). Below pH 3, the actual concentration of hydro-

[a]Applicable in closed gas tight vessels only.

nium ions becomes high enough to obviate the need for buffering.

Not all buffers listed can be applied for the isolation and cultivation of all prokaryotes. Phosphate buffers, although widely employed, inhibit the growth of bacteria from low nutrient environments such as freshwater lakes even at comparatively low concentrations of 10 mM (Bartscht et al., 1999). At higher concentrations (≥30 mM), phosphate buffers are inhibitory also to many other microorganisms (Bast, 2001). A second disadvantage of phosphate buffers is their tendency to form precipitates with Ca^{2+}, Mg^{2+} and Fe^{3+} ions already at rather low concentrations (e.g., 7 mM PO_4^{3-} and 0.7 mM Ca^{2+}). In these cases, the Ca^{2+} concentration needs to be decreased to 200 µM, which (as calculated from the cellular Ca^{2+} content; Table 2) still permits a sufficient cell yield of ≥7 grams dry weight·liter^{-1} (for exceptions such as gliding bacteria, see General Composition of the Prokaryotic Cell). The sulfonate buffers listed in Table 5 have been found to be useful in several instances (Slonczewski and Foster, 1996; Bartscht et al., 1999). Substituted amines such as TRIS (tris[hydroxymethyl]aminomethane) and triethanolamine should be avoided as they cross the cytoplasmic membrane in their deprotonated form. In general, the ionic form of a buffering substance is less toxic than its undissociated form, since the charged molecules penetrate the cellular membrane much more slowly. Consequently, cationic buffers (e.g., TRIS) are used at pH values below their p*K*, while anionic buffers are employed at a pH above their p*K* value.

Osmolarity

Microorganisms differ considerably in the amount of water they require in their immediate surroundings (Brown, 1976; Kushner, 1978; Yancey et al., 1982). At higher concentrations of aqueous solutions, forces between solutes and solvent lead to a lower "effective concentration"—the so-called "activity"—of water. Availability of water is measured as the water activity a_w, which is defined by the mole fraction of water N_w and the activity coefficient γ_w according to Schopfer and Brennicke (1999)

$$a_w = \gamma_w \cdot N_w \tag{10}$$

According to Raoult's law, the water activity in a dilute solution is equal to the ratio of the vapor pressure P of the solution relative to the vapor pressure P_0 of pure water at the same temperature

$$a_w = \frac{P}{P_0} = \frac{n_1}{n_1 + n_2} \tag{11}$$

Here, n_1 is the number of moles of the solvent and n_2 the number of moles of ideal solute. Values of water activity range between 0 and 1. The majority of microorganisms known grow well only at values between 0.9 and 1.0 (Nichols et al., 1999), as they are commonly found in aquatic and soil environments. Freshwater media used for routine cultivation usually have a_w values ≥0.99, whereas seawater (3.5% NaCl) has a value of approximately 0.98. Salt lakes in which *Halobacterium* and *Halococcus* thrive are saturated with NaCl, and a_w values are around 0.75. The lowest value reported at which growth of microorganisms still occurs is 0.61 for the xerophytic fungus *Xeromyces bisporus*, which can grow on dry foods.

Since the chemical potential of water μ_w is determined by the chemical potential of the pure solvent μ_w° and the water activity by

$$\mu_w = \mu_w^\circ + RT \ln a_w \tag{12}$$

(where R is the gas constant and T the absolute temperature), higher concentrations of solutes decrease the chemical potential of water. Most prokaryotes maintain an internal activity of water lower than that of the surrounding medium. At the same time, the cytoplasmic membrane is highly permeable to water, and bacteria have a high surface-to-volume ratio. Essentially, the chemical potential of intracellular water must be equal to that outside. As a result of the lower intracellular water activity, a tendency exists for water to enter the cell. The direct consequence is osmosis, defined as diffusion of solvent (water) through a semipermeable membrane in the direction of a decreasing chemical potential of the solvent. During this process, the free enthalpy of the entire system decreases.

Osmotic pressure π is the hydrostatic pressure (in MPa) that must be applied to a solution of lower chemical potential of the solvent to stop net diffusion of solvent through the semipermeable membrane

$$\pi \cdot V^\circ_w = -RT \cdot \ln a_w \tag{13}$$

with V°_w being the partial molal volume of water. In diluted solutions, equation (13) can be simplified (with $N_2 = n_2/(n_1 + n_2)$; $\ln a_w = \ln(1 - N_2) - N_2$; and $n_2 << n_1$):

$$\pi = \frac{R \cdot T}{V^\circ_w} \cdot N_2 \approx \frac{R \cdot T}{V^\circ_w} \cdot \frac{n_2}{n_1} = R \cdot T \cdot c_2 \tag{14}$$

where c_2 denotes the concentration of the solute. Hence, a concentration of 0.1 M of a solute at 25°C results in an osmotic pressure of 2.48 bar or 0.248 MPa. If n different solutes are present, the osmotic pressure amounts to

$$\pi = R \cdot T \cdot \sum\nolimits_i^n c_i \tag{15}$$

The presence of a cell wall permits bacteria to maintain the intracellular osmotic pressure, termed "turgor pressure." Maintenance of this turgor pressure is essential for the growth and division of the prokaryotic cell. It is therefore understandable that bacteria regulate their turgor pressure over a wide range of extracellular values of a_w. Gram-negative bacteria have turgor pressures of 0.3–0.6 MPa, while Gram-positive bacteria such as *Bacillus* sp. maintain a turgor pressure of up to 2 MPa (Reed and Walsby, 1985; Overmann et al., 1991; Ingraham and Marr, 1996; Lengeler et al., 1999).

Two major strategies have been found by which prokaryotes adjust intracellular a_w during changes of extracellular salt concentrations. Aerobic, extremely halophilic Archaea (Halobacteriales) and anaerobic, halophilic bacteria (Haloanaerobiales) accumulate inorganic ions, especially K^+ and Cl^- (Oren, 1986; Oren, 1999; Galinski and Trüper, 1994). As a special adaptation to the resulting high intracellular ion concentrations, these prokaryotes contain salt-adapted or even salt-requiring enzymes that contain a large fraction of polar and acidic amino acids (especially aspartate and glutamate), but only a low fraction of hydrophobic amino acids. Aspartate and glutamate residues bind intracellular water especially well. Consequently, correct folding of these enzymes occurs despite low intracellular water concentrations (Oren, 1999).

At lower external osmolalities (≤1 Osm), turgor pressure in *E. coli* is also mainly regulated by increasing intracellular K^+ concentrations (and its counterion, glutamate) parallel to an increase in external osmolality. The intracellular concentration of Na^+ does not vary directly with external osmolality, and intracellular concentrations of the divalent polyamine putrescine are reduced by excretion of this compound into the medium, thereby decreasing the intracellular concentration from 50 to 5 mM. It has been suggested that putrescine bound to nucleic acids is displaced by high K^+ concentrations (Csonka and Epstein, 1996).

As a second type of osmoregulation, small soluble organic molecules are accumulated upon an increase in extracellular salt concentrations. This type is found widely distributed among bacteria. The solutes accumulated do not strongly interfere with cellular metabolism and have thus been termed "compatible solutes" (Brown and Simpson, 1972; Brown, 1976). In addition, these molecules stabilize cellular proteins and increase their solubility (Cayley et al., 1992; Bolen, 2001). Thus, *E. coli* cells accumulate trehalose (*O*-α-D-glucosyl[1→1]-α-D-glucoside), accompanied by a reduction in the concentration of K^+ and glutamate. It has been suggested that this decrease in ionic strength relieves the inhibition of transcription and translation and that the cytoplasmic membrane is stabilized by interaction of compatible solutes with the polar head groups of the phospholipids (Ingraham and Marr, 1996). Various compatible solutes, zwitterionic derivatives of amino acids, sugars or polyols, have been identified and include proline, glutamate, glutamine, alanine, α-aminobutyrate, glycine betaine (*N*,*N*,*N*-trimethylglycine), ectoine, N^{ε}-acetyl-β-lysine, N^{δ}-acetyl-ornithine, β-dimethylsulfoniopropionate, sucrose and choline (Csonka and Epstein, 1996). Some of these, especially proline, glycine betaine, and choline, are also termed "osmoprotectants," since they can be added to the growth medium where they are taken up by the bacterial cells and alleviate osmotic stress effects through direct interactions with intracellular macromolecules. It has also been proposed that glycine betaine increases the fraction of free water in the cell and it is believed that osmoprotectants stabilize and protect enzymes by being excluded from the protein surface (Cayley et al., 1992). Thus, tolerance of *E. coli* towards high external osmolalities can be increased further by the addition of osmotic protectants such as proline, glycine betaine, choline (which is metabolized to glycine betaine), trimethyl-γ-aminobutyrate, β-alanine betaine, taurine betaine, carnitine, or even MOPS (3-[*N*-morpholino] propanesulfonic acid) to the growth medium (Csonka and Hanson, 1991). The latter is a buffer commonly used in growth media, which has been shown to accumulate in *E. coli* at high osmolality (Cayley et al., 1989). Glycine betaine is the most effective osmotic protectant of *E. coli* and *Salmonella typhimurium*. Accumulation of glycine betaine reduces the concentration of endogenous trehalose as well as ionic solutes.

The osmoregulatory potential varies between microorganisms, which can be divided according to their osmotic tolerance. This classification has been used most often for NaCl tolerance. Nonhalophiles thus are organisms capable of growth at NaCl concentrations of >0.2 M, whereas moderate halophiles and marine species usually grow from 0.2–3.5 M NaCl, and extreme halophiles grow from 1–5.5 M NaCl (Kushner, 1978; Yancey et al., 1982; Epstein, 1986; Imhoff, 1986; Larsen, 1986).

Temperature

Prokaryotes can grow at temperatures between –10 or even lower (Morita, 1975; Baross and Morita, 1978; Mazur, 1980; Carpenter et al., 2000) and +113°C (in the case of the archaeon *Pyrolobus fumarii*; Blochl et al., 1997; Stetter, 2001). The upper limit for microbial growth is suggested to be between 110 and 150°C owing

to constraints on the thermostability of several essential cell components. The half life for ATP under these conditions is <1 second, and it is ~1 millisecond for polynucleotides (Bernhardt et al., 1984; White, 1984; Jaenicke, 1988). At the other extreme, bacterial activity has been shown to proceed at –17°C (Carpenter, 2000), and microbial life has been discovered below 3500 m of ice in the Antarctic subglacial Lake Vostok (Price, 2000). Individual strains can grow over a temperature range of 10 to maximally 60°C (usually 30–35°C; Wiegel and Ljungdahl, 1986; Brock, 1987; Wiegel, 1990). On the basis of their minimum, optimum, and maximum temperatures for growth (the so-called "cardinal temperatures T_{min}, T_{opt}, T_{max}"), organisms are currently divided into four major groups: psychrophiles (T_{opt} ≤20°C), mesophiles (T_{opt} between 20 and 42°C), thermophiles (T_{opt}, 42–70°C) and hyperthermophiles (T_{opt}, >70°C). In addition, the term "psychrotolerant" (previously "psychrotrophic") has been coined to describe those prokaryotes capable of growing at temperatures between 0 and 5°C but reach maximum temperatures of growth exceeding 25°C (Morita, 1975). Different temperature ranges for psychrophilic and psychrotolerant prokaryotes have been used, however (Isaksen and Jørgensen, 1996).

Generally, the optimum temperature for growth is only a few °C lower than T_{max}. Consequently, it is advisable to perform routine cultivation at incubation temperatures below T_{opt}. It is very difficult to determine the minimum growth temperature, as doubling times can become extremely long at the low end of the temperature range.

As a rule of thumb, the rate constants of chemical reactions increase by a factor of about 2 (the so-called "Q_{10} value;" range, 1.5–4) when the temperature is increased by 10°C. This exponential dependence on temperature exists for biochemical reactions (e.g., firefly bioluminescence reaction) and likewise for microbial metabolism (e.g., sulfate reduction; Bak and Pfennig, 1991; Isaksen and Jørgensen, 1996) and microbial growth. Hence, the specific growth rate doubles with a 10°C increase in temperature for many bacteria. Like rate constants of chemical reactions, the temperature dependence of the microbial growth rate between the minimum and optimum temperature can be described by the Arrhenius equation (Arrhenius, 1889):

$$\mu = A \cdot e^{-\frac{E_o}{R \cdot T}} \tag{16}$$

in which μ represents the specific growth rate, E_a the activation energy, R the gas constant (8.31 $J \cdot K^{-1} \cdot mol^{-1}$), T the temperature (in K), and the constant A the collision or frequency factor (in h^{-1}), which in chemical reactions describes the collision frequency and orientation of reacting molecules. If applied to bacterial growth or physiological activity, E_a does not represent activation energy in the chemical sense, but rather a measure of the temperature response of the bacteria. Consequently, E_a has sometimes also been termed "the temperature characteristic" (King and Nedwell, 1984). This equation permits an assessment of the temperature dependence of growth or physiological activity within certain limits. If the logarithm of μ is plotted versus the reciprocal of T, a straight line is obtained with a negative slope of $-E_a/2.303 \cdot R$ (Ingraham, 1962; Harder and Veldkamp, 1971; Ratkowsky et al., 1983):

$$\ln \mu = -\frac{E_a}{R} \cdot \frac{1}{T} + \ln A \tag{17}$$

Typical E_a values for the specific growth rate or the physiological activity of bacteria are in the range of 23–132 $kJ \cdot mol^{-1}$ (Bak et al., 1991; Ingraham and Marr, 1996; Knoblauch et al., 1999b). On the basis of equation (3), the Q_{10}-value can be calculated according to:

$$Q_{10} = \exp\left[\frac{E_a \cdot 10}{R \cdot T(T+10)}\right] \tag{18}$$

At the low, and especially at the high, temperature end, the data of the logarithmic plot of log μ versus T^{-1} deviate from linearity. In the case of psychrophiles, the slope of the Arrhenius plot is linear down to 0°C, whereas for psychrotolerants, it deviates from linearity at about 5°C, and for mesophilic bacteria, it tends to deviate from a straight line at even higher temperatures (Harder and Veldkamp, 1971). At high temperatures, the growth rate decreases sharply due to the thermal inactivation of enzymes and disruption of the membrane structure. It should be mentioned that alternative models for the relationship between temperature and growth rate constant have been developed which fit the experimental data of many bacterial strains more precisely (Ratkowsky et al., 1983).

One important factor that determines minimum and maximum temperatures for growth is the fluidity of the membrane lipids, affected particularly by the ratio of monounsaturated and saturated fatty acids, their length, and by proportion of cyclic fatty acids (Russel, 1984; Herbert, 1986; Russel and Fukanaga, 1990; Jones et al., 2002). For example, if the viscosity of the membrane cannot be maintained within certain limits, it may ultimately become leaky to ions at high temperatures. A second factor is the solute transport capability of the membrane (Baxter and Gibbons, 1962; Rose and Evison, 1965), which is dependent on its fluidity. Thirdly, the forces governing the formation of proper tertiary and

quartenary structure of proteins (Jaenicke, 1988) limit bacterial growth especially in the high temperature range. The first enzyme inactivated (e.g., homoserine transsuccinylase in *Escherichia coli*; Ingraham and Marr, 1996) determines T_{max}. Hence, the latter can be increased when the product of this critical enzyme is supplied exogenously (methionine in *E. coli*). Several lines of evidence suggest that the inability to initiate translation and hence to synthesize protein determines the minimum temperature for growth (Ingraham and Marr, 1996). Finally, an important factor determining maximum and minimum growth temperatures is the temperature sensitivity of regulatory mechanisms, which in case of malfunctioning may cause fatal imbalances in cellular metabolism.

At very high temperatures >80°C, proton circuits can no longer be maintained owing to a high proton permeability of the cytoplasmic membrane. Hyperthermophiles switch to energy coupling via Na^+ since the permeability of the membrane to this ion is less affected by high temperature (Lengeler et al., 1999). Also, the pattern of proteins changes significantly with growth temperatures outside the normal range. Changes that occur at higher temperatures are under the control of the heat shock response. About 20 proteins, many of them molecular chaperones or proteases, exhibit a large (10- to 20-fold) but transient increase in synthetic rate upon temperature upshift (Gross, 1996).

In mesophilic bacteria, a specific group of 14 cold shock proteins (none of which is a heat shock protein) is produced during the period of growth cessation following a shift from 37 to 10°C in *E. coli* (Graumann and Marahiel, 1996). Considerable evidence suggests that the inability to synthesize protein determines the minimum temperature of growth in *E. coli* and that the sensitive step is the initiation of translation (Ingraham and Marr, 1996; Graumann and Marahiel, 1996). Additional limiting factors of growth at low temperature are the fluidity of the cytoplasmic membrane and rate of local melting of DNA by RNA polymerase (Graumann and Marahiel, 1996). In psychrophiles, cell membranes tend to contain more unsaturated fatty acids and short-chain fatty acids than membranes of mesophiles (Bhakoo and Herbert, 1979; Chan et al., 1971). Finally, the affinity for substrate uptake is decreased at low temperatures (Nedwell and Rutter, 1994). Psychrophiles synthesize enzymes with high catalytic activities at low temperatures (Feller et al., 1994b; Trimbur et al., 1994) and produce more enzymes upon a decrease in temperature (Feller et al., 1994a). The lowest optimum temperature for an extracellular enzyme recovered from a bacterial culture was 20°C for a protease. The corresponding bacterial isolate produced the maximum amount of protease at –1°C, thereby counteracting the effects of very low temperatures on the catalytic efficiency of the enzyme (Huston et al., 2000). Chitobiase and leucine-aminopeptidase in situ even have lower T_{opt} values of 15°C (Huston et al., 2000). Enhancement of the catalytic activity of psychrophilic enzymes generally is attributed to an increased flexibility of some of their structural components, which at the same time leads to a reduction of their thermostability. Cold-active enzymes thus exhibit a pronounced heat lability and sensitivity to protein denaturants (Lonhienne et al., 2000). As another aspect of psychrophily, posttranscriptional modification of tRNA is much less pronounced in psychrophiles than in mesophiles. However, significantly higher levels of dihydrouridine occur in psychrophiles as compared to psychrotolerants or mesophiles (Dalluge et al., 1997). This latter finding has been explained by the high conformational flexibility, which is maintained by a high dihydrouridine content of tRNA molecules.

Not only the overall specific growth rate, but also the physiology of a given strain changes upon changes in incubation temperature. Examples are the formation of different fermentation products (Jung et al., 1974), change in yield and maintenance coefficients (Brooke et al., 1989), altered specific extracellular xylanase activity (Suh et al., 1988), changes in the affinity for H_2 and acetate consumption by *Methanosarcina barkeri* (Westermann et al., 1989), changes in the content of unsaturated or branched fatty acids in membrane lipids (Russel, 1984; Kaneda, 1991), and formation of secondary metabolites like pigments, e.g., prodigiosin formed only below 30°C by *Serratia marcescens* (Burkhardt, 1992). Thus, different enzymes in one and the same prokaryotic strain appear to exhibit considerable differences in thermostability.

Over 80% of the biosphere is permanently below 5°C, which is mainly due to a rather constant temperature of about 2°C in two thirds of deep ocean water (Graumann and Marahiel, 1996). Chemostat experiments and isolation attempts suggest that nutrient cycling in the maritime Antarctic may be due to the activities of psychrophilic bacteria (Herbert, 1986). Evidence has been obtained for low rates of bacterial DNA and protein synthesis, which indicates that bacteria clustering with the *Deinococcus-Thermus*-group are metabolically active at ambient subzero temperatures of –12 to –17°C (Carpenter et al., 2000). If some simple procedural precautions are observed, psychrophilic microorganisms can be readily isolated from natural environments. Besides using precooled pipettes, media, diluents, etc., the inoculum should not be exposed to lethal temperatures

above 20°C (room temperature). Isolates obtained belong to the low G+C Gram-positive bacteria, high G+C Gram-positive bacteria, α-, β-, γ- and Δ-subclasses of the Proteobacteria (and include purple nonsulfur bacteria, methanotrophs and sulfate-reducing bacteria), and the *Cytophaga-Flavobacterium* group (Bowman et al., 1997c; Gosink and Staley, 1995; Knoblauch and Jørgensen, 1999a; Knoblauch et al., 1999b; Madigan et al., 2000a). An overview of the diversity of recently described psychrophilic bacteria is presented in Table 6.

Most temperate environments, like deeper parts of the water column of lakes and deeper soil strata, are permanently below 20°C. It therefore appears possible that bacteria in these environments are adapted to these lower temperatures. Indeed, first experiments indicate that the fraction of lake water bacteria growing in artificial liquid media reaches maximum values at 16°C (Bussmann et al., 2001). Hence the preferred temperature used for enrichments of freshwater or marine planktonic bacteria is 15°C. Some psychrotolerant bacteria have been isolated from packed food after storage at 2–4°C for several weeks (Broda et al., 2000; Kato et al., 2000). Like psychrophilic bacteria, psychrotolerants also fall in various phylogenetic groups such as low G+C Gram-positive bacteria (including acetogens; Nozhevnikova et al., 2001), high G+C Gram-positive bacteria, Proteobacteria, but also methanogenic archaea (Nozhevnikova et al., 2001; Table 6). Sulfate-reducing bacteria isolated from cold sediments are psychrotolerants with respect to growth rate and show a T_{opt} of 18–19°C, whereas the maximum growth yield was attained at much lower temperatures of 0 and 12°C (Isaksen and Jørgensen, 1996). However, the sulfate-reducing activity of bacteria in Antarctic sediments had a temperature optimum well above the in situ temperature, exhibiting a mesophilic response (Isaksen and Jørgensen, 1996). Consequently, the temperature response of a given bacterial strain cannot be judged solely on the basis of respiratory activity or growth rate alone.

Hydrostatic Pressure

Besides temperature, osmolarity and pH, hydrostatic pressure has been shown to directly influence the growth of prokaryotes. Hydrostatic pressure is a decisive environmental variable in the deep sea. At nearly 11,000 m, the Challenger Deep is the deepest known oceanic site where pressure values greater than 100 MPa (1000 atm) exist. Since the oceans cover about 71% of the earth's surface at a mean depth of 3700 m, the high-pressure, cold habitat (37 MPa, ≤5°C) represents the largest portion of the biosphere by volume.

As early as 1872, the Challenger expedition definitely revealed the occurrence of living material from depths of at least 8000 m. Twelve years later, the bacteria found in samples from the deep sea were shown to be more pressure tolerant than terrestrial species (Marquis and Matsumura, 1978). These findings have now been rigorously confirmed. Barophilic microorganisms, recently also termed "piezophilic," are defined as those well adapted to growth at high pressure (ZoBell and Johnson, 1949; Jannasch and Taylor, 1984), and hence they exhibit optimum growth rates at elevated pressures. Barophilic prokaryotes are usually found below a depth of 2000 m in the ocean. At high hydrostatic pressures and 2°C, doubling times as short as 7 hours have been observed (Yayanos, 1986). Obligate barophiles grow only at pressures exceeding 0.1 MPa (1 atm). In studies of more than 100 bacterial strains from depths between 2000 and 7000 m, obligate barophily has been detected only in isolates from ≥ 6350 m (Yayanos, 1986). The maximum pressure permitting growth of an obligate barophile was determined as 115 MPa (Deming et al., 1988). Some barophilic bacteria grow at pressures >100 MPa (in one case even 130 MPa, a value reached nowhere in the ocean; Yayanos, 1986). Many abyssal and hadal prokaryotes were shown to be barophilic (Yayanos, 1986). On the contrary, barotolerant microorganisms, which are also abundant at great depth, grow fastest at 0.1 MPa and more slowly as hydrostatic pressure is increased. Barophilic bacteria isolated from the deep sea are also psychrophiles (T_{opt} 8–10°C). However, the maximum temperature of growth (T_{max}) is higher at high pressure (Yayanos, 1986). On the other hand, barophilic bacteria show barotolerant properties if cultured not at 10–15°C, but at 4°C, which corresponds to the actual temperature of their environment, and decreasing substrate concentrations induce a more efficient barophilic response in certain deep-sea psychrophiles (Wirsen and Molyneaux, 1999).

Pressure-retaining devices have been designed which allow the sampling of barophilic prokaryotes without decompression (Jannasch et al., 1976; Yayanos, 1978). Phylogenetically, many barophilic bacteria fall in the γ-subclass of Proteobacteria (DeLong et al., 1997). The major genera of cultivated barophiles include the γ-proteobacterial genera *Shewanella*, *Photobacterium*, *Colwellia*, and *Moritella*. In addition, members of other physiological and phylogenetic groups have been described, e.g., the sulfate-reducing *Desulfovibrio profundus* (Bale et al., 1997). Most characterized barophiles are thus closely related to shallow-water marine bacteria. Most of the prokaryotes isolated are also psychrophiles and some are capable of growing at

Table 6. Some psychrophilic and psychrotolerant bacteria described to date.

very low nutrient concentrations (Deming and Colwell, 1985; Deming, 1986). The latter observation indicates that barophiles are not confined to nutrient-rich niches, such as fecal pellets and inside higher organisms, but are also found free in the water column and in the sediment. Since at least some barophilic prokaryotes are oligotrophs, high-pressure continuous culture techniques had to be developed which now permit a study of barophilic prokaryotes at pressures of up to 71 MPa and at low and precisely controlled nutrient concentrations (Jannasch et al., 1996; Wirsen and Molyneaux, 1999).

High pressures affect different aspects of cell structure and metabolism, such as membrane structure, transcription, translation, and the quartenary structure of enzymes, and hence their activity (Marquis, 1976; Marquis and Matsumura, 1978; MacDonald, 1984; DeLong and Yayamos, 1986; Morita, 1986; Wirsen et al., 1987; Jaenicke, 1988; Somero, 1992; Welch et al., 1993). On the basis of direction of the change in molecular volume, biochemical reactions can be slowed down or accelerated. In fact, increased hydrostatic pressure can accelerate the fructose bisphosphate reaction in a barophilic organism, while decreasing it in a non-barophilic one (Hochachka et al., 1972). However, most of the biological reactions are slowed down at pressures of 30 MPa or more (Ingraham and Marr, 1996). *Escherichia coli* are moderately barotolerant and withstand a maximum pressure of 56 MPa in complex medium. Five MPa cause a detectable decrease in growth rate. The pressure sensitive steps are polysome formation (Schultz et al., 1976) and translocation. Genetic changes in ribosome structure can increase the barotolerance of *E. coli* (Ingraham and Marr, 1996).

The molecular adaptations required for barophily are largely unknown. Changes in membrane fluidity (which is negatively influenced by high pressures) are known to occur through changes in the ratio of unsaturated over saturated fatty acids in membrane phospholipids (MacDonald, 1984; DeLong and Yaymos, 1986; Wirsen et al., 1987), similarly to responses to temperature changes. The barophilic bacterium *Photobacterium profundum* strain SS9 preferentially synthesizes a 37-kDa protein, designated "OmpH," in response to an elevated pressure of 290 atm (29 MPa). On the basis of amino acid sequence comparison, OmpH is an outer membrane porin and possibly especially adapted to a high pressure (Bartlett et al., 1989), and it may represent a member of a high-pressure regulon (Bartlett and Welch, 1995). Control of the abundance of OmpH is probably regulated at the transcriptional level. Unusual putative regulatory sequences have been found upstream of the *ompH* gene (Bartlett et al., 1993; Bartlett and Welch, 1995). In addition to hydrostatic pressure, OmpH is induced by carbon starvation and subject to catabolite control (Bartlett and Welch, 1995). Additional pressure-regulated operons have been identified, and for instance comprise, a gene involved in the assembly of the cytochrome *bd* complex (Li et al., 1998). Alternative RNA polymerase σ factors (e.g., the *rpoE* gene product) and modifiers are involved in genetic regulation by hydrostatic pressure (Chi and Bartlett, 1995; Nakasone et al., 1998).

Treatment of Growth Media

Types of Culture Media

Conventional bacteriological culture media are provided as either liquid broths or solid media. Liquid media are used in studies of growth and metabolism in which homogenous media conditions are mandatory. Usually, optical density can be followed easily in liquid media and subsamples for the analysis of substrates and metabolic products can be withdrawn. In addition, many bacteria, especially from planktonic samples, do not appear to grow on solid media and have to be isolated in liquid dilution series. To maintain an adequate supply of oxygen, cultures of aerobic prokaryotes need to be shaken vigorously, leaving a large head space (gas phase volume).

Solid media were originally designed for the enumeration and isolation of bacteria, but are now also used routinely for general culture work. On solid media, colony morphology and other properties (such as swarming over the agar surface) can be easily observed. Extracellular enzymes originating from the cells but diffusing into the surrounding non-colonized media can be detected as a result of their action on insoluble substrates (cellulose, starch, and lipid emulsions), which can be maintained evenly distributed in solid as opposed to liquid media. Hydrolysis of starch can be visualized after flooding plates with iodine, since only the intact starch molecules produce the characteristic deep-blue to purple color. Lipids can be stained with Sudan black. Furthermore, the effects of antibiotic substances on colony growth can be tested on solid media. Solidifying agents include agar, Gelrite and silica gel. Agar is used most frequently and is sulfated polygalactans (D-galactose and 3,6-anhydrogalactose linked by $1 \rightarrow 3$ and $1 \rightarrow 4$ bonds) produced by marine red algae of the genera *Gelidium*, *Pterocladia* and *Gracilaria*. This polymer is degraded by only very few bacteria such as some *Cytophaga*, *Pseudomonas* and *Vibrio* spp. Unusual is the large difference between the temperatures for melting (~100°C) and solidification (~40°C).

Consequently, many temperature-sensitive constituents of the media, e.g., vitamins, may be added at temperatures slightly above 40°C. Agar-containing media should not be adjusted to pH values <6.0 before sterilization, because the agar may be hydrolyzed. If lower pH values are required, the adjustment should be done by aseptic addition of acid after heat treatment or, alternatively, solid silica gel media should be used. Agar may contain variable amounts of impurities such as Ca, Mg, and other minerals (Bromke and Hammel, 1987). One means of reducing soluble nonpolymeric contaminants is the repeated washing in distilled water (e.g., five times in double-distilled water, using 300% of the final volume; Widdel and Bak, 1992). Alternatively, agar has been purified by subsequent extraction with acetone and ethanol. For direct plating of oligotrophs from the marine environment and if even the washed agar inhibits growth, a glass filter may be used as a substitute.

Gellan gum (or Gelrite, Phytagel, Sigma-Aldrich) is another alternative for solidification of microbial media. Harris (1985) proposed gellan gum as an agar substitute since agar at high concentrations may be toxic to methanogens. Gellan gum (which is produced by strains of *Sphingomonas* spp.) is an anionic acidic heteropolysaccharide consisting of glucose, glucuronic acid and rhamnose. Gellan gum overcomes some of the toxic effects that agar has on some groups of microorganisms (Ferris et al., 1996; Liesack et al., 1997) and starts to solidify upon addition of Ca^{++}; the concentration of divalent cations influences gel strength and solification temperature (Bast, 2001).

Silica gel media have been developed for use when solid media free of any organic contamination are needed, low pH is desired, or agar-degrading microorganisms are to be cultivated (Funk and Krulwich, 1964; Bast, 2001).

Media may affect the growth of microorganisms nonselectively or selectively. Selective media favor the growth of only some bacteria by the inclusion of a particular substrate as a carbon/energy source, by the presence or absence of specific nutrients (e.g., nitrogen or vitamins), or by the presence of compounds with differential toxicity. Inhibitory compounds include: 1) antibiotics with rifampicin (2.4), kanamycin (5.0), erythromycin (50), penicillin (50), tetracycline (100) and fosfomycin (100 [maximum concentrations in $mg \cdot liter^{-1}$]) acting against bacteria, and cycloheximide (100), tunicamycin (0.25), colchicine (20) or cordycepin (25) inhibiting eukarya; 2) dyes (such as crystal violet, methylene blue, or brilliant green) inhibit many Gram-positive bacteria; 3) high concentrations of glycine and LiCl, which permit the growth of many staphylococci but not that of physiologically similar other bacteria; 4) bile salts, which permit the growth of enteric bacteria but not that of many other bacteria; and 5) bromoethane sulfonate (BES) for inhibition of methanogenic archaea, or sodium molybdate for the inhibition of sulfate-reducing bacteria.

Selective media are especially used for the isolation, detection and recognition of pathogenic bacteria from mixed cultures, but are equally important for the isolation of selected groups of slow-growing bacteria from environmental samples. In a strict sense, however, all media are at least slightly selective.

Differentiating media are designed to distinguish one type of microorganism from another in a mixed culture. A differentiating medium contains a special ingredient that changes during growth of a certain type of bacterium. They are designed to differentiate between morphologically or physiologically similar microorganisms (e.g., hemolytic reaction on blood agar, urease, production of acetoin, and reduction of tellurite). Differentiating media can be selective or nonselective.

Assay media are used for the quantification of organic substances such as vitamins, amino acids, and growth factors in bioassays, in which the growth response of a certain organism requiring the factor is directly proportional to the concentration of the factor under investigation.

Media Preparation and Sterilization

Heat-labile supplements such as serum, vitamins, or growth factors (e.g., freshly prepared yeast extract or fermented rumen fluid) are added to the basal medium after sterilization to avoid deterioration. This is also a recommended practice for compounds that might react with other medium ingredients during autoclaving. Glucose and other sugars, when autoclaved with salts such as phosphate, may form inhibitory sugar phosphates. The carbonyl groups of reducing sugars react with free amino groups of primary amines and may result in the formation of toxic Maillard reaction (or "browning" reaction) products such as furfurals or furaldehyde. Oxygen or oxidation products accelerate Maillard reactions. Reducing agents such as cysteine and sulfide will be oxidized by other medium ingredients during autoclaving and form toxic radicals (Carlsson et al., 1979; Cypionka et al., 1985) and thus have to be added separately afterwards. The formation of mineral precipitates (e.g., struvite or $MgNH_4PO_4$; Schink et al., 2002) can often be avoided by separate sterilization of solutions of the calcium, magnesium, and/or iron salts, which are added to the cooled medium. Addition of chelating agents such as EDTA helps to prevent the precipitation in some cases.

In many instances the microelements are present in adequate amounts as contaminants of the mineral salts used in media or as contaminants of glassware and water. In several cases, however, microelements need to be added separately to the growth media. Dispensing of media is usually carried out after cooling to below 50°C to avoid formation of condensation.

Treatments can be distinguished on the basis of their effect on total and viable cell numbers with exposure time. Bacteriostatic substances inhibit growth of bacterial cells, while total cell numbers and the viable cell count (determined, e.g., by plating of cells after diluting out the inhibitory substance) remain constant. Bacteriocidal compounds lead to a decrease, hence an irreversible damage, of viable cells, while total cell numbers remain constant. Finally, bacteriolytic compounds lead to a decrease in viable as well as total cell numbers owing to prokaryotic cell lysis.

Sterilization—the complete inactivation or removal of microorganisms—is achieved by applying heat or irradiation (physical methods) or by treatment with toxic compounds and gases (chemical methods). Gases and liquids can also be sterilized by filtration through filters with extremely small pores (preferably ≤0.1 μm). Disinfection is a procedure that results in the inactivation of only a fraction of the microbial population from an object or from a culture and is most often used to inactivate pathogens. When a pure culture is exposed to a lethal agent, the kinetics of death are exponential, i.e., when the logarithm of the number of survivors (usually determined by counting colony-forming units on a suitable medium) is plotted against time, a straight line is obtained whose downward slope is called the "death rate." The time course of killing is described by the *D*-value, which gives the decimal reduction time, i.e., the time it takes for a 10-fold reduction in the microbial population at a particular temperature. The *Z*-value is the number of degrees that the temperature must be raised to reduce the *D*-value 10-fold, hence

$$Z = \frac{T_1 - T_2}{\log D_1 - \log D_2} \qquad (19)$$

The actual number of survivors is then determined by the initial size of the population and the death rate. Differences exist among microbial species in their resistance to heat, radiation, and other treatments. Hence, sterilization procedures need to be designed to kill the most resistant forms of life, namely the endospores of Gram-positive bacteria. Of the latter, *Moorella thermoacetica* forms unusually heat-resistant endospores which reach decimal reduction times of up to 111 min at 121°C (Byrer et al., 2000). Consequently, purified suspensions of bacterial endospores are used as indicators for the effectiveness of the sterilization process. Routine sterilization procedures are designed to provide a wide margin so that the chance of having even a single survivor is less than one in a million.

Direct heat, dry heat, and moist heat are the three most common methods of sterilization. For sterilization by direct heat, objects are exposed to an open flame, and the adhering microorganisms are quickly burned. Small equipment such as inoculating needles and loops, forceps, open ends of culture tubes, and Pasteur pipettes are routinely flame-sterilized. In addition, combustion is the method of choice for destruction of disposables and contaminated wound dressings in hospitals. When employing a bunsen burner for sterilization, it has to be kept in mind that air supply must be regulated such that the flame generated is completely blue (not yellow-orange) and that the point where the highest temperature is reached is found atop of the inner (dark-blue) cone within the flame. A yellow color of the flame indicates the presence of sooty particles, hence incomplete combustion and lower temperatures. Dry heat is used to sterilize empty glassware and other heat-resistant objects such as laboratory instruments, surgical tools, glass syringes, needles, mineral oils, and dry powders of heat-stable substances and involves baking at 170°C for 2 hours in a hot-air oven. The objects should be protected from subsequent contamination by wrapping them in aluminum foil prior to sterilization.

Obviously, dry sterilization cannot be used to sterilize liquids, which would boil at temperatures above 100°C at atmospheric pressure. Also, the method is not suited for the sterilization of heat-sensitive materials such as cotton wool, plastics and rubber. In addition, heat conduction is less rapid in moist air and dried bacterial cells and spores intrinsically have a higher heat resistance than wet cells and wet spores, which makes sterilization by dry heat a more time-consuming process. Therefore, moist heat is the most effective and most commonly used method for sterilization. Autoclaving denotes a heat treatment with a water-saturated atmosphere under pressure. In principle, the autoclave represents a type of pressure cooker in which a pressure of 1 atm and a temperature of 121°C are reached simply by heating or by inflow of preformed pressurized steam. Only if the autoclave chamber is completely filled with steam can a temperature of 121°C be reached. This temperature, provided a sufficient exposure time is chosen, is sufficient to kill even bacterial endospores. Therefore the temperature has to be monitored when checking the reliability of the sterilization procedure. As a

rule of thumb, 50 minutes of autoclaving are sufficient to sterilize one liter of liquid even when contaminated with endospore-forming bacteria (but compare *Moorella thermoacetica*). After sterilization, the steam is allowed to escape slowly to prevent boiling of liquids, which would otherwise occur upon a sudden drop in pressure.

Pasteurization is a mild treatment with moist heat employed to control spoilage of food products and to extend their shelf life without significant decay of heat-labile constituents such as vitamins. One treatment is the low-temperature-long-time (LTLT) procedure in which, e.g., milk is heated for 30 min at 63°C. In the more frequently used high-temperature-short-time (HTST) or flash procedure, heating lasts for 20 sec at a temperature of 72°C followed by rapid cooling to minimize undesirable changes in taste and nutrient content. Pasteurization reduces the number of viable cells by between 97 and 99% and is intended to eliminate pathogens. It was introduced by L. Pasteur to control the spoilage of wine. However, even vegetative cells of certain non-sporeforming bacterial species, such as *Microbacterium lacticum*, *Enterococcus* spp., and *Coxiella burnetii*, are capable of surviving pasteurization and lead to subsequent food spoilage.

Filtration is the method of choice for the sterilization of heat-sensitive liquids and gases, which are passed through filter material with pores small enough to retain the microorganisms. Membrane filters consisting of mixed cellulose esters, polycarbonate, polytetrafluoroethylene bonded to polyethylene, or polypropylene are most frequently used for sterilization of liquids. Pore size of membrane filters is precisely determined during manufacture and different pore sizes between 0.05 and 12 μm are currently available. Passage time is inversely related to pore-size diameter and permeability can be affected by the chemical or electrostatic properties of the filtrate. In some instances (such as natural water samples containing larger concentrations of dissolved organic matter present in colloidal form), filters will be rapidly clogged. The application of prefilters with larger pore sizes will reduce clogging of the membrane. Certain prokaryotes, such as *Flexibacter* (Little et al., 1987), mycoplasmas, or spirochetes, may pass membrane filters. For safe sterilization, 0.1 μm pore-size membrane filters should be employed since the cells of some prokaryotes are known to have diameters of around 0.2 μm. In most cases, viruses cannot be removed by filtration, however. Depth filters clog less rapidly and are therefore frequently used for the clarification of liquids. Depth filters consist of a matrix of randomly oriented fibers bound together in a tortuous maze of flow channels. However, depth filters differ considerably from membrane filters since organisms are trapped within the matrix and gradually go through and hence eventually contaminate the filtrate. This is not the case for dry (sterilized) cotton plugs which therefore can be employed for the sterilization of gases. Also, high-efficiency particulate air filters (HEPA) have become available commercially for the filtration of large volumes of air, e.g., to supply clean rooms or laminar-flow cabinets. Also, glass pipettes plugged with cotton wool or plastic pipet tips equipped with sterile filters should be used in the laboratory, especially where dealing with medically important bacteria.

Chemical sterilization is the method of choice for sterilizing solid objects that cannot be treated without damage by physical methods, such as certain disposable plastic ware, plastic tubing, surgical supplies (sponges), optical equipment, and samples of plant material (if sterile seeds are required; Shockey and Dehority, 1989). While polypropylene plasticware can be autoclaved without problems, polyethylene polymers, polystyrole, and some polysulfonates or polyfluoroethylene materials are more temperature sensitive. Microorganisms are killed by exposing them to toxic chemicals, mostly propylene oxide, β-propiolactone, or the most widely used ethylene oxide (EtO). The latter is an alkylating agent that reacts with hydroxyl-, sulfhydryl, and amino groups in proteins and nucleic acids. Ethylene oxide volatilizes above 10.8°C and sterilization involves an exposure of materials for at least 4 hours to EtO gas in a closed chamber, after which they must be thoroughly flushed for 8–12 hours with sterile inert gas or air. EtO is explosive, flammable, causes skin burns, and is highly toxic. Therefore, nonflammable mixtures of EtO and freon or carbon dioxide with the same microbicidal activity as EtO alone are in use.

For decontamination of laboratory surfaces, clear phenolics and hypochlorites (3%) are most commonly used, but alcohols (ethanol at a final concentration of 70%) or mixtures of alcohols and formaldehyde and iodophores are most effective against spores.

Ionizing radiation is employed in large laboratories for the sterilization of heat-sensitive solid objects such as powdered pharmaceuticals, disposable plastics, or clothing. Because it has the power of penetrating solids, radiation is also used to retard or eliminate spoilage of foods (Murray, 1989). Gamma radiation emitted by a radioactive cobalt source is most commonly applied. A high dose of 2.5 Mrad is sufficient to kill microorganisms, spores, and viruses, but chemical changes in media are possible. Gamma rays interact with water molecules to produce ions (OH^-) and free radicals ($OH^{\cdot}$) that can significantly alter and destroy many different biomolecules in the cell.

Handling of Glassware and Equipment

An important element of the handling of glassware is its proper cleaning. New glassware needs special treatment for the removal of free alkali. Detergents alone often are not sufficient to remove adsorbed compounds that may later inhibit growth especially of fastidious bacteria from natural bacterioplankton. Soaking in 0.2 N HCl often alleviates these problems. Detergents such as Mucasol® have been found to aid in proper cleaning of glassware. Glassware should be rinsed thoroughly with bidistilled water after treatment with detergents, since even traces of the latter are inhibitory to certain bacteria such as certain cyanobacteria or marine oligotrophs (Gottschal et al., 1991).

In extreme cases, in which prokaryotes from oligotrophic environments are to be isolated, it is necessary to rigorously clean water samplers, storage containers, and culture vessels with acid followed by repeated washings with ultrapure deionized or double quartz-distilled water (Waterbury, 1991). Soaking in appropriate detergent for 1 week and subsequent rinsing with especially clean water, followed by 1 week of soaking in 0.5 N HCl and repeated washing with clean water has been recommended for the culturing of cyanobacteria (Waterbury, 1991). At least in some cases, such as cyanobacteria of the genus *Trichodesmium*, special precautions against traces of organic or inorganic contaminants are mandatory (Orcutt et al., 2002). Nonglass systems consisting of Teflon® vessels are used in which natural seawater is sterilized by gentle Tyndalization in a microwave. Furthermore, Millipore Q water is employed for dilution and cultures grown in Nalgene polycarbonate flasks.

Because of the potential danger involved in working with infectious microorganisms, irrespective of their known pathogenic nature, the requirements for sterile working conditions and safe handling of contaminated glassware and equipment should be rigid. All used glassware and other materials should be autoclaved first before unloading in the wash-up room.

Sterile rooms and sterile cabinets supplied with gas, electricity, sterile air, and ultraviolet (UV) irradiation are useful, because they considerably reduce the possibility of air contamination. For the sterilization of inoculation rooms and other work areas, UV irradiation (wavelength, 260 nm) is often applied. Laminar flow (clean air) cabinets are designed to provide a work area that is protected from the environment and are useful for preventing airborne contamination when handling sterile media, such as during aseptically dispensing sterile fluids and culture media. Filtered air is passed in a vertical or horizontal unidirectional (laminar) flow through the cabinet. This air is made sterile by filtering through high-efficiency air filters that can remove particles down to 0.3 μm. In one type of cabinet, the flow of filtered air is directed toward the front. In a second type of cabinet, the flow occurs vertically downward, forming a curtain of sterile air and is subsequently in part recirculated. For decontamination of laminar flow hoods, 3% hypochloric acid can be used. Laminar flow hoods are certified for handling microorganisms of different hazard classes. For handling bacteria from natural samples and with unknown properties, safety class II cabinets should be used.

Removal and Exclusion of O_2, Cultivation of Anaerobes

The fundamental methodology for the cultivation of anaerobic prokaryotes is the Hungate technique (Stewart and Bryant, 1988; Widdel and Bak, 1992). Modifications of the original Hungate technique include the use of butyl rubber stoppers (Hungate et al., 1966) and of serum bottles closed with crimp-closure aluminum seals holding butyl rubber stoppers (Miller and Wolin, 1974), the syringe technique (Macy et al., 1972), and the use of pressurized tubes and vessels for the culture of methanogens (Balch and Wolfe, 1976). Usually, anoxic media contain a bicarbonate-CO_2 buffer system (Table 5), mineral salts, and a reducing agent. Depending on the requirements of the prokaryotes to be cultivated, clarified rumen fluid or low concentrations of yeast extract are added. Resazurin can be used as a redox indicator, provided it does not inhibit growth of the prokaryotes as in the case of many phototrophic sulfur bacteria.

Reductants frequently employed are sulfide or cysteine. A sulfur-free reducing agent is titanium (III) citrate. Owing to complex formation between titanium and citrate, $Ti(OH)_3$-precipitate formation is minimized (Zehnder and Wuhrman, 1976). The solution can be prepared by adding 5 ml of a 15% (w/v) titanium (III) chloride solution to 50 ml of a 0.2 M sodium citrate solution, followed by neutralization with saturated sodium carbonate. Moench and Zeikus (1983) reported an easy method for preparing this reductant with the use of nitriloacetic acid (NTA) instead of citrate as the complexing agent. However, NTA inhibits growth of certain prokaryotes. Furthermore, titanium (III) citrate may be inhibitory to anaerobic prokaryotes at low growth rates (Wachenheim and Hespell, 1984). In cases where organic reducing agents are to be avoided and free sulfide is toxic to the prokaryotes, amorphous ferrous sulfide has been employed as a reducing agent. This reductant can

be easily prepared in the laboratory and reacts much more rapidly with O_2 than does either soluble sulfide or cysteine (Brock and O'Dea, 1977). After preparation, media are dispensed anoxically as described by Widdel and Bak (1992).

Three-electrode poised-potential amperometric culture systems have been developed which consist of a platinum counter electrode, a platinum working electrode, and a AgCl-Ag reference electrode connected to a potentiostat (Emde et al., 1989; Emde and Schink, 1990; Ohmura et al., 2002). These systems can be used to grow anaerobic prokaryotes at a carefully controlled constant redox potential despite continuing redox reactions and flow of electrons to the working electrode. During growth experiments, the redox potential of the growth medium and the electron flow between working and counter electrodes can be recorded.

Even fastidious anaerobic prokaryotes such as methanogenic archaea can now be cultivated on solid agar media, if anaerobic chambers are employed (Leedle and Hespell, 1980). This adaptation of the technique for anaerobes permits the application of replica-plating techniques to ecological and genetic studies of bacterial populations from anaerobic habitats. Sufficient CO_2 (10–20%) should be present in the gas phase to maintain the pH of the medium if a bicarbonate buffer system is used.

Culture Systems

Batch Culture The typical sequence of lag phase, exponential phase, stationary phase (see Prokaryotic Growth) is observed when prokaryotes are grown in batch culture. In this most frequently employed culture system, cells grow suspended in a medium containing sufficient carbon and energy sources and other required nutrients to allow growth at maximum rate for a limited period of time. Since fresh supply of essential components and removal of metabolic waste products do not occur after inoculation, batch cultures are closed systems, and cells grow in a continuously changing environment, which shifts from a nonlimiting supply of nutrients to conditions of starvation. Because of its relative simplicity and ease of operation, the batch culture is nevertheless most widely used as a routine procedure for propagation of bacteria both in research and industry. Various degrees of control can be obtained by regulating important parameters such as pH, temperature, and oxygen tension.

Fed-Batch Culture A further elaboration of the batch cultivation technique was developed especially for certain industrial fermentations (Yoshida et al., 1973; Pirt, 1974; Pirt, 1975). In fed-batch cultures, a continuous supply of fresh medium is fed to a batch culture as soon as the substrate concentrations drop to low (sometimes growth-limiting) levels. As a result, prokaryotic cells continue to grow. Since no medium is allowed to flow out, the culture volume and cell biomass increase. At the same time, the ratio of biomass per amount of nutrients entering the vessel increases such that nutrient limitation becomes more severe over time and the microbial growth rate decreases continuously. Ultimately, fed-batch culture systems provide the means to largely extend the transition between the exponential and stationary growth phases. For some industrial fermentations, these very conditions have proven vital for optimal production of metabolites, e.g., citric acids, penicillin, some enzymes, and alcohols (Yoshida et al., 1973; Esener et al., 1981; Cleland and Enfors, 1983; Gond et al., 1986; Dawson et al., 1988; Kole et al., 1988). Especially for industrial fermentations, the possibility of turning a fed-batch culture into a "repeated fed batch-culture" by withdrawing part of the culture volume at regular time intervals allows the productive growth phase in principle to be extended indefinitely. The major difference with truly continuous culture systems remains that the volume is not kept constant, thus introducing permanent transience in growth rate, which is possibly essential for certain metabolic activities.

Recycling Fermenter, Dialysis Culture, Retentostat, and Recyclostat To overcome the problem of permanently changing volumes and concentrations of metabolic end products, the recycling fermenter was introduced. In this type of fermenter, either complete or partial recycling of the biomass is accomplished, but the culture liquid is continuously replenished with fresh medium and removed at the same rate. This is achieved by a cross-flow type of external membrane that retains prokaryotic cells while allowing spent medium to leave the fermenter (Müller and Babel, 1996; Ahn et al., 2001). Typically, crossflow dialysis membranes with large total membrane areas together with peristaltic pumps are employed for efficient and rapid filtration without clogging of the membrane (Pörtner and Märkl, 1998). This type of fermenter has proven an especially valuable tool to obtain cultures of high cell density since inhibitory metabolic products such as short-chain fatty acids or alcohols are removed. Another important use is to study growth rate dependence of microbial metabolism at very long generation times (i.e., very low specific growth rates; Chesbro et al., 1979; van Verseveld et al., 1984; Chesbro, 1988; Bulthuis et al., 1989; Müller and Babel, 1996). Under natural

conditions, the transition from exponential to stationary phase is expected to occur much more gradually than in conventional batch cultures (Mason and Egli, 1993). Hence physiological properties, such as maintenance energy requirements and resuscitation, of cells at extreme substrate limitation can be studied best in retentostats (Mason and Egli, 1993; Tappe et al., 1996; Tappe et al., 1999). A very simple means of prolonging the transition time between the exponential and stationary phase is through biphasic culture. In this type of culture, a bottom gel layer containing 4% agar is overlain by liquid medium. This arrangement results in a rapid exponential growth based on the nutrients in the liquid, and a subsequent prolonged deceleration phase of growth when cells utilize substrates slowly diffusing out of the agar layer (Chesbro, 1988).

CHEMOSTAT The main difference between continuous culture and other batch-type cultures is that it is a typical open system in which fresh nutrient medium is added at a constant rate to a well-mixed culture while the volume is kept constant through an overflow device (Fig. 3). In general, this culture system is designed to provide a culture growing permanently in an exponential fashion at a constant sub-maximum growth rate. The growth rate is dictated by the rate at which the limiting nutrient is fed to the culture. In this type of arrangement, the continuous culture is termed "a chemostat." In continuous-culture approaches with a chemostat, the continuously changing conditions characteristic of a batch culture are eliminated (Veldkamp and Kuenen, 1973) and relatively large populations of prokaryotic cells with constant physiological state can be maintained in the presence of low concentrations of a limiting nutrient, which resemble those under natural conditions. It has to be acknowledged, however, that in certain natural systems, nutrient supply and cell removal are not closely linked; these environments therefore do not exhibit steady-state conditions (Wirsen and Molyneaux, 1999). Chemostats offer a tremendously powerful tool for studying the physiology and ecology of prokaryotes. Its characteristics render the chemostat one of the most widely used culturing devices for studying microbial metabolism under carefully controlled environmental conditions in both pure and mixed cultures (Tempest, 1970a; Tempest, 1970b; Veldkamp, 1977; Tempest and Neyssel, 1978; Matin, 1981; Kuenen and Harder, 1982b; Gottschal, 1986; Gottschal, 1990; Gottschal and Dijkhuisen, 1988; Overmann and Pfennig, 1992; van den Ende, 1996; van den Ende, 1997).

In a chemostat, growth of prokaryotes is determined by the dilution rate D, defined as the rate of nutrient supply F (dimension: volume per time) divided by the volume of the culture vessel V, and by the concentration of the limiting nutrient in the reservoir medium S_R (Monod, 1950; Novick and Szilard, 1950; Herbert et al., 1956; Tempest, 1970a; Pirt, 1975; Calcott, 1981a; Gottschal, 1990). The combined effect of growth and dilution by the inflowing medium will eventually result in a steady state in which no further change in biomass concentration X occurs:

$$\frac{dX}{dt} = (\mu - D) \cdot X = 0 \qquad (20)$$

At this point, the specific growth rate exactly balances the dilution rate, and therefore a chosen rate of culture dilution fixes the specific growth rate of the culture at a value below μ_{max}. When the specific growth rate is described by the Monod equation (Monod, 1942)

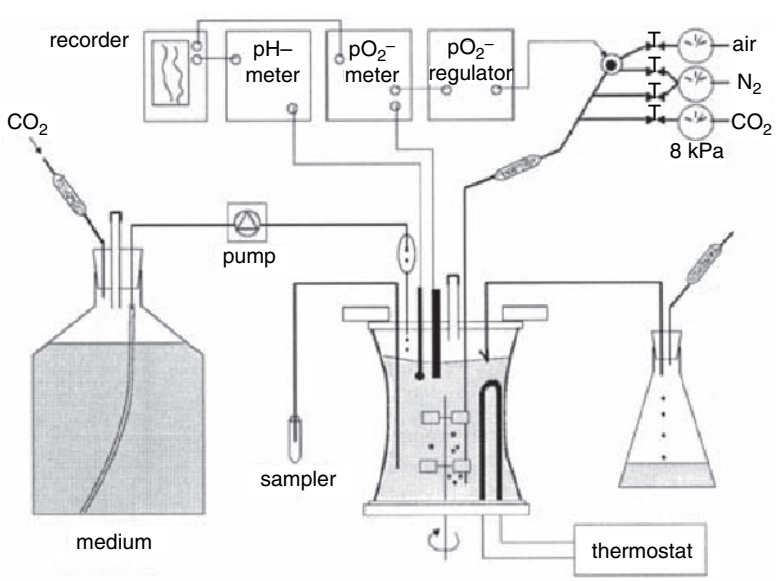

Fig. 3. Example for a chemostat arrangement designed for the continuous cultivation of anaerobic or microaerophilic bacteria. The partial pressure of oxygen can be set to any value between 0 and 21%. A simple regulation of pH is possible by manually controlling the CO_2 flow into the chemostat culture with a high precision needle valve and using a CO_2/bicarbonate buffering system. From Overmann and Pfennig (1992).

$$\mu = \mu_{max} \cdot \frac{S}{K_s + S} \quad (21)$$

in which K_s is the half-saturation constant for growth, the actual substrate concentration S in the culture is fixed at a low, rate-limiting value. In the steady state, the substrate concentration and biomass density are

$$S = K_s \cdot \frac{D}{\mu_{max} - D} \quad (22)$$

$$X = Y \cdot (S_R - S) \quad (23)$$

if the biomass yield Y (the amount of biomass formed per substrate consumed) remains constant over the range of dilution rates employed.

For the optimal production of some microbial metabolites, a continuous culture system is required in which the cells pass through various stages of growth (Ricica and Dobersky, 1981; Thompson et al., 1983; Parkes and Senior, 1988). In these coupled systems, two or more chemostats are arranged serially, by connecting the outlet of the first chemostat to the inlet of the second. Conditions vary between the different chemostat vessels, e.g., with respect to dilution rate, O_2 supply, temperature, or substrate supply. Culturing different prokaryotes in coupled chemostats for instance permits the study of sequential mineralization of recalcitrant organic compounds. Two-stage cascade chemostats are also employed to investigate predator-prey relationships, in which bacteria grown in the first stage are transferred to a second one to serve as food for bacterivorous protozoa (Jost et al., 1973; Swift et al., 1982; Sambanis and Fredrickson, 1987; Simek et al., 1997; Pernthaler et al., 2001).

Even more complex, but rarely used, systems are the bidirectionally linked multistage chemostats, which permit the mutual exchange of bacteria and/or nutrients. In a "gradostat" (Lovitt and Wimpenny, 1981), a series of chemostats (linked by tubing) is fed from both sides with media of different, sometimes complementary, composition. The inoculated bacteria will be exposed to different physicochemical conditions in the different chemostat vessels. In "bidirectional compound diffusion-linked chemostats," the various chemostat vessels are not linked by tubing but through membranes, permitting diffusion of solutes but not bacteria (Keith and Herbert, 1985). Multistage chemostats are especially suited to study prokaryotes under conditions prevailing in the natural habitat, since heterogeneous conditions of environmental parameters and interactions between different species can be reproduced with these systems.

For growth studies at extremely low nutrient concentrations, the chemostat is not a suitable tool since extremely low dilution rates ($<< 0.5\ h^{-1}$) give rise to inhomogeneities due to mixing problems and low steady state biomass concentrations. As a more realistic approach, a retentostat can be employed which offers the advantage of studying physiological properties of cells at extreme substrate limitation (Mason and Egli, 1993; Tappe et al., 1999).

Redox-Controlled Sulfidostat As a special type of continuous culture, the redox-controlled sulfidostat permits the cultivation of phototrophic sulfur-oxidizing bacteria under constant concentrations of hydrogen sulfide (Sánchez et al., 1996). In this type of culture, a constant concentration of sulfide is maintained despite light intensity variations that affect photosynthetic rate and hence sulfide oxidation. A redox controller modulates the rate at which the medium is pumped into the culture and therefore governs the dilution rate. In a similar manner, the system can adjust to new rates of sulfide oxidation caused by changes in light intensity.

Auxostat An essential property of chemostat cultures is that their rate of growth is fixed by the rate at which fresh medium is fed to the culture. Although this rate can be varied over a considerable range of values, steady state cannot be obtained near μ_{max}, and washout of the cells occurs at the critical dilution rate (Pirt, 1975). Furthermore, unbalanced growth (and in some cases washout) may occur when inhibitory metabolites accumulate or potentially toxic substrates are used. An alternative for obtaining controlled growth at an appreciable and constant cell density in such cases is by switching over to some type of internal control of the rate of medium supply. Such a control must be based on a growth-dependent parameter. The first continuous culture with internal control was named "turbidostat" because the feedback control was based on measurements of culture turbidity (Myers and Clark, 1944; Bryson and Szybalski, 1952). However, a continuous and accurate measurement of turbidity represents a major problem in these systems because of wall growth, inhomogeneity of the culture, etc. Therefore, other parameters directly dependent on the culture density are measured with electrodes in more recent systems. Parameters include CO_2, O_2, pH, redox potential, fermentation products, and sulfide (Watson, 1969; Martin and Hempfling, 1976a; Oltmann et al., 1978; Kjaergaard and Jørgensen, 1979; Schauer et al., 1982; Cypionka, 1986; de la Broise and Durand, 1989). These more recent designs have proven reliable and their use is most rewarding in studying growth of microbes in the presence of inhibitory concentrations of substrates or products, and possibly also in selecting mutant strains exhibiting the highest growth rates under such conditions.

Possible Reasons for "Non-culturability"

The titer of colony-forming units obtained from a given sample in almost all cases is significantly lower than the actual titer of prokaryotic cells in the sample as determined by culture-independent microscopic techniques. This observation has been termed the "great plate count anomaly" and is attributed to several factors. One simple explanation would be that only a fraction of the prokaryotic cells are culturable under a certain set of conditions such that no single medium will allow growth of all types of prokaryotes. Indeed, the efficiency of plate counting could be significantly increased when 25 different media were employed instead of a single medium (Balestra and Misaghi, 1997). However, in most cases the numerically dominant species of prokaryotes from natural samples are not recovered. Certain bacteria and archaea, among them the mesophilic crenarchaeota which constitute a fraction of up to 34% of the prokaryotic plankton in subpolar or polar latitudes (DeLong et al., 1994), the clone T78-group of the green gliding bacteria (Coolen et al., 2002), or most of the acidobacteria detected by molecular methods in soils (Barns et al., 1999) have never been isolated in any of the media tested.

It therefore appears reasonable to suggest that 1) cells of not-yet-cultured prokaryotes in natural samples are in a specific physiological state which prevents them from growing in conventional cultivation media and/or 2) the physiology of not-yet-cultured species of prokaryotes is fundamentally different from that of known prokaryotes such that cultivation methods applied do not meet the requirements for growth.

Physiological State of Prokaryotic Cells

Starvation Response The gene product of *rpoS*, namely the transcription factor σ^S, is involved in cellular responses to a diverse number of stresses (Loewen et al., 1998). Induction of *rpoS* results in an increased survival of cells under unfavorable conditions (Munro et al., 1995). Accordingly, and dependent on the growth state of the cells, RpoS (σ^S) can positively influence the culturability of *E. coli* and *Salmonella typhimurium* in oligotrophic seawater (Munro et al., 1995). However, σ^S is also involved in the transition to stationary phase, and cAMP (in a complex with the cAMP receptor protein [CRP-cAMP]) acts as a negative regulator of the transcription of *rpoS* (Loewen et al., 1998). Addition of extracellular cAMP has the same effect (Lange and Hengge-Aronis, 1991). Scavenging transporters (such as LamB), which are regulated by cAMP or endoinduction, are turned on at higher substrate concentrations than RpoS-dependent functions (Notley and Ferenci, 1996). Therefore it appears feasible that, by addition of extracellular cAMP, cells could be maintained more easily in a nutrient scavenging state and hindered from entering the protective stationary phase response, which potentially could facilitate cultivation in the absence of other stress factors.

Presence of Dead Cells, Prevention, and Reversal of Cellular Damage The presence of non-growing cells has been shown in laboratory cultures of *Enterobacter aerogenes*, which at maximum doubling times of 100 h contained up to 50% of cells not capable of growing on agar plates (Tempest et al., 1967). Since culture-independent methods such as microautoradiography or the direct viable count technique have revealed that up to 50%, and in some cases even 90%, of the prokaryotic cells may be metabolically active (Kogure et al., 1979; Fry, 1990; Karner and Fuhrman, 1997), dead cells may actually not be present at high numbers in the natural environment. However, elongating cells may be capable of completing only a limited number of division cycles, which prevents detection of growth by standard methods (Binnerup et al., 1993). This limitation of division cycles can be caused by injury (e.g., to the cell envelope, proteins, or DNA; Barer and Harwood, 1999), caused for instance by oxidative stress. Hence, dormant cells of *Micrococcus luteus* are permeant to certain fluorescent stains but restore the cytoplasmic membrane barrier upon resuscitation (Kaprelyants et al., 1996). Other factors that may limit multiplication are limiting nutrients or an (as yet unexplained) upper limit of cell density as described for *Sphingomonas* sp. strain RB2256 (Schut et al., 1997). Injury of DNA may activate the SOS response which includes expression of SulA, a protein that interacts with the tubulin-like protein FtsZ, thereby preventing septation and thus resulting in a filamentous growth of cells (Bi and Lutkenhaus, 1993; Walker, 1996). Detoxifying enzymes like catalase and superoxide dismutase are involved in the prevention of oxidative stress. Heat shock proteins, peptide methionine sulfoxide reductase, and glutathione reductase are involved in the reversal of damage within the cell (Dukan and Nyström, 1998; Barer and Harwood, 1999).

Dormancy Dormancy is defined as a reversible state of low metabolic activity in which viability is maintained. This physiological state has been studied extensively for *Micrococcus luteus*. Incubation of stationary-phase cultures at room

temperatures for several months results in large numbers of dormant cells. In the case of *Micrococcus luteus*, dormant cells show reduced activity, as exemplified by uptake of the membrane energization-sensitive dye rhodamine-123 (Kaprelyants and Kell, 1993). However, such temporarily non-culturable cells can be resuscitated in the presence of supernatants from growing *M. luteus* cultures (Kaprelyants et al., 1994; Kaprelyants et al., 1996). The agent responsible for resuscitation of dormant cells (Rpf, the resuscitation promoting factor) was identified as a 17-kDa protein exported by *M. luteus* (Mukamolova et al., 1998). In *E. coli*, the protein SdiA regulates the *ftsQAZ* cluster of essential cell division genes and the P_2 promotor (Wang et al., 1991) and is a member of the LuxR subfamily of transcriptional activators. The expression of SdiA is regulated in turn by a factor released by growing cells into the medium (García-Lara et al., 1996). The factor was identified as a *n*-acyl homoserine lactone (Sitnikov et al., 1996). Cell-cell signalling between cells of the same clone therefore may be important in regulating cell division.

Substrate-Accelerated Death If a growth limiting substrate (e.g., glycerol, glucose, ribose, phosphate or ammonia) is added in concentrations of ≥1–10 μM to cells previously starved for the same substrate (Postgate and Hunter, 1963; Postgate and Hunter, 1964; Calcott and Postgate, 1972a), growth of the cells is inhibited. This phenomenon has been called "substrate-accelerated death." Cells challenged with this substrate exhibit low levels of cAMP, and in the presence of extracellular cAMP, substrate-accelerated death disappears (Calcott et al., 1972b). Also, the addition of Mg^{2+} protects cells against substrate-accelerated death. Substrate-accelerated death has been reported to occur in *Klebsiella*, *Escherichia*, *Streptococcus*, *Azotobacter*, *Arthrobacter* and *Mycobacteria* (Calcott and Calvert, 1981b). The significance of substrate-accelerated death on recovery of bacteria from environmental samples remains unknown. However, it has recently been demonstrated that addition of cAMP at low concentrations (10 μM) in certain cases can significantly increase the culturability for natural samples (Bruns et al., 2002).

The Viable But-Non-Culturable State In addition, it has been proposed that certain bacteria may acquire a state termed "viable but-non-culturable" (VBNC; Xu et al., 1982; Roszak and Colwell, 1987). In the proposed VBNC state, bacterial cells, especially of pathogenic bacteria like *Vibrio cholerae* or *Campylobacter jejuni* (Bovill and Mackey, 1997), are believed to become temporarily non-culturable until they are exposed to an environment that stimulates their resuscitation. In *Vibrio vulnificus*, exposure of cells to temperatures around 4°C results in a decline of culturability without cell lysis (Oliver, 1995). Temperature-upshift results in a resuscitation of these non-culturable cells (Whitesides and Oliver, 1997). Those cells that retain the capacity for resuscitation appear to maintain physiological activity. Replacement of the term VBNC by "temporarily non-culturable" or "not immediately culturable" has been proposed since it is unclear whether VBNC is the result of a specific programmed differentiation or an adaptive process (Barer and Harwood, 1999). The view that the VBNC state is a single phenomenon and a valid operational concept has recently been challenged (Barer and Harwood, 1999).

Lysogenic Phages Lysogenic phages may be induced upon plating onto agar media by SOS response-related induction (Barer and Harwood, 1999), leading to a rapid decrease of culturability.

Low Nutrient Concentrations, "Oligotrophic Bacteria"

Media supplemented with comparatively low concentrations of complex carbon sources like yeast extract and peptone (i.e., 0.25 g·liter^{-1} each) have been established for the isolation of fastidious bacteria such as planctomycetes (Schlesner, 1986; Staley et al., 1992). Using concentrations of ≤5 mg of organic carbon·liter^{-1}, which are supplied as casamino acids, or employing straight filtered autoclaved seawater can increase the apparent cultivation success (determined as the ratio of most probable numbers in relation to total cell counts) up to 20–60% (Button et al., 1993; Eguchi et al., 2001). In addition, the qualitative composition of carbon sources determines the cultivation success of naturally occurring prokaryotes. Complex media have been shown to yield higher numbers and a higher diversity of isolates than similar media containing only one defined carbon source at the same concentration: single substrates yielded almost exclusively strains of the γ-subclass of Proteobacteria (Uphoff et al., 2001). For soil pseudomonads, nutrient-poor media containing only ~15 mg C·liter^{-1} have been shown to yield higher numbers of culturable cells than conventional organic-rich media (Aagot et al., 2001). Strongly diluted nutrient broth resulted in significantly increased numbers of Acidobacteria, Actinobacteria, α-Proteobacteria, Low G+C-Gram-positive bacteria, and Verrucomicrobia from soil samples (Janssen et al., 2002). This combined evidence suggests that the majority of heterotrophic prokaryotic cells in many natural

samples require lower concentrations of organic carbon for growth. The cultivation success of freshwater planktonic bacteria could also be increased in media with reduced nitrogen and phosphorus concentrations. In the latter case, nutrient levels were decreased to match the maximal ambient levels in the planktonic environment (50 μM nitrogen and 1.5 μM phosphorus; Eilers et al., 2001). In general, viable cell counts of freshwater or marine planktonic bacteria reached on agar-solidified media are orders of magnitude smaller than those obtained as most probable numbers in liquid extinction dilution series (Eguchi et al., 2001; Jaspers et al., 2001).

Ultramicrobacteria are defined by a cell volume of <0.1 μm^3 (Eguchi et al., 2001) and prevail in oligotrophic marine waters (Schut et al., 1997). In this respect, an important question is whether ultramicrocells represent a distinct class of prokaryotes that maintain their small biovolume independently of their growth status, or whether they are capable of becoming larger. In many bacterial species, nutrient deprivation results in pronounced changes of cell morphology and size (Torella and Morita, 1981; Morita, 1982; Amy and Morita, 1983; Kjelleberg et al., 1993). Upon starvation, many non-growing marine isolates produce ultramicrocells by reductive division and these can have volumes as little as 1% that of rapidly growing cells. The resulting daughter cells retain measurable metabolic activity, at least in an initial period following their formation (Amy and Morita, 1983). It appears likely that such ultramicrocells contribute significantly to observed populations of prokaryotes in ocean waters. However, in cells of other species, like for instance *Sphingomonas alaskensis* within the α-Proteobacteria (Eguchi et al., 2001; Vancanneyt et al., 2001) or the Verrucomicrobiales, a small cell volume (0.03–0.06 μm^3) is a stable characteristic and independent of substrate concentrations (Schut et al., 1993; Janssen et al., 1997).

Oligotrophic bacteria are defined as those that on first cultivation develop on media containing 1–15 mg C·$liter^{-1}$ (Kuznetsov et al., 1979). Consequently, such bacteria cannot be cultivated directly on nutrient-rich agar (Vancanneyt et al., 2001). Actually, the range of carbon concentrations reported for the pelagic and deep ocean is 30–200 μM, corresponding to 0.36–2.4 mg C·$liter^{-1}$ (Jannasch et al., 1996). Therefore, bacto yeast extract (Difco) is added from autoclaved stock solutions to a final concentration of 10–1 mg·$liter^{-1}$ (corresponding to 3.3–0.33 mg C·$liter^{-1}$ or 270–27 μM carbon; Jannasch et al., 1996) in media designed to recover marine pelagic prokaryotes. It has been demonstrated, however, that prolonged incubation over 1 year at 5–8°C or storage and monthly reculturing at 15°C yields cultures which eventually can multiply on high-nutrient laboratory media (Eguchi et al., 2001; Vancanneyt et al., 2001). Oligotrophic bacteria may generally represent novel types of bacteria with unknown physiological properties. In contrast to all other (mostly copiotrophic) bacteria investigated to date, the marine ultramicrobacterium *Sphingomonas alaskensis* RB2256 exhibits a high level of inherent stress resistance towards oxidative stress (hydrogen peroxide [H_2O_2]), but no starvation-induced stress against H_2O_2 (Ostrowski et al., 2001). Stress resistance is negatively correlated to growth rate, but only marginal changes in catalase activity were observed; hence, other factors must be critical to the stress resistance of this strain.

Growth on Multiple Substrates

In spite of the fact that bacteria in natural environments grow in the presence of a large diversity of compounds, most laboratory studies have focused on growth with single substrates. When bacteria are grown in batch culture with more than one growth substrate, sequential utilization of these substrates is often observed. In some cases, this results in a typical diauxic growth pattern (Monod, 1942; Lengeler et al., 1999) in which the substrate that is used first represses the synthesis of enzymes required for the utilization of the other substrates. Only after (almost) complete utilization of the first substrate is growth on the second one induced. It is noteworthy that sugars may cause catabolite repression of inducible enzyme systems even if the sugars are not utilized themselves (Pastan and Perlman, 1969). In enteric bacteria, cAMP is part of the pleiotropic *crp* activation system which regulates most peripheral catabolic operons and carbohydrate transport systems, and it typically mediates carbon catabolite repression (Lengeler et al., 1999). Sugars transported by the phosphotransferase system (PTS) decrease intracellular cAMP levels which in turn prevents the expression of genes necessary for the uptake of non-PTS sugars. After depletion of glucose, intracellular cAMP concentrations rise from 0.3 up to 3 μM, and other sugars can be taken up and metabolized after a lag period required for the induction of the necessary genes. This regulatory pattern leads to a biphasic growth curve. The intermediate lag phase can be abolished by addition of extracellular cAMP when added at millimolar concentrations (Epstein et al., 1975), whereas the growth rate itself does not change (Okada et al., 1981). The involvement of cAMP in regulation of catabolic enzymes has also been demonstrated for a wide range of nonenteric bacteria, including other γ-Proteobacteria, the α-Proteobacteria, β-Proteobacteria, and the cyanobacteria (Botsford et al., 1992).

However, this type of clearcut diauxic pattern with a lag period between consumption of the first and the second substrate is by no means very common. More often, a gradual transition between the use of two (or more) substrates is observed, and in some cases, no enzyme repression is evident at all (Harder and Dijkhuizen, 1982; Gottschal, 1986). Moreover, it is questionable whether distinct preferences for one substrate would be functionally valuable in nutrient-poor natural environments with many different substrates available at the same time. Under nutrient limitation, one would rather expect organisms to develop physiological strategies enabling them to make use of several nutrients simultaneously. Growth in chemostats under limitation of mixtures of different substrates has provided ample evidence that a multitude of substrates, serving similar physiological functions, can be growth limiting at the same time (Harder and Dijkhuizen, 1982; Egli et al., 1983; Gottschal, 1986; Gottschal and Dijkhuizen, 1988). Low K_s values have been found in marine isolates (Schut et al., 1995). However, the reported V_{max} values are generally so low that specific affinities and oligotrophic capacities are insufficient to allow growth on single substrates. In a marine coryneform bacterium, the presence of amino acids can enhance the uptake of glucose and lowers the threshold concentations for growth (Law and Button, 1977). On the other hand, growth on alanine of *Sphingomonas alaskensis* strain RB2256 occurred with a lower affinity in the presence of glucose (Schut et al., 1995).

Metabolically versatile bacteria exist that are specialized in using several different substrates at the same time if the latter are present at growth-limiting concentrations (Laanbroek et al., 1979; Dykhuizen and Davies, 1980; Gottschal and Kuenen, 1980; Beudeker et al., 1982; Legan and Owens, 1988). Since these prokaryotes usually display lower maximum growth rates relative to more specialized species, metabolically versatile bacteria will in most cases be missed when batch-type enrichment techniques are used, even if mixtures of several substrates are present. Instead, chemostat cultures need to be employed for enrichment.

Effect of Inhomogeneities

Inhomogeneities can have a profound effect on the physiology of prokaryotes. Many environments such as soils, sediments and marine snow are highly heterogeneous, and therefore microbial substrates and bacterial productivity are distributed in microscale patches of variable concentration and size (Azam, 1998; Ploug, 1999). Under such conditions, steep gradients, e.g., of molecular oxygen, may result in a close proximity of aerobic and anaerobic species and transformations (Revsbech and Jørgensen, 1986).

Attachment of prokaryotic cells has been shown to be of significance under some conditions. Some compounds are optimally metabolized only if oxygen-dependent and strictly anoxic steps are coupled by diffusion of metabolic products and thus proceed in close proximity. This principle has been demonstrated in an elegant study of the degradation of DDT (1,1,1-trichloro-2,2-bis[4-chlorophenyl]ethane), using calcium alginate beads for immobilization of bacteria (Beunink and Rehm, 1988). In this system, the attached cells of *Alcaligenes* species and *Enterobacter cloacae* performed reductive dechlorination of DDT inside the beads, and the partly dechlorinated products were metabolized oxidatively. Since highly chlorinated compounds are dehalogenated more readily under anoxic conditions, this same principle may hold for many other halogenated xenobiotics as well.

Besides affinity for a given substrate and cell yield, attachment to solid surface is an additional determinant of the outcome of competition between prokaryotes with similar physiology. Attachment to solid surfaces can thus change the metabolic interrelations between competing bacteria. When growing in suspension, *Pseudomonas putida* R1 and *Acinetobacter* C6 compete for the substrate benzyl alcohol, with *Acinetobacter* largely outcompeting *P. putida*. However, both strains formed stable and structured biofilms when glass as solid substrate was available (Christensen et al., 2002). Under the latter conditions, *P. putida* is capable of utilizing benzoate which *Acinetobacter* uses only inefficiently and therefore excretes to a large extend.

In the natural environment, nonpolar organic carbon substrates occur in the adsorbed state. In the adsorbed state, these substrates are often not directly available and rates of desorption control the rate of degradation. However, some prokaryotes can degrade adsorbed substrates more rapidly than can be accounted for by the rates of desorption into the aqueous phase (Harms and Zehnder, 1995). Prokaryotes thus differ in their capability of using adsorbed substrates (Guerin and Boyd, 1997; Stringfellow and Aitken, 1994; Crocker et al., 1995). Consequently, enrichment strategies, in which especially nonpolar substrates are offered in the adsorbed state, may provide a more relevant low-bioavailability environment, and hence lead to the enrichment and isolation of novel types of prokaryotes (Tang et al., 1998; Grosser et al., 2000).

Interactions with Other Microorganisms

Most likely, one considerable problem in current enrichment and cultivation techniques is that

microbial interactions cannot be reproduced adequately (see Alternative and Novel Concepts for Cultivation). In nature, prokaryotes reach cell densities of about $10^6 \cdot ml^{-1}$ in most aquatic environments, $10^9 \cdot cm^{-3}$ in sediments, and $10^{11} \cdot cm^{-3}$ in soils. If a homogenous distribution of the cells is assumed, the average cell-to-cell distance at these increasing densities would amount to 112, 10 and 1 μm, respectively. Over such small distances, transport of small molecules by molecular diffusion proceeds at a rapid rate and takes between microseconds and a few seconds (Overmann, 2002a). Owing to the laws of three-dimensional diffusion, the flux of metabolites experienced in the vicinity of a prokaryotic cell by another one decreases to as little as 0.01% when the cell-to-cell distance increases to 10 μm (Overmann and Schubert, 2002b). This simple calculation indicates that 1) interactions between prokaryotes may influence their growth under natural conditions and most likely need to be considered in cultivation attempts of some not-yet-cultured bacteria, and 2) a strong selective pressure must exist for interacting prokaryotic cells to maintain close spatial proximity.

At high cell densities, even monospecific associations of some bacteria exhibit physiological traits that differ from those of dilute cultures. In the case of quorum sensing, the excretion of autoinducer molecules signals high cell density and triggers light production, expression of virulence factors, and swarming (Fuqua and Greenberg, 1998) or prevents cell aggregation (Puskas et al., 1997). Similarly, myxobacteria exhibit complex social interactions: when deprived of nutrients they enter into a complex developmental cycle that results in the formation of a multicellular fruiting body that contains myxospores (Reichenbach, 1984). Other cases of monospecific associations have been described occasionally (Lins and Farina, 1999). However, it has also been found that different types of bacteria can form associations. These comprise highly structured associations of defined composition, so-called "consortia" (Schink, 1991; Overmann, 2002a). In addition, less structured assemblages, like microcolonies, net-like structures, biofilms, or aggregates of up to 18 different prokaryotic genera, have commonly been observed in natural samples (Weise and Rheinheimer, 1978; Paerl, 1982; Alldredge and Youngbluth, 1985; van Gemerden et al., 1989; Dubinina et al., 1993; Kolenbrander and London, 1993; Seitz et al., 1993; Overmann et al., 1996; Jacobi et al., 1997; Moissl et al., 2002). Least structured and hence difficult to detect are 10–100 μm-large patches of free-living bacterial cells, but evidence has accumulated for the existence of such inhomogeneities in the pelagic habitat (Krembs et al., 1998). Under certain natural conditions, the growth of prokaryotes is therefore not only influenced by the various physicochemical factors, but also by interactions with other microorganisms. Cells may need to communicate with each other for growth.

So far, the compounds known to be exchanged between prokaryotes include signal compounds (as in the case of quorum sensing), growth factors, and compounds directly involved in energy metabolism (mostly electron donors/electron acceptors such as hydrogen or inorganic sulfur compounds in syntrophic interactions). Besides enabling prokaryotes to perform novel syntrophic reactions, interactions can also lead to altered kinetics of microbial transformations. For example, the high affinity oxidation of methane observed in soil could be reproduced in a coculture of a non-novel methanotroph with a *Variovorax* strain (Dunfield et al., 1999). This finding indicates that the physiology and ecology of prokaryotes can only be completely appreciated if interactions with other prokaryotes are considered as well.

Overall, eight types of interspecies interrelationships can be distinguished based on the effect of each of the two populations (Atlas and Bartha, 1993; Table 7), ranging from mutualistic to antagonistic interactions. It has to be kept in mind, however, that the different categories listed in Table 7 represent only concepts, which in many cases fail to account for all facets of microbial interactions.

Neutralism This describes the situation of a complete lack of interaction between two populations. This situation is more likely to occur

Table 7. Types of interspecies interactions.

Name of interaction	Effect of interaction
Neutralism	Neither population affects the other
Competition	Populations inhibit each other when resources are in limiting supply
Amensalism	Population 1 is negatively affected by 2, but 2 is not affected by 1
Parasitism	Population 1 consumes population 2, but usually not in a destructive manner
Predation	Population 1 consumes population 2 in a destructive manner
Commensalism	Population 1 benefits from population 2 without affecting it in a negative sense
Synergism (protocooperation)	Both populations benefit from the interaction, which is not obligatory
Mutualism (symbiosis)	Both populations benefit from the interaction, which is obligatory

between populations with very different metabolic capabilities. However, neutralism is defined in a negative way and therefore is most difficult to verify experimentally. Most likely interactions are absent at very low population densities and if prokaryotes form physiologically largely inactive resting stages (Atlas and Bartha, 1993). However, it has been demonstrated that even endospores can affect the surrounding environment by the presence of extracellular enzymes (i.e., Mn^{2+} oxidase; Francis and Tebo, 2002).

Competition Since energy and nutrient sources are often present in limiting concentrations, competition for growth-limiting resources is one of the major types of interactions between cells of one population or between different prokaryotes, and it results in a reduction of growth rate. Eventually, it may lead to the exclusion of the slower-growing species, a process also termed "competitive exclusion" (Gause, 1934; Hardin, 1960). Since the introduction of continuous culture techniques which allowed cultivation under conditions of permanent nutrient limitation, the competition in mixed cultures has been studied under a great variety of environmental conditions (Powell, 1958; Veldkamp and Jannasch, 1972; Fredrickson, 1977; Veldkamp, 1977; Fredrickson and Stephanopoulos, 1981; Kuenen and Gottschal, 1982a; Kuenen and Harder, 1982b; Gottschal and Dijkuizen, 1988; Visscher et al., 1992b). These studies were mostly concerned with simple and pure competition for single growth-limiting nutrient in the absence of other interactions, and the results supported the competitive exclusion principle. The outcome of the competition between two or more species is merely dependent on the shape of the μ versus S relationship of the competitors (Fig. 2). Those prokaryotes which reach a higher specific growth rate at a given substrate concentration always outcompete the slower-growing species. In some instances, the μ versus S curves cross and as a result the outcome of the competition depends on the dilution rate chosen. Apparently, certain species are much better adapted to growth at very low substrate concentrations (and exhibit a relatively low μ_{max} value), whereas others are more specialized in growth at high rates in the presence of high substrate concentrations. Examples have been reported for aerobic and anaerobic heterotrophs, chemolithotrophic species, and phototrophic organisms (Harder and Veldkamp, 1971; Jannasch and Mateles, 1974; Fredrickson, 1977; Harder et al., 1977; Mur et al., 1977; Veldkamp, 1977; Matin and Veldkamp, 1978; Kristjansson et al., 1982; Lovley et al., 1982; Laanbroek et al., 1983; Laanbroek et al., 1984; King, 1984; Kuenen and Robertson, 1984; Robinson and Tiedje, 1984; Veldkamp et al., 1984; Legan et al., 1987; Legan and Owens, 1988). Competition between microorganisms exists not only for organic carbon but also for nutrients like phosphate (Rhee, 1972; Currie and Kalff, 1984).

Amensalism The production of lactic acid by lactic acid bacteria or sulfuric acid by *Thiobacillus thiooxidans*, which inhibit other non-acidophilic microorganisms, are examples of amensalistic relationships. Similarly, the inhibition of *Salmonella enterica* by acetate and propionate produced by *Clostridium lactatifermentans* at low pH (5.8) has been demonstrated (van der Wielen et al., 2002). At these low pH values, considerable acetate and propionate present as undissociated acids penetrate the cytoplasmic membrane and hence decrease the membrane potential (see pH).

Predation The best documented example for predatory prokaryotes are bacteria of the genus *Bdellovibrio* which attack Gram-negative bacteria by attaching to their prey, penetrating the cell wall, and subsequently multiplying within the periplasmic space. Multiplication of *Bdellovibrio* sp. occurs at the expense of cellular components of the host cell and leads to the formation of 4–20 daughter cells by segmentation within 2–3 hours after infection (Stolp and Starr, 1963; Stolp and Starr, 1965; Varon and Shilo, 1980; Shilo, 1984). The cell content of the host is partially degraded and utilized. Although growth and survival of wild-type *Bdellovibrio* spp. is strictly dependent on the availability of appropriate prey cells, this parasite differs fundamentally from viruses in that it does not depend directly on the metabolic machinery of the host cell. *Bdellovibrio* species and similar bacteria appear to be widespread, having been isolated from many different aquatic and terrestrial ecosystems (Varon and Shilo, 1980; Burnham and Conti, 1984). Additional predatory bacteria that require cell contact have been described. *Vampirococcus* sp. is a nonmotile, Gram-negative anaerobic bacterium which occurs as an epibiont of phototrophic *Chromatium* spp. to which it adheres by means of specific attachment structures without penetrating the outer cell layers. Concomitant to growth and division of the epibiont, the host cell cytoplasm is degraded, leaving behind an almost empty cell envelope (Guerrero et al., 1986). A second type of predatory bacterium, *Daptobacter* sp., penetrates the cell envelope of cells of various genera of the Chromatiaceae and degrades the cytoplasm of its prey. The Gram-negative *Daptobacter* is a facultative predator, facultatively anaerobic and motile (Guerrero et al., 1986). Other bacteria can lyse prokaryotes without direct contact. An isolate of *Stenotrophomonas maltophilia* was

found to lyse cells of *Chlorobium limicola* and several heterotrophic bacteria (Nogales et al., 1997). Finally, myxobacteria can cause lysis of susceptible strains at some distance, apparently with the aid of exoenzymes. The myxobacteria derive their nutrition from material released by the lysed cells.

Commensalism In the non-obligatory commensal relationship, one population benefits, e.g., from growth factors excreted by a second population, while the latter remains unaffected. This type of relationship thus is unidirectional in character. Commensalism within one and the same population is of significance if, for instance, the growth substrates are insoluble (such as lignin or cellulose). These substrates are made available by extracellular enzymes, and while the exoenzymes themselves are kept at the cell surface (i.e., in the periplasmic space in the case of Gram-negative bacteria or by attachment to the cytoplasmic membrane in the case of Gram-positives), the resulting substrates often are rapidly lost by diffusion from the vicinity of single cells. In contrast, soluble products can be utilized at high efficiency if cell densities are high. As an example, *Mxyococcus xanthus* does not grow on insoluble casein at cell densities lower than 10^3 per ml, whereas growth rates increased with cell densities above this value (Rosenberg et al., 1977). This effect of cell density is not observed on prehydrolyzed casein.

Not in all cases does the limitation of two populations of prokaryotes by one substrate lead to competitive exclusion, but it can result in stable mixed cultures. The underlying reasons include the occurrence of additional interactions, especially commensalism and mutualism, the formation of self-inhibitory products, the presence of predators, selective adhesion, fluctuations in physical parameters (pH, temperature, light, and oxic/anoxic conditions), or an alternating supply of differing growth-limiting substrates (Bungay and Bungay, 1968; Megee et al., 1972; Jost et al., 1973; Meers, 1973; van Gemerden, 1974; Meyer et al., 1975; Lee et al., 1976; Fredrickson, 1977; de Freitas and Fredrickson, 1978; Slater and Bull, 1978; Gottschal et al., 1979; Miura et al., 1980; Bull and Slater, 1982; Kuenen and Robertson, 1984; Kuenen et al., 1985). For example, purple sulfur bacteria and colorless sulfur bacteria, which are expected to compete for H_2S as electron-donating substrate, are found to thrive in high population densities in the same layer of microbial mats (Visscher et al., 1992a). This has been explained by the removal of oxygen by colorless sulfur oxidizers and the formation of incompletely oxidized inorganic sulfur intermediates, which then serve as alternative electron donor for the anoxygenic phototroph (Visscher et al., 1992b; van den Ende et al., 1996). Also, competition can be alleviated and stable cocultures obtained if conditions for competition do not exist over an entire 24-h period but only for a shorter time interval (van Gemerden, 1974). This fact for instance can be exploited for the enrichment of more fastidious purple sulfur bacteria (like the large-celled *Chromatium* spp.) by using light-dark cycles instead of continuous light.

As an example of a commensalistic relationship based on crossfeeding between nonrelated bacteria, *Propionibacterium shermanii* can grow in mixed continuous culture at the expense of lactate produced by *Lactobacillus plantarum* from glucose, the growth-limiting nutrient in the chemostat (Lee et al., 1976). Lactate was also the mediator in a commensal relationship between *Streptococcus mutans* and *Veillonella alcalescens*. Both strains are commonly found in dental plaque and were shown to coexist in mixed continuous cultures supplemented with glucose as the limiting nutrient (Mikx and van der Hoeven, 1975). In this mixed culture, the lactate produced by *S. mutans* was metabolized to acetate, propionate, and ethanol, which, owing to lower dissociation constants, might reduce the demineralization of tooth enamel. Also, consumption of lactate by a second organism (*Pseudomonas stutzeri*) under anaerobic conditions and in the presence of nitrate in a lactose-limited mixed chemostat culture results in a marked stimulation of the growth yield of *Lactococcus cremoris* (Otto et al., 1980). The latter is capable of an electrogenic lactate export during which two H^+ are translocated across the cytoplasmic membrane together with one lactate molecule, thereby generating a membrane potential. Since the driving force of this transport is the transmembrane lactate gradient, the stimulatory interaction is based on the very low external lactate concentration maintained by *Pseudomonas*. This enables *S. cremoris* to gain more energy from the efflux of lactate than at higher external concentrations (Michels et al., 1979). Commensalistic interactions are also established in mixed cultures where either stimulatory compounds are formed or inhibitory compounds are being removed. As an example of the removal of inhibitory compounds, methane-consuming pseudomonads grew in a mixed culture with a *Hyphomicrobium* species, the latter removing small inhibitory amounts of methanol formed during methane oxidation (Wilkinson et al., 1974).

Synergism Synergism (protocooperation) occurs between *Lactobacillus arabinosus* and *Enterococcus faecalis* in a minimal medium (Nurmikko, 1956) in which each organism is unable to grow on its own. The synergism is

based on the fact that *S. faecalis* requires folic acid, which is produced by *Lactobacillus*, whereas the latter requires phenylalanine, which is produced by *Streptococcus*. Reciprocal stimulation also can occur in yoghurt, where *Lactobacillus bulgaricus* produces amino acids that stimulate the growth of *Streptococcus thermophilus*. The latter produces small quantities of formic acid, which in turn stimulates *L. bulgaricus* (Driessen, 1981). Chemolithotrophic and phototrophic organisms growing with CO_2 as carbon source are known to excrete substantial quantities (>50%) of the carbon fixed as carbohydrates, peptides, amino acids, lipids or vitamins (Clark and Schmidt, 1966; Czeczuga, 1968; Fogg, 1971; Cohen et al., 1979; Jones, 1982; Coveney, 1982; Wolter, 1982; Soendergaard et al., 1985; Bateson and Ward, 1988). In these interactions, the benefit for the chemo- or photolithoautotrophic partner is often less evident and may comprise the supply of vitamins (Jones, 1982), the reduction of oxygen concentration around heterocysts (Bunt, 1961; Paerl, 1978; Paerl, 1982)—which has been disputed on physical grounds (Overmann, 2002a)—and the formation of CO_2 (Lange, 1971). A reciprocal relationship was also suggested in a mesophilic estuarine microbial mat system in which the cyanobacterium *Microcholeus chtonoplastes* excreted organic matter that stimulated growth of *Thiocapsa roseopersicina*, which in turn prevented accumulation of excess amounts of hydrogen sulfide (de Wit and van Gemerden, 1988).

Many different types of interspecies interactions occur in laminated microbial ecosystems, or so-called "microbial mats," which are found on seashores, estuarine areas, salt marshes, and along the effluents from geothermal springs. Metabolic interactions include 1) the excretion of photosynthates and cell lysis of cyanobacteria as the primary colonizers, 2) respiration of the organic substances by heterotrophic bacteria, thereby generating anoxic conditions, 3) fermentation and reduction of sulfate by anaerobic bacteria, and 4) oxidation of the reduced sulfur compounds by anoxygenic phototrophs and chemolithotrophs (Stal et al., 1985). In addition, a multitude of interactions, most of them beneficial, occur between the different groups of prokaryotes (Overmann and van Gemerden, 2000). In microbial mats, sulfate-reducing bacteria can reach their highest abundance at the surface, rather than at the deeper, permanently anoxic sediment layers. Accordingly, the sulfate-reducing bacterium *Desulfovibrio desulfuricans* has been found to be capable of syntrophic growth with the colorless sulfur-oxidizing bacterium *Thiobacillus thioparus* under oxygen limitation and with lactate as the electron-donating substrate (van den Ende et al., 1997). In this association, *Thiobacillus* removed molecular oxygen inhibiting *Desulfovibrio* and provided the latter with soluble polysulfide compounds as electron acceptor. *Desulfovibrio* in turn oxidized lactate to acetate, forming sulfide concomitantly, which served again as electron-donating substrate of *Thiobacillus*.

Syntrophic Interactions Under certain conditions, synergism between different groups of anaerobic prokaryotes is essential for the degradation of organic matter. In contrast to aerobic decomposition, anaerobic mineralization involves the participation of different groups of prokaryotes with only a limited physiological flexibility. Consequently, a tight cooperation of mixed populations exists. In this multistep process, polymeric organic matter (such as cellulose, proteins, and lipids) is first hydrolyzed to oligomers and monomers that are subsequently fermented (Hungate, 1960; Bryant, 1976; Laanbroek and Veldkamp, 1982; Wolin, 1982; Nedwell, 1984). The first step in anaerobic degradation of sugars, most amino acids, and other readily fermentable substrates is the formation of H_2, CO_2, formate, alcohols, acetate and other short-chain fatty acids, sulfide, and ammonia. In the presence of oxidized sulfur compounds, further mineralization may proceed directly through activity of sulfate-reducing bacteria, which, as a group, can directly oxidize the (long-chain) fatty acids, amino acids, alcohols, aromatic compounds, and hydrogen (Widdel, 1988). In the absence of sulfate, CO_2 will serve as the major electron acceptor resulting in the formation of methane. Methanogenic bacteria, however, have a very narrow range of substrates (mainly H_2, acetate, formate, methanol, and several methylamines; Oremland, 1988). Hence, an additional group of prokaryotes, the "acetogenic" bacteria, are involved in the formation of suitable methane precursors. In the absence of sulfate, the subsequent fermentative degradation of some of the products like propionate, butyrate, or benzoate to hydrogen, CO_2, and acetate is an endergonic process under standard conditions, however. A syntrophic relation, the so-called "interspecies hydrogen transfer," is established between hydrogen-producing bacteria (also called "obligate proton-reducing bacteria") on one hand and hydrogen-consuming prokaryotes such as methanogens on the other.

Anaerobic chemotrophic syntrophic cocultures are the only associations of prokaryotes that so far have been investigated in sufficient detail to understand the physiological basis of the interaction (Schink, 1991). Interspecies hydrogen transfer in these cocultures is decreased to values below 10 Pa (Zehnder and Stumm, 1988),

which renders the oxidation of short-chain fatty acids exergonic. Thus, *Syntrophomonas wolfei* in coculture can metabolize even-numbered fatty acids such as butyrate, caproate, and caprylate to H_2 and acetate; odd-numbered fatty acids such as valerate and heptanoate are metabolized to propionate, acetate, and hydrogen (Dwyer et al., 1988; McInerney et al., 1979; McInerney et al., 1981). *Syntrophobacter wolinii* was shown to degrade propionate to acetate, CO_2, and H_2 in coculture with an H_2-consuming *Desulfovibrio* species (Boone and Bryant, 1980). Although acetate can be cleaved to CH_4 and CO_2 by several methanogenic species, a thermophilic acetate-oxidizing organism was shown to convert acetate to CO_2 and H_2 only in coculture with *Methanobacterium thermautotrophicum* (Zinder and Koch, 1984). Benzoate and several other aromatic compounds were also shown to be degraded by cocultures of a proton-reducing species and methanogens, sulfate-reducing bacteria, or both (Mountfort and Bryant, 1985; Dolfing and Tiedje, 1986; Mountfort and Asher, 1986; Szewzyk and Schink, 1989). Although hydrogen represents the best-documented agent for transfer of reducing equivalents, formate serves the same purpose in species lacking hydrogenases (Thauer et al., 1975; Thiele and Zeikus, 1988a; Thiele et al., 1988b). Syntrophic associations can involve even three different physiological types of prokaryotes, e.g., two different sulfate-reducing bacteria and one methanogenic archaeon (Thiele and Zeikus, 1988a).

In other fermentations, proton reduction and subsequent hydrogen transfer is not a strict requirement since the reaction is exergonic under standard conditions, but interspecies hydrogen transfer shifts the fermentation pattern toward the production of more oxidized products plus hydrogen in contrast to the reduced fermentation products formed in pure culture. For example, *Ruminococcus albus* ferments glucose to acetate, H_2, and CO_2 (instead of to ethanol) if cocultured with *Wolinella succinogenes*, which uses hydrogen as electron donor in the reduction of fumarate to succinate (Ianotti et al., 1973). Hydrogen transfer results in an additional energy gain for *R. albus* as more acetyl-CoA is converted to acetate in an ATP-yielding route. Shifts in fermentation products were also demonstrated for cocultures of *Clostridium thermocellum* and *Methanobacterium thermautotrophicum* (Weimer and Zeikus, 1977).

A second type of syntrophic interaction has been found in cocultures of green sulfur bacteria with sulfur- or sulfate-reducing bacteria (Wolfe and Pfennig, 1977; Biebl and Pfennig, 1978; Warthmann et al., 1992). Under conditions of limitation by inorganic sulfur compounds as they prevail in freshwater ecosystems, the sulfide-producing bacterium relies on the activity of the sulfide-oxidizing phototroph for the availability of the electron acceptor, while the activity of the green sulfur bacteria is controlled by the activity of the sulfide-producing organism. In this way, a closed sulfur cycle is established through which each sulfur atom cycles many times (Pfennig, 1980).

Symbiosis Mutual relationships between different prokaryotes render them capable of occupying niches that could not be occupied by either organism alone. "Symbiosis" in its orginal sense is a close association between different species of organisms (de Bary, 1879). Currently, symbiosis is often defined as an obligatory and highly specific mutual relationship that benefits both partners (Atlas and Bartha, 1993; Table 7). Most symbioses of prokaryotes known to date are with eukaryotes. Besides the endosymbiosis of chloroplasts (cyanobacteria) or α- mitochondria (Proteobacteria; Margulis, 1981), the root nodule symbiosis of rhizobia with legumes is another well-studied example. In the latter association, the bacteria provide combined nitrogen and the plant host dicarboxylic acids. In their symbiosis with anaerobic protozoa, prokaryotes appear to act as hydrogen sinks in interspecies hydrogen transfer (Hackstein et al., 1999). In ectosymbiotic association with marine nematodes, especially adapted γ-Proteobacteria oxidize sulfide with concomitant CO_2-fixation (Ott et al., 1991), as do the endosymbionts of the same group in gutless marine oligochetes (Dubilier et al., 1995). Cellulolytic nitrogen-fixing bacteria in shipworms (Bivalvia: Terebrenidae) provide exoenzymes necessary for the digestion of cellulose or keratene (Waterbury et al., 1983). Bacterial symbionts of insects synthesize nutrients such as vitamins (Aksoy, 1995) or recycle amino acids (Douglas, 1998). Intracellular bacterial symbionts of protozoa can provide toxins, which in turn are of selective value for the host in competition with protozoal competitors (Görtz and Brigge, 1998). In other cases, the cytotoxicity of the protozoal host is increased by endosymbiotic bacteria (Fritsche et al., 1998). Most of the prokaryotic symbionts of higher organisms could not be cultured to date and thus have only been identified by 16S rDNA analyses.

In contrast to the hundreds of cases of symbiotic relationships between prokaryotes and eukaryotes, only very few examples of symbioses between different prokaryotes have been described to date (Overmann and Schubert, 2002b). However, evidence from very different environments, which range from the termite hindgut and dental plaque to the chemocline of stratified lakes and deep-sea sediments, indicates

that many more symbiotic associations exist among prokaryotes (Overmann, 2002a; Overmann and Schubert, 2002b). As indicated by microscopic studies, morphologically conspicuous associations of prokaryotes exist in the form of "consortia," in which two or more prokaryotes maintain a permanent cell-to-cell-contact (Hirsch, 1984; Schink, 1991; Trüper and Pfennig, 1971), and most likely represent the extreme case of a mutual interdependence of different prokaryotes. To date, some 16 different types of such consortia have been described (Huber et al., 2002; Overmann, 2002a; Overmann and Schubert, 2002b) and are comprised of very different phylogenetic groups, e.g., filamentous cyanobacteria associated with heterotrophic bacteria, associations between giant sulfur-oxidizing γ-Proteobacteria (*Thioploca*) and sulfate-reducing *Desulfonema*, or the aggregates of sulfate-reducing bacteria with methanogenic archaea, which were detected in methane-hydrate-rich marine sediments. An additional novel type of association has been described (*Nanoarchaeum equitans*; Huber et al., 2002). Recently, advancements have been made towards a more detailed understanding of the structure and function of phototrophic consortia consisting of green sulfur bacterial epibionts surrounding a colorless motile central α-Proteobacterium (Fröstl and Overmann, 1998; Fröstl and Overmann, 2000; Overmann et al., 1998; Tuschak et al., 1999; Overmann and Schubert, 2002b).

Enrichment Techniques

When the desired prokaryote is present in very small numbers, the enrichment-culture technique is used to enable this particular type of microorganism to grow faster than all others in the sample. During selective enrichment, a natural sample harboring many different microorganisms is kept under conditions which favor the growth of a particular physiological type of prokaryote or a group of prokaryotes, thus allowing them to grow faster than accompanying physiologically different types of microorganisms (Schlegel and Jannasch, 1967; Aaronson, 1970; Norris and Ribbons, 1970a; Norris and Ribbons, 1970b; Veldkamp, 1977; Gerhardt et al., 1981; Poindexter and Leadbetter, 1986; Austin, 1988). Usually, no inhibitory ingredient is added to the medium, but the enrichment medium is designed to favor growth of the desired organism. The technique was essentially developed by microbiologists (e.g., Beijerinck and Winogradsky) early in the twentieth century. The enrichment technique is applied if 1) a prokaryote with particular metabolic properties is known to exist or 2) it is to be determined whether prokaryotes exist which grow under specific conditions, e.g., high/low temperature, high osmolarity, extreme pH values, or with xenobiotic carbon substrates.

By far the most common method of enrichments is the batch culture technique, resulting in the selection of those prokaryotes that attain the maximum specific growth rate under the conditions chosen. Since at the same time, bacteria are growing for a substantial period of time at high substrate concentrations, batch culture enrichments frequently select for prokaryotes with high maximum growth rates and low substrate specificity (the so-called "zymogenous organisms" [Winogradsky, 1949], also referred to as "*r*-strategists" [Andrews, 1984; Andrews and Harris, 1986]). It has been argued for many years that prokaryotes obtained in this way are not representative of those which dominate microbial transformations in the natural environment (Jannasch, 1967a; Jannasch, 1967b; Veldkamp and Jannasch, 1972; Veldkamp, 1977; Kuenen and Harder, 1982b; Gottschal, 1986; Poindexter and Leadbetter, 1986; Gottschal and Dijkhuizen, 1988). Nevertheless, nonlimiting growth conditions possibly also occur under natural conditions at least as transient phenomena, for instance after the burial of organic matter (leaves and fecal pellets), during algal blooms, tidal flooding, or upon sudden changes in physicochemical conditions. Similarly, in gastrointestinal tracts, feeding may provide for conditions most suitable for a rapid response of opportunistic microbial species. The batch culture technique can be employed for the enrichment and isolation of *K*-strategists, if the latter outnumber the accompanying *R*-strategists in the original sample and are capable of (albeit slow) growth in the medium used. In these cases, serial dilution series are established, such that *R*-strategists are absent at higher dilutions and cannot overgrow the target prokaryotes (Ferris et al., 1996; Sekiguchi et al., 2001).

The second, less frequently employed technique is the use of a chemostat with one or more growth-limiting nutrients in the inflowing medium. Using this approach, organisms specialized in growing at very low substrate concentrations and usually exhibiting relatively low μ_{max} values and fairly high substrate specificities (so-called "autochthonous" prokaryotes or *K*-strategists) can be obtained and studied (Andrews, 1984; Jannasch, 1967a; Jannasch, 1967b; Schlegel and Jannasch, 1967; Harder et al., 1982; Kuenen and Harder, 1982b; Poindexter and Leadbetter, 1986; Gottschal and Dijkhuizen, 1988). Another advantage of continuous cultures systems over batch cultures is that physical and chemical parameters can be maintained constant over prolonged periods. Alternatively, these conditions may be changed in a controlled fashion,

such as during light/dark cycles or oxic/anoxic transitions.

Isolation of Prokaryotes

The purpose of isolation is the generation of a single clone, i.e., a population consisting of bacteria all derived from a single cell. The strains obtained in this manner are an essential, but not sufficient (see Interactions with Other Microorganisms), prerequisite for thorough, in-depth and unambiguous studies of the ultrastructure, physiology, molecular biology, genetics and autecology of prokaryotes. When free from other (contaminating) microorganisms, a culture is called "axenic." Not all individuals in this population need to be genetically identical as mutation and selection of mutants can take place, but this heterogeneity is accomodated in the pure culture concept.

Since pure cultures almost never occur in nature, their preparation involves the physical separation of single cells from others, inoculation into sterile medium, and incubation under conditions allowing axenic growth. In general, samples are diluted by means of different methods and concomitantly placed on a nonselective medium. Either direct samples or aliquots from appropriate enrichments may be used for isolation of strains. Separation of single prokaryotic cells can be accomplished by streaking on solid media such as agar plates, separation in liquid media as occurs during preparation of pour plates, in liquid dilution series, or with the aid of micromanipulators. Each colony on solid media or culture developing in the highest positive dilutions potentially has grown from a single cell.

For inoculation with diluted sample material, a small amount of liquid (≤100 µl for agar plates) containing not more than about 200 cells is brought on the surface of an agar plate and spread evenly by the use of a Drigalski spatula. Samples with higher cell densities, for instance material from cell colonies, are streaked on the surface with a sterile loop after dipping the latter in the sample. One of the most efficient ways of streaking is the "13-streak method" (Cypionka, 1999), which involves intermittent sterilization of the loop and provides the highest chance to obtain single, well-isolated colonies from samples of widely different cell densities. Physically separated cells grow out into distinct populations visible on the solidified medium as small heaps or spots, called "colonies," varying in shape, color, and size. When streaking an alleged pure culture, all colonies should be identical in appearance, color, and texture, but in crowded parts of the plate, the size of the colonies will be smaller owing to nutrient depletion. Consequently, size difference as a criterion can only be applied to plates with well-separated (>5 mm) colonies. Motile and swarming prokaryotes cannot easily be isolated on agar plates unless the plates are thoroughly dried and chemicals (mostly detergents like Pril® at a concentration of 0.2% w/v, as used in Pril-Mannitol-Agar [Merck]; Pietzsch, 1969; Reusse and Meyer, 1972) added to disintegrate bacterial flagella and thus stop motility. Some bacteria cannot be cultivated or isolated on solid agar media and require sloppy agar or a liquid medium.

An alternate method is the inoculation of agar plates in the liquid stage, shortly before solidification (the so-called "pour-plate" technique). A known volume of a bacterial suspension is mixed with molten agar (kept at 42°C to just prevent solidification) and then poured into a sterile Petri dish where the mixture is allowed to solidify. With some experience, mixing can also be performed in the Petri dish itself. Upon incubation, cells will grow into colonies that mostly develop below the surface. The latter colonies often show a lenticular shape. Gas-forming colonies may produce cracks in the surrounding agar. The pour-plate technique is suited for the isolation of organisms requiring oxygen at pressures lower than atmospheric (microaerobic bacteria). It is not easy, however, to isolate or count subsurface colonies or to assess colony morphology as a criterion for culture purity. Also, some prokaryotes may be killed by exposure to the higher temperatures of the molten agar.

Anaerobic bacteria most frequently are isolated in deep-agar dilution series in pre-reduced media (see Cultivation of Anaerobes in this Chapter). The first tube is inoculated and mixed and an aliquot (usually a tenth of the volume) is transferred to the following tube. In this manner, a serial dilution series is obtained, which is subsequently solidified by cooling in a 20°C water bath, rapidly gassed with N_2 or a mixture of N_2/CO_2, and sealed with gas-tight butyl rubber stoppers.

Liquid dilution series are preferentially employed for more sensitive bacteria that do not readily grow on agar-solidified media or for inocula with cell titers too high for direct plating on solid media. An additional advantage of this technique is that physical separation of bacterial cells in serial dilutions may promote growth of those bacteria which are otherwise inhibited by antibacterial substances (e.g., bacteriolytic enzymes) produced by the accompanying bacteria (Talamoto et al., 1994). Heterogeneous liquid samples are first homogenized by shaking or agitation in some sort of mechanical device, e.g., a tube containing sterile glass beads, or in a mixer. A nontoxic detergent and complexing agents, e.g., Tween 80 (final concentration, 0.05% v/v) and sodium pyrophosphate (10 mM in

10 mM *n*-[2-hydroxyethyl] piperazine-*N*′-[2-ethanesulfonic acid] [HEPES] buffer), respectively, may be added for detachment of cells adhering to solids. Subsequently, serial dilutions (mostly in 1 : 10 dilution steps) are prepared in sterile medium. Directly after inoculation, each tube has to be mixed carefully, and a fresh glass pipette or pipette tip must be employed for the following dilution step. By inoculating tubes with cell suspensions so dilute that some tubes receive just one single cell or no cell at all, pure cultures may ultimately be obtained and most probable numbers (MPN) of culturable bacteria can be calculated. This method is based on the assumption that bacteria are normally distributed in the liquid media. Numbers of viable cells from natural samples obtained in this way frequently surpass those obtained on agar media (Bartscht et al., 1999; Jaspers et al., 2001). However, the opposite was observed for soil samples, which yielded highest numbers of cultivated bacteria on improved solid media (Janssen et al., 2002).

One drawback of MPN dilution series when employed for the isolation of bacterial strains is that only few cultures can be obtained from the highest positive dilutions (i.e., based on the number of parallel dilution series, usually 3–8). However, provided the average viability for cells in a given sample is known, the number of pure cultures produced can be increased by orders of magnitude without increasing the total number of cultures inoculated. To this end, one appropriate size of inoculum is chosen which statistically contains 0.5 viable cells for parallel inoculation of media. A very efficient way of automated inoculation is the MICRODROP® technique, in which microdroplets (volume of ~100 pl) of a cell suspension are generated by a piezoelectric actuator and positioned directly on agar plates (Schober et al., 1993) or into each well of microtiter plates filled with liquid media. If the procedure is automated, large numbers of inoculation can be performed very rapidly (e.g., 100 inoculations in less than a minute). If each droplet statistically contains 0.5 viable bacterial cells, the number of positive positions on the agar plate or of wells in a microtiter plate follows a Poisson distribution and the most probable number of culturable bacteria can be calculated from fraction p of positive tubes (i.e., the number of positive tubes divided by the total number of tubes n) according to Button et al. (1993)

$$MPN = -\ln(1-p) \tag{24a}$$

The standard deviation is

$$\text{S.D.} = \sqrt{\frac{p}{[n\cdot(1-p)]}} \tag{24b}$$

A much more tedious isolation procedure involves the use of micromanipulator devices (Skerman, 1968), which nowadays include computer-assisted electronic controls, and is used to physically separate single cells or morphologically defined symbiotic consortia under an inverted microcope (Fröhlich and König, 1999; Fröstl and Overmann, 2000). The isolated cells can then be transferred into sterile media. This latter method is especially valuable if morphologically conspicuous prokaryotes, which are easily overgrown by other microorganisms, are to be isolated. This procedure has been used to isolate cyanobacteria, myxobacteria, budding bacteria, and manganese-oxidizing bacteria and phototrophic consortia (Fröhlich and König, 1999; Fröstl and Overmann, 2000; Sly and Arunpairojana, 1987).

Alternative and Novel Concepts for Cultivation

The usually low cultivation success and the molecular detection of entire not-yet-cultured groups of prokaryotes (see Introduction in this Chapter) strongly indicate that specially adapted or novel techniques have to be developed for the isolation of not-yet-cultured prokaryotes from natural samples. Most importantly, novel or alternative cultivation techniques should account for those factors most likely responsible for the low culturability.

Ionic Composition of the Growth Media

Fully synthetic media have been developed which correspond to the ionic strength of freshwater (Bartscht et al., 1999) or seawater (Schut et al., 1993; Sass et al., 2001). For the cultivation of soil prokaryotes, ionic concentrations have been adapted to those typically found in soil solution (Angle et al., 1991; Grosser et al., 2000; for Winogradsky's salt solution, compare Aagot et al., 2001). Synthetic seawater medium has been used in several investigations of the culturability of marine bacteria (Schut et al., 1993; Eguchi et al., 2001; Sass et al., 2001). The various recipes differ slightly with respect to trace element content, salt composition, and the type of buffer used, and they represent an improvement over other types of media employed previously. Reduction or elimination of phosphate and copper concentrations, respectively, has proven very successful for the isolation of "unculturable" cyanobacteria (Waterbury, 1991). Recently, artificial freshwater media have been developed which facilitate the cultivation of planktonic bacteria from limnic sources (Bartscht et al., 1999; Jaspers et al., 2001).

Exploring Novel Types of Metabolism

Novel types of microbial reactions may be postulated on the basis of measurements of concentration changes in potential microbial substrates and products in the environment (Zengler et al., 1999; Schink and Friedrich, 2000). Any reaction can theoretically be assessed for its potential to drive prokaryotic growth by calculating the free energy change. A negative value of the free energy change indicates that a postulated reaction can actually promote microbial growth and can then be verified by trying to enrich for the respective prokaryote.

Cultivation-Independent Physiological Testing of Target Bacteria

The enrichment and isolation of numerically abundant prokaryotes or specific groups of interest can be followed by a phylogenetic screening of enrichments, e.g., by fluorescent in situ hybridization (FISH; Kane et al., 1993; Spring et al., 2000). FISH has recently been used in a combined approach to identify potential growth substrates of target prokaryotes for subsequent enrichment and isolation experiments. In this new approach, the uptake of radiolabeled substrates by target bacteria can be followed if microautoradiography is combined with FISH using oligonucleotide probes designed for selected prokaryotes (Lee et al., 1999; Cottrell and Kirchman, 2000; Gray et al., 2000; Nielsen et al., 2000; Ouverney and Fuhrman, 2000). Pitfalls of this novel technique are 1) that only one growth substrate can be tested at a time and 2) that the added substrate may be rapidly degraded by other (nontarget) microorganisms and that target prokaryotes are actually the only organisms present capable of assimilating the (unidentified) metabolites.

Stable isotope probing is a parallel approach based on labeling with ^{13}C-labeled substrates of genomic DNA of selected prokaryotes. Active prokaryotes can subsequently be identified by 16S rDNA sequencing of the heavy DNA (Radajewski et al., 2000). A limitation of the latter technique is that 1) only those substrates can be tested which are utilized by very few types of prokaryotes (e.g., C_1-compounds), 2) a large excess of labeled substrate and long incubation times are necessary to maximize ^{13}C-uptake and obtain sufficiently heavier genomic DNA—possibly resulting in pronounced shifts in microbial community structure, and 3) unknown intermediates may be rapidly generated by other bacteria thus preventing a correct identification of potential growth substrates.

Thirdly, prokaryotes stimulated by defined substrates can be identified on the basis of the incorporation of bromodeoxyuridine (BrdU) into genomic DNA by metabolically active cells, subsequent immunocapture of BrdU-labeled DNA, and sequencing of the corresponding 16S rDNA sequences (Urbach et al., 1999). An important limitation of the latter approach is that not all prokaryotes assimilate BrdU, even when metabolically active.

As a fourth approach to identify potential growth substrates and optimize growth conditions for yet-to-be-cultured prokaryotes, specific oligonucleotide probes can be developed which are directed against the internal transcribed spacer region of the rRNA (*rrn*) operon and used for FISH to detect selectively, physiologically active cells (Cangelosi and Brabant, 1997; Licht et al., 1999; Oerther et al., 2000; Schmid et al., 2001). All of the above techniques in principle can be employed to perform substrate tests for target prokaryotes under close to in-situ conditions without prior cultivation of the microorganism of interest.

Types and Concentrations of Growth Substrates

Sometimes, specific substrates can selectively promote the growth of numerically abundant bacteria (González et al., 1997). However, target bacteria are frequently slow-growing *K*-strategists and hence easily overgrown by the more rare but rapidly dividing large-celled *R*-strategist bacteria during enrichment in the presence of higher substrate concentrations. Consequently, one novel approach for the isolation of bacteria from natural samples is the utilization of low substrate concentrations of carbon substrates added to synthetic media of appropriate ionic strength (see Ionic Composition of Growth Media). In addition, reduction of the concentrations of N and P compounds (which at certain times may represent the growth-limiting natural substrates) has been found to significantly increase colony counts (Eilers et al., 2001). An alternative approach is to employ sterile filtered seawater directly (Button et al., 1993), which already contains naturally occurring organic carbon substrates as potential substrates for the growth of prokaryotes. Media for the cultivation of soil bacteria can be supplemented with cold soil extract (Olsen and Bakken, 1987) as a carbon and energy source or as a source of supplies. In some instances, application of low nutrient media has yielded comparably high cultivation success (up to 60%; Button et al., 1993). Application of complex mixtures of organic carbon substrates from natural sources can also increase growth of selected groups of anaerobic bacteria. For example, anaerobically prepared sterilized sludge or sediment slurries resulted in higher

MPN of sulfate-reducing bacteria as compared to conventional media (Vester and Ingvorsen, 1998).

As an alternative, typical *K*-strategists can be preconcentrated and potential *R*-strategists selectively excluded by a prefiltration step during which the inoculum is filtered through sterile 0.8-μm pore size membrane filters. This treatment can significantly increase the enrichment efficiency of certain target bacteria. As an example, members of the *Holophaga*/*Acidobacterium* lineage could be successfully enriched from freshwater lake sediments using prefiltration (Spring et al., 2000).

Especially adapted cultivation techniques have been developed to meet the exact physiological requirements of fastidious bacteria. Gradient plates or gradient tubes represent a simple means to cultivate prokaryotes dependent on two substrates, each present at a defined and very narrow concentration range. Examples include chemolithotrophic sulfur-oxidizing bacteria, which are naturally occurring in highly stratified environments such as the chemocline of stratified lakes or sediments. In such cases, artificial agar-stabilized oxygen-sulfide-countergradients have been used very successfully to isolate for the first time *Beggiatoa alba* or magnetotactic cocci (Nelson et al., 1986; Meldrum et al., 1993). In a second type of system, a quartz sand core is employed for gradient stabilization and is sandwiched between a lower anoxic sulfide-containing compartment and an upper oxic compartment (benthic gradient chamber; Pringault et al., 1996). As a great advantage of such gradient systems, the bacteria of interest (by means of their own physiological activity) precisely create the necessary environmental conditions for growth (Jørgensen, 1982).

Recently, the testing of novel classes of substrates has led to the discovery of novel physiological capabilities of known bacterial species, or even to the enrichment and isolation of novel bacteria of a broad phylogenetic diversity (Coates et al., 2002). Many investigations have focussed on the role of humic substances on bacterial growth. Humic substances consist of a skeleton of alkyl or aromatic units which are cross-linked mainly by oxygen and nitrogen groups and which carry carboxylic acid, phenolic and alcoholic hydroxyls, ketone, and quinone groups (Schulten et al., 1991). Contrary to the conservative view of humic substances as being refractory, they in fact can be utilized in different ways by a large number of prokaryotes. Besides the utilization as growth substrates by *Rhodococcus* spp. (Goodfellow, 1992a), and probably also by *Actinoplanes* and related genera (Vobis, 1992), *Microbispora*, *Streptosporangium* (Goodfellow, 1992b), and *Pedomicrobium* spp. (Poindexter, 1992), humic substances represent redox-active compounds that act as electron carriers in abiotic as well as biotic redox reactions (Coates et al., 2002). The redox-active moieties in these reactions are the quinone groups (Lovley et al., 1996; Scott et al., 1998). Humic compounds can act as an electron acceptor for respiratory and fermentative bacteria belonging to diverse bacterial lineages, such as the high G+C Gram-positive bacteria (*Propionibacterium freudenreichii*), γ-Proteobacteria (*Shewanella alga*), δ-Proteobacteria (*Geobacter metallireducens*), or the *Holophaga*/*Acidbacterium* division (e.g., *Geothrix fermentans*, Benz et al., 1998; Coates et al., 1998; Lovley et al., 1999b). Humic compounds as water soluble carriers can shuttle electrons between microorganisms and insoluble terminal electron acceptors (e.g., Fe(III) oxides; Lovley et al., 1996). In addition, humic substances have been shown to be utilized as electron-donating substrates during respiration with nitrate or fumarate, while organic carbon compounds (e.g., acetate) are assimilated heterotrophically (Lovley et al., 1999b; Coates et al., 2002). This latter type of metabolism has been shown for *S. alga*, *G. metallireducens* and *G. fermentans*, but also for the denitrifying bacterium *Paracoccus denitrificans*, the α-Proteobacterium *Agrobacterium* strain PB, the β-Proteobacteria *Dechloromonas agitata*, *Dechloromonas* strain JJ, *Azoarcus* strain HA, the γ-Proteobacteria *Pseudomonas* strain BU, *Pseudomonas* strain NMX, and *Marinobacter* strain SBS, and a γ-Proteobacterium (strain KC; Lovley et al., 1999b; Coates et al., 2002). These microorganisms are capable of exploiting a part of the large pool of humic substances in soils and sediments and gain a competitive advantage over prokaryotes that depend on limited organic compounds (e.g., acetate) as energy source.

Cocultivation

Often, positive interactions between cells of one clone are required for growth of a single cell. This is exemplified by the fact that in the case of fastidious prokaryotes, small inocula can result in an extended lag period or a complete failure of growth. This effect has been attributed to the presence of low-molecular-weight metabolic intermediates excreted by living cells whose introduction into fresh medium depends on the size of the inoculum. This type of isolation difficulties can be remedied by preparing a sterile filtrate of spent enrichment culture medium and including this filtrate as a major constituent of the new medium on which single cells of fastidious microorganisms are to be isolated (Atlas and Bartha, 1993).

As a third point of concern, evidence has accumulated that different prokaryotes may actually depend on phylogenetically nonrelated partner bacteria for a successful enrichment (see Interactions with Other Microorganisms). For example, bacteria of the *Holophaga*/*Acidobacterium* lineage in enrichment cultures as well as natural microbial communities are frequently accompanied by α-Proteobacteria of the *Beijerinckia* group (Felske et al., 1998; Nogales et al., 1999; Radajewski et al., 2000; Spring et al., 2000). Another example is the not-yet-cultured β-Proteobacterium associated with green sulfur bacteria in phototrophic consortia (Fröstl and Overmann, 2000) and to date not enriched or grown in pure culture. Double culture vessels for cocultivation of different bacteria have been described earlier (Jannasch and Mateles, 1974; Wirsen and Jannasch, 1978). Meanwhile, simple incubation devices have been developed which permit the growth of two different prokaryotes in coculture, but separate them by a membrane permeable to metabolites (Fig. 4).

The addition of cAMP, which represents one type of bacterial signal compound at least in some cases, resulted in a significant increase of culturability in natural samples (Bruns et al., 2002). An isolated *Roseovarius* strain exhibited increased cell yield in the presence of cAMP. Similarly, the addition of pyrophosphate to cultures of *E. coli* has been proposed to confer upon the cells a better capacity to use carbon sources, induce biosynthetic processes, and enhance stationary phase survival of *E. coli* cells (Biville et al., 1996).

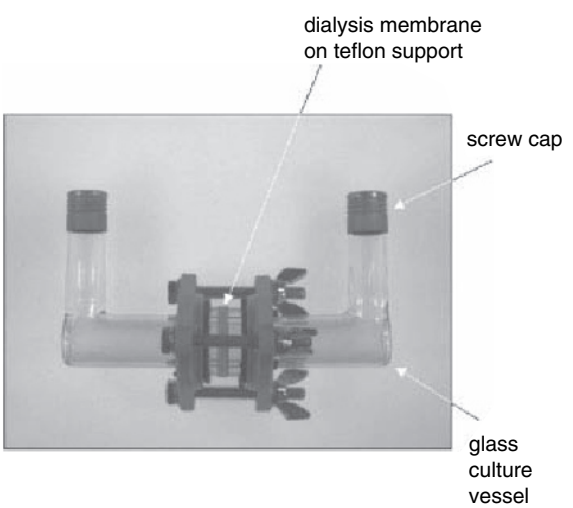

Fig. 4. A simple dialysis coculture setup that permits the growth of two separate prokaryotic cultures while contact via a dialysis membrane is maintained. For growth of aerobic cultures, the screw caps are replaced by cotton plugs and the glass vessels are only half full. Homogeneous cell suspensions can be maintained by adding a small stirring bar to each of the two chambers and placing the set up on a magnetic stirrer.

Chemical Protection

Upon exposure to stress, e.g., heat, osmotic or ethanol shock, bacterial cells may stop growing while their metabolism continues. As a result of this uncoupling, a burst of free radical production occurs which may be lethal to the cells. Exponentially growing bacterial cells are significantly more sensitive to this so-called "suicide response" than cells in the stationary phase (Aldsworth et al., 1999). Entry of *E. coli* into stationary phase growth leads to expression of genes for resistance mechanisms under the control of the alternative sigma factor σ^s, and they include those for resistance against oxidative stress such as *katE* (Loewen and Hengge-Aronis, 1994). At least in some bacteria, cellular damage by oxidative stress can be prevented by the addition of H_2O_2-degrading compounds such as catalase, sodium pyruvate, or α-oxoglutaric acid (Martin et al., 1976b; Brewer et al., 1977; Mossel et al., 1980; Mizunoe et al., 1999). The addition of ascorbic acid to the growth medium or lowering of the oxygen partial pressure has similar effects (Jannasch and Mateles, 1974). The addition of chemical protectants or antioxidants may thus improve the recovery of abundant bacteria from natural samples. Accordingly, addition of activated charcoal as another scavenger of toxic oxygen forms increased the number of colony-forming units in samples from the deep terrestrial subsurface (Stevens, 1995).

Solid Surfaces

Solid surfaces may lead to stimulation of cell division and growth of starved bacteria (Kjelleberg et al., 1982). (See Effect of Inhomogeneities.) So far, however, the capability of attachment has rarely been exploited as a selective factor for the enrichment and isolation of novel types of prokaryotes.

Conservation of Prokaryotic Cultures

For future studies, as reference for standardized assays and tests, for taxonomic purposes, and as valuable stock for biotechnological applications, strains of prokaryotes need to be maintained and preserved over extended periods of time. For long-term maintenance, cultures are routinely stored in a lyophilized or deep-frozen form to prolong their viability and to reduce changes due to the occurrence of mutations.

Maintenance of Working Cultures

Usually, maintenance of working cultures requires the periodic transfer of strains to fresh minimal media. Aerobic strains are streaked on cotton-plugged agar slants or agar plates, whereas stab cultures in agar deeps are produced for facultative anaerobes or microaerophiles and closed by screw caps. Obligate anaerobes are transferred to fresh liquid media. After cultivation, cultures are stored in the refrigerator in the dark at 5–8°C to reduce metabolic activity while maintaining viability. The frequency of transfer should be kept to a minimum, but it has to be determined separately for each organism: some require transfer after just a few days, while some sporeformers can survive in liquid cultures for years. During storage, agar slants and stab cultures must be prevented from drying. To avoid selection of mutants, it is advisable to subculture from the whole plate or slant and not just from one colony.

For different physiological groups of bacteria, specific maintenance requirements exist. Working cultures of rumen bacteria and other fermentative anaerobes can be maintained in slants or sloppy agar (0.5–0.7% [w/v]) prepared from nonselective media. The cultures are incubated at 39°C until growth is just apparent and then stored at 4°C. Such cultures remain viable for a few weeks at least, although the viable count is decreased. Purple sulfur bacteria of the family Chromatiaceae are precultured in sulfide-containing media until the sulfide is depleted and intracellular sulfur has been formed as the intermediate oxidation product in the cells; cultures in this phase of growth have a chalky appearance macroscopically in reflected light. Subsequently, cultures are transferred to the dark at 4°C and can be stored for at least 3 months. Green sulfur bacteria (Chlorobiaceae) are maintained best after the accumulated sulfur has also been depleted. However, cultures of many microorganisms kept at 4°C still show slow growth and turnover of cellular components. Special preservation of cultures is required for extended storage and to prevent genetic and metabolic alterations.

Preservation of Stock Cultures

Spore-Forming Bacteria One method of long-term preservation for spore-forming bacteria is based on the use of sterile soil or sand. A sample of soil or sand is sterilized in a screw-capped bottle by autoclaving for several hours on at least two successive days. Then, 1 ml of the suspension of the organism is added, and the contents dried in a vacuum desiccator with the cap of the tube loosely closed. When the contents are dry, the cap is closed tightly and the bottle stored in the refrigerator. Even easier is the use of sterile filter paper discs or strips soaked with the bacterial suspension. The discs are stored as described for sand above. One may keep several discs in one screw-cap container and remove one disc at a time, taking care not to contaminate the remaining discs.

Lyophilization Freshly grown cells are harvested by centrifugation and placed in an ampoule containing suspending medium and frozen at –60 to –80°C. Rapid freezing is often accomplished in a metal chamber with dry ice (solid CO_2) and ethanol. The water is then removed from the frozen state directly by sublimation in a vacuum. Freeze-dryers consist of a manifold connected to a vacuum pump capable of reducing the pressure to less than 0.01 mmHg. The ampoule is sealed and stored in a cool place. The suspending medium is critical for the rate of survival during the freeze-drying process and for the rate of death of dried bacteria during storage. Among the most commonly used suspending media are serum plus 30% glucose nutrient broths or sterile skimmed milk fortified with 5% sucrose, sterilized in 3-ml amounts.

A percentage of survivors of freeze-thaw stress may lose the ability to form colonies on a minimal salts-glucose medium. In *E. coli*, this effect was not due to a particular nutrient that was absent, but rather to a pertubation of the cell control system since cyclic GMP or ppGpp singly or in combination partly restored the efficiency of plating on a minimal medium of frozen-thawed cells. Mutagenic effects of freeze-thaw stress have been shown to be related to single-stranded breaks in DNA, an effect that might be similar to that of ionizing radiation. The damage can be repaired in nutrient media. In *E. coli*, both the *uvrA*-, *polA*-dependent (excision repair) and the error-prone *rec*-, *polA*-dependent (recombinational repair) DNA repair pathways are required for repair of freeze-thaw-induced DNA damage.

Many bacteria (e.g., purple sulfur bacteria [Chromatiaceae]) cannot be preserved by lyophilization (Pfennig and Trüper, 1989)

Freezing and Ultrafreezing Cultures of rumen bacteria can be kept viable for up to one year by adding 20% (v/v) glycerol as a cryoprotectant and storage at –20°C (Teather, 1982). For long-term storage, cultures are kept at –196°C in liquid nitrogen in the presence of 5% dimethylsulfoxide (Hespell and Bryant, 1981; Pfennig and Trüper, 1989).

Culture Collections

A complete list of worldwide culture collections may be obtained from the following (http://www.dsmz.de/species/abbrev.htm) DSMZ website.

CHAPTER 1.6

Prokaryotes and Their Habitats

HANS G. SCHLEGEL AND HOLGER W. JANNASCH

Prokaryotes are well recognized as essential members of the biosphere. They inhabit all possible locations in which life exists from those offering ideal conditions for growth and reproduction to those representing extreme environments at the borderline of abiotic conditions.

The ubiquity of microorganisms is based on three major properties: their small size for easy dispersal by air and water, their metabolic versatility and flexibility, and their ability to tolerate unfavorable conditions. A predominant population is commonly composed of species able to grow under the particular conditions of a habitat. Many other species may also be present but in low numbers of individuals. As a rule, ecosystems of indistinct physicochemical and nutritional characteristics, such as many soils or sea water, which neither suppress nor specifically support microbial growth, usually carry low numbers of microorganisms but a high diversity of species. In contrast, ecosystems of strong environmental characteristics, such as acid mine waters, salt brines, and hot springs, commonly contain high cell numbers of very few species.

Experimental enrichment procedures bring about the predominance of certain species by controlling the supply of specific nutrients or the use of certain physicochemical conditions. If the growth conditions of a particular microorganism are known and reproducible, enrichment and isolation usually pose no problem. But if the particular requirements for growth of an organism are unknown, isolation procedures may be difficult to discover (Pfennig, 1961; Schlegel and Pfennig, 1961). For that reason, a number of organisms long known from microscopical observations, such a *Thiovulum* or *Achromatium*, have not yet been isolated in pure culture. Furthermore, organisms that have hitherto unknown growth characteristics and that are too small and inconspicuous for easy microscopical recognition have often escaped detection. An excellent example is *Desulfuromonas acetoxidans* (Pfennig and Biebl, 1976).

In characterizing an ecosystem microbiologically, it is important to distinguish between 1) organisms introduced incidentally by air, soil runoff, etc., physiologically just making the best of it, and 2) organisms typically adapted to the particular habitat and not occurring in any other except in the form of survival stages. An example of the former is *Escherichia coli*, as frequently found in polluted waters. An example of the latter is the above-mentioned *Thiovulum* sp., whose need for dissolved oxygen and hydrogen sulfide at the same time requires a high motility combined with chemotactic orientation in an aquatic oxic/anoxic interface.

Although their morphological differentiation is limited, prokaryotes have evolved a number of structural and chemical mechanisms that enable them to inhabit various extreme environments. The presence of a specified pigment, for instance, protects a cell against detrimental radiation or may provide for the absorption of light energy at specific wavelengths encountered in deeper water. Some filamentous cyanobacteria show a certain degree of cell differentiation, a feature that permits the fixation of elemental nitrogen concomitantly with oxygenic photosynthesis in oligotrophic environments. More importantly, however, the metabolic versatility of the prokaryotes, which reflects the development of metabolism during the evolution of life, enables them to live in many parts of the biosphere, including several where eukaryotes are not able to exist.

The vegetative microbial cell, with its relatively large reactive surface, responds quickly to changing physicochemical conditions of its immediate surrounding. As a consequence, the effective habitat of a microorganism is its microhabitat, the immediate surrounding of the cell in a compatible scale of space and time as determined by the radius of its metabolic action and interaction.

Naming microorganisms for their occurrence in certain characteristic macrohabitats, for example, soil and water bacteria, is of limited use. The two apparently very different habitats, soil and water, can be characterized as representing different proportions of the two phases, solid surface and water. The continuum of habitats ranges from highly arid desert soil with no or firmly bound pore water to offshore pelagic sea water containing a minimum of suspended particulate matter. Within the range of suitable physicochemical conditions, the abundance of microorganisms in an ecosystem is determined by the availability of the required energy and carbon sources and essential nutrients. All the more or less specific environments—e.g., the surface of leaves or skin, intestinal tracts, and symbiotically or parasitically invaded tissues—conform to this general description.

The concept of microenvironments eliminates the sharp dividing lines between aquatic, terrestrial, and even medical microbiology. Indeed, in ecological research the distinction between these academic disciplines is now more and more deemphasized by encompassing them under the label of environmental or biogeochemical microbiology. This chapter does not try to cover all the habitats of all organisms treated in this Handbook; the individual habitats and their characteristics are considered chapter by chapter for single species or physiological groups of prokaryotes. This chapter reviews the versatility of prokaryotic metabolism in relation to a few principles that determine the distribution of prokaryotes in nature.

This chapter was taken unchanged from the second edition.

The principal methods for the enrichment and isolation of the major metabolic types of microorganisms were discovered within a relatively short time. Details of the techniques developed by Winogradsky and Beijerinck are dispersed through the journals. Their collected papers (Beijerinck, 1921–1940; Winogradsky, 1949) are treasure troves for microbiologists; only one contemporary compilation exists (Stockhausen, 1907). Since the enrichment principles and methods were the subject of a symposium (Schlegel, 1965), several reviews have appeared (Aaronson, 1970; Schlegel and Jannasch, 1967; Veldkamp, 1970).

The aim of this Handbook is to encourage biologists to continue and intensify the search for bacteria in their natural environments, define habitats and ecological niches, and understand the flux of matter and energy through the biosphere. One may remember that in many soil and water samples there are more kinds of bacteria present than we can cultivate. Furthermore, much data on the flux of carbon and of trace gases through ecosystems cannot yet be accounted for by the bacteria cultivated so far. The gaps need to be filled by laboratory and field studies.

Ecological Terminology

Ecosystems

"The ultimate aim of ecology is to understand the relationships of all organisms to their environment" (Hungate, 1962). The principles of ecology were developed independently for the sciences dealing with plants, animals, and microorganisms. Identical terms are used to designate ecological units and parameters when dealing with macro- and microorganisms, but the implications of these terms are slightly different. The differences sometimes lead to considerable confusion (Whittaker, Levin, and Root, 1973). Furthermore, microorganisms, especially bacteria, exhibit properties not encountered in higher forms of life. The ecology of microorganisms has, therefore, been studied separately, and emphasis has been given to those microorganisms and their habitats that live under conditions not tolerated by the majority of the higher forms of life (Alexander, 1971, 1977; Hungate, 1962; Kushner, 1978). The recognition of the principles of microbial ecology is not yet complete and requires studies in many areas of experimental science (Atlas and Bartha, 1987; Brock, 1986a, b, 1987; Stetter, 1986, 1989; Megusar and Gantar, 1986). Therefore, the usage of terms in microbial ecology is not uniform and partially deviates from that used for the ecology of macroorganisms. A short survey of the present usage of some terms found in this chapter is presented below.

The ecology of microorganisms is concerned with the relationships between different species of microorganisms and between microorganisms and the environment. The basic unit of ecology is the community or biocoenosis. The community has to be considered in relation to the physical and chemical characteristics of the site. Both the biotic components—the community—and the abiotic, physicochemical components make up the ecosystem. The abiotic component of the ecosystem is frequently referred to as the environment, although when speaking about a particular member of the community, for example a species or its population, the term environment is often used to designate both the physicochemical and the biotic components of the ecosystem. In this case the term environment is used synonymously with "habitat."

Ecosystems differ from each other with respect to their extension. Ecosystems may be as large as a pond, a lake, a river, or a fir forest, or they may be as small as the rumen, the intestinal tract of an earthworm, or the rhizosphere of a plant. Some ecosystems, such as a cultivated field or the human skin, are characterized by weak (normal) environmental factors. Other ecosystems, such as hot springs or solar salt ponds, are characterized by strong environmental factors which cause a strict selection among potential inhabitants.

Habitats

Within an ecosystem a habitat for each species can be defined. The habitat is the location or dwelling place of a particular organism. For each microorganism, at least one habitat can be defined where it lives and grows and from which it may be recovered and isolated. Within a distinct ecosystem, a microorganism usually has only one kind of habitat. However, a microorganism may have two or more habitats, each in a different ecosystem. For example, many rhizobia are able to grow in the soil as well as intracellularly in root nodules; opportunist pathogenic bacteria such as *Pseudomonas aeruginosa*, *P. pseudomallei*, and *Erwinia* live in aquatic habitats as well as in mammalian hosts; and luminescent bacteria are met as free-living forms as well as living symbiotically in light organs of fish and invertebrates. Some bacteria are associated with both plant and animal hosts. A particular species of cellulolytic bacteria or of methanogenic bacteria may have its habitat in a lake bottom sediment, in the rumen, and in the sewage-sludge fermentor. In other words: the habitat designates the street and house number of a particular organism; some organisms may have several addresses.

When a species or a particular group of microorganisms is discussed, the word habitat is often used to denote an ecosystem, i.e., the entirety of the biotic and abiotic factors to which the particular microorganism is exposed in its dwelling place. This meaning of the term is in general usage in bacterial ecology. Since the operational area of many bacteria is small, the

term "microhabitat" is frequently used synonymously with "microecosystem" or with "microenvironment."

Inhabitants of an Ecosystem

Each ecosystem harbors a variety of diverse microorganisms. Two principal categories of microorganisms are distinguished: 1) autochthonous or indigenous (resident) microorganisms and 2) zymogenous, allochthonous, or nonindigenous (transient) microorganisms. This concept of two large groups of microorganisms, which are different with respect to their function, was first suggested by Winogradsky (1925). This concept, originally developed in soil microbiology (Winogradsky, 1925, 1926, 1947, 1949), has been adopted in general ecology (Alexander, 1971; Savage, 1977a). Autochthonous microorganisms in the strict sense are those that are native to a distinct soil (e.g., humic soil) and are always present. The population of autochthonous bacteria does not depend on exterior organic matter or on periodic increases of nutrients. Instead it reflects a more or less constant flux of nutrients. Indigenous microorganisms are known for many ecosystems, such as humus soil, the intestinal tract of animals, the rumen, the skin, and plant leaves.

The terms zymogenous, allochthonous, or nonindigenous refer to microorganisms that are dependent on occasional increases of nutrient concentrations or the occurrence of unusual substrates. As aliens and transients, they may persist in the absence of their required substrate or substrate concentration in dormant or starvation-resistant cell stages.

The ecosystem may be occupied by metabolically highly specialized organisms that are restricted to a distinct environment. These microorganisms are easily recognized as belonging to the indigenous flora of the ecosystem. Various obligately parasitic bacteria are specialized to certain animals or plants or even to certain tissues; some bacteria have only been isolated from hot springs, from sewage, or from other extreme environments. At the opposite extreme are the ubiquitous bacteria that are able to grow in distinctly different environments. Examples are soil and water bacteria that occasionally become opportunistic pathogens in animals (*Pseudomonas aeruginosa*, *P. pseudomallei*) or that may switch from plants to animals (*Erwinia*).

Ecological Niches

The term ecological niche was originally used in the sense of an area or location, the properties of which enabled an organism to live there. The functional concept of the niche led to some confusion. The different meanings were discussed by Whittaker, Levin, and Root (1973). Now "ecologists use the term ecological niche to mean the role that the organisms play in the ecosystem" (Odum, 1977). The ecological niche means the function of a species in a community of species in the ecosystem. Each species or strain of a bacterium has particular nutritional requirements, kinetic properties, biochemical abilities, and structural particularities; furthermore, it has distinct degrees of tolerance to environmental conditions. The ability or inability to fulfill a particular function in a distinct ecosystem is dependent on those properties.

For example, many cellulose-hydrolyzing bacteria are not highly specialized. They occupy a broad niche. However, in some ecosystems they may be restricted to cellulose utilization only, because they cannot compete with other organotrophic bacteria in performing other functions such as glucose fermentation. In these ecosystems they occupy a narrow niche. This description agrees with the general observation that the actual distribution of a species or population is usually more limited than its predicted one. In other words, real niches are always smaller than potential niches. Secondary factors determine the predominance of one species among those which could potentially occupy the niche. In the rumen, for example, among the cellulolytic bacteria only those that are able to hydrolyze cellulose under anaerobic conditions and to generate energy for growth by fermentation will be suited to fulfill the function of cellulose hydrolysis. Furthermore, cellulose degradation in the rumen requires tolerance to the particular environmental conditions in the rumen, such as temperatures up to 39–40°C, presence of various fatty acids, enzymes, ammonia, gases, etc. Finally, the function of the cellulolytic population of the rumen is influenced by the activities of other members of the community. In some rumen bacteria the metabolic processes are either impeded or modified if a product of their fermentation, hydrogen, is not removed by methanogenic bacteria. In this case, interspecies hydrogen transfer may be involved, as demonstrated for the S-organism and strain MoH of *Methanobacterium omelianskii* (Reddy, Bryant, and Wolin, 1972a), *Ruminococcus albus* and *Vibrio succinogenes* (Iannotti et al., 1973), *Ruminococcus flavefaciens* and *Methanobacterium ruminantium* (Latham and Wolin, 1977), and *Clostridium thermocellum* and *Methanobacterium thermoautotrophicum* (Winfrey and Zeikus, 1977). Therefore, the organism fulfilling a certain function in a particular ecosystem is determined by many physical and chemical factors and by all of the organisms constituting the community.

Studies on bacteria in pure culture attempt to define their entire ecological potential. The conclusions derived from pure-culture studies can be used to describe the potential niche of the particular bacterium. In nature, the predicted niche may be narrowed by competition. For example, it is possible to grow a pure culture of *Chromatium vinosum* in the laboratory in a medium containing malate as the sole electron donor (Thiele, 1968; van Niel, 1932, 1936). In its natural habitat, *Chromatium vinosum* would not dominate on this medium; members of the Rhodospirillaceae would outgrow the Chromatiaceae.

Finding the explanation for the dominance of a particular species in the habitat requires nutritional and kinetic pure-culture studies. For example, in aquatic environments where hydrogen sulfide is generated in the bottom sediment, bright purple or salmon-colored suspensions of the phototrophic bacterium *Chromatium okenii* or *Thiospirillum jenense* are often seen. Microscopic inspection reveals the presence of several small species of the Chromatiaceae in addition to the large species. Both types evidently coexist in their habitat. However, when samples of these natural enrichments are used for inoculating enrichment cultures in the laboratory, the dominant large bacterial species are overgrown by small species of the same physiological group, such as *C. vinosum* (Pfennig, 1965; Schlegel and Pfennig, 1961). The dominance of the large species in the natural habitat was not understood until Van Gemerden (1974) studied the competition of a representative of the large species, *C. weissei*, and a representative of the small species, *C. vinosum*, for the same substrate, hydrogen sulfide, in chemostat culture.

The dominance of *C. weissei* in the natural habitat turned out to depend upon the diurnal rhythm of illumination. The two species differ from each other with respect to the affinity (the K_s of intact cells) for hydrogen sulfide and to the rate of its uptake and oxidation to sulfur globules stored intracellularly. The maximal rate of hydrogen sulfide uptake (on the basis of total cell number) by *C. weissei* is about two and a half times higher than that by *C. vinosum*. In contrast, *C. vinosum* has a lower K_s for hydrogen sulfide and has a higher maximum growth rate. On the basis of experimental evidence, the dominance or the coexistence of *C. weissei* in the natural habitat can be explained: when both strains are growing in continuous light, most of the hydrogen sulfide will be consumed by *C. vinosum* due to its high growth rate and high affinity for hydrogen sulfide. In the dark, hydrogen sulfide accumulates; on illumination the major amount of the accumulated hydrogen sulfide is oxidized by *C. weissei* and sulfur is stored intracellularly, allowing at least moderate growth for a few hours. Under intermittent illumination both species can coexist. The example demonstrates that competition in the natural habitat can be based on kinetic properties. It further emphasizes the necessity of pure-culture studies for understanding the ecological niches of some microorganisms.

The importance of the substrate affinity, expressed in the K_s constant, can be easily demonstrated by growing mixed bacterial populations in the chemostat at varying dilution rates. At high dilution rates with substrate excess, the fast-growing bacteria are favored. At low dilution rates, when the substrate limits growth, the organism endowed with high substrate affinity (low K_s) will successfully compete. Continuous culture enrichment procedures with natural populations are based on these species-specific substrate affinities (Jannasch, 1967). Competition studies were conducted with psychro- and mesophilic bacteria (Harder and Veldkamp, 1971), a spirillum, and a rod-shaped bacterium in phosphate-limited medium (Kuenen et al., 1977). Such studies have been used to describe the characteristics of prokaryotes living in habitats where growth is largely limited by carbon compounds utilized by a large number of competing species. The use of the chemostat and the kinetics of microbial growth at characteristic ecological niches have been repeatedly reviewed (Jannasch and Mateles, 1974; Veldkamp, 1976; Veldkamp and Jannasch, 1972).

Understanding the ecological niche of a bacterial species is necessary to design enrichment culture conditions. Elective enrichment requires knowing more about a bacterium than its basic features. The knowledge of general growth conditions is not sufficient. For elective enrichment, only those properties can be considered which allow successful competition within a mixed population. The determining feature for occupying the actual narrow niche may be as obvious as in the case of the dinitrogen-fixing *Azotobacter*, abundantly growing and dominating in a sample of soil to which sucrose has been added without providing a source of combined nitrogen. The determining feature, however, may still be hidden, as in the case of enriching for green sulfur bacteria (Chlorobiaceae), which compete successfully at low light intensities but succumb to purple sulfur bacteria at high light intensities (Biebl and Pfennig, 1978; Pfennig and Cohen-Bazire, 1967).

Bacterial Metabolism as an Ecological Determinant

Many ecosystems, both natural and artificial, are almost exclusively occupied by prokaryotes. Environments characterized by the absence of

eukaryotes are the strictly anaerobic regions of freshwater lakes and of marine estuary sediments and any organic material fermented or decomposed under the exclusion of air (sauerkraut, silage, biodigestion with methane production). Prokaryotic cells have also adapted almost exclusively to certain extreme conditions of temperature, acidity, and salinity.

The exclusiveness of bacteria is based on unique metabolic capabilities either absent from or only rudimentarily present in eukaryotes. The uniqueness of bacteria pertains to their modes of energy conversion, to their wide range of growth substrates, and to their tolerance toward extreme environmental conditions.

Modes of Energy Conversion

All forms of life use energy for maintenance as well as for biosynthesis of cell material. Biochemical energy is generated by metabolic reactions. Energy sources are organic or inorganic substrates that are taken up from the environment. In the cell they are converted via a series of metabolic pathways. These pathways fulfill two essential functions: they provide precursors for the macromolecular cell constituents and they make energy available for biosynthetic and other energy-requiring processes.

The principle of "unity in biochemistry" (Kluyver and Donker, 1925, 1926) is one of the few lasting dogmas of this century. Although the original concept referred to the basic energy relationships of organisms, it is now clear that "unity" expresses the assumption that the biochemistry of all organisms on this planet follows a few basic principles, for example, the uniformity of cell constituents, the universality of ATP as the principal carrier of biological energy, the universality of the genetic code, and the distribution of the degradative pathways, the respiratory chain, and the basic mechanisms of cellular energy conversion. Even the main metabolic pathways are almost identical in all organisms. Only a few groups of bacteria have modified patterns of central metabolic routes. The metabolic pathways arose during evolution. The biochemical apparatus that is typical for aerobic organisms developed when oxygen became available.

The prokaryotes developed billions of years before the atmosphere became aerobic and before carbohydrates became abundant products of primary biomass production. They may be regarded as relics of the evolution of life. During their early evolution, the prokaryotes learned to exploit a multitude of sources of energy and cell carbon different from the predominant present-day nutrient sources. The morphological uniformity of prokaryotes contrasts astonishingly with their versatility in substrate utilization, peripheral metabolic pathways, and modes of energy conversion. The most outstanding metabolic capacities, which are either restricted to only a few eukaryotes or completely lacking among eukaryotes, are anaerobic growth, use of inorganic electron donors for growth, fixation of molecular nitrogen, and the utilization of methane and a few polymers.

Anaerobic Growth

The ability to grow indefinitely under anaerobic conditions is almost exclusively confined to prokaryotes (see The Anaerobic Way of Life in Volume 2). In the majority of eukaryotes, anaerobic energy generation is only a transient process occurring during intense activity and exposure to hypoxic environments (Bennett, 1978). There are a few exceptions; among the protozoa two ciliate groups, holotrichs and entodiniomorphs, live in the rumen (Hungate, 1975). *Entamoeba*, *Diplomonas*, and *Trichomonas* lack mitochondria and grow under strictly anaerobic conditions (Bauchop, 1971; Müller, 1975; Steinbüchel, 1986; Williams, 1986; Stumm and Zwart, 1986; Hobson, 1988). Among the helminths there are various facultative anaerobes, such as *Ascaris lumbricoides*, *Trichuris vulpis*, *Trichinella spiralis* larvae, various tapeworms, and *Schistosoma mansoni* (Fairbairn, 1970; Hochachka and Mustafa, 1972; Hochachka and Somero, 1973). The question of whether fungi are able to grow anaerobically has now been definitely settled. An early statement ["One of the major metabolic differences between fungi and bacteria is that there are no anaerobic moulds either obligate or facultative" (Foster, 1949)] has been shown to be wrong by experimental evidence for anaerobic growth of species of *Mucor* (Bartnicki-Garcia and Nickerson, 1962) and *Fusarium* (Gunner and Alexander, 1964), *Aqualinderella fermentans* (Held, 1970; Held et al., 1969), and *Neocallimastix frontalis* (Mountfort and Asher, 1983; Orpin and Joblin, 1988). The latter belongs to the Chytridiomycetes and ferments polysaccharides, cellulose included, with the formation of lactic and acetic acids and H_2 and CO_2.

The contribution of eukaryotes to anaerobic decomposition appears to be negligibly small. The presence of various protozoa, fungi, and lower metazoa in the anaerobic layers of coastal marine sediments, especially within the sulfide system, and their disappearance when the sediment becomes oxidized suggest that the number of eukaryotes able to live under anaerobic conditions is large (Fenchel, 1969; Fenchel and Riedl, 1970; Schroff and Schöttler, 1977; Zebe, 1977).

The forms of anaerobic metabolism are briefly discussed here because of the uniqueness of

anaerobic metabolism in prokaryotes and its function in whole ecosystems. The energy for bacterial growth under anaerobic conditions can be provided by three fundamental types of anaerobic energy generation: 1) anoxygenic photosynthesis, 2) anaerobic respiratory energy generation, and 3) fermentative energy generation.

Anoxygenic photosynthesis is the light-driven process that anaerobic phototrophic bacteria use to generate energy (Table 1). Unlike green plants, these bacteria are not able to use water as the ultimate reductant; consequently they do not evolve oxygen and they require the presence of other reduced compounds such as organic acids, alcohols, carbohydrates, hydrogen sulfide, sulfur, or hydrogen (Gromet-Elhanan, 1977; Jones, 1977). Two major groups are different by their pigmentation: the purple and the green bacteria. On the basis of their source of reducing power, the purple and green bacteria are subdivided into sulfur and nonsulfur bacteria. The purple and green sulfur bacteria can use reduced sulfur compounds and oxidize them via elemental sulfur to sulfate. The nonsulfur purple bacteria require reduced organic compounds or, when using hydrogen sulfide, oxidize it to sulfur or sulfate. In contrast to the purple sulfur bacteria they lack the ability to oxidize elemental sulfur. The green bacteria comprise two groups, the *Chlorobium* group and the *Chloroflexus* group. The chlorobia use hydrogen sulfide as reductant and comprise strictly anaerobic bacteria; the latter are facultative and versatile (Pfennig, 1979; Trüper, 1976). The majority of phototrophic bacteria require light for growth; a few species can equally well obtain energy via aerobic respiration.

Anaerobic respiratory energy conversion is similar to aerobic respiration with respect to the electron donors, which may be either organic or inorganic compounds. Oxygen serves as the ultimate electron acceptor in aerobic respiratory energy generation, but anaerobic respiration depends on the presence of inorganic compounds, which, under anaerobic conditions, are reduced. The physiological groups listed in Table 2 are differentiated with respect to the electron acceptors used and to respective end products of the respiratory process. Each of these physiological groups comprise strains and species belonging to various taxonomic groups.

Fermentative energy generation depends on organic compounds serving as electron donors and as electron acceptors. These compounds are usually two different metabolites derived from sugar by cleavage or, in a few cases, derived from two different compounds. Fermentation is accompanied by the production of more or less reduced compounds, such as alcohols, organic acids, ammonia and hydrogen and of carbon dioxide as the oxidized product.

The fermentative bacteria are usually separated into groups on the basis of one or several fermentation products which reflect their metabolic pathways (Table 3).

Table 1. Groups of anaerobic phototrophic bacteria.

Bacterial group	Typical species	Growth: Anaerobically in light	Growth: Aerobically in dark	Photosynthetic electron donors	Sulfur deposited
Nonsulfur purple bacteria	*Rhodospirillum rubrum*	+	(+)	H_2, organic, (S^{2-})	(extracellularly)[1]
Purple sulfur bacteria	*Chromatium okenii*	+	–	S^{2-}, S^0, $S_2O_3^{2-}$, H_2	Intracellularly
Green sulfur bacteria	*Chlorobium limicola*	+	–	S^{2-}, S^0, $S_2O_3^{2-}$, H_2	Extracellularly
Chloroflexus group	*Chloroflexus aurantiacus*	+	+	Organic (S^{2-})	(extracellularly)
Heliobacterium	*Heliobacterium chlorum*	+	–	Organic	—

Parentheses indicate substrates used by only a few strains or species.

Table 2. Physiological groups of bacteria able to grow under anaerobic conditions using external electron acceptors for electron transport ("erobic respiration").

Bacterial group	Typical species	Metabolic process	Electron acceptor	Reduction products(s)
Denitrifiers	*Pseudomonas denitrificans*	Nitrate respiration	NO_3^-	N_2, N_2O, NO_2^-
Sulfate reducers	*Desulfovibrio vulgaris*	Sulfate respiration	SO_4^{2-}	S^{2-}
Sulfur reducers	*Desulfuromonas acetoxidans*	Sulfur respiration	S^0	S^{2-}
Methanogenic bacteria	*Methanobacterium thermoautotrophicum*	Carbonate respiration	CO_2	CH_4
Acetogenic bacteria	*Acetobacterium woodii*	Carbonate respiration	CO_2	CH_3—COOH
Succinogenic bacteria	*Wolinella succinogenes*	Fumarate respiration	Fumarate	Succinate
Iron reducers	*Pseudomonas* GS-15	Iron respiration	Fe^{3+}	Fe^{2+}

Table 3. Groups of fermentative bacteria able to grow under anaerobic conditions, and their fermentation products.

Fermentation characterizing bacterial groups	Typical species	Substrate	Fermentation product	
			Major	Minor
Ethanol fermentation	*Zymomonas mobilis*	Glucose	Ethanol	CO_2
Lactate fermentation:				
Homofermentative	*Lactobacillus casei*	Glucose	Lactate	
Heterofermentative	*Leuconostoc mesenteroides*	Glucose	Lactate	Ethanol, CO_2
Heterofermentative	*Bifidobacterium bifidum*	Glucose	Acetate	Lactate
Butyrate fermentation	*Clostridium butyricum*	Glucose	Butyrate	Acetate + H_2 + CO_2
	Clostridium acetobutylicum	Glucose	Butyrate, butanol	Acetone, 2-propanol
	Clostridium kluyveri	Ethanol + acetate	Butyrate	Caproate, H_2
Homoacetate fermentation	*Clostridium aceticum*	Fructose	Acetate	
Propionate and succinate fermentation	*Propionibacterium pentosaceum*	Sugars, lactate	Propionate	Succinate
	Veillonella alcalescens	Lactate	Propionate	Acetate, H_2, CO_2
	Bacteroides ruminicola	Sugars	Propionate	
Mixed acid and butanediol fermentation	*Escherichia coli*	Glucose	Lactate, ethanol, acetate	Formate, H_2 + CO_2, succinate
	Enterobacter aerogenes	Glucose	2,3-Butanediol, ethanol	Formate, H_2 + CO_2
Nitrogenous compounds fermentation	*Clostridium tetanomorphum*	Glutamate	Butyrate	Acetate, CO_2, NH_3
	Clostridium sticklandii	Lysine	Butyrate	Acetate, NH_3
	Clostridium oroticum	Orotate	Acetate	CO_2, NH_3

Table 4. Groups of bacteria able to use inorganic electron donors for growth ("chemolithoautotrophs").

Bacterial group	Typical species	Metabolic process	Electron donor	Electron acceptor	Carbon source	Product
Hydrogen-oxidizing bacteria	*Alcaligenes eutrophus*	H_2 oxidation	H_2	O_2	CO_2	H_2O
Carbon monoxide-oxidizing bacteria	*Pseudomonas carboxydovorans*	CO oxidation	CO	O_2	CO_2	CO_2
Ammonium-oxidizing bacteria	*Nitrosomonas europaea*	Ammonium oxidation	NH_4^+	O_2	CO_2	NO_2^-
Nitrite-oxidizing bacteria	*Nitrobacter winogradskyi*	Nitrite oxidation	NO_2^-	O_2	CO_2	NO_3^-
Sulfur-oxidizing bacteria	*Thiobacillus thiooxidans*	Sulfur oxidation	S, $S_2O_3^{2-}$	O_2	CO_2	SO_4^{2-}
Iron-oxidizing bacteria	*Thiobacillus ferrooxidans*	Iron oxidation	Fe^{2+}	O_2	CO_2	Fe^{3+}
Methanogenic bacteria	*Methanobacterium thermoautotrophicum*	Methanogenesis	H_2	CO_2	CO_2	CH_4
Acetogenic bacteria	*Acetobacterium woodii*	Acetogenesis	H_2	CO_2	CO_2	CH_3-COOH

Growth with Inorganic Electron Donors

The ability to use inorganic compounds as electron donors for growth, called lithotrophy, is exclusively restricted to prokaryotes (see The Chemolithotrophic Prokaryotes; The H_2-Metabolizing Prokaryotes; The Colorless Sulfur Bacteria; and Oxidation of Inorganic Nitrogen Compounds as an Energy Source all in Volume 2). The electrons are used for electron transport phosphorylation, either aerobically with oxygen or anaerobically with inorganic compounds (nitrate, sulfate, carbonate) as the ultimate electron acceptors. The electrons also serve to reduce carbon dioxide, which is the common carbon source for a physiological group of bacteria called chemolithoautotrophs. These bacteria are usually separated into groups on the basis of their electron donors (Table 4). In memory of S.N. Winogradsky, who developed the concept of chemolithotrophy and autotrophy in 1887–1891, a symposium on lithoautotrophy was held in 1987 (Schlegel and Bowien, 1989).

Fixation of Molecular Nitrogen

Only prokaryotes are able to fix molecular nitrogen (dinitrogen = N_2) and to grow in the absence of a source of combined nitrogen (see Chapter 22). Dinitrogen fixation requires the presence of a special enzyme system, nitrogenase, and particular environmental conditions. The ability to fix dinitrogen is distributed among many species of oxygenic and anoxygenic phototrophic bacteria, chemoautotrophic and chemoheterotrophic bacteria, and both aerobic

and anaerobic bacteria—in short, in all major physiological groups. There is almost no correlation with the taxonomic unit. A recent symposium considered all aspects of research in this area (Bothe et al., 1988).

Range of Organic Substrates for Growth

The bacteria as a whole are considered to be omnipotent with respect to their substrate spectrum. All natural (biosynthetic) compounds are subject to degradation by microorganisms. There are a few compounds that can be utilized exclusively by prokaryotes. Among the low-molecular-weight compounds, methane is oxidized only by highly specialized bacteria, the methylotrophs. Some of these bacteria are obligate methylotrophs, being able to use methane, methanol, and dimethyl ether as substrates.

No macromolecular compounds are used only by prokaryotes. Cellulose, hemicelluloses, pectins, xylanes, galactan, mannans, chitin, and others are subject to degradation by bacteria and fungi; some polymers are hydrolyzed by protozoa and a few metazoa. Under anaerobic conditions, however, the degradation of polysaccharides is almost exclusively confined to prokaryotes.

Extremes of Environmental Conditions Allowing Bacterial Growth and Survival

Room or body temperature, the oxygen partial pressure of the atmosphere, neutrality of pH, and abundant nutrients supporting luxurious growth of the kinds of organisms studied in the laboratory are generally considered to be "normal" conditions for growth of microorganisms. Any conditions substantially deviating therefrom are regarded as being extreme. The ecologically minded biologist will define those conditions under which the greatest species diversity develops as normal. Environmental conditions different from the norm have an elective effect on organisms; as a rule, the species diversity decreases with the increase of environmental adversity. The greater the severity of an adverse environmental factor, the smaller is the number of species of actively growing microorganisms. In addition, among the organisms adapted to extreme conditions the abundance of physiological types is restricted. However, this trend of limitation of species and number of individuals may not be as pronounced as is presently assumed. It may just reflect reluctance to examine extreme environments and to isolate new organisms, many of which cannot easily be grown in laboratory cultures.

In general, the microorganisms that tolerate and grow under the most extreme conditions are obligately adapted to their particular environment and fail to grow at lower intensities of the same environmental factor. Such an organism has acquired the ability to grow in one extreme environment at the expense of its ability to grow in others. Less rigid or extreme environmental conditions are tolerated by a greater number of organisms; some of these are obligately bound to these conditions and others grow there facultatively. There are several examples of low numbers of species and of high specialization in habitats of extreme conditions, such as low and high temperature, high salt concentrations, low moisture, low pH, low nutrient concentrations, and others. Much attention has been given during recent years both to microorganisms that either tolerate or are dependent on extreme conditions and to their habitats. Life in extreme environments was the subject of several symposia, and emphasis was paid to the microorganisms, to the regulatory or molecular mechanisms that make life under adverse conditions possible, and to the possible existence of life on other planets (Alexander, 1971, 1976; Brock, 1969; Ellwood et al., 1980; Heinen, 1974; Hochachka and Somero, 1973; Kushner, 1971, 1978; Shilo, 1979; Brock, 1986a, b; Stetter, 1986, 1989; Larsen, 1986; Tindall and Trüper, 1986).

Thanks to the amount of attention that the "extremophiles" and their habitats have received during recent years, there is no need to add another exhaustive review. However, it is likely that more as yet unidentified microorganisms representing various metabolic groups are present in extreme environments. They can only be discovered by experimental approaches based on new ideas on possibly existing organisms. The following short survey is meant to encourage relevant research.

Low Temperatures

The temperature of the natural environments of water and soil bacteria is distinctly lower than their optimum growth temperature. The average soil temperature in the temperature climate zone is 12°C, and 90% of the ocean water is 5°C or colder. Many mesophilic bacteria do not find their optimum growth temperature in their natural habitats; they are, however, able to tolerate the seasonal fluctuations of temperature, which in the summer can easily span 30°C or more. This tolerance is lacking in psychrophilic bacteria. As defined by Morita (1975), "the psychrophiles are those organisms having an optimum growth temperature of 15°C or lower, a maximal temperature for growth at about 20°C and a minimal temperature for growth at 0°C or lower." Many

bacteria that have been isolated from Arctic and Antarctic Ocean waters and sediments have optimal growth temperatures of about 10°C but do not survive exposure to 20°C. True psychrophiles will, therefore, be found only in habitats that never become warmer than 20°C. At temperatures below 10°C, psychrophiles do have selective advantage as demonstrated in continuous culture experiments (Harder and Veldkamp, 1968, 1971). One of the ecological niches of psychrophiles in the ocean is chitin degradation. The vast majority of psychrophilic bacteria are members of *Pseudomonas*, *Flavobacterium*, *Achromobacter*, and *Alcaligenes* (Rose, 1968).

Food preservation added another habitat for psychrophilic bacteria (Schmidt-Lorenz, 1967). However, the majority of bacteria that grow on food near the freezing point are apparently facultative psychrophiles or psychrotrophs that have temperature maxima for growth above 20°C, but are able to grow at low temperatures also. With respect to growth at temperatures down to –18°C, the capacities of prokaryotes do not seem to exceed those of the eukaryotes.

Microbial life at low temperatures has been comprehensively reviewed and discussed on the basis of ecological aspects (Baross and Morita, 1978) and molecular aspects (Inniss, 1975; Inniss and Ingraham, 1978).

High Temperatures

Growth at temperatures higher than about 60°C is restricted to the prokaryotes. Habitats with such temperatures include piles of self-heating hay, compost, or other organic materials (Hussain, 1973), circulating hot or cooling water in industrial plants, and hot springs and other geothermal sources.

The ecology of hot springs has been especially well studied and reviewed (Brock, 1967, 1970, 1978, 1986; Castenholz, 1969, 1979). The runoff of a hot spring is an ideal location to study the upper temperatures for continual growth of organisms. As in most extreme habitats, the species diversity decreases with increasing severity of the environmental factor. When the temperature gradient rises from 50 to 70°C, thermophilic bacteria such as the yellow-pigmented *Thermus aquaticus* (Brock and Freeze, 1969), which has an optimum temperature for growth at 70°C and a maximum at 79°C, can be found. In many runoff channels, thick mats consisting of the cyanobacterium *Synechococcus lividus* and the phototrophic, gliding, filamentous bacterium *Chloroflexus aurantiacus* are present (Pierson and Castenholz, 1974) (see also Chapter 207). In these mats, several layers of *Chloroflexus* are covered by a thin surface layer containing a mixture of *Synechococcus* and *Chloroflexus* (Bauld and Brock, 1973; Madigan and Brock, 1977).

Several strains of the facultative autotroph *Sulfolobus acidocaldarius,* with a growth pH range of 0.9–5.8 and temperature optimum of 70–75°C, and of an extreme thermophile growing at 85°C have been isolated from acid, hot, aqueous and soil habitats (Brock et al., 1971, 1972; Fliermans and Brock, 1972). Thermophilic *Thiobacillus*-type bacteria growing at 60 or 75°C were found in Icelandic thermal areas (Le Roux, Wakerley, and Hunt, 1977). The habitats par excellence of these bacteria are volcanic hot springs where magmatic hydrogen sulfide is oxidized to elemental sulfur and sulfuric acid. Thermophilic iron- and sulfur-oxidizing bacteria may be involved in metal leaching from low-grade ore (Brierley, C.L., 1977; Brierley and Lockwood, 1977; Brierley, J.A., 1978; Golovacheva and Karavaiko, 1978; Levi and Linkletter, 1989; Hughes and Poole, 1989).

Yellow-pigmented *Thermus* strains have also been isolated from Icelandic hot springs (Pask-Hughes and Williams, 1977). Nonpigmented thermophilic bacteria, otherwise similar to *Thermus aquaticus*, were found in laundry heaters (Brock and Boylen, 1973), hot tap water (Pask-Hughes and Williams, 1975), and a stream receiving hot-water effluents (Ramaley and Hixson, 1970) (see also The Family Chloroflexaceae in Volume 7). The range between 50 and 70°C is occupied by a multitude of bacteria, among them members of the genera *Bacillus*, *Thermoactinomyces* (Cross, 1968), *Methanobacterium* (Zeikus and Wolfe, 1972), *Methylococcus*, and others. Several thermophilic bacteria find excellent growth conditions in canned foods (Gillespy and Thorpe, 1968) and sugar (Scarr, 1968).

Our knowledge of microbial life at high temperatures has been greatly extended by studies of continental and marine hot springs of volcanic origin. A considerable number of organisms have been isolated that cover a range for optimal growth at 85–105°C and are generally termed extreme thermophiles or hyperthermophiles (Stetter, 1986; Stetter et al., 1990) (see also Thermoproteales; The Order Thermococcales; The Genus *Archaeoglobus*; and Thermoplasmatales, all in Volume 3). These organisms are mainly archaebacteria and appear to be so well adapted to these high temperatures that they do not grow below 60°C, and some of them do not grow below 80°C. Acidic terrestrial sulfotaric environments have primarily yielded acidophilic, hyperthermophilic autotrophs of the order Sulfolobales (see Thermoproteales in Volume 3) that aerobically oxidize H_2S and S°, with the exception of *Acidianus,* which is able to grow anaerobically on H_2 and S° forming H_2S (Huber

et al., 1987a). The same is true for some neutrophilic isolates that exist in neutral and anaerobic zones of terrestrial sulfotaras and are members of the genera *Thermoproteus* and *Pyrobaculum* (Zillig et al., 1981, 1982; Stetter and Zillig, 1985). A facultatively autotrophic isolate (*Pyrobaculum islandium*) grows by sulfur respiration of organic matter (Huber et al., 1987a).

Another habitat that has recently yielded a number of extremely thermophilic bacterial isolates are the deep-sea hydrothermal hot vents found at depths from 1,800–3,700 m. The high pressures make possible the presence of liquid water at temperatures far beyond the 1-atm boiling point of water, i.e., at a depth of 2,500 m, extruding vent water will not boil below approximately 460°C. This habitat provides an ideal situation to look for the upper temperature limit of prokaryotic life. Early indications that growth might occur at 250°C (Baross and Deming, 1983) have not yet been confirmed, although active growth at 110°C has been found in a culture of a new group of methanogenic archaebacteria (*Methanopyrus,* Huber et al., 1989). While this organism grows with its optimum doubling time of about 1 h just below 100°C, isolates of the genus *Pyrodictium* (Stetter et al., 1983) grow optimally at 105°C. *Pyrodictium,* as well as a large number of physiologically diverse hyperthermophilic archaebacteria, were isolated from a shallow marine hot spring (Stetter, 1986) and an erupting volcano (Huber et al., 1990).

Using $^{35}SO_4^{2-}$, hyperthermophilic sulfate reduction has been demonstrated in sediment cores freshly collected from a hydrothermal vent field (Jørgensen et al., 1990), and the organisms responsible (*Archaeoglobus profundus*, Burggraf et al., 1990) could be isolated at the same time. This particular vent field, located in the Gulf of California at a depth of 2,000 m, is overlayed by 3–400 m of organic-rich sediment (Jannasch, 1989). In the upper 60 cm of these sediments, downward temperature gradients of 3–180°C have been measured, overlayed by ambient bottom water with a temperature of 2.1°C. In these sediments, methanogenic hyperthermophiles of the genus *Methanococcus* (Jones et al., 1983, 1989; Zhao et al., 1988) appear to be common in addition to those of the above-mentioned *Methanopyrus.* The majority of the newly described hyperthermophiles were found in both the deep and the shallow marine hot vents. This includes the genera *Pyrococcus*, *Pyrodictium*, and *Staphylothermus* and the only eubacterial genus of extreme thermophiles, *Thermotoga* (Fiala et al., 1986; Belkin et al., 1986; Huber et al., 1986; Jannasch et al., 1988; Windberger et al., 1989). Some of them depend on the reduction of elemental sulfur, while others conduct an unknown type of fermentation.

Although many thermophilic water and soil bacteria were reported to be present only in samples of thermal habitats, experience indicates that they are much more widespread. The isolation of thermophilic, hydrogen-oxidizing bacteria from hot springs and the failure to isolate them from other places indicated a very narrow distribution of these highly specialized bacteria (Goto, Kodama, and Minoda, 1977). Surprisingly, attempts to isolate thermophilic, hydrogen-oxidizing bacteria from cold lake sediments (Aragno, 1978; Schenk and Aragno, 1979) and from the oxidation ponds of a sugar factory (H.G. Schlegel, unpublished) were successful. The search for thermophiles among other highly specialized bacteria resulted in equally encouraging findings, for example, thermophilic, nitrifying bacteria (Golovacheva, 1976), iron-oxidizing bacteria (Brierley, J.A., 1978), sulfur-oxidizing bacilli (Golovacheva and Karavaiko, 1978), and carbon monoxide-oxidizing bacteria (O. Meyer, unpublished). These recent findings indicate that the ability to grow at temperatures higher than 50°C is not confined to only a few metabolic types.

Research in the ecology of thermophilic microorganisms has recently yielded spectacular results; they are summarized by Brock (1978), Tansey and Brock (1978), Brock (1986), and Castenholz (1979).

Water Stress

Without water, life is not possible. The normal environment of microorganisms is an aqueous solution. The water body may differ in size, and the water may be free or adsorbed to external or internal surfaces of materials. The availability of water to microorganisms is a function not only of the water content of a material, but also of solution and adsorptive factors. In order to compare solutions and solid materials with respect to available water, the parameters "water activity" (a_w, ranging from 0 to 1.0) and "relative humidity" (expressed as a percentage) are used. These parameters express the ratio of water in the vapor phase to the amount of water the air would contain when vapor-saturated at a given temperature. Another parameter, the "water potential," is based on the free energy of molecules in water and makes differentiation of the matric and solute components of the system easy (Brown, 1978; Griffin and Luard, 1979; Smith, 1978, Griffin, 1981).

Microbial growth is possible in the range of water activity between 0.998 and 0.6 (Duckworth, 1975; Mossel, 1975; Mossel and Ingram, 1955). Bacteria are not very successful at extracting water from environments of lowest water activities. Fungi lead the list of organisms arranged with respect to the lowest water activity

at which they can grow. The osmotolerant yeast, *Saccharomyces rouxii*, and the osmophilic mold, *Xeromyces bisporus*, are able to grow down to $a_w = 0.60$; even *Aspergillus glacus* can survive at $a_w = 0.80$. In contrast, the majority of bacteria need water activities higher than 0.98 (which is the a_w of sea water at 25°C); only a few bacteria grow at 0.95 to 0.91. The halophilic bacteria are exceptions, growing at $a_w = 0.75$. The data are in accordance with the results of measurements on the microbial degradation of plant residues and straw mixed with field soil. If the soil was kept in equilibrium with pure water, the rate of carbon dioxide evolution was maximal. With decreasing humidity, the activity of bacteria decreased and reached zero at 92% relative humidity.

One has to distinguish between two effects of humidity, that on the activity and that on the viability of microorganisms. Some bacterial species are more resistant to drying than others. After some weeks of air-drying in the laboratory, the remaining viable population consists of bacteria that are able to form endospores, cysts, and other resting stages resistant to desiccation (Boylen, 1973; Robinson, Salonius, and Chase, 1965). However, under certain conditions even vegetative cells survive (Clark, 1967). Survival of vegetative cells depends on the type of soil, the velocity of the drying process, and the water activity. Several reports indicate that processes like nitrification, sulfur oxidation, and nonsymbiotic nitrogen fixation proceeded after rewetting without any soil reinoculation. Apparently, the endospores of some bacilli can survive for hundreds of years. On the basis of viable counts made on soil granules from the roots of plants gathered and dried in 1640 (Herbarium, Royal Botanical Gardens, Kew), "one can estimate that a ton of dry soil would still contain a few viable spores even after 1,000 years" (Sneath, 1962).

Salinity

High salt concentrations represent a special case of low water activity. Sea water ($a_w = 0.98$) is not tolerated by the majority of bacteria living in soil and in fresh water. Ecosystems containing salt (sodium chloride) at saturating concentrations are inhabited by only a few organisms. Many bacteria (Brison, Courtois, and Denis, 1974) as well as the flagellated alga *Dunaliella viridis* and the brine shrimp *Artemia salina* can tolerate such high salt concentrations, but only members of the prokaryotes find their optimum growth conditions there. The extreme halophiles have their best growth at 20–30% salt, moderate halophiles at 5–20%, and slight halophiles at 2–5% (Dundas, 1977; Larsen, 1967, 1971, 1973, 1986; Tindall and Trüper, 1986).

Extremely halophilic bacteria, such as *Halobacterium cutirubrum*, *H. salinarium*, and *Halococcus morrhuae*, are distributed in evaporation ponds for the production of solar salt and occasionally on salted fish and hides. They are easily recognized by their red color caused by carotenoids. Moderately halophilic bacteria live in similar habitats, namely salt brines and mud, and are often found in curing brines for meat, fish, and vegetables. About a dozen different bacteria are reported to find their optimum growth conditions in the range of 5–20% sodium chloride. The majority of the bacteria inhabiting the sea and marine mud require 2–5% sodium chloride; some of these slight halophiles fail to grow at lower salt concentrations.

The general aspects of halophilism and life in high salt concentrations have been recently discussed by Kushner (1978); Lanyi (1979); Brock (1979); Bayley and Morton (1978, 1979); and Csonka (1989).

From the ecological point of view, salinity plays a more important role than the water potential suggests. The following differences between freshwater and saline ecosystems cannot be overemphasized. As long as a saline water body or a water-soaked sediment is aerobic, the water potential may be the dominating factor among the selective environmental conditions for the growth of bacteria. The sequence of dominance of selective factors changes as soon as the location becomes anaerobic. Many saline waters, either marine or salt-polluted inland waters, contain sulfate; in the absence of oxygen, sulfate is the preferred terminal electron acceptor in anoxic environments and gives rise to the generation of hydrogen sulfide. The concentration of hydrogen sulfide may then exert a selective pressure on the bacterial flora in the location and govern the composition of the anaerobic food chain. In many freshwater lakes, the sulfate concentration is just high enough to provide sufficient hydrogen sulfide for securing the redox potential necessary for methanogenes to grow, but in marine ecosystems, such as sublittoral and estuarine sediments, the concentration of sulfate and, in consequence, that of hydrogen sulfide exceed the threshold where methanogenesis is possible (Cappenberg, 1974a,b; Winfrey and Zeikus, 1977).

Environments of Extreme pH Values

Hydrogen and hydroxyl ions are the most mobile of all ions. The concentration of these ions affects the growth of microorganisms either directly or indirectly via its influence on the ionic state and the availability of many inorganic ions and metabolites to the cells. The majority of bacteria prefer neutral or slightly alkaline conditions.

Acid Environments The hydrogen ion concentrations of the ocean and the major part of the land vary only within a narrow range, allowing growth of both fungi and bacteria. Only volcanic lakes and soils of recently claimed land have drastically reduced pH values. An extreme aquatic habitat of low pH is represented by the drainage of coal mines and coal mine refuse piles; the acidity is due to the oxidation of pyritic minerals, reduced iron, and sulfur compounds associated with coal (Colmer, Temple, and Hinkle, 1950; Leathen, Braley, and McIntyre, 1953). Sulfuric acid produced by thiobacilli causes a decrease of the pH down to 2.0 or even 0.7. Iron- and sulfur-oxidizing bacteria are present wherever mine water enters a stream. *Thiobacillus ferrooxidans*, involved in metal-leaching processes (Tuovinen and Kelly, 1972), can tolerate even pH 1.0, as well as ions of copper, cobalt, zinc, nickel, and iron up to extremely high concentrations (Torma, 1977). Organic acids are excreted in laboratory cultures (Schnaitman and Lundgren, 1965); their ecological significance is unknown. In acidic water, most Gram-positive, aerobic and anaerobic, heterotrophic bacteria die quickly, while yeasts and molds predominate (Marchlewitz and Schwartz, 1961). Among the heterotrophic bacteria only *Bacillus*, *Pseudomonas*, *Achromobacter* (Tuttle, Randles, and Dugan, 1968), *Flavobacterium acidurans* (Millar, 1973), and other slime-forming bacteria (Dugan, MacMillan, and Pfister, 1970) were encountered. Waters of acid hot springs are further habitats of acidophilic bacteria, such as thermophilic bacteria related to *Sulfolobus acidocaldarius* (Brierley and Brierley, 1973; Brock et al., 1971; De Rosa, Gambacorta, and Bu'lock, 1975) and, at lower temperatures, of mesophilic thiobacilli.

Many lakes, bogs, pine forests, and tea soils are slightly acidic, with pH values between 3 and 5.5. Bacterial life in these locations is scarce and, especially under anoxic conditions, degradation of plant polymers is slow. Nitrification proceeds slowly in acidic soils, and the question of whether nitrification in these areas is partly due to autotrophic nitrifying bacteria (Bhuiya and Walker, 1977) and to heterotrophs is still open (Focht and Verstraete, 1977). Acid bogs apparently offer the marginal conditions under which some rarely encountered bacteria, such as *Planctomyces*, *Bactoderma*, *Caulobacter*, and *Microcyclus* (Hirsch and Pankratz, 1970), as well as other stalked and prosthecate bacteria, can thrive (Henrici and Johnson, 1935; Schmidt, 1971).

Alkaline Environments The environment where human or animal urine undergoes a urea fermentation cannot be ignored because of the penetrating odor of ammonia. The causative agents of this noticeable process were first studied by Pasteur in 1862 and designated *Torule ammoniacale.* The ureolytic bacterium, *Bacillus pasteurii*, is an alkalophile that requires pH values of 8.5 or higher and high ammonia concentrations (Wiley and Stokes, 1963). *Sporosarcina ureae* grows at lower alkalinities (pH 8.5) (Mazanec, Kocur, and Martinec, 1965).

The isolation of alkaliphilic bacteria, able to grow in culture media of pH 10–11, is apparently rather easy. Such variants growing up to pH 11 were isolated after adapting *Bacillus circulans* (Chislett and Kushner, 1961). *Bacillus alcalophilus* growing at pH 8–10 was isolated from human feces (Vedder, 1934) and from dried sewage sludge (Boyer, Ingle, and Merver, 1973). Several *Bacillus* strains originated from projects on the production of alkali-tolerant enzymes and were isolated from indigo balls and plain soil (Ohta et al., 1975).

The Szik (salt and alkali) soils with pH values of 8–9 in the Hungarian lowlands have been extensively studied with regard to soil ecology and agriculture; however, their bacterial flora was not characterized in detail (Bokor, 1933). Alkali soils in India were reported to contain only few microorganisms, the total count decreasing drastically with increasing pH (Rupela and Tauro, 1973). With these exceptions, alkaline environments have not attracted much attention. Investigations of strictly alkaline springs in northern California led to the isolation of an anaerobic sporeformer and an aerobic, pigmented bacterium. The latter grew between pH 8 and 11.4 with the optimum within the range of pH 9–9.5 (Souza and Deal, 1977; Souza et al., 1974). The lakes of the Wadi el Natrun in Egypt are most interesting aquatic habitats, with pH values ranging from 9 to 11. Topographically and geochemically described by Schweinfurth and Lewin in 1898, these shallow salt pans harbor a rich population of halophilic and phototrophic microorganisms. Sodium is the major cation of the saturated brine (98%); the major anions are chloride, sulfate, and carbonate/bicarbonate (56, 26, and 17%, respectively; Jannasch, 1957). Species of the genus *Ectothiorhodospira* and other phototrophic bacteria have been isolated from these and other alkaline waters (Grant, Mills, and Schofield, 1979; Imhoff and Trüper, 1977). Alkaline lakes such as those in Ethiopia and Anatolia, with ambient values of pH 10–11, are also worth study.

Life at extreme pH values has been discussed by Langworthy (1978), Horikoshi and Akiba (1982), and Krulwich and Guffanti (1983).

Oxygen

When considering oxygen as an environmental factor, at first glance the anoxic environment appears to be the extreme one. However, if the peculiarities of generating biochemical energy

under anaerobic conditions are not considered, the anoxic environment is not difficult for life. Oxygen causes troubles for living cells. It plays a dual role: it acts as an effective electron acceptor, making energy conversion with high efficiency possible; however, oxygen can be considered toxic to life processes that depend on slow and thoroughly controlled oxidations. The toxic effect is intensified in light. Oxygen is reduced by univalent or single electron steps, and by the uptake of one electron, the superoxide anion radical (or simply the superoxide) is formed, which by further reactions gives rise to hydrogen peroxide and to the hydroxyl radical; this radical is the most reactive and, therefore, the most detrimental product. From the onset of photosynthetic oxygen production in the early atmosphere of this planet, it was the major task of biochemical evolution to develop an enzyme system for tetravalent reduction of oxygen, cytochrome oxidase, which does not release any toxic intermediates, and to develop elaborate detoxification systems (Fridovich, 1974, 1975, 1976). Although forms of life are still susceptible to oxygen toxicity (Gottlieb, 1971), there now exist a variety of defense mechanisms in different organisms (Hassan and Fridovich, 1979; Morris, 1975, 1976, 1978, 1979).

The rise of the oxygen level in the early atmosphere may have started not only the evolution of aerobic organisms, but also that of modestly oxygen-tolerant, anaerobic, fermentative bacteria as well. There is a wide spectrum of degrees of oxygen tolerance, starting with the strict anaerobes such as *Bacteroides*, *Butyrivibrio*, *Fusobacterium*, *Megasphaera*, *Peptococcus*, *Ruminococcus*, *Selenomonas*, *Succinivibrio*, *Methanobacterium*, *Methanococcus*, *Methanospirillum*, and *Methanosarcina* and continuing to the moderately oxygen-tolerant clostridia (*C. tetani*, *C sporogenes*) and the highly oxygen-tolerant clostridia (*C. perfringens*, *C. acetobutylicum*) and to the majority of the lactic acid bacteria, which can grow in the presence of air (Loesche, 1969; Morris and O'Brien, 1971; O'Brien and O', Morris, 1971; Uesugi and Yajima, 1978).

Although the obligately anaerobic bacteria have in common a hypersensitivity to oxygen, they are apparently not restricted to places like mud and intestinal tracts but can also be found in seemingly aerobic locations. The wide distribution of *Clostridium* can be explained by their possession of oxygen-insensitive spores. However, nonsporeforming, strictly anaerobic bacteria are similarly widely dispersed, perhaps because under field conditions the anaerobes are associated with oxygen-consuming bacteria that keep the local oxygen concentration low. These apparent discrepancies caution one not to overemphasize the results of pure culture studies when extrapolating to the behavior of microorganisms in their natural environment.

In some cases, the oxygen concentration is the deciding factor in the ability of the organism to develop potential metabolic activities. The oxygen concentration may determine whether various nitrogen-fixing bacteria can occupy a niche in an environment low in combined nitrogen. In contrast to members of the *Azotobacter* group, which fix nitrogen in the presence of air (Mulder and Brotonegoro, 1974), the nitrogen-fixing, hydrogen-oxidizing bacterium *Xanthobacter autotrophicus* (Berndt et al., 1976; Wiegel and Schlegel, 1976; Wiegel et al., 1978) is able to grow with molecular nitrogen as the sole nitrogen source only at oxygen concentrations below 2% oxygen (by volume), while in the presence of combined nitrogen the bacterium grows under air. Other nitrogen-fixing bacteria, such as *Azospirillum lipoferum* (Okon, Albrecht, and Burris, 1976), *Aquaspirillum fasciculus* (Strength et al., 1976), and *Methylosinus* species (De De Bont and Mulder, 1974), respond to oxygen in a similar manner (see also The Genus *Azospirillum* and The Genus *Herbaspirillum* in Volume 5). A number of aerobic marine bacteria have been demonstrated to be microaerophilic; they survive but do not grow in air-saturated seawater medium (Jannasch, 1977).

Whether there are differences among microorganisms with respect to their tolerance to oxygen at higher concentrations than that of air-saturated water is not known. Many strictly aerobic bacteria that form colonies from single cells on petri dishes exposed to air can tolerate gas mixtures up to 40% oxygen by volume but fail to grow at 50%. Also, 100% oxygen is usually considered to suppress growth; however, many cyanobacteria that form blooms are certainly tolerant to high oxygen concentrations. During photosynthesis in the sun, blooms of cyanobacteria and algal mats near the water surface, as well as the lawn of submerged water plants like *Elodea canadensis*, *Chara fragilis*, or *Ranuculus aquaticus* in ditches, shallow ponds, and estuaries, are covered with bubbles of oxygen. This growth indicates that the water body must contain higher concentrations of oxygen than in equilibrium with air and that the epiphytic and other bacteria are exposed to oxygen concentrations supersaturated with respect to oxygen. It is not known whether bacteria exist able to grow at these oxygen concentrations of almost 100%. Furthermore, it would be interesting to know whether among the variety of bacteria a continuum of thresholds of oxygen tolerance exists or whether there are certain discontinuities of threshold concentrations for certain species or metabolic types, e.g., at 2, 20, 40, and 100% oxygen and whether correlations between oxygen-tolerance thresholds and habitats are encountered.

Low-Nutrient Environments

The most commonly cited low-nutrient environments are desert soils, oligotrophic lakes, and, most prominently, the oceans. Considering suspended detrital matter, decaying plankton organisms, and fecal pellets, isolated high-nutrient habitats abound in various parts of the sea. However, if this amount is divided by the vast volume of the ocean, which amounts to about 90% of the biosphere, the dissolved organic carbon in sea water is rarely more than 1 mg/liter. Particulate organic carbon commonly amounts to 10–20% of the total organic carbon. A large fraction of the latter is "refractory," that is, unavailable for microbial attack (Barber, 1968; Menzel and Ryther, 1970). The description of low-nutrient habitats is, therefore, more realistically based on the flux of nutrients across the ecosystem rather than on the standing nutrient concentrations (Hirsch, 1979).

Many prokaryotes will survive in such conditions, as amply documented by the fact that poor soils and natural waters have often been used as a source for the isolation of microorganisms. Low-nutrient habitats may be extreme with respect to stress exerted toward some vegetative cells, but these conditions are hardly selective.

Vegetatively growing cells may be carried into the ocean from land run-off or be exposed to low nutrient levels after separation from relatively nutrient-rich particles. These cells may adopt one of a variety of strategies in order to cope with starvation conditions. Two general strategies have been pinpointed whereby: 1) the survival of the individual cell is achieved by the most efficient use of the limited amount of food available or 2) the survival of the species is achieved by producing the maximum amount of progeny in the form of dormant stages capable of immediate growth and multiplication at the renewed availability of nutrients.

In terms of population dynamics studied in continuous culture, the "K-strategists" have been described as organisms adapted to highly efficient growth or uptake at low substrate concentrations, as indicated by a low substrate saturation constant ($K[s]$). In contrast, μ_{max}-strategists (μ_{max} = maximum growth rate, in non-prokaryotes also called r-strategists) will outgrow the former in the presence of relatively high nutrient concentrations (Koch, 1979).

Early continuous culture studies on the synthesis and activity of prokaryotic enzyme systems led to the discovery of catabolic derepression by Gorini (1960) in the presence of extremely low concentrations of the growth-limiting substrate. Subsequently, the mechanisms of adaptation to low-nutrient environments have been intensively studied (Tempest and Neijssel, 1976, 1979). These studies resulted in the discovery of the high-affinity mechanism for assimilating ammonia into glutamate via glutamine synthetase and glutamate synthase (Tempest, Meers, and Brown, 1970, 1973) and of dual mechanisms for the assimilation of glycerol: the glycerol kinase route at carbon-limiting conditions and the glycerol dehydrogenase route in glycerol-sufficient environments (Neijssel et al., 1975). Matin (1979) reported the onset of a multiple substrate utilization technique as a response to decreasing dilution rates and pools of intracellular metabolites. Adaptation of distinctive species to low-nutrient environments is well illustrated by a comparison with respect to starvation and survival of a freshwater *Spirillum* sp., apparently belonging to the oligotrophic flora, with a *Pseudomonas* sp. adapted to environments richer in nutrients (Matin and Veldkamp, 1978). The spirillum accumulated poly-β-hydroxybutyric acid (PHB) during carbon-limited growth in the chemostat; the stored amount was highest at the lowest dilution rate examined. After growth at D = 0.03 to 0.05 h^{-1}, the spirillum was much more resistant to starvation than the pseudomonad that did not accumulate PHB (Matin et al., 1979). The survival value of storage materials and the regulation of their synthesis in various types of bacteria may assist the understanding of adaptation to low-nutrient environments.

One of the most important characteristics of low-nutrient habitats is the strong influence of solid surfaces in the colonizing of microbial films and layers (Marshall, 1976). In a summary of work done on the effect of inert particulate material suspended in low-nutrient aquatic habitats, Jannasch and Pritchard (1972) included studies using the chemostat for the enrichment of bacterial strains that exhibit a tendency for specific attachment mechanisms. In Caulobacteriales, typical low-nutrient organisms, Poindexter (1979) postulates a morphological-physiological mechanism that regulates an efficient metabolic response to low-nutrient conditions, including the role of holdfast organelles (see also Dimorphic Prosthecate Bacteria in Volume 5).

Life under conditions of low-nutrient concentrations was a topic of a Dahlem Konferenz (Jannasch, 1979; Koch, 1979; Poindexter, 1979; Rittenberg, 1979) and an international symposium on microbial ecology (Hattori et al., 1989).

Resting Stages and Survival

In order to survive under adverse environmental conditions, a few bacterial groups are able to form resting cells, which are more resistant to deleterious environmental conditions than their vegetative cells. The transformation occurs when the metabolic activities decline because of nutrient depletion or transfer to a growth-limiting environment. The resting cells are characterized

by thick, frequently multilayered walls. Typical is endospore formation by the genera *Bacillus* and *Clostridium*. Many endospores are extremely resistant to heat, desiccation, radiation, and chemical agents. The formation of exospores is, as far as is known, restricted to the methane-utilizing bacterium, *Methylosinus trichosporium*; the thermoresistant exospores are formed by a process similar to budding of vegetative cells (Whittenbury, Davies, and Davey, 1970).

The rod-shaped cells of the genus *Azotobacter* frequently turn into spherically shaped cells called cysts. Unlike endospores, the vegetative rod as a whole is transformed into a cyst. These cysts share with endospores structural rigidity and resistance to desiccation and to ultraviolet radiation; however, they lack heat resistance (Sadoff, 1975). Similarly, myxobacteria (*Myxococcus*) turn into spherical cells called myxospores (Sadoff, 1973; Voelz and Dworkin, 1962). In the genus *Methylocystis*, the rodlike cells round up and turn into desiccation-resistant cysts similar to those of *Azotobacter* species. *Methylomonas* and *Methylococcus* form spherical cells that are neither thick walled nor resistant to desiccation (Whittenbury, Davies, and Davey, 1970). A modest resistance to desiccation is shown by *Arthrobacter* coccoid cells (Boylen, 1973; Ensign and Wolfe, 1964; Veldkamp, van den Berg, and Zevenhuizen, 1963).

Bacteria that are not able to transform into resting stages are less apt to survive under adverse environmental conditions. Their resistance, however, varies from species to species; it may be high as in mycobacteria or arthrobacters, which survive desiccation for several weeks, or low as in *Neisseria gonorrhoea* or *Treponema pallida*, which respond to desiccation by immediate death. Furthermore, maintenance of the viability of vegetative cells under a mild environmental stress is a function of a multitude of factors, such as growth conditions, content of storage materials, speed of transition from growth to resting conditions, and many others (Strange, 1976). Many observations on the effect of drying and rehydration of vegetative bacteria have been made during long-term preservation in culture collections (Bousfield and MacKenzie, 1976; Lapage et al., 1970; Martin, 1964; Miller and Simons, 1962). These observations indicate that the survival of bacteria depends on many factors and may vary among species and environments. Many aspects were reviewed by Kjelleberg et al. (1987) and Matin et al. (1989).

Light as an Extreme Environment

The well-known predominance of pigmented colonies on nutrient-agar plates exposed for some time to air, compared to plates inoculated with soil, indicates the selective action of sunlight and air and the survival value of pigments. Yellow, orange, and red pigments point to members of the genera *Micrococcus*, *Corynebacterium*, *Mycobacterium*, and *Nocardia*, which contain carotenoids. In nonphototrophic bacteria there is a good negative correlation between the presence of carotenoids in the cell and the anaerobic way of life; carotenoids are rarely found in strict anaerobes except the phototrophic bacteria. Selective effects similar to those observed in air are exerted in several sunlight-exposed environments, such as leaf surfaces, fresh waters, and salt brine. The radiation resistance of pigmented bacteria has been studied with *Halobacterium salinarium* (Dundas and Larsen, 1962), *Rhodospirillum rubrum*, *Corynebacterium poinsettiae* (Cohen-Bazire and Stanier, 1958), and other microorganisms.

Resistance to radiation also seems to be positively correlated with a high GC content of the cellular DNA; this correlation agrees with the conclusion that inactivation of cells by ultraviolet light is mainly due to thymine dimerization (Singer and Ames, 1970). The hypothesis was in accordance with the distribution of GC contents of the purple and green bacteria, the majority of which possess DNAs with 60–70 mol% GC (Mandel et al., 1971). However, in contrast to the anoxygenic phototrophic bacteria, the cyanobacteria show a markedly different mean DNA base composition, the majority of species having only 40–50 mol% GC (Herdman et al., 1979). Cyanobacteria obviously need solar radiation and are more exposed to ultraviolet light than most bacteria. One would have expected them to possess a high GC content, if the hypothesis of Singer and Ames holds true. Solar radiation should, therefore, not be considered as the selective factor that led to the great divergence of DNA base composition among prokaryotes. The effect of high irradiation, mainly of ultraviolet-light damage to DNA and its repair, has been recently reviewed by Nasim and James (1978).

The bactericidal action of diffuse sunlight has not gained much attention. The growth-retarding and lethal action of wavelengths of light not absorbed by DNA has been shown for *Serratia marcescens* (Swart-Füchtbauer and Rippel-Baldes, 1951), *Nitrobacter winogradskyi* (Müller-Neuglück and Engel, 1961), and *Nitrosomonas europaea* (Schön and Engel, 1962). The inhibitory effect is apparently most pronounced and therefore easily recognizable with slowly growing bacteria. Further studies were reviewed by Jagger (1983) and Cornax et al. (1990).

Light exerts its killing effect on microorganisms primarily in the presence of oxygen; in its absence, the effect is smaller by several orders of magnitude. The killing effect is apparently due to photooxidation reactions that are mediated by singlet oxygen. This highly toxic oxygen type is

produced by photosensitized activation of triplet oxygen. Protection against single oxygen is readily provided by carotenoids that possess more than seven conjugated double bonds. These carotenoids are able to quench singlet oxygen as well as excited photosensitizers very effectively. Experimental results and a literature review "on the mechanisms for coping with the stress of photosensitized oxidations" have been presented by Krinsky (1979).

The information on the tolerance to intense solar radiation is still scarce. The generalizations on the protective effect of carotenoids just outlined are mainly based on studies of anaerobic, phototrophic bacteria. Among the aerobic bacteria only those containing carotenoids were considered. There are many more bacteria characterized by remarkable pigments different from carotenoids, such as pyocyanine *Pseudomonas aeruginosa*), prodigiosin (*Serratia marcescens*) and related pigments (Gerber, 1975), indochromes, violaceine, xanthomonadines, and others. It would be interesting to know the ecological significance of these pigments in the natural habitats of the bacteria containing them.

The sensitivity of bacteria and protozoa to visible light and oxygen can be increased by the addition to the medium of sensitizing pigments such as methylene blue, toluidine blue, eosin, or acridine orange. Although this photodynamic effect has long been known and is advantageously applied on animal farms to keep the microbial number in drinking water low (Acher and Juven, 1977), the ecological significance of photosensitization by natural pigments liberated by autolysis of part of the population is far from clear. Carotenoid pigments also exert a protective effect against photosensitized killing, as has been shown for *Micrococcus luteus* (Anwar et al., 1977; Matthews and Sistrom, 1959; Prebble and Huda, 1977).

Surfaces as Habitats

The microbiologist dealing with homogeneous suspensions of bacteria for physiological studies usually pays little attention to the growth of bacteria on surfaces. In nature, however, the growth of bacteria as a surface film may be more frequent and important than growth in homogeneous suspensions (Marshall, 1976, 1984; Fletcher and Marshall, 1982) (see also Planktonic Versus Sessile Life of Prokaryotes in Volume 2). Three kinds of interfaces have to be considered: 1) liquid-solid interfaces, such as stationary objects in a river, the tidal zone, and ponds; the inner surfaces of the mouth and the intestinal tract; the outer surfaces of rocks piled up for bacterial leaching of ore or of rocks stacked in columns for waste-water purification in trickling filters; food particles in the digestive system; and silt particles in rivers or marine environments; 2) liquid-gas interfaces, such as the water surface of a pond and gas bubbles in the ocean; and 3) liquid-liquid interfaces, such as oil droplets in an aqueous solution.

Liquid-Solid Interfaces

Adhesion to surfaces is an important ecological determinant in many ecosystems. The colonization of a suitable liquid-solid interface may be the prerequisite for exploitation of a habitat. Many organisms that inhabit rushing rivers stick to solid surfaces. In open ecosystems, sessile animals as well as bacteria take advantage of being fixed to a privileged location. In a running river that receives organic waste from upstream, slow-growing bacteria could not compete with fast-growing bacteria if they were not attached to stationary objects at a location where food is still available in concentrations sufficient for growth. Growth in locations of this kind is restricted to those bacteria that can attach themselves to a solid surface. Thick plaits of *Sphaerotilus natans* were found in rivers where waste water of sugar factories was discharged (Cohn, 1881; Demoll and Liebmann, 1952; Dondero, 1961, 1975; Kolkwitz, 1904–1906). A similar habitat for mass development is held by *Leptothrix ochracea* in field drains (Dondero, 1975), by *Crenothrix polyspora* in water wells (Völker, Schweisfurth, and Hirsch, 1977; Wolfe, 1960), and by *Toxothrix trichogenes* in iron springs (Krul, Hirsch, and Staley, 1970; van Veen, Mulder, and Deinema, 1978; see The Genera *Leptothrix* and *Sphaerotilus* in Volume 5). The trickling filters of waste-disposal plants resemble the river habitat. In some of these habitats, *Sphaerotilus*, *Caulobacter*, *Asticcacaulis*, *Zoogloea ramigera*, and other stalked, prosthecate, or slime-forming bacteria have been found in addition. In many of these habitats, the bacteria form thick, slimy layers on rocks and pebbles.

In the marine environment, *Leucothrix mucor* holds a similar position to *Sphaerotilus* in fresh water. *L. mucor* forms sessile filaments and grows as a bacterial epiphyte on seaweed, such as filamentous red and green algae living in habitats where water flows and aeration is good (Kelly and Brock, 1969; Raj, 1977). The filament is attached to the seaweed by a holdfast (Harold and Stanier, 1955) that is part of the sheath (Pringsheim, 1957). By scanning electron microscopy (Fig. 1), bacterial lawns were revealed that consisted of long and short end-attached bacteria, including *Leucothrix mucor* and flexibacteria (Cundell, Sleeter, and Mitchell, 1977). *Thiothrix nivea* was observed to grow in tufts attached to

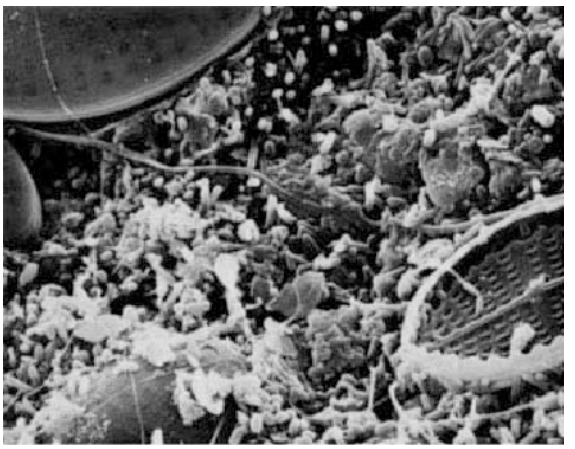

Fig. 1. Microflora on the surface of the brown alga *Ascophyllum nodosum.* Scanning electron micrograph. (Courtesy of Ralph Mitchell.)

pebbles in the runoff of a sulfur spring in Seattle, Washington (Bland and Staley, 1978).

In rivers and sea water, small, floating particles such as silt, clay, or detritus particles have a remarkable growth-promoting effect on microorganisms. At low nutrient concentrations, which are suboptimal for efficient growth in homogeneous suspension, the addition of suspended particles favors the growth of bacteria (Heukelekian and Heller, 1940) due to adsorption of nutrients to the particle surface. The attachment of bacteria to dense suspensions of silt particles, as is characteristic for certain river waters, has a marked effect on growth and oxygen uptake (Jannasch, 1955). The degree of attachment was affected by the concentration of the dissolved organic substrate (Jannasch, 1958; Jannasch and Pritchard, 1972). Dense growth of bacteria on suspended particles may lead to anoxic microenvironments, as demonstrated by model experiments on denitrification (Jannasch, 1960, 1978).

The ability to attach to surfaces may be considered as a means to escape low-nutrient environments. Interfaces play an eminent role in the transport and accumulation of nutrients, such as polysaccharides or proteins. Not only do these nutrients accumulate at solid-liquid interfaces, but they even accumulate at liquid-gas interfaces, and gas bubbles serve as vectors for nutrients (Marshall, 1979).

Bacteria are able to stick to solid surfaces in several ways. The outer layers of the bacterial cell envelope (Costerton, Ingram, and Cheng, 1974) evidently play a special role. The cells are either attached by a sheath as in the case of *Sphaerotilus*, *Leptothrix*, and *Leucothrix*; by holdfast substances, which are apparently a gum-like outer layer of the cell envelope and consist of polymers (Umbreit and Pate, 1978); or by nonflagellar, filamentous appendages such as fimbriae or pili. The attachment of bacteria to solid surfaces by polymers is apparently widely distributed.

As mentioned above, at high flow rates of a nutrient medium, sessile bacteria are able to exploit the nutritional opportunities of the habitat better than nonattached forms. Cells that do not stick to the surfaces of stationary objects are washed out into another ecosystem; the nutrient exchange is not facilitated by the movement of the medium past the cell. The ability to adhere to surfaces confers a selective advantage on certain metabolic types. Studies on the fine structure of extracellular polysaccharide fibers (Cagle, 1975) gave rise to a generalized view of the ability of bacterial cells to adhere to surfaces. The fiber network that extends from the bacterial surface, called bacterial "glycocalyx," mediates adhesion not only to abiotic surfaces, but also to other cells, either host or prey.

Adhesion is a way for a bacterium to enter a habitat. The adhesion of the causative agent of caries, *Streptococcus mutans*, to the enamel surface of the tooth, the adhesion of *Vibrio cholerae* to intestinal cells, and other bacterium-host relationships are examples for the potential role of glycocalyx formation in the establishment of infectious diseases (Costerton, Geesey, and Cheng, 1978; Costerton et al., 1987). Several unidentified, segmented filamentous bacteria attached to the epithelium of the mucosa of the small bowels of mice have been revealed by scanning electron microscopy (Blumershine and Savage, 1978).

For utilization of some solid substrates, a close contact is necessary between the bacterium and its substrate. *Cytophaga* cells adhere closely to cellulose fibers, the rods being aligned with the orientation of the microfibrils. Cellulose degradation by *Cytophaga* and *Sporocytophaga* requires direct contact between the bacteria and the cellulose fibers (Berg, van Hofsten and Pettersson, 1972; Stanier, 1942). The attachment of rumen bacteria to plant particles (Akin, 1976; Akin and Amos, 1975) is well documented. *Ruminococcus* species were shown to adhere strongly to cotton cellulose fibers and to the cell walls of leaf sections of rye grass, evidently by means of their prominent glycoprotein coats (Latham et al., 1978; Minato and Suto, 1978; Patterson et al., 1975). Further examples concern the adherence of starch-digesting bacteria to starch grains, of chitin-hydrolyzing bacteria to chitin, of *Sulfolobus* to sulfur globules (Weiss, 1973), and of a thermophilic sulfur oxidizer to sulfide minerals (Golovacheva, 1979). Knowledge about the specific mechanisms of attachment of bacteria to solid substrates suggests methods for their enrichment.

Specific interactions between the bacterial cell coat and the plant cell wall apparently precede the invasion of rhizobia into the root hairs of their host plants. Phytohemagglutinins or lectins (Liener, 1976) of the plant may be involved in the recognition process by binding only the corresponding bacteria and not bacteria that infect other legumes (Dazzo, Yanke, and Brill, 1978; Kato, Maruyama, and Nakamura, 1979; Marx, 1977).

Fimbriation is apparently another means of bacterial attachment to submerged objects (Hirsch and Pankratz, 1970). The possession of filamentous, nonflagellar appendages seems to be distributed mainly among members of the Enterobacteriaceae and Pseudomonadaceae but is not restricted to members of these families (Ottow, 1975). The ecological importance of fimbriae or pili may consist in their initiating both attachment to solid surfaces as well as contact with other members of the community. The solid surface may be a substrate of low solubility, such as sulfur oxidized by *Sulfolobus* (Brierley, C.L., 1978; Weiss, 1973) or *Thiobacillus* A2 (Korhonen, Nurmiaho, and Tuovinen, 1978). Attachment to surfaces has not been studied as well as the phenomenon called star formation. The formation of stars, rosettes, or cellular aggregates was originally observed when strains of *Agrobacterium tumefaciens* and *Rhizobium* were studied (Stapp and Bortels, 1931; Stapp and Knösel, 1954). Since both *Agrobacterium tumefaciens* and rhizobia normally invade plant tissues and must attach to the surface of the plant beforehand, the connection between attachment, important in the natural habitat, and the formation of aggregates as observed in slide cultures under the microscope is obvious. The formation of the frequently very regular rosette-like aggregates in pure cultures of bacteria, such as *Pseudomonas "rhodos"* (Marx and Heumann, 1962), *Pseudomonas "echinoides"* (Heumann and Marx, 1964; Mayer, 1971; Mayer and Schmitt, 1971), and *Agrobacterium "luteum"* (Ahrens, Moll, and Rheinheimer, 1968) may be regarded as a consequence of the presence of polar fimbriae and slime in these bacteria. Similar aggregates are formed on the surface of liquid media (Ahrens, Moll, and Rheinheimer, 1968).

Aggregation may be either specific, as in the cases of bacterial conjugation, host cell infection, and growth at special surfaces, or may be due to a rather nonspecific process (Fletcher and Loeb, 1979), when extracellular polymers such as complex polysaccharides and polyamino acids are excreted or are exposed at the cellular surface under varying physiological conditions, especially during the stationary growth and the death phases and at low-nutrient concentrations. The formation of microbial aggregates is of considerable importance in the soil, in floc formation, in activated sludge treatment, and in industrial biomass production (Harris and Mitchell, 1973).

Microbial adhesion has recently grown into a self-contained field of research (see Planktonic Versus Sessile Life of Prokaryotes in Volume 2). The phenomenon is studied on the physiological (Costerton et al., 1981, 1985; Berkeley et al., 1980), biochemical (Kefford et al., 1982), molecular (Switalski et al., 1989), and biotechnological level (Savage and Fletcher, 1985; Characklis and Marshall, 1990).

Liquid-Gas Interfaces

The liquid-gas interface is a unique habitat in many respects. Depending on the ecosystem, this environment harbors a diverse bacterial flora, sometimes called the bacterial neuston. Common to the liquid-air interfaces are: 1) direct exposure to the oxygen of the air; 2) accumulation of hydrophobic substances either originating from the air or from the water body; and 3) high light intensities.

The surface film of lakes and ponds formed in summer during calm weather harbors bacteria such as *Pseudomonas*, *Caulobacter*, *Hyphomicrobium*, *Nevskia*, *Flavobacterium*, *Alcaligenes*, *Micrococcus*, and others (Babenzien, 1965, 1967; Hirsch, 1974; Hirsch and Pankratz, 1970). Bacteria that contain gas vacuoles may dominate under certain conditions (Walsby, 1978).

The surface layer of the ocean is a separate environment (Zaitsev, 1971). It has gained special attention because oil pollution has increased and wide areas of the ocean are occasionally covered with petroleum (Bartha and Atlas, 1977). A considerable proportion of organic substances accumulating in the marine neuston is released from planktonic organisms; fatty acids, lipids, polysaccharides, hydrocarbons, and proteins have been identified in the surface film (Wangersky, 1976). The marine neuston is the habitat of various marine bacteria (Bezdek and Carlucci, 1972).

The surface film of water baths in laboratories offers a special habitat for bacteria that either utilize traces of conventional substrates inadvertently added to the water or that utilize volatile or gaseous substrates present in laboratory air (Leifson, 1962). The gum formed within several weeks contains *Bacteriogloea*, *Hypomicrobium*, *Caulobacter*, *Mycobacterium*, and *Norcardia*.

Gradients as Habitats

In nature, the distribution of nutrients or environmental factors is generally patchy. In many ecosystems vertical gradients of concentrations

of various nutrients exist. The nutrients produced in sediments diffuse into the aqueous layer and, in the absence of mixing by convection or currents, form a concentration gradient. Such gradients are to be expected either in a microscale in sediments, soil, or shallow water bodies or in a macroscale in lakes or oceans. The gradients may either be of substances used as nutrients or of physical factors such as redox potential, temperature, and radiation. Of primary importance for growth and distribution of microorganisms are the concentration gradients of organic acids, hydrogen sulfide, carbon dioxide, and oxygen.

The major amount of organic matter that is decomposed by microorganisms in nature consists of fresh plant litter. Another fraction enters the soil or sediments of aquatic ecosystems after partial degradation by herbivorous animals. Only a comparatively small fraction of the plant tissue is degraded by animals; the major part, cellulose and lignin, is released and becomes the major substrate of the microbial food chain.

Terrestrial and aquatic ecosystems differ greatly with respect to further degradation of the primary biomass and the cellulose-rich detritus derived therefrom. On the land, the solid organic matter stays on or near the surface of the soil and is decomposed mainly aerobically. Only part of the organic matter is transported into the soil by animals as vectors and is degraded by microorganisms either aerobically or anaerobically, depending on aeration and moisture content. Undoubtedly, diffusion processes and concentration gradients play a role in the soil. However, due to the heterogeneous distribution of organic matter, the basic features of anaerobic and aerobic food chains cannot easily be recognized in terrestrial systems.

In contrast, in a stagnant body of water the solid organic matter produced in the surface layers sinks, either immediately or after passage through a short, animal food chain, to the bottom of the water body. There microbial degradation occurs. Due to its low solubility in water, the oxygen may soon be exhausted in the course of the initial aerobic degradation of organic substances. In highly productive waters and in the absence of convection, the deeper layers become anoxic, which results in anaerobic microbial degradation processes. These processes give rise to the production of various soluble or gaseous substances such as organic acids, hydrogen sulfide, hydrogen, methane, carbon dioxide, and ammonia. These products freely diffuse upwards, each forming its own concentration gradient.

The chemical conditions may be further diversified by the liberation of ions from the sediment. These upward gradients are overlayerd by the downward gradients of temperature, light, and oxygen. Thus, due to the gradients of various nutrients and other environmental factors, a stagnant water body offers a variety of diverse living conditions for microorganisms. The study of concentration profiles and of the zonation of aquatic ecosystems and the assignment of the microorganisms to the particular conditions of their habitat are a major concern of microbial ecology. Several lakes have been studied as model systems (Clark and Walsby, 1978b; Gorlenko, Dubinina, and Kuznezow, 1977; Kuznezow, 1959, 1977). The stratified lake will be presented here as an example. The principles derived from these studies can be easily applied to zonations and processes occurring in waterlogged soils, tundras, and rice fields. They apply with slight variation also in shallow ponds, sediments, and shallow mats in the runoffs of hot sulfur springs.

Gradients of a Macroscale: The Stratified Lake

Many lakes are temporarily or permanently stratified (Figs. 2 and 3). Stratification occurs when a dense, either cold or saline (salt-rich) water body is overlayered by a less dense, either warm or salt-free water body. The stratification patterns vary with different climate zones. In temperate climates, normal stratification occurs in freshwater lakes more than 10 m in depth.

The holomictic stratified lake may serve as an example of the stratification and gradient-forming process (Overbeck, 1972; Pfennig, 1979; Sorokin, 1970). After total circulation in winter time, the warming of the surface layers during the summer yields a less dense upper layer (epilimnion) of circulating, aerated water and a dense, cold, stagnant bottom layer (hypolimnion). The intermediate layer (metalimnion) is characterized by a temperature gradient (the thermocline) and, after oxygen deprivation and anaerobic decomposition of organic matter in the hypolimnion, by a chemical gradient (chemocline) also. In the epilimnion, which is exposed to sunlight, biomass is produced by phototrophic cyanobacteria, diatoms, and green algae; allochthonous matter from the surroundings usually adds to the total organic material. Part of the biomass usually sinks to the hypolimnion and to the bottom of the lake where it is degraded. Degradation is accompanied by oxygen consumption, resulting in a decrease in oxygen concentration and, finally, in anoxic conditions, first in the sediment, then in the bottom layer. Continued anaerobic degradation results in the production of organic fermentation products as well as hydrogen, methane, hydrogen sulfide, and carbon dioxide, which diffuse upwards forming concentration gradients. Methane,

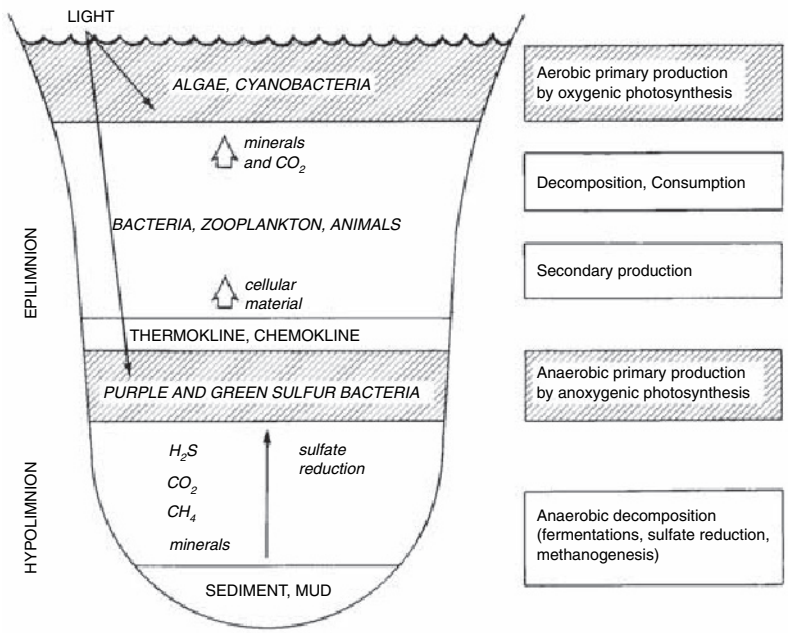

Fig. 2. Diagram of production, consumption, and decomposition in an aquatic ecosystem with a chemocline.

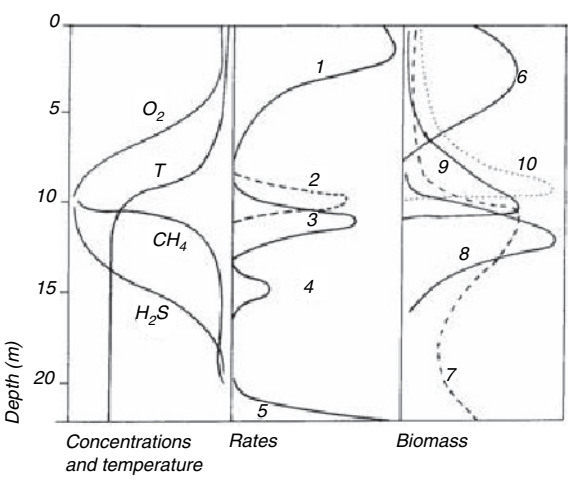

Fig. 3. Idealized vertical profile of a freshwater lake in the temperate climate zone in summer, showing concentrations, conversion rates, and biomass. The figure is based on drawings and data of Sorokin (1970), Gorlenko, Dubinina, and Kuznezow (1977), and Overbeck (1972). Symbols: T, temperature; (1–5, conversion rates) 1, CO_2 fixation in the light (oxygenic photosynthesis); 2, CO_2 fixation in the dark; 3, CO_2 fixation in the light (anoxygenic photosynthesis); 4 and 5, sulfate reduction; 6, biomass of algae and cyanobacteria; 7, total bacterial biomass; 8, biomass of phototrophic bacteria; 9, biomass of protozoa; 10, biomass of Copepoda and Cladocera.

which is the major carbonaceous substance released from the sediment, is discharged in the form of gas bubbles. Part of the methane is dissolved in the water as it moves upwards and is oxidized by methane-utilizing aerobic bacteria. The quick removal of oxygen from the hypolimnion is primarily due to the quick dispersal of methane and the growth of methane-oxidizing bacteria. Finally, the hypolimnion becomes totally anoxic.

As soon as anaerobic conditions have been established in the bottom layer or in the total hypolimnion, the anaerobic conversion processes, which started with the degradation of solid material, mainly cellulose, in the sediment, continue in the water body. Primary soluble fermentation products, hydrogen gas included, are used to reduce sulfate to hydrogen sulfide. The major amount of hydrogen sulfide originates from sulfate reduction in the free water. Simultaneously, nitrate is reduced to nitrite, which transiently accumulates and forms a distinct layer, and then to nitrogen.

The upper part of the epilimnion is the zone of primary production by the oxygenic phototrophic organisms, such as photosynthetic higher plants, algae, diatoms, flagellates, green algae, and cyanobacteria. These primary producers are accompanied by bacteria, protozoa, and metazoa that consume photosynthetized biomass, which results in secondary production and release of cellulosic detritus (Fenchel and Jøorgensen, 1977). The thermally stratified lake is a very common habitat for cyanobacteria that contain gas vacuoles. *Oscillatoria rubescens*, *O. agardhii*, *Aphanizomenon flosaquae*, and *Microcystis aeruginosa* form stable populations near the bottom of the epilimnion (Clark and Walsby, 1978a,b).

The chemocline and the hypolimnion are the favored habitats of the anaerobic prokaryotes. Provided hydrogen sulfide is present and the light intensity allows, anoxygenic phototrophic

bacteria develop underneath the chemicline and form a second layer of primary biomass production (Sorokin, 1970). The upper hypolimnion just below the chemocline is the habitat of the purple and green sulfur bacteria, among which the brown forms dominate (Fig. 2). They produce biomass by anoxygenic photosynthesis from carbon dioxide and hydrogen sulfide. Bacteria that are either buoyant by gas vacuoles or motile by flagellation dominate. The buoyancy of *Lamprocystis*, *Amoebobacter*, *Thiodictyon*, *Thiopedia*, *Pelodictyon*, and *Ancalochloris* is apparently just sufficient to allow them to float in the heavy cold water beneath but insufficient to float in the light warm water above the thermocline. Among the motile purple sulfur bacteria (Chromatiaceae), the large *Chromatium* species (*C. okenii*, *C. weissei*, *C. warmingii*, *C. buderi*) and *Thiospirillum* live in this layer.

Further details on the ecology of photosynthetic bacteria with emphasis on the distribution in stratified lakes were presented in a comprehensive review (Pfennig, 1979). The efficiency of biomass production by anoxygenic photosynthesis is remarkable. Part of the biomass that by slight turbulences reaches the upper chemocline is grazed by copepods, cladocera, and protozoa and transported into upper aerobic regions. Photosynthesis by the purple and green sulfur bacteria is accompanied by sulfate production. The sulfate produced is immediately reduced to hydrogen sulfide. As documented by measurements of the sulfate-reducing activity and cell counts of sulfate-reducing bacteria in various depths, the activity of sulfate reduction has two maxima: one in the hypolimnion bottom layers and one below the chemocline (Sorokin, 1970). While the reduction power for the first process originates from the sediment, sulfate reduction below the chemocline seems to be supplied by indigenous solutes released from cells within the region, either by excretion or by decay.

The metalimnion is a layer of high biological activity. Because of its richness in inorganic nutrients as compared to the epilimnion, it is inhabited by a few aerobic photosynthetic prokaryotes that can tolerate hydrogen sulfide and anaerobic conditions. One of them is *Oscillatoria limnetica*, which has been isolated from the sulfide-rich layers of Solar Lake (Elat, Israel) and studied in detail (Cohen, Padan, and Shilo, 1975; Padan, 1979a,b). It is able to use hydrogen sulfide as an electron donor in a photosystem I-driven reaction and to photoreduce carbon dioxide; hydrogen sulfide is oxidized to elemental sulfur. Once the system has been induced, *O. limnetica* can grow under anaerobic conditions (Oren and Padan, 1978; Oren and Shilo, 1979). After they return to the oxic zones, the cells switch from anoxygenic to oxygenic photosynthesis. This study of *O. limnetica* explained the predominance of cyanobacteria in sulfide-containing microaerophilic habitats or in habitats of frequently alternating conditions (Padan, 1979).

Because of the oxidation of hydrogen sulfide by the purple sulfur bacteria in the light and diffusion of oxygen from the epilimnion, the chemocline moves downward several meters during the daytime. Diurnal vertical fluctuations of the redox discontinuity layer obviously represent a major selective factor for the organisms occupying this habitat.

Gradients of a Microscale: The Sediments

Among the various types of sediments, only the coastal marine sediment and the lacustrine sediment will be discussed here. In principle, the degradative and biosynthetic processes that occur in sediments are similar to those in stratified lakes. The organic material that supplies the energy for life processes in the sediment is mainly allochthonous. Either leaves or large algae are buried in the sand of coastal marine areas or detritus is incorporated into the mud.

If sulfate is present in excess, as in marine ecosystems, the anaerobic food chain yields mainly hydrogen sulfide and gives rise to the activities of bacteria involved in the sulfur cycle. Habitats of this sort gained early attention by the smell of hydrogen sulfide and the bright red layers and bloom of purple sulfur bacteria and have repeatedly been described (see Bavendamm, 1924). There are numerous kinds of sulfureta, most of them estuaries, limans, salt marshes, tidal flats, and swamps.

In typical sulfureta of littoral marine areas, buried organic material is covered by sand and the water layer is 10–20 cm deep (Fenchel, 1969). Hydrogen sulfide production may be high. The sulfide concentration in a few centimeters' depth of these sulfide systems may easily reach 10 mM H_2S (Fenchel and Riedl, 1970). The diffusing hydrogen sulfide may give rise to emission to the atmosphere during the night. During the day the emission of hydrogen sulfide amounts to only 4% of that during the night (Hansen, Ingvorsen and Jørgensen, 1978). The diurnal fluctuations of the hydrogen sulfide concentration indicate the significant role of the purple sulfur bacteria in the photic zones of these coastal areas. The bacteria respond to the exhaustion of sulfide and the alternation of the oxygen tension by chemotactic (aerotactic) movements and disappear in the course of illumination into the sediments. The movements parallel the diurnal vertical migrations observed in stratified lakes. Depending on the particular environmental condition, the ecological niche of sulfide oxidation may be occupied by colorless sulfur bacteria such as

Thiovulum, *Macromonas*, *Achromatium*, and *Beggiatoa*, or by phototrophic purple sulfur bacteria.

A characteristic ecosystem, with a very steep gradient from the anoxic hydrogen sulfide-rich zone to the oxic layer, has been described as the "Farbstreifen-Sandwatt" (Hoffmann, 1942); the name was coined due to the succession of green, red, and black layers of the sand of marine coastal areas. The phenomenon is restricted to localities with a high level of ground water, sand of grain diameter to provide capillary ascension almost up to the sand surface, sufficient organic material and sulfate in the lower sediment layers, and high light intensities to penetrate the uppermost layers of sand. The green layer contains cyanobacteria exclusively, demonstrating their tolerance to hydrogen sulfide compared to green algae as emphasized by Padan (1979). The red layer underneath is an almost monospecific culture of purple sulfur bacteria, which is in direct contact with the black zone. These observations confirm the ecological significance of the complementary spectral absorption of green plants and purple bacteria (Buder, 1919) and are in accordance with measurements showing that long wavelengths penetrate in sand further than short wavelengths (Fenchel and Staarup, 1971), in contrast to water (Pfennig, 1967).

Multilayered microbial communities in aquatic ecosystems resembling the "Farbstreifen-Sandwatt" have been observed in areas of hot springs and in solar ponds. Various kinds of mats have been described and studied in detail (Cohen and Rosenberg, 1989).

A particular environment is apparently required by the sulfide-oxidizing, nonphotosynthetic bacteria such as *Beggiatoa*, *Thiothrix*, *Achromatium*, *Macromonas*, *Thiovulum*, *Thiospira*, and a few others. Their habitats appear to be areas where the gradients of both hydrogen sulfide and oxygen are overlapping or, as in running waters, where the hydrogen sulfide-providing sediment is covered by running water containing oxygen.

Due to the instability of hydrogen sulfide in the presence of oxygen, a habitat requiring the simultaneous presence of both compounds will be small and transient. The coexistence of hydrogen sulfide and oxygen has already been convincingly demonstrated by Beijerinck (1895). He introduced a solution of hydrogen sulfide containing a small amount of oxygen into an anaerobic suspension of luminous bacteria—precautions to exclude the access of air were taken. Luminescence occurred, indicating that the hydrogen sulfide solution contained free oxygen and that the affinity of the bacteria for oxygen is high. Hydrogen sulfide and oxygen will be simultaneously available for a long period of time only in areas to which both compounds are continuously supplied. Observations in nature and when attempting to grow isolates of colorless sulfur-oxidizing bacteria are in agreement with this idea (Bland and Staley, 1978; la Rivière, 1963, 1965; Strohl and Larkin, 1979; The Colorless Sulfur Baeteria in Volume 2 and The Genus *Beggiatoa* and *Thioploca* in Volume 6). In a study on the chemolithotrophic nature of *Thiovulum* species (Wirsen and Jannasch, 1978), the difficulty of obtaining pure cultures is ascribed to the instability of the oxygen/hydrogen sulfide environment. The individual cells of *Thiovulum* aggregate in "veils" by extruding slime threads, a possible means of stabilizing an oxygen/hydrogen sulfide interface for a period of time (la Rivière, 1963).

Careful studies using microelectrodes for the measurement of oxygen and hydrogen sulfide have been carried out on *Beggiatoa* populations at natural oxic/anoxic interfaces of estuarine sediments (Jørgensen, 1982; Jørgensen and Revsbech, 1983; see also Chapter 166). In *Beggiatoa* "plates" prepared in artificial agar-gelled interfaces or O_2/H_2S gradient cultures, chemoautotrophy was demonstrated (Nelson and Jannasch, 1983), and the growth pattern and yield were studied in detail (Nelson et al., 1986). The thickness of these filament plates never reached more than a few mm.

The unusual occurrence of thick mats of *Beggiatoa*-like filaments was observed on the surface of hydrothermal sediments covering hot vents at a depth of 2,000 m in the Guaymas Basin of the Gulf of California (Nelson et al., 1989). These mats were 3-cm thick on the sediments and up to 30-cm thick between stands of vestimentiferan tube worms, the characteristic hosts of symbiotic, sulfide-oxidizing prokaryotes (see below). The unusual mass development of *Beggiatoa* at the hydrothermal vents is speculated to be due to: 1) a more efficient flux of H_2S and O_2 than by mere diffusion; 2) a continuous supply of an organic growth factor; 3) facultative chemoautotrophy providing an efficient metabolic flexibility in case of intermittent or turbulent vent emissions; and 4) an optimal temperature gradient (Jannasch et al., 1989). Furthermore, the unusually large diameter of the filaments (up to 122 μm) and an "empty" inner space (a liquid vacuole filling more than 80% of the cell, the cytoplasm being distributed only along the outer cell wall) may contribute to their growth and survival in this environment. These allow the cells to grow to an enormous size without diffusional problems, thus providing them with a structural rigidity necessary for exploiting a larger ambient space than smaller cells can without support of a substratum (e.g., sediment). Moreover, an inner low-redox reservoir may enable these organisms to survive in the absence of reduced chemical substrates during flushing by oxygenated ambient seawater for a certain period of time.

The classical filamentous and stalk-forming iron bacteria have to be considered as gradient organisms also. Bacteria such as *Leptothrix ochracea* and related bacteria, as well as *Gallionella ferruginea*, grow in drainage tubes in moist fields, preferably in the narrow zone between the anaerobic bottom layer, which is the source of ferrous iron, and the flowing water, which contains oxygen.

Horizontal Gradients

Horizontal gradients of environmental factors exist where water of unusual properties and contents is discharged into running water. Gradients are formed in the vicinity of hot springs; sulfur springs; effluents of coal, iron, and salt mines; rivers; ditches; and drainage tubes.

The water discharged from sulfur springs gives rise to a gradient in sulfide concentrations, providing sulfide-rich water and photoanaerobic conditions at the origin and photoaerobic conditions downstream. Hot sulfur springs as they occur in New Zealand, North Island (Castenholz, 1976), and Yellowstone National Park (Brock, 1978; Castenholz, 1977) provide gradients of temperature, sulfide and oxygen concentration, pH value, and secondarily, in the concentration of minerals and organic nutrients; near the spring, the effluent sulfide-rich water of 60–70°C enables the gliding green bacterium, *Chloroflexus*, to grow and form reddish orange or orange-green mats (see The Family Chloroflexaceae in Volume 7). Downstream, this green bacterium is accompanied by the cyanobacteria *Oscillatoria*, *Synechococcus*, and, eventually, *Mastigocladus*. The patterns do not vary greatly at different localities (Bauld and Brock, 1973; Castenholz, 1976, 1977, 1979).

Possible Mechanisms for Finding or Remaining in the Beneficial Layer of the Gradient

Motility and buoyancy may be involved in keeping the bacteria in horizons of favorable growth conditions. Many motile bacteria manage, by means of their chemotactic response mechanisms, to reach and stay in an area where the concentration of a nutrient or of oxygen is optimal. Bacteria that are motile by flagellation, as well as gliding bacteria, are able to move to and stay in their beneficial environment. Gas vacuoles, occurring exclusively in aquatic microorganisms (Cohen-Bazire, Kunisawa, and Pfennig, 1969), provide buoyancy and may be a means by which bacteria maintain their vertical position (Clark and Walsby, 1978a, b).

Chemotaxis Chemotaxis is widespread among motile microorganisms (Weibull, 1960) and is of ecological importance in many systems (Chet and Mitchell, 1976). Usually, the chemotactic response mechanisms result in the accumulation of microorganisms in areas of favorable metabolic conditions and depletion in areas of adverse conditions. However, there is almost no correlation between the properties of a substance to act as an attractant and to serve as an energy source (Adler, 1974; Weibull, 1960). The effect of an attractant has been shown to increase swimming periods toward the attractant after tumbling, while the swimming periods in the opposite direction are shortened (Koshland, 1974, 1976, 1980, 1981; Repaske and Adler, 1981; Adler, 1988; Hazelbauer, 1988). The role of chemotaxis in the vertical distribution is still a matter of speculation.

Aerotaxis The response of bacteria to oxygen may be a dominant mechanism enabling bacteria to find and remain in an environment favorable with respect to oxygen concentration. Vertical movements of clouds of phototrophic bacteria in Winogradsky columns observed during diurnal cycles of light and dark may serve as a model for investigating the response of bacterial populations toward oxygen and substrates.

Phototaxis Phototaxis is apparently shared by all anoxygenic phototrophic bacteria that are motile by flagellation. The phototactic response mechanism results in keeping the bacteria in an area of favorable light intensity after they accidentally enter. The response, reversal of flagellar movement, usually occurs when the cells enter an area of lower light intensity. Although phototaxis has been well studied in laboratory cultures (Hustede, Liebergesell, and Schlegel, 1989), investigations relevant to the significance of phototactic behavior in the vertical distribution of phototrophic bacteria in lakes are lacking. The function of photokinesis, the initiation or acceleration of linear velocity by light, has not yet been studied by ecologists (Nultsch, 1975).

Magnetotaxis Bacteria containing magnetite (Fe_3O_4) crystals have been discovered (Blakemore, 1975) and isolated (Blakemore et al., 1979; Frankel et al., 1979). It is hypothesized that the downward orientation of the cell within the earth's inclined magnetic field lines on the northern hemisphere provides favorable growth conditions for these motile and strongly microaerophilic organisms. However, when the studies were repeated in New Zealand and Australia, very similar organisms were found that exhibited a reversed polarity (Blakemore et al., 1980).

The anaerobic formation of magnetite by a marine magnetotactic bacterium (designated strain MV-1) was demonstrated using nitrous oxide as an electron acceptor (Bazylinski et al., 1988). This finding obliterated the notion that the biological production of magnetite can only occur in aerobic top sediments. Some nonmagnetotactic, dissimilatory iron-reducing bacteria were described by Lovley and Phillips (1987) and found also to synthesize extracellular magnetite from hydrous ferric oxide under anaerobic conditions. The formation or "biomineralization" of a ferrimagnetic iron sulfide called greigite (Fe_3S_4) has been reported in a multicellular magnetotactic bacterium that has not been isolated but is common in brackish sulfide-rich water and sediments (Mann et al., 1990). These crystals are often aligned in chains and associated with single crystals of nonmagnetic pyrite (FeS_2).

Buoyancy Assuming that gas vacuoles provide buoyancy to the cells (Walsby, 1975, 1977), there may be two ways by which distinct layers are formed. The bacteria may be able to migrate to the favorable depth, or the gas vacuoles may provide neutral buoyancy to guarantee a long residence time to the bacteria at depths supporting their growth. The second alternative has been supported by experimental evidence (Clark and Walsby, 1978b).

Gas vacuoles may also serve the distribution of cells and resting stages; this function is exemplified by the gas vacuoles of some clostridia, which are only formed during the transition phase from the vegetative cell to the spore (Duda and Makar'eva, 1977).

An interesting alteration of buoyancy and its significance in the natural habitat has been described in the case of *Metallogenium. Metallogenium* has been found in all oligotrophic lakes that contain manganese and also in mesotrophic and eutrophic lakes. Its development occurs during the periods of circulation. The vertical distribution of *Metallogenium* in these lakes is dependent on the concentration of manganese. Manganese is soluble in the reduced state. If oxidized by *Metallogenium*, manganese is precipitated at the cell surface, and the heavy manganese oxides make the cells sink down to the sediment. Under anaerobic conditions, manganese is reduced, the buoyancy is increased, and the cells return to the aerobic layers. Thus the movement of *Metallogenium* is strictly correlated to the availability of manganese and oxygen.

Microbial Associations

Under natural conditions, the various types of prokaryotes live in more or less close associations. Interactions between bacteria in a common habitat may be either weak or absent; only species with quite dissimilar nutrient requirements can be expected to show neutralism. The interactions may be strong and may be characterized as mutualism, commensalism, or parasitism. The relationships may be loose or tight, facultative or obligatory. Several examples of microbial associations studied in open systems have been reviewed by Meers (1973).

The most spectacular examples of syntrophic or of mutualistic associations have been discovered in the course of metabolic studies on bacterial cultures presumed to be pure cultures. One example concerns the partners of the culture of *Methanobacterium omelianskii* and illustrates a symbiosis with unidirectional substrate supply of mutual benefit. The other concerns symbiotic associations with bidirectional transfer of small molecules involved in energetic coupling.

Another striking discovery is the symbiotic association between chemolithotrophic sulfide- and thiosulfate-oxidizing prokaryotes and newly described marine invertebrates found to live tightly clustered around deep-sea hydrothermal vents (Cavanaugh et al., 1981; Felbeck et al., 1981; Belkin et al., 1986; Distel et al., 1988; Fisher et al., 1989). Furthermore, a new genus of marine blue mussels was found to contain methylotrophic endosymbionts in their gill cells enabling the animal to thrive near methane emissions in the vicinity of "cold seeps" on the seafloor (Childress et al., 1986). A similar association was later described in certain polychaetes collected from marine sediments at the Skagerak in the Baltic Sea (Schmaljohann and Flügel, 1987).

Interspecies Hydrogen Transfer

The concentration of many metabolites in the cell is below measurable levels. The intermediates of reactions, especially those which are catalyzed by multi-enzyme complexes, scarcely reach measurable concentrations. The intermediates are used as substrates of subsequent enzyme reactions at the same site or in the same compartment where they are produced. The absence of measurable concentrations of a compound does not mean that the compound is not involved in a metabolic reaction.

Similar situations are encountered in many ecosystems where very important intermediates of anaerobic food chains are present at scarcely detectable concentrations. In the rumen, lactate and hydrogen are present only at low concentrations, although they are major products of the predominating anaerobic fermentations; in contrast, acetate, butyrate, propionate, valerate, and formate, which are not subject to further fermentative conversion, may accumulate. In anaerobic ecosystems, only the end produces of anaerobic

food chains accumulate or are released into the environment. The concentration of some degradation products, such as hydrogen, acetate, lactate, and ethanol, is low. These compounds are consumed as soon as they are produced.

Metabolic products may be inhibitory to the cells that produce them; subsequent utilization of inhibitory products by commensals, therefore, is useful to the ecosystem. In several cases the cooperation of two or more organisms is essential, since a substrate would not be degradable at all if the concentration of the product were not kept very low. Interspecies hydrogen transfer is the most significant example of a symbiosis with unidirectional substrate supply from which mutual benefit is drawn.

The principle of interspecies hydrogen transfer became clear when the culture called *Methanobacterium omelianskii* was separated into a strain that produced hydrogen (S-organism) and a strain that oxidized hydrogen (Moh-strain) (Bryant et al., 1967; see also Virulence Strategies of Plant Pathogenic Bacteria in Volume 2). These strains carry out the following reactions:

$$\text{S-organism: } 2C_2H_5OH + 2H_2O \rightarrow 2CH_3\text{-}COOH + 4H_2$$

$$\text{Moh-strain: } 4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$$

The S-organism grows poorly as a pure culture in media with ethanol or other utilizable alcohols because the accumulated hydrogen inhibits growth. The S-organism lacks the ability to dispose of electrons resulting from the oxidation of ethanol via electron sinks other than hydrogen. For efficient growth of the S-organism, a hydrogen-utilizing bacterium has to be included to remove the hydrogen produced (Reddy, Bryant, and Wolin, 1972a, 1972b). The methanogenic bacteria keep the partial pressure of hydrogen low; for the bovine rumen a value of about 3 times 10^{-4} atmospheres (2 times 10^{-7} M) was reported (Hungate, 1967). Therefore, both organisms benefit from this symbiotic association. The methanogenic bacterium is continuously supplied with hydrogen, and the hydrogen-producing organism can even degrade and generate energy from substrates such as lactate or ethanol, which, for thermodynamic reasons (Wolin, 1976), could not be degraded when hydrogen accumulated in the medium (Wolin and Miller, 1982).

As a result of interspecies hydrogen transfer between partners of close symbiotic associations, therefore, special ecological niches can be occupied. The principle has been exemplified by coculturing methanogenic bacteria with various hydrogen-producing bacterial species (Table 5).

For the fermentative degradation of substrates such as lactate or ethanol, the removal of hydrogen by a hydrogen-utilizing partner is obligatory; without continuous removal of hydrogen, anaerobic growth on these substrates is slight. For the degradation of other substrates, glucose included, the removal of hydrogen is not obligatory; however, it enables the cell to obtain more energy than would be otherwise possible.

In media that contain little sulfate, *Desulfovibrio vulgaris* grows only modestly on ethanol or lactate producing acetate and hydrogen. Like the S-organism, it lacks the ability to produce a sink for electrons other than protons. In coculture with *Methanobacterium,* ethanol and lactate were actively fermented with the production of acetate and methane (Bryant et al., 1977). Stable methanogenic mixed cultures, which converted glucose to methane, were also obtained by enrichment in the chemostat (Siñeriz and Pirt, 1977). Benzoate, which under anaerobic conditions can be utilized by phototrophic bacteria in the light or by chemoorganotrophs through anaerobic respiration, has been shown to be biodegradable even under fermentation conditions (Nottingham and Hungate, 1969; Boyd et al., 1983; Sleat and Robinson, 1984; Tschech, 1989); methane and carbon dioxide are the main fermentation products. Apparently, a microbial consortium of more than two bacteria is involved in methane production from benzoate (Ferry and Wolfe, 1976).

The examples discussed above of interspecies substrate transfer concerned the unidirectional transfer of substrates within food chains. In the

Table 5. Examples of interspecies hydrogen transfer by coculturing hydrogen-utilizing (methanogenic) bacteria with various H_2-producing bacterial species.

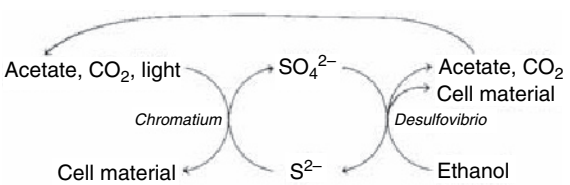
Substrate	H_2-producing species; products of pure culture	H_2-utilizing species; products of coculture	Reference
Glucose	*Ruminococcus albus*; ethanol, acetate, H_2, CO_2	*Vibrio succinogenes*; acetate, succinate	Iannotti et al., 1973
Glucose	*Selenomonas ruminantium*; lactate	*Methanobacterium ruminantium;* acetate, methane, CO_2	Chen and Wolin, 1977
Cellulose	*Clostridium thermocellum*; ethanol, acetate, H_2, CO_2	*Methanobacterium thermoautotrophicum;* acetate, methane, CO_2	Weimer and Zeikus, 1977
Cellulose	*Ruminococcus flavefaciens*; succinate, acetate, formate, H_2, CO_2	*Methanobacterium ruminantium;* acetate, methanol, CO_2	Latham and Wolin, 1977

next section, bidirectional transfer will be discussed.

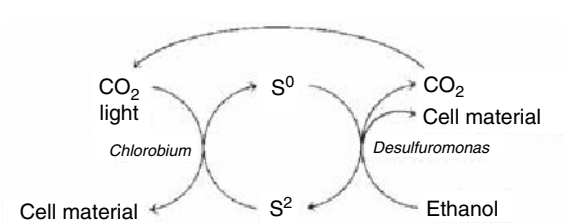
Bidirectional Transfer of Small Molecules

A bidirectional transfer of small molecules is the basis of some symbiotic associations in which sulfate (or sulfur) and hydrogen sulfide are involved in the energetic coupling of two different strains of bacteria kept in mixed culture.

Sulfate-reducing bacteria such as *Desulfovibrio vulgaris* growing with organic acids as hydrogen donors provide the hydrogen sulfide used for anoxygenic photosynthesis by *Chromatium*, which in turn reoxidizes hydrogen sulfide with the production of sulfate. The occurrence of this light-driven sulfur cycle has been repeatedly described. When sulfate is continuously added to the system, part of the sulfur intracellularly accumulated in the *Chromatium* cells may leave the cycle and be deposited. The deposition of sulfur in certain Cyrenaican (North African) lakes has been attributed mainly to this cycle (Butlin and Postgate, 1954), which is as follows:



Although the direct reduction of sulfur was already observed 80 years ago (Beijerinck, 1895), a chemoorganotrophic bacterium able to use elemental sulfur as hydrogen acceptor for growth was not known until the 1970s when a bacterium was found capable of oxidizing acetate to carbon dioxide linked to the reduction of sulfur to hydrogen sulfide (Pfennig and Biebl, 1976). This bacterium, *Desulfuromonas acetoxidans*, was isolated from a culture called *Chloropseudomonas ethylica*, which had been held as a stable mixed culture for many years. The syntrophic association of the green phototrophic bacterium, *Chlorobium*, and of *D. acetoxidans* occurs because hydrogen sulfide and sulfur permit energetic coupling of the life processes of both partners, as shown below:



In mixed cultures, low concentrations of hydrogen sulfide (7–8 mg/l) are sufficient to allow maximum growth of *Desulfuromonas* strains and of *Chlorobium* or *Prosthecochloris* strains (Biebl and Pfennig, 1978). The cell yield of the green bacterium is not limited by the hydrogen sulfide added to the culture; it depends rather on the amount of ethanol, the hydrogen donor.

To understand the function of a species in a habitat doubtless requires studies in mixed culture. Only in mixed culture under conditions of competition is the true actual niche revealed. According to van Niel (1955), Winogradsky "argued convincingly that pure culture studies may reveal characteristics that can express themselves only in the absence of potential competitors." The examples presented demonstrate the necessity for pure culture studies. Ironically enough, superb examples for the mixed culture concept were noticed when it was discovered that the "pure" cultures were not really pure.

Specific Aquatic Ecosystems: Marine Environments

Although the borderline between the aquatic and terrestrial habitat of microorganisms is diffuse, certain physical and chemical properties of water characterize the predominantly aqueous environment distinctly with respect to the indigenous microbial population. Inorganic and organic nutrients are available in dissolved and ionic form and are highly mobile and constantly dispersed by diffusion, convection, and currents. These characterizations of nutrient regime, together with the high heat capacity of water, provide the characteristic constancy of the environmental conditions upon which many of the typical aquatic microorganisms depend.

Another typical characteristic of aquatic environments is the variety of interfaces that are of special microbiological importance: the surface film (neuston); the interface between oxygenated and anoxic water or sediment; horizontal layering of water with respect to gradients of light, temperature, and salinity in stagnant waters; and finally the aqueous–solid interface of submerged surfaces. These interfaces provide specific and often highly selective environmental conditions for the accumulation and growth of microorganisms on the micro- as well as on the macroscale (see above, "Surfaces as Habitats," and Planktonic Versus Sessile Life of Prokaryotes in Volume 2).

The literature in "aquatic microbiology" largely deals with environments on the macroscale: the qualitative and quantitative assessment of populations in springs, ponds, rivers, lakes, and parts of the ocean. In addition, applied problems

led to the investigation of ground waters, acid mine waters, sewage lagoons, cooling water in pipe systems, etc. Only some of these studies focused specifically on the particular aquatic characteristics.

It was stated earlier that the lack of water-preserving mechanisms makes prokaryotes as a group appear to be typically aquatic organisms. Over and beyond this fact, certain microorganisms are specifically adapted to life at the typical conditions of aquatic environments. An example is *Thiovulum*, a highly motile and large (spherical cells of up to 25-µm diameter) chemolithotrophic organism that oxidizes hydrogen sulfide aerobically (see The Colorless Sulfur Bacteria in Volume 2). Growth of *Thiovulum* depends on its ability to locate in areas of the short-lived coexistence of hydrogen sulfide and oxygen as spontaneously reacting compounds (Wirsen and Jannasch, 1978). The biology of the typically aquatic *Caulobacter* group (see Dimorphic Prosthecate Bacteria in Volume 5) has been reviewed by Poindexter (1964) and Schmidt (1971). These prokaryotes are uniquely adjusted to metabolize at low nutrient levels (Poindexter, 1979) while largely attached to submerged solid surfaces with the aid of characteristic appendages, the prosthecae.

A large number of typically aquatic microorganisms are microaerophilic, a point of evolutionary interest, and take advantage of the fact that water provides a barrier against a quick replenishment of oxygen, as determined by the rates of dissolution and diffusion. Except for areas of high mixing, as in mountain streams, or of high photosynthesis, as in the surface layer of eutrophic lakes, concentrations of dissolved oxygen in most natural waters are well below saturation values.

The occurrence of a large number of other microorganisms, which can be easily and repeatedly isolated from natural waters, is not necessarily diagnostic for their aquatic specialization but merely for 1) their ability to survive well under these conditions or 2) a high rate of introduction from other habitats. Obvious examples are the seasonal occurrence of typical soil bacteria in streams and rivers or the common existence of enteric bacteria in waters polluted by domestic sewage.

The limited ability of enteric bacteria, as an extreme example, to compete for survival in natural waters indicates another general characteristic of aquatic habitats. The constant dispersion of dissolved nutrients by diffusion and currents has a dilution effect and leads to generally low concentrations of most of the substrates essential for microbial growth. A central theme of aquatic microbiology is the study of the physiology of growth and metabolism in the presence of low nutrient concentrations (see "Low-Nutrient Environments" in this Chapter).

Relating specific groups of prokaryotes with specific aquatic macrohabitats such as ponds, lagoons, rivers, or parts of the ocean is of limited value. A number of characteristic traits of these ecosystems, however, are of microbiological interest and are dealt with in the following sections.

Seventy-one % of the globe is covered by sea water, three-quarters of which lies below a depth of 1,000 m. Comparing the mean depth of the ocean to an arbitrarily assumed thickness of the terrestrial biosphere (depth of live soil and the zone of plant and animal life on and above the surface) at 38 m results in an aquatic/terrestrial volume ratio of 99/1. Productivity, on the other hand, is related to surface area and the availability of light and nutrients. It is limited in the sea to the phototrophic surface layer and is estimated, in spite of the above-mentioned volume ratio, in the same order of magnitude as the terrestrial photosynthetic production.

The ambient concentration of dissolved organic carbon in sea water lies in the range of 0.3–1.5 mg/liter (Menzel and Ryther, 1970). Particulate organic carbon reaches not more than one-tenth to one-fifth of that concentration. Much of this material, especially in deeper waters, is "refractory" to microbial attack ("Low-Nutrient Environments"). Except for a few nutrient-rich areas of high oxygen consumption by microorganisms, off-shore waters are aerobic down to the greatest depths. The only attempt to cover the area of marine microbiology was made by ZoBell in 1946. More recent literature reviews deal with particular problems (see below). Initial efforts in reviewing the systematics of the characteristic indigenous bacterial flora, obligately and facultatively aerobic rods, were carried out by Baumann et al. (1972). Luminescent bacteria, largely restricted to the marine environment, are described as belonging to a new genus of the Enterobacteriaceae, the *Beneckea*, and to the genus *Photobacterium* (Baumann and Baumann, 1977; Reichelt and Baumann, 1973). The former occur as free-living forms and the latter as free-living and quite distinct symbiotic forms living in specific organs of marine fishes and invertebrates (Greenberg, Hastings, and Ulitzur, 1979; Hastings and Nealson, 1977).

The Deep Sea

The deep sea comprises the largest volume of sea water characterized by the absence of light, by constant temperature around 2–3°C, by limited input of organic energy sources from the remote surface water, and by considerable hydrostatic pressure. Because of the continuous increase of

the last factor with depth, about 1 atm every 10 m, there is no particular depth at which the start of the deep sea can be defined. Oceanographers distinguish between shelf waters of up to 200 m deep, the continental slope area ranging to a depth of about 3,000 m, and the abyssal plains reaching 6,000 m. The deep trenches may reach depths of up to 11,000 m, but the total area of the world's ocean below 6,000 m covers not more than 1.2% and the total volume amounts to only 0.01% (Sverdrup, Johnson, and Fleming, 1942).

The remoteness of the deep sea from productive surface waters or from coastal input of organic energy sources causes the sparsity of life in deep waters. Yet a large number of bacteria can be isolated from sediments of almost any depth. The early work in deep-sea microbiology was reviewed by ZoBell (1970) and Morita (1976). Interest in this area was rekindled by experimental work on deep-sea in situ incubation (Jannasch and Wirsen, 1973).

The hydrostatic pressure and its possible effect on prokaryote metabolism (Marquis, 1976; Marquis and Matsumara, 1978) is of special interest. Based on physicochemical considerations, hydrostatic pressure may be assumed to affect metabolic processes only through differential volume changes. Unless dissolution and liberation of gases are involved, in principle, little or no effect can be expected at pressures below 1,000 atm.

A high variability of barotolerance in marine bacteria, mostly documented in terms of growth in various media, has long been known but is not fully understood yet. This is principally also true for "barophilism," a term introduced by ZoBell and Johnson (1949) and today defined as optimal growth response at pressures higher than normal atmospheric pressure. Pure cultures of true barophilic bacteria only first became available at the time Dietz and Yayanos (1978) introduced a technique for their isolation by using pressurized enrichments from decaying deep-sea amphipods in an organic-rich, silica-gel medium. Subsequent isolations from materials collected at depths of 5,800 and 10,500 m yielded organisms that grew optimally at pressures of about 500 and 690 atm (Yayanos et al., 1979, 1981). While some isolates grew at normal atmospheric pressure but at a rate 30-fold-lower than at optimum pressure, others did not grow at all after decompression and were called "obligate barophiles." Because of the more striking psychrophilic/barophilic behavior of isolates from greater depths, much of the earlier work concentrated on deep-sea trenches, i.e., at depths below 6,000 m, although their seawater volume is only 0.1% of the oceans' total. Thus, the results are more of physiological than of ecological significance.

Since this pioneering work appeared, large numbers of barophilic bacteria have been isolated from various depths (Deming and Colwell, 1982; Deming et al., 1981; Yayanos et al., 1982; Jannasch et al., 1982; Jannasch and Wirsen, 1982). The data generally indicate a close association between barophilism and psychrophilism, confirming earlier observations (Wirsen and Jannasch, 1975) on high barotolerance found primarily, but not exclusively, in psychrophilic isolates. The large variability of barophilism seems to merge gradually with barotolerant growth characteristics.

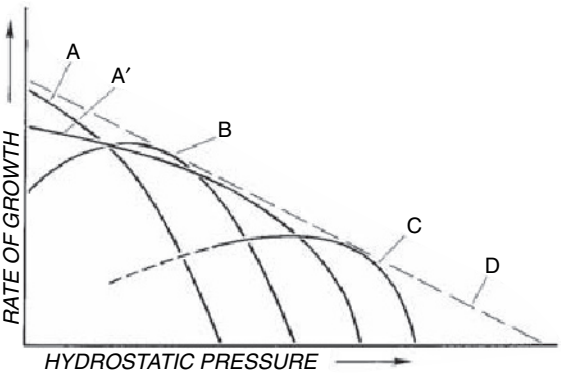


Fig. 4. Summarizing scheme of growth responses by marine bacterial isolates to hydrostatic pressure. A, low barotolerance; A′, high barotolerance; B, barophilic; C, obligate barophilic; D, slope of line indicates decrease of activity with increasing pressure. (Modified from Jannasch and Taylor, 1984.)

A direct comparison of all the published data is difficult, since they have been obtained in different growth media. However, the general situation can be schematically depicted as in Fig. 4, where A and A′ indicate a range of pressure between low and high barotolerance. Barophilic bacteria (B) also exhibit a considerable range of optimal growth pressures and are termed obligate barophiles (C) if they cannot grow at normal atmospheric pressure. The slope indicated by line D is a simplified expression of the overall decrease of microbial activity as a function of increasing pressure with depth. When considering microbial growth in the deep ocean, it should not be forgotten that both the nutrient concentration (mainly the available organic carbon) and the temperature are of predominant importance. It is now technically possible to sample enrich and isolate bacteria from the deep sea in pure culture while maintaining full pressure continuously (Jannasch et al., 1982).

Hydrothermal Vents

The decreasing cell density observed in the oceans with increasing depth has been explained as the result of the increasing remoteness from

the photosynthetically productive surface waters. A striking exception to this general rule was discovered when copious populations of large, sessile invertebrates were found at a depth of 2,700 meters clustered around warm-water vents of volcanic origin in the Galapagos Rift area (Ballard, 1977). The hydrogen sulfide content of the extruding waters (Fig. 5) was shown to provide the energy (the electron donor) for the chemosynthetically rather than photosynthetically sustained ecosystem either by free-living or by symbiotic sulfide- and thiosulfate-oxidizing prokaryotes (Jannasch and Wirsen, 1979; Grassle, 1986; Jannasch, 1989). Thus, these deep-sea animal communities are supported by terrestrial rather than solar energy (Fig. 6), the caveat to this statement being the use of photosynthetically produced oxygen in the pathway for aerobic sulfur oxidation. Although quantitatively of less importance for the production of organic carbon, anaerobic chemosynthesis has also been demonstrated by the isolation of methanogens from various sites at hydrothermal vents (Jones et al., 1989; Huber et al., 1989). Many of the aerobic chemoautotrophic and heterotrophic isolates from the warm and hot hydrothermal vent sites were extremely thermophilic (see above).

Marine Anoxic Ecosystems

Shallow estuaries are similar to rich freshwater environments, except for frequently and some-

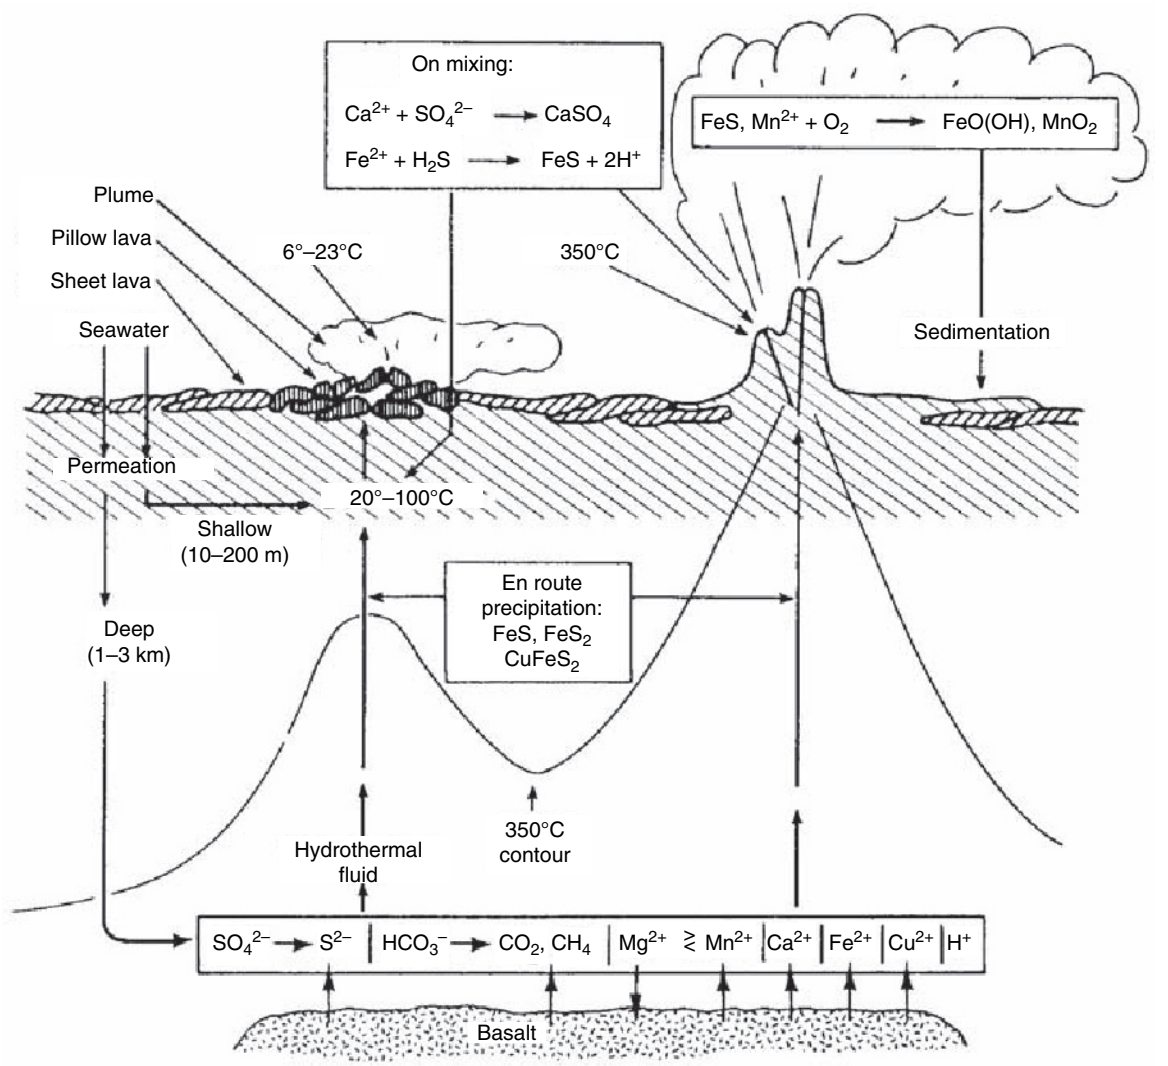

Fig. 5. Major geochemical processes occurring within the oceanic crust and on the deep-sea floor. As seawater penetrates several km into the crust, it is heated to 350–400°C, reacts with basaltic rocks, and leaches various chemical species into solution. The highly reduced "hydrothermal fluid" rises and reaches the sea floor either directly (hot vents) or after mixing with cold, oxygenated seawater before emission (warm vents). On mixing, polymetal sulfides and calcium sulfate (anhydrite) precipitate, either within subsurface lava conduits or as "chimneys" and suspended particulate matter in the "black smokers." (Modified from Jannasch and Mottl, 1985.)

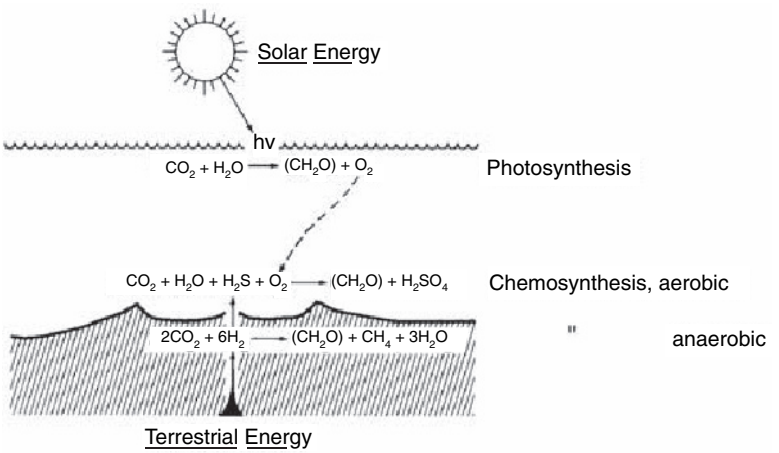

Fig. 6. Scheme of the energy supply pathway for photosynthesis and chemosynthesis, showing the role of free oxygen (O_2) at deep-sea hydrothermal vents. (From Jannasch, 1989.)

times drastically changing salinities and for the presence of certain characteristic anions and cations. The former is dealt with in the chapters on the habitats of halotolerant and halophilic prokaryotes (see The Order Halobacteriales in Volume 3; The Order Haloanaerobiales in Volume 4; and The Family Halomonadaceae in Volume 6). Next to chloride, the anion most characteristic for the marine environment is sulfate. In organically rich marine environments, the microbial reduction of sulfate to sulfide initiates the cycling of sulfur compounds with a number of concomitant environmental phenomena: the production of hydrogen sulfide, the precipitation of ferrous (and other heavy metal) sulfide often followed by the formation of a disulfide (e.g., pyrite), the deposition of elementary sulfur, and the rich populations of sulfur-oxidizing prokaryotes at the oxic/anoxic interface. Acidification rarely occurs, due to the high buffer capacity of sea water. Anaerobic marine basins, chemically stabilized by high concentrations of sulfide, range from small estuarine pockets to anoxic water masses on the scale of the Black Sea (see below). The high sodium concentration of sea water has been the key determinant for typically marine bacteria by constituting strict requirements for the cation (McLeod, 1968).

The largest anoxic ecosystems in the biosphere are marine. The Black Sea contains no free oxygen from a depth of about 150 m down to the bottom at a 2,000-m depth. In an extensive team effort, the geological, chemical, and biological characteristics have been studied (Degens and Ross, 1974). Skopintsev, Karpov, and Vershinina (1959) and Sorokin (1964) have done earlier microbiological work, finding that about 95% of the sulfide present in the deeper Black Sea water stems from sulfate reduction and that the oxidation of sulfide at the oxic/anoxic interface accounts for the large amounts of dark carbon dioxide fixation (4–6 mg C/m^3 · day). The auxiliary role of the cycling of sulfur compounds in the turnover of organic and inorganic carbon has been described (Jannasch, Trüper, and Tuttle, 1974), and the biomass and total number of microorganisms in the depth of the Black Sea have been measured (Mitskevich, 1979).

A series of research cruises on the Black Sea (April–September 1988) has resulted in some unusual oceanographic data. The oxic/anoxic interface, historically at depths between 125–175 m in the 2,000-m water column, had risen within the last decade to 80–90 m (Fig. 7). At the same time, a maximum for bacteriochlorophyll *e* was detected at the same depth where hydrogen sulfide first appears on a downward profile in the water column (Repeta et al., 1989). Such a high concentration of a prokaryotic pigment has never been observed before in the Black Sea, and it exceeded the concentration of the phytoplanktonic chlorophyll *a* in the oxic waters above (Fig. 8). This first observation of mass bacterial photosynthesis in offshore waters indicates that the rising sulfide level has reached the lower range of the photic zone. Slow-growing isolates from this zone appear to be adapted to low light intensities and are undistinguishable from *Chlorobium phaeobacteriodes* (N. Pfennig and H. Cypionka, personal communication). Other organisms isolated from the interface are aerobic, neutrophilic, obligately chemolithotrophic sulfide oxidizers, tentatively placed into the genus *Thiomicrospira*. A number of new sulfide-reducing and methanogenic bacteria were also isolated from the sediment.

The Carciaco Trench off the Venezuelan coast is another permanently anoxic basin of a depth of 1,400 m (Richards, 1975; Richards and Vaccaro, 1958). Another site is the Orca Basin in the northern gulf of Mexico, which features an anoxic and saline layer of bottom water at a depth of 2,300 m (Shokes et al., 1977). Trüper (1969) and Watson and Waterbury (1969) inves-

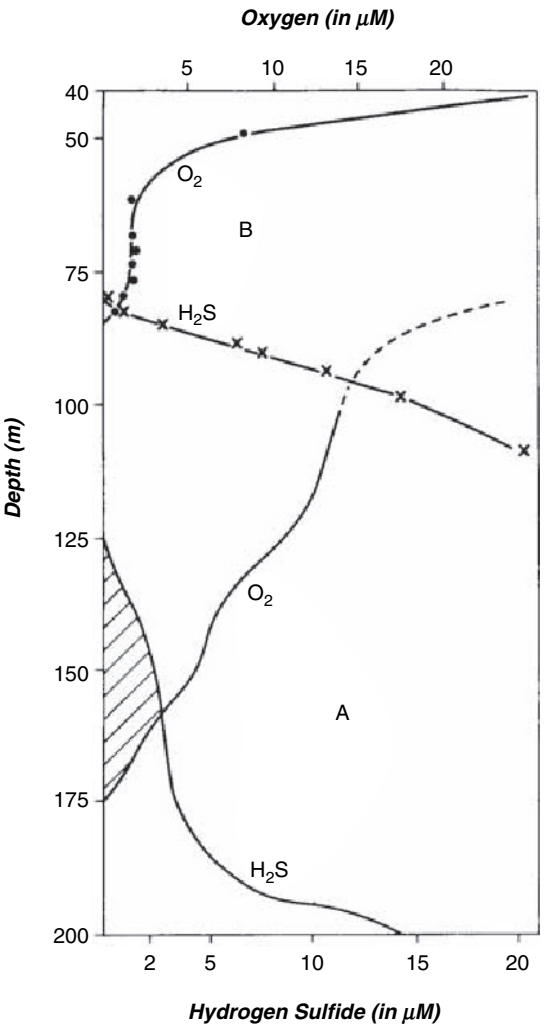

Fig. 7. Profiles of dissolved oxygen and hydrogen sulfide in the upper water column of the Black Sea, central western gyre. (A, data from Sorokin, 1972; B, data from Repeta et al., 1989.)

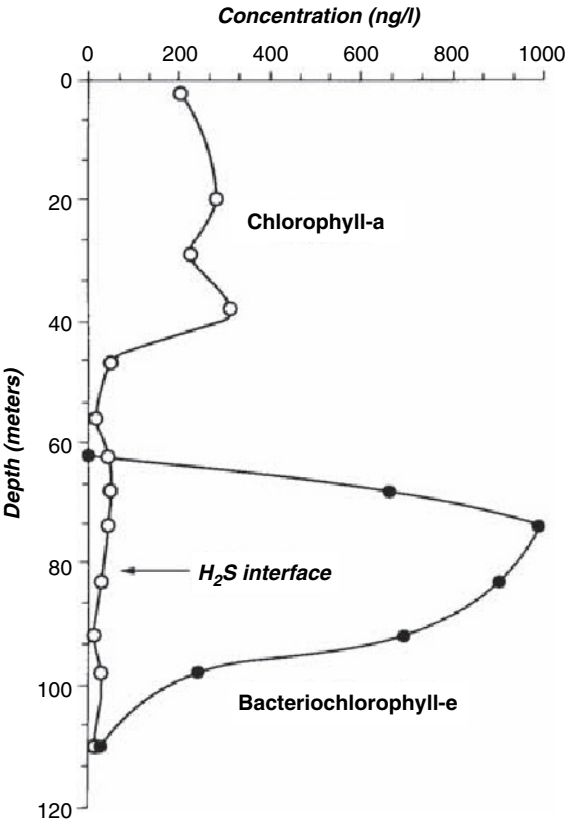

Fig. 8. Distribution of phytoplanktonic and bacterial chlorophylls in the upper water column of the Black Sea, central western gyre. (Data from Repeta et al., 1989.)

tigated anoxic hot brines (56°C) found at the bottom of the Red Sea and ascribed the absence of readily growing bacteria to toxic concentrations of heavy metals. A unique environment for the discovery of a number of new metabolic types of prokaryotes, especially the anaerobically photosynthesizing cyanobacteria, is the Solar lake near Elat in the Gulf of Aqaba, which has been described in a series of papers (see Cohen et al., 1977). The relatively low concentration of methane in most of the anoxic marine waters as compared to anoxic fresh waters is in agreement with the competitive behavior of sulfate versus carbon dioxide reduction originally suggested by Cappenberg (1974a, 1974b) and discussed in detail by Rudd and Taylor (1979).

Eukaryotes as Habitats for Bacteria

Eukaryotes present a multitude of habitats for bacteria. The surfaces, cavities, crevices, and intercellular spaces open to the air, as well as the intestinal tracts, exudates, and excretory substances, offer opportunities for the growth of many bacteria. During evolution, more or less close associations or symbioses between the eukaryotic organisms and bacteria have developed. The symbiotic relationship between the host, the larger partner, and the bacterium is either neutralistic, e.g., when bacteria feed on the waste products of the host, or mutualistic. Both of these relationships will be discussed here.

Two kinds of special abilities of the prokaryotes are exploited by the eukaryote and have opened highly specialized habitats: the ability to fix nitrogen and to hydrolyze cellulose.

Nitrogen fixation is exploited by plants. The bacterial symbionts are either held as ectosymbionts in intercellular spaces of leaves, stems, or at the root surface or as endosymbionts in root nodules and rhizothamnia. Animals do not take much advantage of nitrogen-fixing bacteria; nitrogen fixation has only been observed in the

hindgut of termites (Benemann, 1973; Breznak et al., 1973) and in the gut of humans who eat a carbohydrate-rich diet (Bergersen and Hipsley, 1970).

The ability to hydrolyze cellulose is lacking in animals that are higher on the evolutionary scale than the molluscs, with exception of the silverfish, *Lepisma lineata.* Symbiotic relationships between animals and cellulolytic protozoa and bacteria were established because of the abundance of cellulose as food and the general inability of animals to produce cellulolytic enzymes.

Associations of eukaryotic hosts with bacteria have evolutionary aspects. When the plants started to colonize the land and to shape the prerequisites for the evolution of the higher forms of life, the bacteria had already acquired a high degree of biochemical and physiological fitness—presumably the present-day status. Instead of being added to a preexisting system of higher organisms as, for example, plants and animals colonizing the recently emerged island of Surtsey, the bacteria colonized the eukaryotic host during all stages of the host's evolution. The present-day prokaryote-eukaryote relationships must be considered the result of a long selection process. Excluding parasitism, one may hypothesize that in all cases of stable associations, the relationship is of mutual advantage to the partners. The benefit may be as obvious as in the cases of nitrogen fixation in higher plants and of cellulose digestion in animals, or the benefit may just be a protective mechanism of seemingly very little importance, such as preventing harmful bacteria from entering the potential habitat.

Animal Habitats

Eliminating parasitism from this discussion, only some benign relationships will be considered. In this context the endosymbiosis of protozoa and bacteria deserves mention. Progress in this area is enormous and has been reviewed in the handbooks edited by Schwemmler and Schenk (1980) and Schenk and Schwemmler (1983). The inner and outer surfaces of animals, the intestinal tract, the skin, and several organs have to be regarded as microbial ecosystems with specific populations of indigenous and nonindigenous bacteria.

Intestinal Tract Among the associations of bacteria and animals, the intestinal tract is the ecosystem with the highest population density. The number of bacterial cells within the intestinal tract may even exceed the number of host cells. With respect to the human gut, this ratio was dramatically described by Savage (1977a): "the normal human organism can be said to be composed of over 10^{14} cells, of which only about 10% are animal cells." The ratio differs from species to species through the animal kingdom.

The intestinal tract is an open ecosystem that resembles a tube receiving food at one end and releasing waste at the other. In omnivores and carnivores, food digestion is accomplished by the animal's own intestinal digestive enzymes without involvement of microbes. There are two modifications of this "straight tube" model. Both types are found especially in herbivores, among the invertebrates as well as the vertebrates. Due to the particular nature of the diet of herbivorous animals, which is rich in celluloses, hemicelluloses, and pectins but is low in protein, the tract has been adapted to accommodate microorganisms. Extensions of the tract function as fermentation vessels and harbor protozoa and bacteria able to convert the plant polymers into microbial cells and degradation products. These fermentation vessels may be located either anteriorly or posteriorly to the areas of the intestinal tract where the gut contents are digested by the enzymes of the animal. In the ruminants, a special compartment of the stomach, the rumen-reticulum, is used as the fermentation vat. Its huge size guarantees a long residence time for the plant material to be degraded by cellulolytic and other microorganisms. Similar vessels destined for foregut fermentation are present in camels, kangaroos, hippopotamuses, and leaf-eating apes. The second modification of the straight tube is represented by extended compartments or blind sacs (ceca) near the end of the intestinal tract. Their function is also that of a fermentation vessel; examples for hindgut fermentation are found among vertebrates (horses, pigs, guinea pigs, rats, rabbits) and insects (termites, wood roaches).

Human Intestinal Tract The tract comprises six major areas: mouth, esophagus, stomach, small intestine, cecum, and large intestine. Each may be the habitat of a particular bacterial flora. And these habitats may be subdivided into further categories, such as epithelial (the bacteria grow in association with epithelial surfaces), lumenal (bacteria live free in the lumen), and crystal (bacteria live in crypts). Different areas harbor different bacteria, and each may be the primary habitat for a certain bacterium or a group of bacteria. The habitats are more or less delineated and offer rather constant conditions.

As was recognized very early (see Miller, 1890), the mouth, nasopharynx, and throat are inhabited by many aerobic and anaerobic bacteria. *Streptococcus salivarius*, *S. mutans*, *Veillonella alcalescens*, *Treponema dentium*, *Fusobacterium*, *Actinomyces*, lactobacilli, corynebacteria, and cocci belong to the normal flora of the human mouth (Hardie and Bowden, 1974). The mouth may be considered as an eco-

system of its own characterized by its anatomical and physiological development, the composition of the saliva, and the succession within the bacterial flora (Russel and Melville, 1978). The interaction of the oral streptococci and the mucosal and enamel surfaces deserves special emphasis; special methods have been developed to investigate the specificity of interactions (Rutter and Abbott, 1978), which are partially due to the kind and properties of extracellular polysaccharides (Ebisu et al., 1975; Germaine, Chludzinski, and Schachtele, 1974).

The intestinal tract contains climax populations of indigenous as well as allochthonous bacteria, yeasts, and protozoa. Hundreds of different bacteria have been isolated from the intestinal tract of many animals. In many cases, it is difficult to decide whether a certain species is autochthonous or not and which physicochemical niche it fills. Applying modern ecological theory (Alexander, 1971) to the ecosystem of the gastrointestinal tract of mammals (Savage, 1977a, 1977b), criteria for determining autochthony of microorganisms isolated from the gastrointestinal tract have been developed. "Autochthonous gastrointestinal microorganisms (i) can grow anaerobically, (ii) are always found in normal adults, (iii) colonize particular areas of the tract, (iv) colonize their habitats during succession in infant animals, (v) maintain stable population levels in climax communities in normal adults, and (vi) may associate intimately with the mucosal epithelium in the area colonized" (Savage, 1977a). These criteria are useful for distinguishing indigenous microorganisms from nonindigenous ones. For detailed information, the excellent reviews on relevant problems and on the present status of knowledge by Savage (1977a, 1977b), Clarke (1977), Bauchop (1977), Costerton et al. (1981a, 1981b, 1987), Costerton and Cheng (1981), Bitton and Marshall (1980), Marshall (1984), and Tannock (1990) and The Medically Important *Bacteroides* spp. in Health and Disease in Volume 7 should be consulted.

Because of its high acidity, the human stomach is not populated by bacteria. Behind the pylorus, fewer than 10 bacterial cells per milliliter have been counted. From the pylorus via the duodenum and jejunum to the ileum, the number of bacteria increases; up to 10^{11} bacteria per gram of feces have been counted; *Escherichia coli* represents less than 1% of the population. The predominant genus is *Bacteroides*, comprising species such as *B. fragilis* (see The Medically Important *Bacteroides* spp. in Health and Disease in Volume 7). The bacteroids are followed by *Fusobacterium*, *Eubacterium*, and *Peptostreptococcus* (Moore and Holdeman, 1974), all strictly anaerobic, Gram-negative rods. Other inhabitants belong to the streptococci, lactobacilli, and bifidobacteria (Drasar and Hill, 1974; Drasar and Barrow, 1985). The dependence of the composition of the flora on the kind of food eaten has not yet been exhaustively studied. The changes caused by the oral application of antibacterial agents like antibiotics and sulfonamides or by special foods such as garlic or cabbage have not been examined with respect to qualitative and quantitative changes of the bacterial flora.

The specific niches of the bacteria in the gastrointestinal tract are not easy to comprehend. The nutritional conditions are certainly optimal for many other bacteria which do not occur there. It is not known whether one or the other special property of intestinal bacteria as discussed by Prins (1977) is responsible for a true autochthony or whether their common occurrence in this habitat is correlated with specific chemical or structural properties.

One could imagine that for lumenal bacteria, high growth rates are required and that bacterial attachment sites and mechanisms favor the colonization of epithelia. The selection of only a few species of bacteria to grow in the gastrointestinal habitats may, among other factors, be due to the tolerance to pH, to lipolytic, peptolytic, and saccharolytic enzymes, to detergent-like bile acids, and to degradation products. Whether certain structural details of the bacterial cell envelope are common to all indigenous inhabitants of the lower intestine is an open question (Costerton et al., 1974, 1981a; Martin, 1969).

Basically, in many intestinal tracts, the presence of microorganisms is not necessary. Many animals can grow as gnotobiotes without microorganisms (Coates and Fuller, 1977). Studies with such animals have shown that the intestinal microflora confers a kind of resistance to intruding pathogens. While *Vibrio cholerae* and *Shigella dysenteriae* colonize the intestinal tract of germ-free rats easily, they do not colonize the normal gut easily. Stability of the microbial population is a major factor in the gastrointestinal ecosystem.

The use of gnotobiotic animals will help to explore neutralistic, mutualistic, and parasitic relationships of bacteria and their host. However, even simple quantitative and qualitative studies on the populations in intestinal habitats are urgently needed. It was not long ago that *Escherichia coli* was considered the dominant bacterium in the human intestinal tract. With the application to the human gut of methods originally developed for studying the ruminant bacteria, it was found that the number of strict anaerobes exceeded the oxygen-tolerant anaerobes such as *E. coli* by a thousandfold. The routine application of anaerobic techniques to other vertebrate or

invertebrate intestinal tracts will certainly result in similar unexpected relationships.

Rumen and Reticulum The best-studied ecosystem of foregut fermentation and most probably of all anaerobic ecosystems is the rumen. Rumen symbiosis is an excellent example of a highly developed ecosystem (Hobson, 1988). The principles derived from these studies have had profound influence on the study of microbial ecology (Hungate, 1966, 1975; Savage, 1977a, 1977b).

The main sources of carbohydrates for ruminants are hay, straw, and grass. About 50% of dried grass consists of fructosanes and xylanes, and the rest of the carbohydrate fraction is cellulose. The alimentary tract of ruminants is adapted to this special diet. The first two parts of the bovine stomach, the rumen and the reticulum, serve as a microbial digestive vessel; the total volume is 100–250 liters. This ruminoreticulum provides ideal conditions for the growth of many microorganisms. The temperature is constant at 37–39°C; 100–200 liters of saliva are secreted per day; it contains phosphate (10–50 mM), bicarbonate (100–140 mM), and urea (10 mM nitrogen) and is a well-buffered (pH 5.8–7.3) solution. Nutrients are periodically added in the form of well-macerated cellulose-containing fodder; the mixture is mechanically agitated by the contractions of the rumen. The rumen may be considered to be a semicontinuous culture of microorganisms (Hungate, 1975).

Between 10^{10} and 10^{11} bacteria and 10^5 and 10^6 protozoa inhabit each milliliter of rumen contents. Most of the bacteria are strict anaerobes and are especially adapted to that habitat. The oxidation-reduction potential amounts to –0.35 V. Because many rumen bacteria are instantly killed by oxygen, special techniques for manipulating nutrient media, inocula, and cultures in the absence of oxygen had to be developed (Holdeman, Cato, and Moore, 1977; Hungate, 1950). The nitrogen source of most rumen bacteria is ammonia. Many rumen bacteria require a carbon dioxide-rich (10% CO_2) atmosphere (Dehority, 1971). *Ruminococcus albus*, *R. flavefaciens*, *Bacteroides succinogenes*, *Butyrivibrio fibrisolvens*, *Eubacterium cellulosolvens*, and *Clostridium lochheadii* are the primary species of cellulose-digesting bacteria of the rumen. The cellobiose and glucose produced from cellulose are fermented by a variety of bacteria which utilize the pectins, starch, fructosanes, proteins, and lipids as well. Fermentative degradation of these compounds leads to the accumulation of fatty acids, carbon dioxide, and hydrogen. The latter two gases are combined by *Methanobacterium ruminantium* to give methane.

Besides the bacteria mentioned above, there are many others able to ferment noncellulose carbohydrates or the products of carbohydrate fermentation. These bacteria can only be mentioned here: *Bacteroides amylophilus*, *B. ruminicola*, *Succinimonas amylolytica*, *Selenomonas ruminantium*, *Streptococcus bovis*, *Veillonella alcalescens*, *Lachnospira multiparus*, *Peptostreptococcus elsdenii*, and *Desulfotomaculum ruminis*.

In addition to these bacteria, which have been grown in pure culture, there are some that have been identified microscopically only. Quin's oval and Eadie's oval have been grown in mixed culture (Orpin, 1972, 1973). The filamentous bacterium *Oscillospira* has been found mainly in the rumen of sheep. *Lampropedia* is an obligatory aerobe; however, it is found in high numbers in the sheep rumen.

The rumen microflora is in a delicate equilibrium. If, for example, rumen methanogenesis is eliminated by the addition of chloroform to the rumen contents, a series of changes occur: gaseous hydrogen accumulates immediately, and the increased partial pressure of hydrogen results in an increase of the ratio of propionic to acetic acid. These observations indicate that interspecies hydrogen transfer plays an important role in the rumen (Iannotti et al., 1973). Hydrogen is an intermediate in substrate conversions in the rumen (Hungate, 1967, 1975).

Hindgut Fermentation Although it is not as efficient for the animal as the rumen-type fermentation, hindgut fermentation is widely distributed among herbivorous animals, vertebrates as well as insects. The fermentative organisms and their function in the blind sacs (ceca) and the large intestine of animals have been less well studied than those involved in rumen symbiosis (McBee, 1977). The majority of studies on hindgut fermentations were limited to anatomical-morphological descriptions, and preserved specimens of insects have been used to recognize or describe microorganisms. Recent investigations show that the isolation and cultivation of bacteria so far only recognized in cross-sections of cecal mucosa epithelia is possible, although with difficulties (Lee and Phillips, 1978). The comprehensive investigations of Buchner (1953) provide an excellent basis and incentive for studies on the axenic culture of protozoa and bacteria present in the insect gut and its appendices. Investigations on the protozoal and bacterial symbionts probably involved in the degradation of plant polymers or having other important functions are urgently needed (Eutick, O'Brien, and Slaytor, 1978; see Foglesong et al., 1975; McBee, 1977). Investigations on the isolation and characterization of heterotrophic bacteria from hindguts of the wood-eating termite, *Reticulotermes flavipes*, revealed the predominance of streptococci and *Bacteroides* species and indicate

the existence of a unidirectional food chain from glucose via lactate to propionate and acetate (Schultz and Breznak, 1978, 1979).

Bacteria of the Human Skin The human skin is a rather homogeneous habitat with respect to temperature. However, moisture conditions vary and create distinctive habitats for a characteristic flora. The available water is the most important environmental factor influencing the size of cutaneous populations. The occlusion of the relatively dry skin of the forearm results in a rapid increase of the bacterial population by a factor of 10^4 (from an initial colony count of 3×10^3 to 3.8×10^7 cells/cm^2) by the fourth day of occlusion. The high relative humidity of the axilla results in the survival of dense populations in this region (Marples, 1965, 1974, 1976; Noble and Somerville, 1974; Woodroffe and Shaw, 1974). Many common bacteria, such as the corynebacteria ("diphtheroids"), mycobacteria, micrococci, and streptococci, in addition to yeasts and other fungi, are inhabitants of the human skin. Nutrients are provided by sweat. Fatty acids may act as antibacterial agents and effect a counter-selection. The bacteria inhabitating the sweat glands (sebaceous glands) and hair follicles cannot be reached by normal cleaning of the skin and guarantee fast repopulation of the skin after cleaning (Noble and Pitcher, 1979; Rosebury, 1972).

Molecular Microbial Ecology

Although the sequencing and hybridization of ribosomal RNAs primarily concern the phylogenetic characteristics of organisms (see How We Do, Don't and Should Look at Bacteria and Bacteriology in Volume 1 and Woese, 1987), first results show that a search for uses of this technique in microbial ecology is well justified (Pace et al., 1986; Giovannoni et al., 1988; DeLong et al., 1988). The advantage of identifying microorganisms within complex natural populations by the use of their individual ribosomal RNA signatures is that the often-difficult procedures for isolation, cultivation, and purification becomes less critical. The disadvantage is that specifically expressed metabolic activities of the phylogenetically identified organisms or their ecological functions in situ or in vitro are not readily apparent from the data. After Torsvick and Goksoyr (1978) pioneered a method for DNA extraction from whole natural populations, hybridization probes were applied to the study of the microbial population in the rumen (Stahl et al., 1988), in soil (Holben et al. 1988), and of communities of marine planktonic microorganisms (Giovannoni et al., 1990), of microbial hot springs (Stahl et al., 1985), and of symbiotic prokaryotes (Distel et al., 1988; Unterman et al., 1989). Much of the present work continues to emphasize methodology (Somerville et al., 1989; Weller and Ward, 1989), especially the development of gene probes for individual species or genera and other methods to assess detection and abundance of microbes at specific habitats or within natural populations.

Outlook

Although the habitat is not specified in the description of a species, it is a major characteristic of a species. Microorganisms have their habitats in various ecosystems and microenvironments. Unfortunately, a discussion of the environments of microorganisms can never be complete. The purpose of the present chapter was to demonstrate the multiplicity of microbial environments with emphasis on the close relationship to the diversity of prokaryotes, their metabolic peculiarities, potential capabilities, and constraints. Obviously, more examples could have been selected, and more will be found in the literature every month. The discoveries of new morphological and metabolic types of prokaryotes, as well as of unsuspected relationships and interactions between microorganisms and their environments, over the last decades can be related, in most cases, to the study of microbial ecosystems which had received no particular attention before. The rumen and its inhabitants have been discussed as one of the most striking examples of this; the illuminated hydrogen sulfide-oxygen interfaces of lakes and lagoons are others. Highly developed symbiotic relationships between bacteria and metazoa in the luminous organs and in the hindguts of mammals and insects as well as between bacteria and protozoa have only been marginally mentioned. The ecosystems consisting of solid matter, such as the various kinds of fertile soils, virgin volcanic soils, and desert soils as well as the rhizospheres of plants, have not been dealt with at all in this chapter.

New artificial microbial ecosystems are arising in increasing numbers in, for instance, the cooling systems of nuclear power plants and the aquatic and terrestrial dumping sites of new, chemically synthesized organic compounds, including herbicides, pesticides, and widely used organic solvents. Special evolutionary pressure is being exerted on prokaryotes by the ever-changing fungicidal and bacteriocidal environments of hospitals. Microbial populations will also be the first to respond to global environmental changes such as those following the thinning of the ozone layer and the greenhouse effect. One may also be realistic enough to include here the exposure of this planet's microorganisms to extraterrestrial conditions some of which, e.g.

certain layers in the atmosphere of Venus, may indeed sustain life of some known chemolithotrophic bacteria. In any case, it can be expected that studies of prokaryotes in relation to their natural environments will remain a most exciting and productive area of microbiology.

CHAPTER 1.7

Morphological and Physiological Diversity

STEPHEN H. ZINDER AND MARTIN DWORKIN

Introduction

Over 5,000 species and nearly 1,000 genera of isolated prokaryotes were tabulated as of 1999 (Garrity and Holt, 2000). Moreover, studies examining 16S ribosomal DNA in natural populations have provided convincing evidence that these cultured organisms are just the "tip of the iceberg" with several entire phyla/divisions having no or few cultured representatives (Hugenholtz et al., 1998). Prokaryotic diversity is an immensely valuable resource—not only as a source of an almost infinite variety of metabolic capabilities, enzymes and genes, but also as a veritable cornucopia of strategies for dealing with the world. If what we wish to understand is not only how an organism operates, but also how what it does enables it to deal with an extremely variable and occasionally hostile environment, then the study of microbial diversity truly holds the answers.

Much attention has focused on understanding the properties of a relatively few organisms (such as *Escherichia coli* and some of its close relatives) in ever greater depth and detail that is unmatched in any other cellular organism. This understanding has tended to serve as a paradigm for understanding bacteria in general, and in a larger sense, all organisms. Its ultimate expression is attributed to Jacques Monod: "What was true for *Escherichia coli* would be true for the elephant" (Judson, 1979), although he was actually referring to an "old axiom" of A. J. Kluyver on the unity in biochemistry: "From elephant to butyric acid bacterium—it is all the same" (Singleton, 2000). In any event, we have come to understand that though some fundamental strategies are indeed universal, each organism has evolved its own combination of tactics to arrive at the solution to its peculiar problems. It is thus appropriate, indeed often even useful, to continue the pursuit of the unusual microbe, so eloquently referred to by Ralph Wolfe in the foreword to this treatise.

Among the many rewards of this pursuit has been the recent recognition that, in addition to the diversity among the familiar and commonly recognized bacteria, there is yet a higher level of diversity. The existence of the Archaea has led to the recognition of a group of prokaryotes that not only does not share many of the properties considered fundamental to bacteria (Stanier and van Niel, 1962), but also has some properties, most notably transcription, more closely resembling those of eukaryotes (Reeve et al., 1997).

To get a sense of the evolutionary diversity of prokaryotes, one need only examine the universal 16S rDNA tree (Fig. 1) to conclude that about two thirds of evolutionary diversity is prokaryotic, and indeed most of eukaryotic evolutionary diversity is also microbial, mainly consisting of protists (Sogin and Silberman, 1998). Some "macrobiologists," notably the eminent evolutionary biologist Ernst Mayr (Mayr, 1998), insist that the phenotypic diversity of prokaryotes pales before that of eukaryotes, which includes "jellyfish, butterflies, dinosaurs, hummingbirds, yeasts, giant kelp, and giant sequoias." Woese in his reply (Woese, 1998) justly states that Mayr is comparing apples and oranges, and that the human visual system has evolved to discern differences in plants and animals as a matter of survival. Whereas, as we will demonstrate presently, there is ample morphological variation in prokaryotes, their specialty is metabolic variation and adaptation to habitats and niches. Can eukaryotes use sulfur or a pesticide as their lunch, fix nitrogen, or grow in boiling water? Clearly not. Indeed, some of Mayr's naturalist colleagues at Harvard now appreciate the importance of prokaryotes. Stephen Jay Gould states (Gould, 1996) that "on any reasonable or fair criterion, bacteria are—and always have been—the dominant form of life on earth," and E. O. Wilson speculates at the end of his autobiography (Wilson, 1995) that were he to start over again in the twenty-first century, he would become a microbial ecologist.

It is not our intention in this essay to construct a bestiary. Nor is it our goal to provide an exhaustive description of prokaryotic diversity; in effect, that is the entire content of this book. Our choice of examples of diversity has been selective, and this essay shall be limited to using a variety of prokaryotes to illustrate the diversity

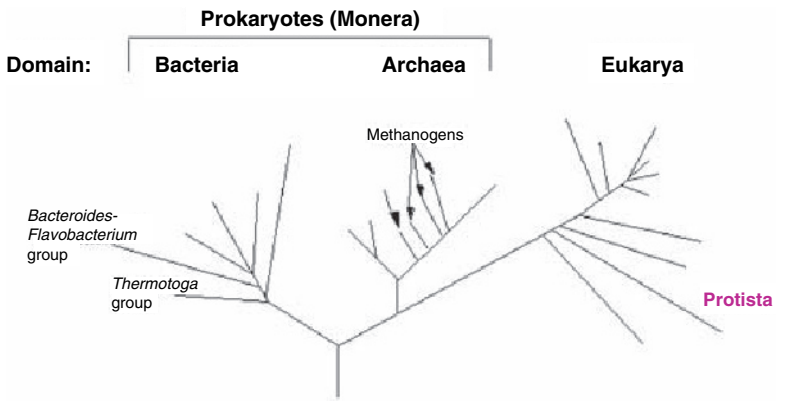

Fig. 1. Phylogenetic tree based on 16S rRNA. The three domains are shown, as well as the five classically defined kingdoms. (From Woese et al., 1990.)

of structural, physiological and metabolic strategies used by bacteria to adapt to the world.

Diversity in Cell Size

The conventional wisdom that prokaryotic cell diameters are typically near 1 μm, whereas eukaryotic cells are 10 μm or larger is generally true, but significant exceptions exist. Members of the Bacteria can show enormous diversity in cell size. For example, one of us works with a disk-shaped organism, *Dehalococcoides ethenogenes*, with a diameter of 0.4–0.5 μm and a height of 0.1–0.2 μm so that its volume is near 0.024 μm^3, about one twentieth that of *E. coli*. On the other hand, *Epulopiscium fishelsonii*, found in the gastrointestinal tracts of certain fish, are cigar-shaped cells with a diameter as great as 80 μm and lengths up to 600 μm (Angert et al., 1993). The volume of these cells is near 2 million μm^3, about eight orders of magnitude larger than of *D. ethenogenes*. Another example of prokaryotic gigantism, *Thiomargarita*, is a sphere (nearly a millimeter in diameter) composed of a thin layer of cytoplasm around a large internal vacuole in which nitrate, concentrated from the surrounding water, can reach concentrations as high as 0.8 M (Schulz et al., 1999). This nitrate-filled vacuole allows the organisms to oxidize sulfide under anaerobic conditions using the nitrate as a respiratory electron acceptor. Curiously, no examples of archaeal cells more than a few μm in diameter are known.

An advantage of existing as micrometer-sized cells is a greater surface-to-volume ratio. For example, if one compares spherical cells with 1 μm and 10 μm diameters, it requires 1,000 of the smaller cells (ca. 0.5 μm^3) to equal the larger cell (ca. 500 μm^3) in volume. Moreover, the smaller cells have 10 times greater total surface area (ca. 3,140 μm^2) than the larger one (ca. 314 μm^2), allowing them to present more surface to the environment for uptake of scarce nutrients. The smaller size apparently obviates the need for the organellar compartmentation and internal membrane systems generally found in eukaryotes because molecules can traverse the distances in the prokaryotic cell more easily by diffusion. Indeed, the cells of *Epulopiscium* contain an extensive internal membrane system (Clements and Bullivant, 1991), indicating that their large size necessitates such a system.

Diversity in Cell Shape

The controversy between the pleomorphists and the monomorphists led to a view of bacterial morphology first propounded by Ferdinand Cohn (Cohn, 1875) and hammered into a dogma by the subsequent work of Robert Koch. The classical textbook view of bacteria described them as spherical or cylindrical, the latter category divided between straight and curved rods. This view, based on the observations made on laboratory-grown cultures cultivated under conditions designed to result in a maximum growth

rate and morphological uniformity, came to represent a picture of the "true" morphology of bacteria. It obscured the spectrum of enormous morphological diversity manifested by the bacteria. It also obscured the fact that that diversity was often the result of life cycles that represented, for bacteria, survival strategies in addition to those of maximizing growth rates.

The shape of a cell is not a trivial or casual aspect of its adaptation to its environment but is instead a strategic consequence of this adaptation. Nor is the shape of a cell limited in any fundamental way to a rod, coccus or spiral. Ferdinand Cohn in 1875 divided bacteria into these three forms in one of the first systematic attempts to classify bacteria. It is now quite clear that the variety of cell shapes and groupings far exceeds those offered in early views. There are bacteria that are amorphous, ovoid, square, stellate, filamentous or stalked (Fig. 3). They may be grouped as pairs, clumps, chains, rosettes, cuboid packets, flat squares, networks, mycelia or fruiting bodies (Figs. 4, 5, 6).

What are the possible functions of cell shape and grouping? Certainly one of the most obvious relates to the surface-volume (S/V) ratio of a cell referred to above in the context of cell size. The sphere has the lowest possible S/V ratio, and as a cell becomes longer and thinner, its S/V ratio increases. One can imagine that a cell such as the oligotrophic *Caulobacter*, whose lifestyle involves the scavenging of extremely low concentrations of nutrients, will benefit from a rod shape, and from the consequent increase in surface area available for nutrient uptake. It has also been suggested (Pate and Ordal, 1965) that the characteristic stalks of *Caulobacter* (and perhaps also *Asticcacaulis*) function to increase the surface area of the cell yet further. Conversely, one may suggest that organisms that characteristically find themselves under conditions of ample nutrient levels would not be disadvantaged by low S/V ratios and may even find spherical shapes advantageous for other reasons. For example, one could imagine that an organism whose cell surface was subject to assault by antibodies or other host-defense factors might evolve a coccal shape that would minimize the amount of accessible surface.

It is conceivable that the shape of a cell may also be related to optimal hydrodynamic properties. It may not be a coincidence that motile organisms are rarely spherical; the number of flagellated cocci is quite small. Gliding bacteria are generally rod shaped (Fig. 6) although an interesting exception to this is found in *Isosphaera pallida*, a budding, chain-forming, gliding coccus (Fig. 4). In addition, the spiral shape of organisms such as spirochetes may be causally related to the ability of the organism to screw its way through a relatively highly viscous medium. In fact, it has been shown that the motility of spirochetes is enhanced at higher than normal viscosities (Canale-Parola, 1978).

It was appropriate at one time to view any departure from the rod—coccus—spiral morphology as a reflection of abnormal conditions. It is now quite clear that there are a variety of cell morphologies, each of which is uniquely appropriate for the ecological niche of that cell.

Diversity in Cell Grouping

It is also interesting to think about the functions of cell groupings. Is it possible that the characteristic clustering of the staphylococci further reduces the amount of accessible cell surface? And what is the conceivable function of the striking tendency of *Thiopedia* and *Lampropedia* (the latter a chemotrophic aerobe and the former a phototropic anaerobe) to grow as sheets of cells (Fig. 3)?

One instance where a characteristic grouping has been rationalized is in the myxobacteria. These organisms undergo a complex life cycle and feed on insoluble macromolecular debris by excreting a complex of hydrolytic enzymes. They are thus at the mercy of diffusion both of their enzymes away from the cell and of the hydrolyzed nutrients back to the cell. However, the complex life cycle of these organisms which causes them to periodically collect into densely packed fruiting bodies, as well as to form swarming, gliding masses of cells (Fig. 6b), guarantees a high local concentration of periodically excreted enzymes. This has been shown to optimize their feeding (Rosenberg et al., 1977) and has been referred to as a "microbial wolf-pack effect" (Dworkin, 1973).

Though the collection of resting cells compressed in the fruiting body represents the potential for releasing a high-density population once germination occurs, one can only speculate as to the function of fruiting body complexity. It is feasible, however, that each germinated cluster of cells has an optimal size, and that the number of cells in each of the sporangiole packages arrayed on the fruiting body determines this size.

There are other groupings that are familiar, e.g., chain formation by cocci or by rods (Fig. 7A, B), clusters (e.g., *Stomatococcus*, Fig. 7C), sheathed cells (e.g., *Sphaerotilus*, Fig. 7E), mycelium formation (e.g., *Streptomyces*, Fig. 7F), rosette formation (e.g., *Caulobacter*, Fig. 7D), cuboidal packets (e.g., *Sarcina*, Fig. 7G), and networks (e.g., *Rhodomicrobium*, Fig. 3). These groupings are probably not casual or accidental properties of the cells but are likely functional and should be viewed as other manifestations of

the diversity of prokaryotic adaptation to the environment. Understanding how these various groupings contribute to a cell's fitness lingers as one of the challenges of structure-function studies.

The Cell Surface

The interface between a bacterial cell and its surroundings is where the cell will first have to deal with a variable environment. It is thus the part of the bacterial cell where one might expect to find the greatest diversity. It is the cell surface that determines the nature of attachment to a substrate or to another cell. The cell surface also determines what gets into and out of the cell and the nature of that transport process.

Diversity in Capsules

Microbiologists have always had a fondness for working with organisms that grow in liquid in a nicely dispersed state. This has tended to obscure the fact that, in nature, most bacteria are not growing in a dispersed state but are clinging tenaciously to a substratum as a clump of cells or in a biofilm. Many organisms are surrounded by a more or less amorphous layer of slime, generally designated as the glycocalyx.

Furthermore, as was pointed out originally by Whittenbury and Dow (1977) and later emphasized by Costerton et al. (1986), the physiological properties of planktonic bacteria growing in a dispersed state are substantially different from those of the same cells when they are in their sessile state, embedded in a matrix of glycocalyces as pure or mixed culture biofilms (Costerton et al., 1999).

The principal component of the glycocalyx may be either polypeptide, as is the case with a number of species of *Bacillus*, or polysaccharide, characteristic of both Gram-positive and -negative organisms. These layers have a variety of functions depending on the organism and the nature of the layer. They serve in some cases to facilitate attachment to surfaces, either cellular or otherwise, and the nature of the capsule must, in some way, determine the kind of substratum to which the cell can attach.

The capsule has been shown to interfere with the function of the phagocytic cells of the immune system and may form a barrier to phage adsorption. Cook and Colvin (1980) have shown that the cellulosic fibers produced by *Acetobacter* serve to maintain these highly aerobic organisms at the liquid-air interface. Finally, it has been suggested that the hygroscopic quality of the glycocalyx may help a cell to resist desiccation. Based on such a variety of functions that a glycocalyx may play, it is no surprise that the composition of this structure varies so widely.

Another aspect of capsular diversity relates to the role of a capsule in interfering with the ability of phagocytic cells to engulf their bacterial prey. Certainly the ability of the pneumococcus to manifest a variety of capsular polysaccharide types plays an important role in the evasion of host defenses by the bacterium; the generation of diversity of the cell surface is a general strategy for compromising host-defense mechanisms.

Cell Wall Diversity

In Stanier and van Niel's classic description of the prokaryotic cell (Stanier and van Niel, 1962), one of the few positive characteristics of prokaryotes (as opposed to lack of nucleus, mitochondria, etc.) was the presence of a muramic acid-containing peptidoglycan cell wall. Indeed, because this structure is not present in eukaryotes, its synthesis is a primary target of several important antibiotics, such as the penicillin/cephalosporin group. At that time, cell walls were divided into Gram-positive, with its thick peptidoglycan layer, and Gram-negative, with a thin peptidoglycan layer and outer membrane (Beveridge, 1995). Stanier and van Niel were aware of mycoplasmas and similar organisms lacking a cell wall. It is now clear that though nearly all members of the Bacteria do indeed have a muramic acid-containing cell wall, many have protein cell walls, such as planktomycetes and chlamydia (Weisburg et al., 1986). The Gram-negative cell wall seems to be the default phenotype in the Bacteria, being found in most branches including the deeply branching Aquificae and Thermotogae. Moreover, even some deep branches of the Firmacutes contain organisms (such as *Sporomusa* and *Desulfotomaculum*) with Gram-negative cell wall structures. On the other hand, there are those who propose that the Gram-positive cell wall is the default structure (Gupta, 1998).

Arguably, the default cell wall architecture in the Archaea is the protein S-layer, a paracrystalline two-dimensional array of protein subunits (Sleytr et al., 1993). S-layers also are found outside the cell wall in many bacteria. In the genera *Methanosarcina* and *Halococcus*, there is a thick fibrous polysaccharide layer outside the S-layer, apparently serving as a corset to prevent lysis at relatively low osmolarities (Kandler, 1994; Sowers et al., 1993). In two methanogenic orders, the Methanobacteriales and Methanothermales, the cell walls consist of a thick peptidoglycan layer called "pseudomurein" which causes them to stain Gram-positive. Pseudomurein is similar to eubacterial murein but differs in a number of interesting aspects. It contains *N*-acetyl

talosamineuronic acid instead of *N*-acetyl muramic acid, the carbohydrate that, along with *N*-acetyl glucosamine, represents the carbohydrate backbone of murein. The amino acids in the peptide chain of the archaebacteria are all L-isomers and the glycosidic linkage is α -1,3 rather than -1,4.

Motility

Motility by multicellular eukaryotes serves a number of different functions. It enables an organism to escape from a predator or some other threat, it facilitates movement toward a potential mate, it allows developmental movement, and perhaps most importantly, it allows an organism to seek out and move toward a supply of food.

In the case of prokaryotes, it seems unlikely that cells can perceive the presence of predators such as protozoa, leucocytes, slime molds, phage or *Bdellovibrio* sufficiently in advance to allow them to exercise an avoidance strategy. Bacteria, however, can detect gradients of repellent chemicals and respond by moving away (see below).

With regard to mating, it does not seem that motility to facilitate mating interactions occurs among the bacteria. In those cases where a mating pheromone has, in fact, been demonstrated (Dunny et al., 1978), the participating organisms are nonmotile and depend on random motion to effect contact. The function of the pheromone is to prepare the organisms for the events involved in adhesion and gene transfer. Prokaryotic movement to accomplish a developmental event seems to be limited to the myxobacteria, where it allows the cells to maintain a high population density and to move into aggregation centers as a prelude to fruiting body formation (Spormann, 1999).

The most common function of motility among the prokaryotes seems to be to allow the organisms to position themselves optimally in their microenvironment, for example, to move along a concentration gradient toward a food source or away from a repellant (See Bacterial Behavior in Volume 2). The notion of a concentration gradient has implicit in it the condition that the substance in question is soluble rather than particulate, and that the milieu is thus an aqueous one. This serves to rationalize the observation that all the bacteria for which chemotaxis has been demonstrated are motile by means of flagella, with which they swim through an aqueous milieu. In fact, it is reasonable to suggest that the only conceivable function of swimming motility in bacteria is to allow the cell to travel along a perceived concentration gradient. The importance for chemotaxis and motility to the hunt for food is underlined by the finding that many naphthalene-degrading *Pseudomonas* strains possess plasmids which carry both the necessary biodegradation genes and genes encoding chemotaxis towards naphthalene (Grimm and Harwood, 1997), thereby forming a biodegradative package. Similarly, prokaryotes can position themselves in a gradient of light, a phenomenon called "phototaxis."

Swimming Motility

In all cases where they have been examined carefully, flagella in the Bacteria are fundamentally similar. They are usually composed of one, and in some cases two or three, species of a self-assembling protein, generically designated as "flagellin." This is attached, via a hook-shaped adaptor, to a motor-like basal body whereby the flagellar filament is inserted into the cell membrane. The flagellin subunits are translocated down the center of the flagellar shaft to the distal growth point where flagella are synthesized. An interesting adaptive use of this system is type III secretion found in pathogens, in which an assembly with protein subunits homologous to those in the flagellar filament is used to inject toxic proteins directly into eukaryotic host cells (Macnab, 1999). Diversity is manifested by the number and arrangement of the flagella around the cell. This varies from the polarly flagellated cell with a single flagellum (Fig. 8) to the profusely and peritrichously flagellated cells (Fig. 11). In between,

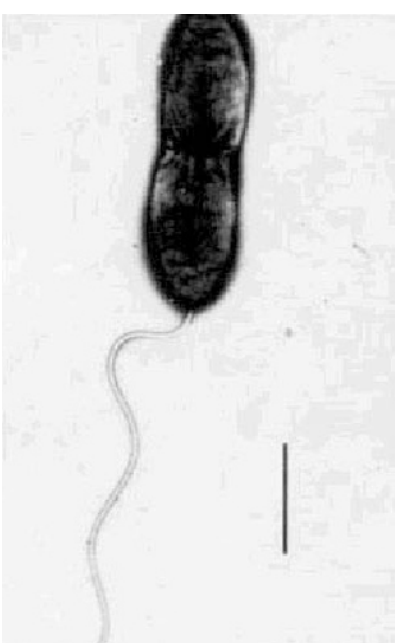

Fig. 8. Polarly flagellated cell of *Pseudomonas andropogonis*. Bar = 0.2 μm. (From Palleroni, 1984.)

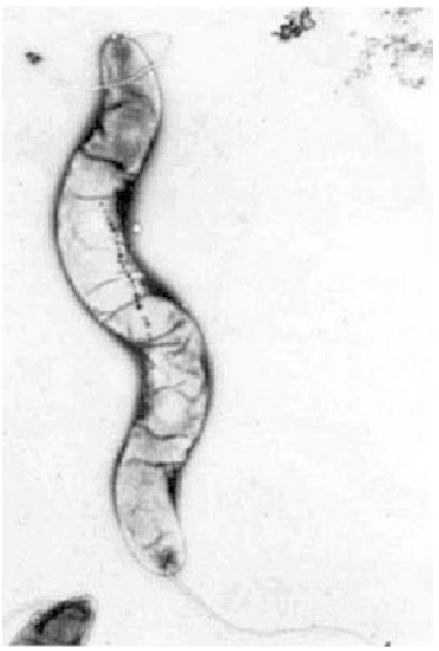

Fig. 9. Bipolarly flagellated cell of a magnetotactic spirillum. (From Balkwill et al., 1980.)

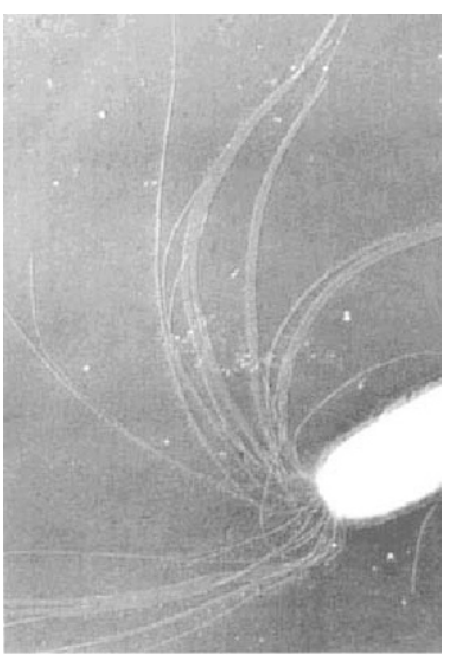

Fig. 10. Flagellar fascicle of *Spirillum volutans*. (From Krieg, 1984.)

there are cells with bipolar flagellation (Fig. 9) or with polar tufts of flagella (Fig. 10).

A most unusual style of flagellation is found among the spirochaetes. Rather than being freely turning propellers, the flagella are enshrouded by an outer cell envelope. It has been suggested (Berg, 1976) that their motion within this outer sheath generates a torque that, in combination with the helical structure of the cell, propels the cell in a screw-like fashion. It has been shown that, for certain of the spirochaetes (Canale-Parola, 1978), flagellar motility is enhanced in a high viscosity medium. This peculiar variation on flagellar organization may have evolved in response to high-viscosity environments that would hamper or prevent ordinary flagellar motility, allowing the spirochaetes to move through viscous media like a corkscrew through a cork. Interestingly, spirochaete motility seems to have at least three modes: swimming forward, swimming backward, and flexing (Fosnaugh and Greenberg, 1988).

Only flagellated prokaryotes move, in effect, via a rotating propeller principle. In this sense it is completely unlike the movement of conventional eukaryotic flagella, whose action is based instead on the sinusoidal beating of the flagellum within a single plane. One might ask either how the bacterium manages to operate an intracellular, rotating structure or, on the other hand, why there are no fish with propellers. The answer may lie in two features of the biophysics of movement. First, the efficiency of converting input energy to thrust is about 96–98% for an oscillating, flexible foil (such as the eukaryotic flagellum; Katz and Weihs, 1979); this is substantially higher than what can be obtained with a propeller-type mechanism. Second, the bacterium does not have this option; the tremendous viscous drag exerted on a small cell would damp out the oscillations of a sinusoidally beating flagellum. A screw-like motion is its solution to the need to move through an aqueous but (from the viewpoint of the bacterium) tar-like milieu.

Swarming Motility

Certain species of *Proteus* and of *Vibrio* carry out a kind of motility called "swarming" (Williams, 1978) that is an alternative to their normal, swimming motility. Under certain conditions, usually the perception of a solid surface or of an increased viscosity (in the case of *Vibrio*), the cell morphology and the manner of flagellation change. The cells become longer and, in the case of *Proteus*, filamentous, and the sparsely or polarly flagellated cells become profusely peritrichous (Fig. 11). In *Proteus*, when the cells are placed on an agar surface under the appropriate conditions, the swarming phase is periodic and alternates with a growth phase, during which shorter, less extensively flagellated swimming cells are formed (Matsuyama et al., 2000).

Twitching Motility

Certain of the Gram-negative cocci and coccobacilli, such as *Neisseria*, *Moraxella* and *Acineto-*

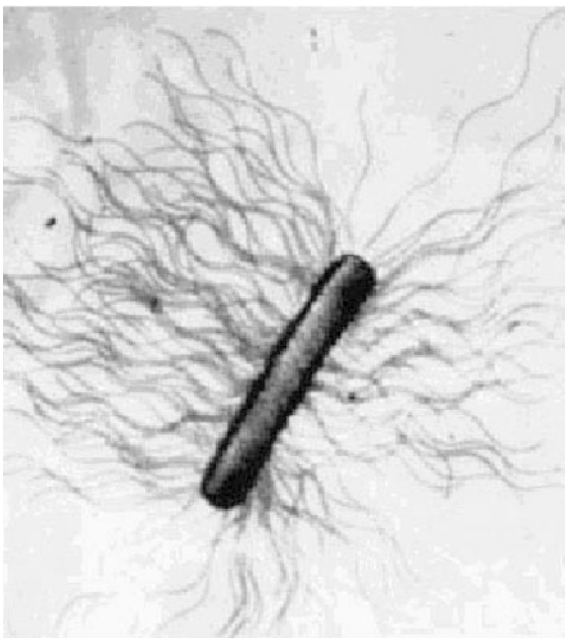

Fig. 11. Peritrichously flagellated swarmer cell of *Proteus mirabilis*. (From Hoeniger, 1965.)

bacter, manifest a peculiar type of movement known as "twitching" (Henrichsen, 1983). The cells exhibit jerking or jumping movements of a few micrometers in any direction. It now appears that retraction of type IV pili is responsible for this motility (Merz et al., 2000).

Gliding Motility

There are, however, alternative mechanisms for motility in prokaryotes. An entire group of bacteria, colloquially termed "the gliding bacteria," move by an undefined mechanism. These organisms are able to glide across solid surfaces such as agar and occasionally glass or plastic. The mechanism or mechanisms of such motility are not understood. The cells do not inch, wiggle or sidle. There seem to be no organelles of locomotion, although various authors have, on occasion, seen structures that they have interpreted as locomotory organelles (Lünsdorf and Reichenbach, 1989; Pate, 1979). Various mechanisms for gliding motility have been proposed (Burchard, 1984). They range from moving tracks (Lapidus and Berg, 1982), rotating organelles (Pate and Chang, 1979), polarized excretion of surfactants (Keller et al., 1983), and contractile fibers (Burchard, 1984). No one of these proposals is supported by other than those who have suggested them and it now appears that there may be more than one mechanism of gliding (Spormann, 1999).

The gliding bacteria, though customarily grouped together, have in common only the facts that they move by gliding and that they all have Gram-negative cell wall architecture. The motility mechanisms seem to be different, and the organisms cross the entire spectrum of physiological types.

While there is no hard evidence, it seems appropriate that those organisms whose nutrition depends on the extracellular solubilization of particulate material would glide rather than swim to gain access to their substrates. Though this seems to be the case for the myxobacteria, it is not clearly the case for the cyanobacteria or other gliding phototrophs.

Motility in Archaea

Some archaea show a flagellar-based motility, though gliding motility has never been detected in the Archaea. Whereas the archaeal flagellar assembly superficially resembles those of the Bacteria, it lacks a hook region, and, interestingly, the amino acid sequences of the subunits of the flagellar shaft resemble those of type IV pili in bacteria, rather than those of flagellins (Jarrell et al., 1996). Moreover, whereas bacterial flagellins are translocated outside the cell via a sec-independent transport system involving transport through the interior of the flagellum shaft, the flagellar subunits in the Archaea are transported using a standard sec-dependent system (Jarrell et al., 1996). Homologues of methyl-accepting chemotaxis proteins and the CheA-CheY two-component signal transduction system (Rudolph and Oesterhelt, 1996) have been found in the haloarchaea. Indeed, the haloarchaea have special sensory rhodopsins that, instead of pumping ions as do bacteriorhodopsin and halorhodopsin, couple with the methyl-accepting chemotaxis proteins to form a phototaxis system (Perazzona and Spudich, 1999).

Cell Division Strategies

Bacterial multiplication is usually thought of as being synonymous with binary transverse fission, the division strategy used by most of the commonly studied bacteria. This process has been intensively investigated, and, though many of the regulatory processes of division remain unknown, the descriptive details of the process are clearly defined (Ingraham et al., 1983). There is, however, a variety of other division strategies found among the bacteria, once one strays from the old laboratory standbys. Thus, division by budding among such organisms as *Hyphomicrobium* and *Rhodomicrobium* (Fig. 3E), by mycelial extension and subsequent fragmentation among the filamentous actinomycetes (Fig. 7F),

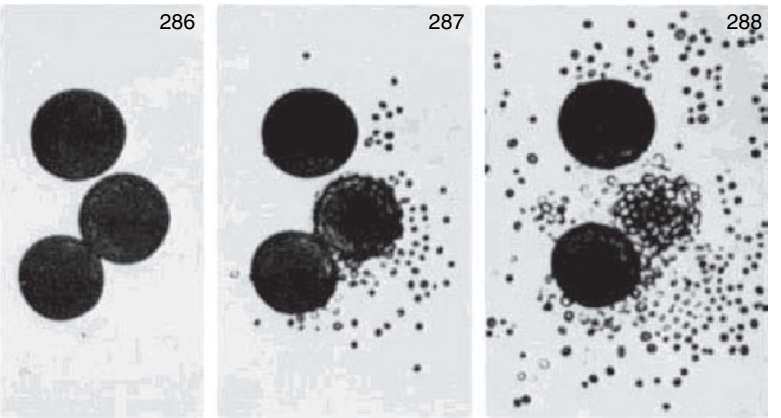

Fig. 12. Multiple fission and release of baeocytes from *Dermocarpa*. The numbers represent the hours that have elapsed during the growth of the initial, small baeocyte. (From Stanier et al., 1981.)

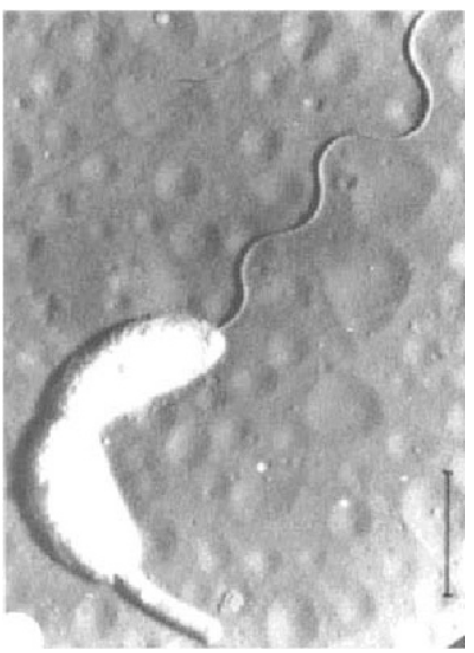

Fig. 13. Generation of swarmer cell from stalked cell of *Caulobacter crescentis*. (From Poindexter, 1964.)

and by multiple fission among the pleurocapsalean cyanobacteria (Fig. 12) has been described among the bacteria.

While it does seem a useful and interesting exercise to wonder what particular advantages are associated with the different strategies for cell division, this is not a subject that has received a great deal of attention from microbiologists. Nevertheless, it does seem obvious that these different mechanisms of cell division must be functionally related to the larger aspects of the biology of the cell. Thus, for example, mycelial extension followed by fragmentation seems a reasonable way to alternate filamentous and single-celled modes. And the unequal division of the stalked cell of *Caulobacter* (Fig. 13) leading to the generation of a flagellated swarmer cell must certainly reflect the division of the organism's activity between a sessile, stalked stem cell and a motile cell that may expand the territory occupied by that clone. Certainly, other speculations are possible to rationalize other modes of prokaryotic cell division.

Developmental Diversity

The chapter Prokaryotic Life Cycles in Volume 2 presents a more extensive discussion of the traditional view (and a more detailed description) of development among bacteria. The purpose of this section is to point out that development represents an additional set of strategies for diversity.

Development implies a set of alternative states. These alternatives may be expressed as a function of time, in which case we think of the alternative states as parts of a life cycle; on the other hand, the heterogeneity may be spatial, with different parts of the cell differentiated so as to fulfill specific functions. An example of the latter would be the stalked cell of *Caulobacter* (Fig. 13). In the case of either temporal or spatial alternatives, prokaryotic development generates considerably greater diversity than was afforded by the traditional nineteenth-century view of bacteria as rods, cocci or spirilla.

The generation of diversity among bacteria by developmental morphogenesis or by differentiation expands the kinds of niches that the bacteria can occupy. As an example, the ability of *Caulobacter* to form both a swarmer cell and a stalked cell allows it to separate the processes of growth and reproduction from dispersal. As an oligotroph, that is, an organism designed to feed on relatively low concentrations of nutrients, its ability to seek out, detect, and move toward such low concentrations must be optimized. That is the presumptive function of the swarmer cell. Once such a site has been discovered, it is the

function of the stalked cell to attach to a surface and begin the process of feeding, growth and reproduction. This sort of alternation between a sessile, feeding and reproductive stage and a nongrowing, swarming stage is also characteristic of organisms such as the actinoplanes, in which a mycelial phase alternates with a motile zoospore-like cellular stage. This type of developmental strategy facilitates the colonization of sites that might otherwise be inaccessible or inappropriate.

The characteristic swarm of the myxobacteria is another developmental strategy used by a bacterium to optimize its feeding. The myxobacteria feed by excreting a battery of potent hydrolytic enzymes that degrade proteins, peptidoglycan, polysaccharides, lipids and nucleic acids. The cells are thus at the mercy of the process of diffusion of enzymes away from the cell and of low-molecular-weight products of hydrolysis toward the cell. The myxobacteria optimize this process by traveling as a swarm—a high population density of cells (Fig. 14). The rate of cell growth on such substrates increases as a function of the cell density—a reflection of the fact that the cells are feeding cooperatively (Rosenberg et al., 1977). This sort of microbial "wolf-pack effect" has been suggested to rationalize the overall life cycle of the myxobacteria (Dworkin, 1973).

The ability of organisms to convert from a vegetative, growing stage to a resting stage allows them to persist in environments that might periodically become inhospitable to normal, prokaryotic life. As was pointed out earlier, the ability to grow in an extreme environment is invariably at the expense of the ability to grow in the so-called "normal environment." However, morphogenesis to a resistant, metabolically quiescent resting cell allows the organism to survive in the absence of growth until conditions are once again suitable for growth. A remarkable feature of this adaptation is that the state of almost total quiescence is juxtaposed with the ability to respond to the reappearance of conditions suitable for growth by germinating in an almost hair-trigger fashion.

Fig. 14. Swarm edge of *Stigmatella erecta* at low magnification. Bar = 110 μm. (From Reichenbach, 1984.)

One particular type of spore is referred to as an "endospore" and is found among the Gram-positive bacteria. This resting cell is formed within the vegetative cell and is usually released as a free spore as the process of sporulation is completed. Endosporulation occurs widely across traditional taxonomic lines and is found among the genera Bacillus, *Clostridium*, *Sporolactobacillus*, *Sporosarcina* and *Thermoactinomyces* (Fig. 15). In all of these organisms, the essential features of the spore and of the process of sporulation are quite similar. Another type of sporulation among the Gram-positive bacteria is found among the actinomycetes. Actinospores include the nonmotile conidial spores of *Streptomyces* (Fig. 16), the sporangiospores of *Actinoplanes* (Fig. 17) and the endospores of *Thermoactinomyces* (Fig. 18), which, despite their traditional taxonomic distance from the Bacillaceae, share many of the properties of *Bacillus* endospores. In this context, it is interesting that molecular techniques have revealed a moderate but distinct phylogenetic relationship between *Bacillus stearothermophilus* and *Thermoactinomyces vulgaris* (Stackebrandt et al., 1987).

The exospores of Gram-negative bacteria are, in general, less resistant to environmental extremes than are endospores. They are, however, metabolically quiescent and substantially more resistant to desiccation, physical breakage, and environmental extremes than the corresponding vegetative cells. Among the Gram-negative bacteria, resistant resting cells that have been fairly well characterized are found among the myxobacteria, as myxospores; among the cyanobacteria, as akinetes; and among *Azotobacter* and related genera, as azotocysts. Less well characterized resting cells have been described for the photosynthetic bacterium *Rhodomicrobium* (Dow and Whittenbury, 1979) and some of the methylotrophic bacteria (Whittenbury et al., 1970). Myxobacterial resting cells are contained in the characteristic fruiting bodies formed by the myxobacteria (Fig. 5), and their shapes vary from the round, resistant, optically refractile cells formed by the genus

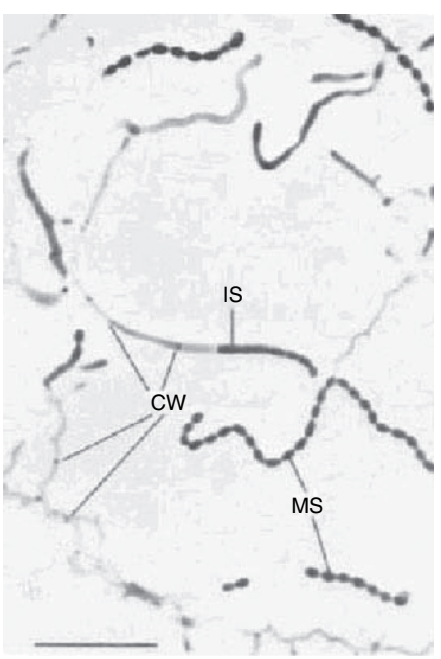

Fig. 16. Phase contrast micrographs of vegetative hyphae and conidiospores of *Streptomyces coelicolor*. CW, cross walls; IS, immature spores; and MS, mature spores. Bar = 10 µm. (From Chater and Hopwood, 1973.)

Myxococcus (Fig. 19A) to the slightly shortened, oval rods formed by *Stigmatella* (Fig. 19B). The myxospore of *Myxococcus xanthus* is formed by the shortening and rounding up of the entire rod-shaped vegetative cell and is finally enclosed by a multilayered spore coat/capsule (White, 1984). The *Myxococcus xanthus* myxospore is the only myxobacterial resting cell that has been well characterized both structurally and biochemically.

The cyanobacteria form a variety of cell types that have been considered to be spores or resting cells. These include the hormocysts of *Westiella*, the exospores of *Chamaesiphon*, the endospores or baeocytes of the Pleurocapsales (Fig. 12), and the akinetes of *Anabaena* and other genera. The cyanobacteria, in general, have not been characterized from a physiological or biochemical point of view with the same intensity that many of the eubacteria have. Thus, information about the properties of cyanobacterial resting cells is quite sparse. Most of the available information centers on the akinetes of *Anabaena*, and even in that case, the difficulty of obtaining large populations of relatively pure akinetes has limited the available information

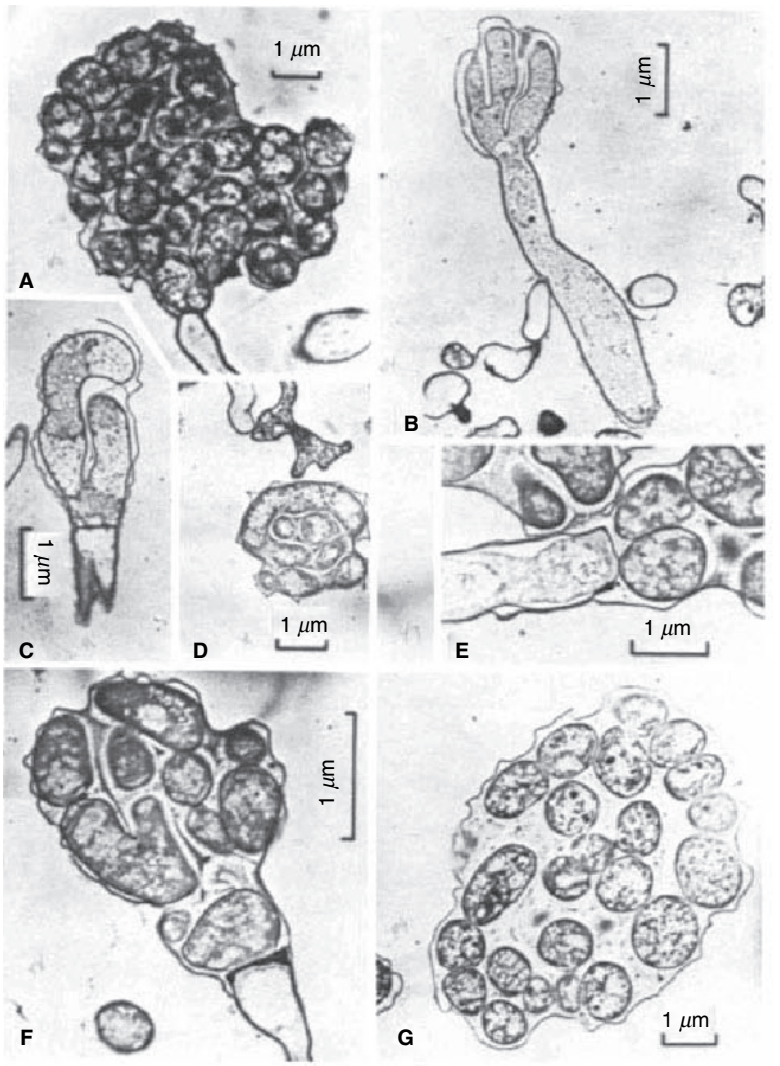

Fig. 17. Electron micrographs of thin sections of sporangiospores and sporangia of *Actinoplanes*. A) Mature sporangium, four days old. B), C) and D) Immature sporangium, two days old. E), F) and G) Mature sporangium, four days old. (From Lechevalier and Holbert, 1965.)

(Nichols and Adams, 1982). While the akinetes of *Anabaena* are more resistant to extreme low temperature and desiccation than the corresponding vegetative cells, their respiratory rate is twice that of the vegetative cells. Figure 20 illustrates the akinetes of *Anabaena*.

Cells of the Gram-negative, nitrogen-fixing genus *Azotobacter* are able to convert to cysts when the cells have exhausted the nutrients of the growth medium (Sadoff, 1976). The resting cells also can be induced by placing the cells in a medium containing hydroxybutyrate as the carbon source. *Azotobacter* cysts (Fig. 21) are superficially similar to myxospores, in that they are only slightly more resistant to temperature extremes than the corresponding vegetative cells but are considerably more resistant to desiccation and seem to be truly metabolically quiescent. (See Sudo and Dworkin, 1973 for an extensive, comparative survey of prokaryotic resting cell properties.)

Another interesting type of life cycle is shown by intracellular pathogens of the chlamydia group. Cells of the chlamydia must be able to carry out three very different kinds of processes. Because they are not transmitted by any sort of a vector, but may exist free in the environment, they must be able to persist in a nutrient-free, desiccated environment, subject to the normal variations of environmental conditions. Second, they must be able, from this state, to infect a specific host and to enter the host cell. Third, they must then be able to grow and reproduce intracellularly. Chlamydia accomplishes these processes by alternating between two states—the elementary body (a small, dense, resistant, and nongrowing cell) and the reticulate body (the vegetative form of the cell that can grow and reproduce).

Readers interested in a more detailed description of the various groups of prokaryotes that undergo development are referred to the excel-

lent recent monograph on the subject (Brun and Shimkets, 2000).

Metabolic Diversity

Catabolism is the part of metabolism involved in conservation of energy that can be used for biosynthesis and other cellular functions. Energy can be conserved from chemical reactions (chemotrophy) or from light (phototrophy). Catabolic diversity in prokaryotes greatly exceeds that in eukaryotes. There are many modes of metabolism, including anaerobic respiration, or lithotrophy, which eukaryotes cannot perform; even in those that the two cell types share, such as fermentation or photosynthesis, the eukaryotes are greatly outstripped by the prokaryotes in terms of substrates utilized and metabolic modes. Majorie Stephenson (Stephenson, 1949) expressed this concept presciently in the introduction to the first edition of her textbook on bacterial metabolism (also in the third edition), written well before the modern era of

molecular biochemistry or bacterial genetics. In it she states:

"Bacteria may be tentatively regarded as biochemical experimenters; owing to their small size and rapid growth, variations must arise very much more frequently than in more differentiated forms of life, and they can in addition afford to occupy more precarious positions in the natural economy than larger organisms with more exacting requirements."

In terms of anabolism, all organisms share essentially the same pathways for biosynthesis of protein, nucleic acids, carbohydrates and lipids. Prokaryotes can biosynthesize certain compounds like vitamin B_{12} or certain antibiotics not found in the eukaryotes, but one must also give due credit to the biosynthetic capabilities of the fungi, and especially those of the plants that biosynthesize an incredible diversity of chemical compounds including hydrocarbons, aromatic compounds, heterocyclics and alkaloids. Indeed the formidable biodegradative abilities of soil microorganisms can be partially attributed to the selective pressures of diverse plant compounds in their environment serving as potential growth substrates.

Two crucial aspects of anabolism are the fixation of carbon and nitrogen, processes that are essential for primary production of biomass on Earth. It has long been known that fixation of nitrogen is a solely prokaryotic process. Moreover, if one considers chloroplasts to be descended from cyanobacteria, which is clearly the case (Moreira et al., 2000), then essentially all fixation of carbon on earth is also prokaryotic.

In the following sections, we will give an overview of various metabolic modes found in prokaryotes, discussing catabolic diversity and the fixation of carbon and nitrogen.

Anaerobic Fermentation

Fermentation can be defined as the utilization of an organic compound in the absence of external electron acceptors, including oxygen. Microbes are unique in their ability to exploit anaerobic environments, and Louis Pasteur's insight into "La vie sans l'air" opened up a whole new area of metabolism. Among the microbes, the prokaryotes have most extensively exploited this modus vivendi. As is the case with almost all aspects of biological diversity, there are few clear-cut categories but rather a spectrum of differences that diminish as one learns more about the property. Thus, the spectrum of relations to oxygen includes those organisms that cannot use oxygen as a terminal electron acceptor and are in fact damaged by exposure to oxygen, those that are likewise obligately anaerobic but are indifferent to the presence of oxygen, those facultative organisms that have the option of metabolizing either aerobically or anaerobically, and finally those organisms that are obliged to use oxygen as a terminal electron acceptor.

Eukaryotes can ferment a few common carbohydrates such as starch, cellulose, glucose or sucrose to a limited number of products: lactate or ethanol and CO_2, or, in the case of hydrogenosome-containing anaerobic protists, to ethanol, acetate and CO_2 and H_2. The fermentative abilities of prokaryotes are more extensive.

Carbohydrates often are the main organic substrate available for fermentation. The canonical pathway for utilization of carbohydrates is the Embden-Meyerhof-Parnas (EMP) pathway found in eukaryotes and many prokaryotes. The Entner-Doudoroff (ED) pathway involves oxidation of glucose-6-phosphate to glucuronic acid-6-phosphate and leads to the conservation of only a single ATP per hexose via substrate-level phosphorylation (Conway, 1992; Fig. 22). The ED pathway is common in the Proteobacteria, especially aerobes, but can be found in some clostridia and bacilli and even some eukaryotic microbes such as *Entamoeba histolytica* and *Penicillium notatum* (Conway, 1992). Most of the organisms that use the ED pathway are aerobes, but the Proteobacterium *Zymomonas mobilis* uses it as a primary fermentative pathway for

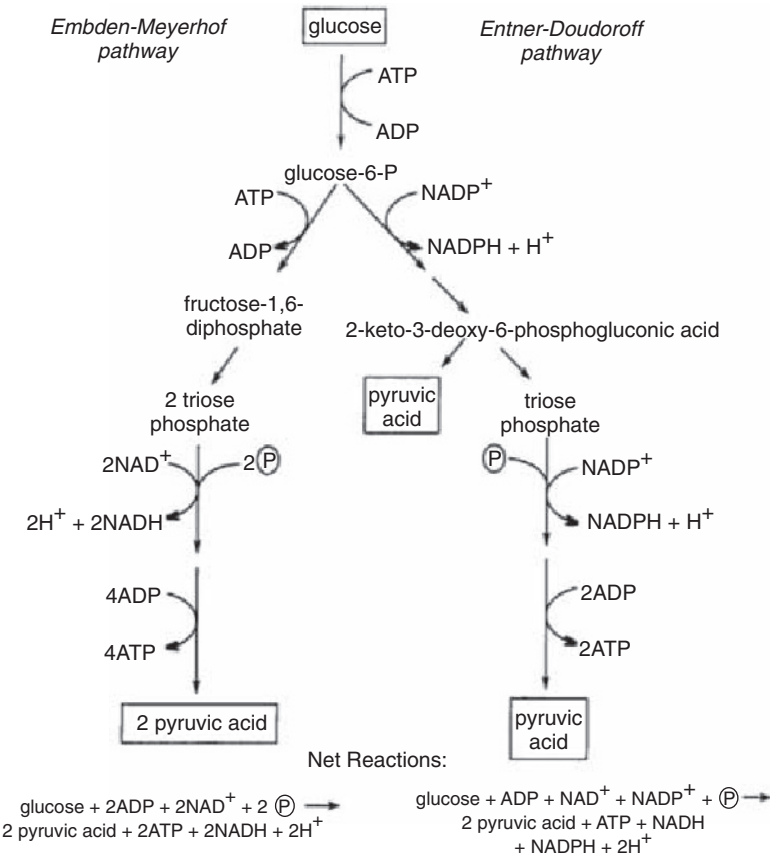

Fig. 22. The Embden-Meyerhof and Entner-Doudoroff pathways. (Adapted from Stanier et al., 1979.)

hexoses. *Escherichia coli* possesses both the EMP and the ED pathways and apparently uses the latter when dining on uronic acids in the gut (Peekhaus and Conway, 1998). Other glycolytic pathways in the Bacteria include that used by heterolactic Gram-positive bacteria (also leading to the conservation of a single ATP per hexose), the pathway found in bifidobacteria, and the pentose phosphate pathway, which is generally used for biosynthesis of five carbon sugars for nucleic acids (Gottschalk, 1986).

When sugar-fermenting Archaea were examined for glycolytic pathways, they were shown to have interesting modifications of both the EMP and the ED pathways (Kengen et al., 1996; Selig et al., 1997). For example, the hyperthermophile Pyrococcus furiosis, which ferments hexoses to acetate, hydrogen, CO_2 and alanine, was found to utilize a modified EMP pathway in which ADP rather than ATP serves as the phosphoryl donor for hexokinase and phosphofructokinase (Fig. 23). Moreover, instead of the standard glyceraldehyde 3-phosphate dehydrogenase, which uses NAD^+ as an electron acceptor and produces 1,3-diphosphoglycerate, *Pyrococcus* and certain other Archaea possess a novel tungsten-containing glyceraldehyde 3-phosphate/ferredoxin oxidoreductase (Adams, 1993) that produces 3-phosphoglycerate. Thus the net high-energy phosphodiester bonds conserved from hexose to pyruvate by this pathway are zero. The ATP from acetyl-CoA produced from pyruvate, however, is conserved by a novel ADP-dependent acetyl-CoA synthetase (previously described acetyl Co-A synthetases cleave ATP to AMP and pyrophosphate in the acetyl-CoA synthesis direction).

In contrast, *Thermotoga maritima*, a phylogenetically deep branching hyperthermophilic fermentative bacterium, converts hexoses to pyruvate using the conventional EMP pathway, and conserves ATP from acetyl-CoA using phosphotransacetylase and acetate kinase, as is found in mesophilic bacteria. The advantage of the glyceraldehyde 3-phosphate/ferredoxin oxidoreductase over the NAD^+-utilizing dehydrogenase is unclear, but one possibility is that ferredoxin is a very strong electron donor capable of reducing protons to H_2. In contrast, H_2 production from NADH is thermodynamically unfavorable at H_2 partial pressures above 10^{-3} atmospheres (Wolin and Miller, 1982). Therefore, the modified EMP pathway is less likely to be inhibited under conditions of high H_2 partial pressures. Indeed, growth of *T. maritima* on sugars becomes inhibited unless an electron

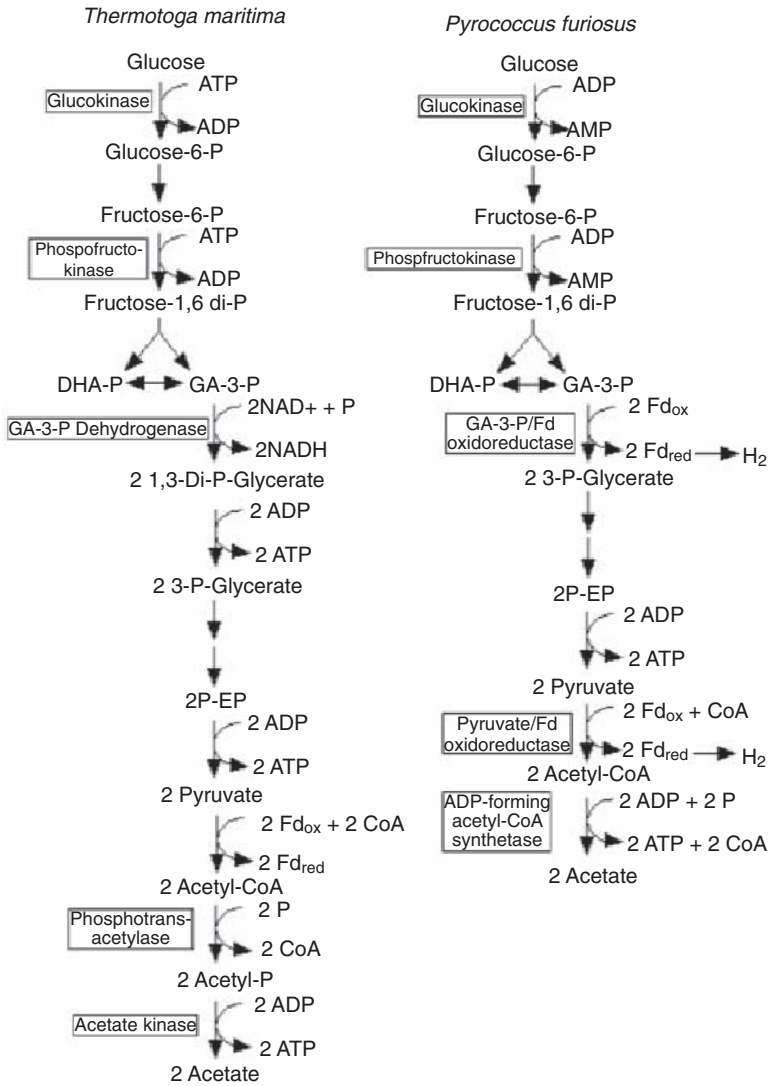

Fig. 23. Comparison of glycolytic pathways in *Thermotoga maritima* and *Pyrococcus furiosis*. P, phosphate; DHA, dihydroxyacetone; GA, glyceraldehyde; P-EP, phosphoenolpyruvate; Fd, ferredoxin; and CoA, coenzyme A.

acceptor such as elemental sulfur or a hydrogen-utilizing methanogen is added to remove H_2.

Archaea possess other variants on the EMP pathway (Menendez et al., 1999). In *Desulfurococcus*, ATP is used in both hexokinase and phosphofructokinase as in the classic EMP pathway, whereas in *Thermoproteus*, ATP is used by hexokinase and pyrophosphate is used by a phosphofructokinase, as has been found in some eubacteria and eukaryotes. All EMP pathways studied in the Archaea thus far utilize glyceraldehyde 3-phosphate/ferredoxin oxidoreductase instead of the NAD^+-utilizing dehydrogenase. A modification of the ED pathway in certain Archaea (including *Sulfolobus*, *Thermoplasma* and *Halobacterium*) has been described in which glucose is not phosphorylated before oxidation to gluconic acid, and phosporylation occurs at a later step in the ED pathway (Conway, 1992).

Besides carbohydrates, amino acids, derived from the hydrolysis of proteins by proteases, are fermented by a variety of prokaryotes, particularly the clostridia, either singly or in pairs, as in the Stickland reaction (Gottschalk, 1986). The products of amino acid fermentation, amines (including putrescine and cadaverine), branched-chain fatty acids, and sulfide and mercaptans from sulfur-containing amino acids, essentially define the word putrid. Our great olfactory sensitivity to these compounds no doubt has played a selective role in protecting us from eating spoiled food potentially containing botulin and other toxins. The purines and pyrimidines derived from nucleic acids are also readily fermented by prokaryotes.

Originally it was thought that only a small number of sugars and amino acids were fermented by prokaryotes. As anaerobic culture techniques have improved, an astounding diversity of compounds has been found to serve as substrates for fermentation, including aromatic compounds and even saturated alkane hydrocar-

bons (Zengler et al., 1999). Many of these fermentations take place in the presence of a hydrogen-consuming anaerobe such as a methanogen. The removal of hydrogen (or acetate in some cases) allows the fermentation to be energetically favorable. This syntrophic interaction is called "interspecies hydrogen transfer" (Schink, 1997).

Indeed, our concepts of fermentation have had to change over the past few decades. It was generally considered that fermentations involved substrate-level phosphorylation. However, consider the example of *Propiogenium modestum*, which grows by decarboxylating succinate to propionate by the following reaction:

There is no net redox reaction, only a decarboxylation. Readers might rightly guess that the pathway is not a simple decarboxylation, but rather involves coenzyme A derivatives and includes a rearrangement to methylmalonyl-CoA. However, the substrate-level phosphorylations in this pathway provide a net ATP yield of zero. Instead, it was shown that membrane-bound methylmalonyl-CoA decarboxylase pumps sodium ions with each decarboxylation it carries out. A sodium-dependent version of an F_1F_0-ATPase can then conserve ATP from the sodium gradient across the cell membrane. Thus, in the absence of electron transport, a chemiosmotic potential is generated in this organism, as well as in others carrying out similar decarboxylations (Dimroth and Schink, 1998).

Anaerobic Respiration

For aerobic respiration, eukaryotes are dependent upon mitochondria, clearly derived from endosymbiotic prokaryotes in the α subphylum of the Proteobacteria (Gray et al., 1999). If the mitochondria were once capable of using electron acceptors other than oxygen, they no longer are, nor have the eukaryotes evolved other mechanisms to use alternate electron acceptors. Thus, anaerobic respiration is solely the domain of prokaryotes. Moreover, prokaryotes can utilize a large range of electron acceptors other than oxygen (Table 1).

Nitrate and nitrite are produced aerobically from ammonia by nitrifyers (see below) and can be used as electron acceptors by diverse members of both the Bacteria and the Archaea (Zumft, 1997). Nitrate is initially reduced to nitrite, and nitrite can be reduced either to N_2 and N_2O gas via the denitrification pathway or to ammonia. The former process is more common as a respiratory process whereas the latter is often used to assimilate nitrate and nitrite but

[a]H_2 is used as a model electron donor for the sake of comparisons of the reactions and its use does not imply that the representative organisms use H_2. Most $\Delta G^{\circ\prime}$ values are taken from Thauer et al., 1977.

can be used as a respiratory process by *E. coli* for example (Stewart, 1994). The energetics of using nitrate and nitrate compounds as electron acceptors is comparable to that of using O_2, and most of the organisms reducing nitrogen oxides are facultative aerobes.

In the final decade of the twentieth century, recognition of the importance of Fe(III) as an electron acceptor in anaerobic habitats increased. Whereas at low pH, Fe(III) mainly exists as the free ion and the Fe(III)/Fe(II) oxidation-reduction potential is near + 0.77v, at circumneutral pH values, Fe(III) exists primarily as hydroxide precipitates, which causes the oxidation/reduction potential to be between +0.2 and –0.2v (Widdel et al., 1993). Amorphous ferric hydroxide precipitates are much more bioavailable than are more crystalline ones. Most known Fe(III) reducers are members of the Proteobacteria, but even certain deep-branching thermophilic Bacteria and Archaea can reduce Fe(III) (Vargas et al., 1998), suggesting a role for this process early in life's history on Earth. Also, certain purple photosynthetic bacteria oxidize Fe(II) to Fe(III) (Widdel et al., 1993), making for a photosynthetic producer-consumer cycle analogous to those for oxygen or sulfur.

Sulfur compounds can serve as electron acceptors, and it is apparent from Table 1 that the amount of energy available from their reduction is considerably less than that of the preceding compounds. Sulfate is an abundant form of sulfur, especially in seawater, where its concentration is near 28 mM. Two genera, *Desulfovibrio* and *Desulfotomaculum*, were essentially the only ones known until better anaerobic techniques were applied, revealing an enormous diversity of organisms. Most sulfate reducers belong to the δ and ε subphyla of the Proteobacteria or to the Firmicutes (Gram-positive bacteria) in the Bacteria and to the genus *Archaeoglobus* in the Archaea. Sulfate reducers and other organisms can generally utilize sulfite or thiosulfate, and these two compounds can be used even in the absence of organic compounds in an inorganic "fermentation" to sulfide and sulfate (Bak and Pfennig, 1987).

Elemental sulfur also is used as an electron acceptor by diverse anaerobes, either as a respiratory electron acceptor leading to energy conservation by an electron transport chain or simply as a way to recycle NADH to NAD^+ for certain fermentative organisms such as *Thermotoga*. Elemental sulfur is reduced to sulfide by many hyperthermophiles growing under conditions of "fire and brimstone," and sulfur reduction is a good candidate for the first respiratory process on earth.

When other electron acceptors in anaerobic habitats are absent or depleted, the acceptor remaining is carbon dioxide, which can be used by either methanogens or acetogens. Methanogens represent the predominant phenotype in the Euryarchaeota phylum in the Archaea, demonstrating an enormous phylogenetic and morphological diversity. Methanogens use only a small number of simple substrates (the most complex is acetic acid) and an intricate pathway for reduction of one-carbon units to methane (DiMarco et al., 1990). This pathway was thought to contain many unique enzymes and cofactors, but a large portion of the pathway is now known to be used to oxidize formaldehyde to CO_2 in aerobic methylotrophic bacteria (Chistoserdova et al., 1998). Moreover, coenzyme M, the immediate precursor of methane in methanogens, has been found in an aerobic alkane-oxidizing *Xanthobacter* species (Allen et al., 1999). Thus, there is indeed unity in biochemistry (Singleton, 2000).

Acetogens are anaerobic eubacteria generally in the Firmicutes capable of reducing two CO_2 moieties to the methyl and acetyl groups of acetyl-CoA (see "Carbon Dioxide Fixation" in this Chapter) by a pathway utilizing an enzyme complex sometimes called the "carbon monoxide dehydrogenase/acetyl coenzyme A synthetase complex" (Ragsdale, 1997). A variant on this enzyme complex is used by methanogenic Archaea to fix carbon dioxide for autotrophic growth and by acetate-utilizing methanogens to split acetyl-coenzyme A. Unlike the methanogens, the acetogens are metabolically versatile, using a wide variety of substrates for acetogenesis.

In most anaerobic habitats, the amount of electron donor is limiting and prokaryotes capable of anaerobic respiration are in fierce competition for those electrons. It has long been known that the outcome of this competition correlates with the free energy available from the reactions, so that denitrifiers could outcompete sulfate reducers, which, in turn, outcompete methanogens, which generally outcompete acetogens. This hierarchy of competitive exclusion is best explained by a threshold model based on thermodynamic principles, so that if the substrate is H_2, sulfate reducers are capable of utilizing that H_2 at concentrations below that at which methanogens can conserve energy from it (Cord-Ruwisch et al., 1988).

Besides these biogeochemically important electron acceptors, a wide diversity of others can be utilized, and we will touch on only a few. It is generally considered that electron acceptors in anaerobic respiration are inorganic, but, for example, *E. coli* and many other organisms capable of anaerobic growth can use fumarate or dimethyl sulfoxide (Weiner et al., 1988) as respiratory electron acceptors. Indeed, during its "fermentation" of glucose, *E. coli* produces suc-

cinate, which is the product of the respiratory reduction of fumarate.

Besides its importance to the biogeochemical cycles of carbon, nitrogen, and sulfur, anaerobic respiration plays an important role in biodegradation of pollutants. One important set of reactions is that involving reductive dechlorination of chlorinated organics, which are among the most important of pollutants. The most highly chlorinated organics are often resistant to aerobic attack, but there is considerable energy available for conservation if they can use the chlorinated organic compound as a respiratory electron acceptor (Mohn and Tiedje, 1992), a process sometimes called "dehalorespiration." It was first demonstrated that 3-chlorobenzoate could serve as an electron acceptor for energy conservation via reductive dechlorination for an organism called *Desulfomonile tiedjei* (DeWeerd et al., 1990; Suflita et al., 1982), a member of the δ-Proteobacteria. Since then, organisms have been shown to conserve energy by reductive dechlorination of chlorophenols and chlorinated ethenes (Holliger et al., 1998; Maymó-Gatell et al., 1997; Mohn and Tiedje, 1992), the latter including the solvents tetrachloroethene and trichloroethene, which are particularly pervasive ground water pollutants. Curiously, although evidence for anaerobic breakdown of less chlorinated methanes is ample (Mägli et al., 1996; Messmer et al., 1993), respiratory utilization of chloroform and carbon tetrachloride has not been described.

Other environmental applications utilizing anaerobic respiration involve reduction of various metals besides Fe(III) (Lovley and Coates, 2000). For example, *Desulfovibrio desulfuricans* can reduce U(VI) to U(IV), which is a precipitate, and allows immobilization of radioactive wastes (Lovley and Phillips, 1992). Another novel reaction with environmental potential is the respiratory reduction of perchlorate, which is part of rocket propellant mixtures and has contaminated several groundwater aquifer sites, to chloride (Coates et al., 1999; Malmquist et al., 1994).

Aerobic Metabolism

In aerobic eukaryotes, respiration is carried out by mitochondria, which are now known to be descended from the α-Proteobacteria (Gray et al., 1999). Thus, all respiration on Earth is prokaryotic. In essentially all aerobic organisms, electrons travel down an electron transport chain from the organic compound to oxygen in a manner such that protons, or sometimes sodium ions, are pumped out of the cell or mitochondrion, leading to development of an electric potential that can be converted to ATP by membrane-associated ATPases (Saraste, 1999).

Diversity of prokaryotic electron transport chains can be considerable. For example, the α-Proteobacterium *Paracoccus denitrificans* utilizes a complex transport chain very closely resembling that in mitochondria consisting of three large membrane-bound enzyme complexes (Fig. 24A). The first is a NADH/ubiquinone

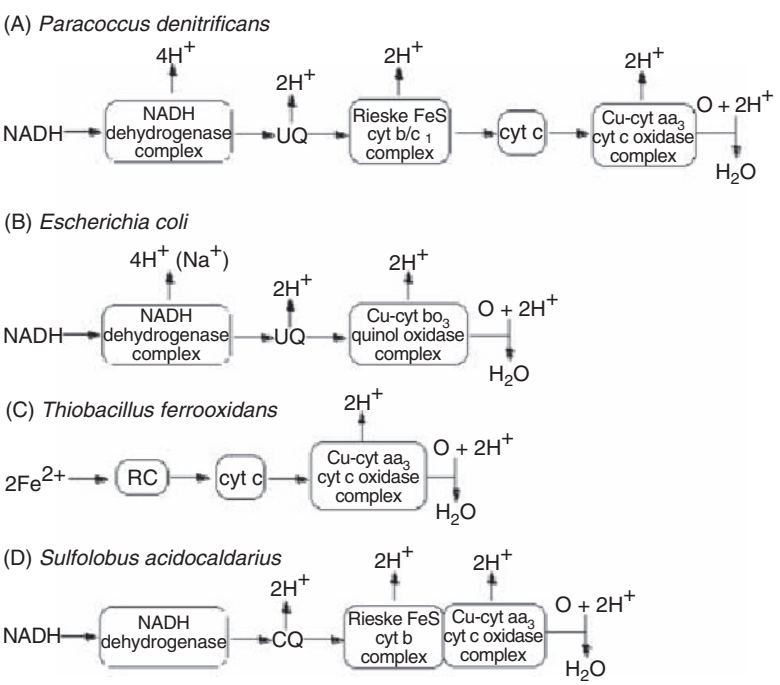

Fig. 24. Electron transport in various prokaryotic aerobes: A) *Paracoccus denitrificans*; B) *Escherichia coli*; C) *Thiobacillus ferrooxidans*; and D) *Sulfolobus acidocaldarius*. UQ, ubiquinone; cyt, cytochrome; RC, rusticyanin; and CQ, caldariellaquinone.

oxidoreductase complex (NADH dehydrogenase or Complex I) containing a bound flavin and several iron/sulfur centers. The second is a ubiquinol/cytochrome *c*-oxidoreductase complex (cytochrome bc_1 complex or Complex III), which contains heme groups, and the high potential Rieske iron/sulfur center carries out a Q cycle (Saraste, 1999), thereby conserving energy from ubiquinone transport. Cytochrome c is reduced in the periplasm and transfers its electrons to a copper- and heme-containing cytochrome c oxidase (Complex IV), which passes the electrons from a periplasmic cytochrome *c* to oxygen. Protons are pumped out of the cell by each of the complexes, and by the asymmetric reduction of ubiquinone on the inside of the cell membrane and its oxidation of the outside (the Q loop) and by the consumption of protons inside the cell by the reduction of oxygen to water. It should be mentioned that *P. denitrificans* actually has several different terminal oxidases that it regulates in response to growth conditions (De Gier et al., 1994).

Escherichia coli has a simpler electron transport chain that lacks Complex III, so that electrons are passed directly from the quinol to an oxidase complex (Fig. 24B). Thus, it does not pump as many protons per oxygen as does *P. denitrificans*. Moreover, under low oxygen conditions, *E. coli* induces more of a quinol oxidase complex containing hemes *b* and *d*. This complex does not pump protons at all, but has a lower K_m for oxygen, which is a useful tradeoff.

Thiobacillus ferrooxidans is an acidophile which transports electrons from Fe(II) to oxygen, and inasmuch as the Fe(II)/Fe(III) couple is near +0.77 v, Fe(II) cannot reduce NADH (–0.32 v) or quinones (ca. 0.0 v). Therefore *T. ferrooxidans* has a truncated electron transport chain in which electrons flow from Fe(II) to a small periplasmic copper-containing protein called "rusticyanin," then to cytochrome c and finally to a typical oxidase (Fig. 24C). Thus *T. ferrooxidans* conserves less energy per electron than do organisms using reactions in which NADH is the electron donor.

As an example of an archaeal electron transport chain, the thermoacidophile *Sulfolobus acidocaldarius* can use elemental sulfur or organic compounds as electron donors for its aerobic growth. When growing on organic compounds, it transports electrons from NADH to oxygen using an electron transport chain that is similar to those in eubacteria, but with some interesting differences (Fig. 24D). Its NADH dehydrogenase complex is relatively small and does not appear to pump protons; it uses a sulfur-containing quinone called "calderiellaquinone," and the electrons then go through a supercomplex equivalent to the two found in *Paracoccus*, but lacking cytochrome *c* (Schäfer et al., 1996). The main subunit of the terminal oxidase complex shows genetic relatedness to other copper-heme oxidases, which form a gene family (Garcia-Horsman et al., 1994) that also includes nitric oxide reductase from denitrifiers, suggesting that the different reductases had a common origin.

The energetics of aerobic respiration is so energetically favorable that the oxidation of essentially any organic compound is thermodynamically feasible, and the only limitation for an organism to utilize a particular organic compound is devising an energy-conserving breakdown pathway. Typically, microorganisms can break down any compound made by nature, as well as many non-natural synthetic compounds (xenobiotics). There are exceptions to this doctrine of microbial infallibility (Alexander, 1981) including some polymers and some smaller molecules that do not resemble natural substrates, leading to persistence of some toxic chemicals in the environment. Nevertheless, a novel compound existing in an environment at a reasonably high concentration may eventually select for organisms capable of using it. For example, *Burkholderia cepacia* strain AC1100 has, apparently by mutation and genetic exchange, developed a pathway to utilize the herbicide 2,4,5-T, originally considered nondegradable, as a growth substrate (Haugland et al., 1990; Huebner et al., 1998).

Lithotrophy and Methanotrophy

Another metabolic capability found uniquely in prokaryotes is lithotrophy, the ability to use inorganic electron donors for energy conservation. Their ability to oxidize inorganic nitrogen and sulfur compounds makes prokaryotic lithotrophs important components of the biogeochemical cycles of these elements. Both aerobes and anaerobes can oxidize inorganic substrates, such as hydrogen oxidation by methanogens, but we will confine our discussion mainly to aerobes. Because they use inorganic substrates for energy conservation, lithotrophs are often autotrophs, i.e., they fix carbon dioxide, but some can incorporate organic carbon. Methanotrophy, the ability to utilize methane as an electron donor, has only been found in certain aerobic members of the Proteobacteria.

The nitrifyers, bacteria that oxidize ammonia and nitrite to nitrate, were originally characterized in the classic studies of Winogradsky. One set of organisms, sometimes called "nitrosofiers," oxidizes ammonia to nitrite, followed by oxidation of nitrite to nitrate. The reason that oxidation of ammonia to nitrate requires two separate microbial groups is not understood. Most extant

Table 2. Reactions carried out by aerobic lithotrophs and methanotrophs.

Reaction	$\Delta G^{\circ\prime}/2e^-$ (kJ)	Organism type	Example species
$NH_4^+ + 1.5\ O_2 \rightarrow NO_2^- + 2\ H^+ + 2\ H_2O$	–137	Nitrosofying bacteria	*Nitrosomonas europea*
$NO_2^- + 0.5\ O_2 \rightarrow NO_3^-$	–76	Nitrifying bacteria	*Nitrobacter winogradsii*
$NH_4^+ + NO_2^- \rightarrow N_2 + 2\ H_2O$	–238	Anammox organisms	*Brocadia ammanoxidans*
$S^\circ + 1.5\ O_2 \rightarrow SO_4^{2-} + 2\ H^+$	–196	"Colorless" sulfur bacteria	*Thiobacillus thiooxidans* *Sulfolobus acidocaldarius*
$2\ Fe^{2+} + 2\ H^+ + 0.5\ O_2 \rightarrow 2\ Fe^{3+} + H_2O$	–66[a]	Iron bacteria	*Thiobacillus ferrooxidans* *Sulfolobus acidocaldarius*
$2\ FeS_2 + 7.5\ O_2 + 7\ H_2O \rightarrow 2\ Fe(OH)_3 + 8\ H^+ + 4\ SO_4^{2-}$	–164[a]	Iron bacteria	*Thiobacillus ferrooxidans* *Metallosphaera sedula*
$H_2 + 0.5\ O_2 \rightarrow H_2O$	–237	Hydrogen bacteria	*Ralstonia eutropha*
$CH_4 + 2\ O_2 \rightarrow HCO_3^- + H^+ + H_2O$	–203	Methanotrophs	*Methylococcus capsulatus*

Abbreviation: Anammox, anaerobic ammonium oxidation.
[a]Values for pH = 2.

nitrifiers are members of the Proteobacteria, although the nitrite oxidizer *Nitrospira* is in a distinct phylum, and all can fix CO_2 by the Calvin cycle. Because organic matter generally inhibits nitrofiers, Winogradsky used silica gel plates rather than agar to isolate them.

The aerobic oxidation of ammonia begins with oxidation to hydroxylamine by ammonia monooxygenase, making that process obligately aerobic. However, an anaerobic oxidation process, called the "anammox reaction," has been found in which ammonia is the electron donor and nitrite is the electron acceptor (Table 2). The organism responsible for this reaction has not been isolated but strong molecular biological evidence shows that the predominant organism in the enrichment culture is a member of the phylum Planctomycetes (Strous et al., 1999).

The "colorless" sulfur bacteria are so named to differentiate them from the purple sulfur and green sulfur photosynthetic bacteria. They oxidize reduced sulfur compounds, often the product of sulfate reducers in anaerobic zones, so they are often found at anaerobic/aerobic interfaces. Typically they can oxidize sulfide, elemental sulfur (to which they can sometimes be attached or which they store in cellular vacuoles), or thiosulfate. Because their main metabolic product is sulfuric acid, some of the sulfur oxidizers are acidophiles. Many of the Gram-negative rods, both acidophilic and neutrophilic, which carry out this reaction, were named "*Thiobacillus*." However, these organisms are scattered throughout the Proteobacteria and many will require new generic assignments. There are also some filamentous sulfur-oxidizing bacteria such as *Beggiatoa* and *Thiothrix*, which are also in the proteobacteria (although *Beggiatoa*, because of its close morphological resemblance to the filamentous cyanobacterium *Oscillatoria*, was once considered by some to be a colorless cyanobacterium). There are also archaeal sulfur oxidizers, such as *Sulfolobus*.

Some sulfur-oxidizers can use nitrate as an electron acceptor. One interesting example is the large (ca. 50 μm in diameter) gliding filaments called *Thioploca*, which form large mats in upwelling zones. When these filaments are in the aerobic zone, they concentrate nitrate from seawater, where its concentration is near 25 micromolar, into intracellular vacuoles, where the nitrate concentrations can reach the remarkably high concentration of 5 M. They can then glide down into the anaerobic parts of the mat, where they can then use the nitrate for oxidation of sulfide (Fossing et al., 1995). An even larger organism, up to 1 mm in diameter, is the spherical organism, called "*Thiomargarita*" (sulfur-pearl), which consists of a thin film of cytoplasm around a large nitrate-filled vesicle. These organisms are uniquely poised to exploit the anaerobic/aerobic interface by using an electron acceptor that allows them to use sulfide in anaerobic layers where aerobic metabolism is excluded.

Ferrous iron spontaneously oxidizes at pH 7, which has hampered studies on neutrophilic iron oxidizers. Several organisms, such as the sheathed bacterium *Leptothrix* and the stalked bacterium *Gallionella*, are known to precipitate iron and manganese oxides, but it is still unclear what role they play in their metabolism. More recently, Emerson and Moyer (1997) used agar gradient cultures in which reduced iron diffused from an agar plug at the bottom while oxygen diffused from the top. Microorganisms grew as a band at the iron/oxygen interface in these cultures, from which neutrophilic iron oxidizers were isolated.

At low pH, ferrous iron is stable in the presence of oxygen, and *Thiobacillus ferrooxidans* and other iron-oxidizing organisms such as *Leptospirillum ferrooxidans* can be readily isolated from acidophilic environments. Acidophilic Archaea such as *Sulfolobus acidocaldarius* and the newly described mesophile *Ferroplasma aci-*

darmanus (Edwards et al., 2000) can also oxidize ferrous iron. Most organisms that can oxidize ferrous iron and sulfur compounds play a role in the leaching of metal sulfide minerals such as pyrite (FeS_2). The exposure of pyrite minerals to oxygen during coal mining leads to their oxidation to sulfuric acid, resulting in acid mine drainage. On the other hand, this ability has been taken advantage of to recover metals such as copper from low-grade sulfide ores. Thus, the iron-oxidizing prokaryotes can have positive or negative economic effects.

The ability to oxidize hydrogen (which only requires the ability to link a hydrogenase with an electron transport chain) is widespread in the Bacteria and Archaea. Because of labile iron/sulfur centers in hydrogenases, often hydrogen oxidation occurs under microaerophilic conditions in aerobes. Some hydrogen bacteria can grow as autotrophs, but many will incorporate organic carbon when available.

Methanotrophy, the ability to oxidize methane, has only been found in two clusters in the Proteobacteria. Methylotrophy, the ability to use single-carbon compounds such as methanol is more widespread, occurring in many bacteria and archaea, as well as in certain yeasts. The first step in aerobic methanotrophs is the hydroxylation of methane to methanol by methane monooxygenase, making the process obligatorily aerobic. However, there is considerable evidence that methane may be oxidized under anaerobic conditions (Boetius et al., 2000), but the organisms involved have thus far proved elusive. It was long believed that the intermediates after methanol in the pathway of methane oxidation were free one-carbon compounds such as formaldehyde and formate (Dworkin and Foster, 1956), but it has recently been shown that the pathway in many methanotrophs and methylotrophs closely resembles that in methanogenic Archaea in which intermediates are bound to tetrahydromethanopterin and methanofuran and which involves enzymes homologous to those in methanogens (Chistoserdova et al., 1998).

Eukaryotes are unable to utilize inorganic energy sources or methane, and therefore, some living in habitats in which these energy sources are abundant, such as anaerobic/aerobic sediment interfaces or near undersea spreading centers, have entered symbioses with lithotrophs or methanotrophs. One of the best known examples is the giant tubeworm *Riftia* living near undersea spreading centers and using intracellular bacteria that oxidize sulfide and fix CO_2 via the Calvin cycle (Robinson et al., 1998). A wide variety of marine invertebrates, especially clams and mussels, have either sulfide-oxidizing or methane-oxidizing symbionts, sometimes both (Distel and Cavanaugh, 1994). Thus, the eukaryotic hosts have used the prokaryotes to augment their metabolic capabilities, much as eukaryotic hosts did when entering symbioses with the ancestors of the mitochondria and chloroplasts or with symbiotic bacteria providing needed nutrients (Moran and Baumann, 2000).

Phototrophy

Phototrophy, the ability to use light as an energy source, is yet another invention of prokaryotes. Photosynthesis in eukaryotes is carried out in chloroplasts, conclusively shown to be derived from cyanobacteria and probably the result of a single endosymbiotic event (Moreira et al., 2000). There are two general classes of phototrophy in prokaryotes. The first is one based on the now inappropriately named "bacteriorhodopsin" (it should be "archaeorhodopsin") found in halophilic Archaea. Bacteriorhodopsin is a polypeptide with a retinal prosthetic group, which allows it to pump protons, thereby generating a protonmotive force. This system seems to be supplemental to normal heterotrophic growth in these organisms, although its actual ecophysiological role is unclear. Besides bacteriorhodopsin, the halobacteria can possess halorhodopsin, a light-driven chloride pump, and two types of sensory rhodopsins used in phototaxis (Spudich, 1993). Recently, a DNA fragment cloned from ocean water was found to have, besides a 16S rDNA gene, which showed it to be from a proteobacterium, a gene encoding rhodopsin-like protein (Beja et al., 2000). When expressed in *E. coli* and provided with retinal, this protein pumped protons, and has been given the name "proteorhodopsin."

The major type of phototrophy is that based on chlorophylls. Among the prokaryotes, there is considerable diversity of pigments, photosystems and electron donors, all adapted to a variety of ecological niches. The photosynthetic bacteria can be placed into five groups, the purple bacteria (traditionally divided into the purple sulfur and nonsulfur bacteria, based on their use of reduced sulfur or organic compounds as the preferred electron donor), the heliobacteria, the green sulfur bacteria, the green nonsulfur bacteria and the cyanobacteria (Table 3). Phylogenetic analysis of the 16S rDNA of the photosynthetic bacteria (Stackebrandt et al., 1996) shows that these groups occupy different phyla.

The purple bacteria are found in three subphyla of the diverse phylum Proteobacteria, which includes many typical "Gram-negatives" such as *E. coli*, *Pseudomonas* and *Rhizobium*. The purple nonsulfur bacteria are spread within the α and β subphyla and the purple sulfur bacteria are associated with the γ-subphylum. This

Table 3. Properties of photosynthetic bacteria and chloroplasts.

	Phylogenetic group	Reaction center chlorophyl	Accessory pigments	Electron donors	Primary electron acceptor	CO_2 Fixation pathway
Purple nonsulfur bacteria	α and β Proteobacteria	bcl *a* or *b*	chl *a* or *b*	Organic compounds, H_2, Fe^{2+}, H_2S (at low concentration)	Q	Calvin cycle
Purple sulfur bacteria	γ Proteobacteria	bcl *a*	chl *a* or *b*	H_2S, etc., H_2, some organic compounds	Q	Calvin cycle
Heliobacteria	Firmacutes	bcl *g*	—	Organic compounds	Fd	Calvin cycle
Green sulfur bacteria	Chlorobi	bcl *a*	bcl *c*,*d*,*e* (chlorosomes)	H_2S, $S_2O_3^{2-}$, H_2	Fd	Reverse TCA cycle
Green nonsulfur bacteria	Chloroflexi	bcl *a*	bcl *c*,*d*,*e* (chlorosomes)	Organic compounds, H_2, H_2S	Q	Hydroxypro-pionate cycle
Cyanobacteria	Cyanobacteria	chl *a*	phycobilins or chl *b*	H_2O	Q (PSI) Fd (PSII)	Calvin cycle
Chloroplasts	Cyanobacteria	chl *a*	phycobilins or chl *b*	H_2O	Q (PSI) Fd (PSII)	Calvin cycle

Abbreviations: Q, quinone; Fd, ferredoxin; TCA, tricarboxylic acid; and PS, photosystem.

distribution strongly suggests that the ancestor of these groups was itself a "purple bacterium" and that the current nonphotosynthetic organisms in the Proteobacteria, like *E. coli*, evolved from photosynthetic ancestors.

Similarly, it was a surprise when the heliobacteria, a group physiologically similar to the purple nonsulfur bacteria, were found to be members of the Gram-positive phylum Firmacutes, although in this case only a single small branch within the phylum contains photosynthetic organisms. The green sulfur bacteria form essentially their own separate phylum, the Chlorobia. According to 16S rDNA phylogeny, the green nonsulfur bacteria, despite similarities of their photopigments, are not closely related to the green sulfur bacteria and are the founding members of the phylum Chloroflexus. Interestingly, the phylogeny of genes for chlorophyll synthesis in the green sulfur and nonsulfur bacteria indicates a relatively close affinity of the two groups, suggesting horizontal gene transfer of the photosynthesis genes (Xiong et al., 2000). Finally, the cyanobacteria also form a separate phylum, which also includes chloroplasts.

The cyanobacteria and chloroplasts contain chlorophyll *a* (chl *a*) as their primary photosynthetic pigment in their reaction centers, which absorbs light maximally at 680–700 nm, depending on whether it is in photosystem I or II. The other photosynthetic bacteria possess only a single photosystem, most containing mainly bacteriochlorophyll a (bcl *a*), which absorbs maximally in the infrared at 800–870 nm. Exceptions include certain purple nonsulfur bacteria which utilize bcl *b*, which absorbs maximally in the far infrared at 1,050 nm, and the heliobacteria, which utilize the interesting pigment bcl g, which absorbs maximally at 790 nm and breaks down to chl *a* upon exposure to oxygen.

All phototrophs contain carotenoids (which make the purple bacteria "purple" and green bacteria green) as accessory pigments to widen the spectrum of light used. In the purple bacteria, the structure of the antenna complex in the membrane, which feeds excitation energy into the reaction center, forms a set of concentric circles around the reaction center (Cogdell et al., 1999). In the green sulfur and nonsulfur bacteria, light energy is transmitted to the reaction center in the cell membrane by the chlorosome (a macromolecular complex containing protein and bacteriochlorophylls *c*, *d*, and *e*), which is associated with the inside face of the cell membrane. In most cyanobacteria, the main accessory pigments that transmit energy to photosystem II are the phycobilins (tetrapyrrole-containing proteins, phycocyanin being the one that confers the blue part of the blue green color of most members of this group). Chloroplasts can contain either phycobilins, as in the case of the red algae, or chl *b*, as found in plants and green algae, as the main accessory pigment. Finding cyanobacteria with chl *b* suggested that they were the ancestors of the green plant chloroplasts; however, phylogenetic analyses have demonstrated that these "prochlorophytes" are simply distinct strains of cyanobacteria with no direct relationship with chloroplasts. The genes for chl *b* synthesis in cyanobacteria and chloroplasts appear to share a common evolutionary origin (Tomitani et al., 1999), but whether that is due to the ancestor of the cyanobacteria and chloroplasts containing chl *b* or horizontal gene transfer has yet to be determined.

Van Niel's insight that the photosynthetic reduction of CO_2 in green plants was a consequence of [H] released by the photolysis of water (van Niel, 1949) was a stroke of genius and led to a unifying equation of photosynthesis: $CO_2 + 2\ H_2A \rightarrow CH_2O\ H_2O + A$, where A could be O, S, an organic constituent, or even nothing in the case of H_2. It also rationalized the diversity among the photosynthetic bacteria, as it became clear that water in the cyanobacteria reduced sulfur in the green and purple sulfur bacteria, and organic molecules in the purple nonsulfur bacteria all served the same purpose—that of providing reducing power for biosynthesis. And each of these sources of reducing power made it possible for that particular group of photosynthetic prokaryotes to exploit a particular ecological niche: water in the case of the cyanobacteria, areas rich in reduced sulfur for the green and purple sulfur bacteria, and areas with organic substrates for the purple and green nonsulfur bacteria.

Photosynthetic pigments have adapted further. All of the chlorophyll molecules have the same basic ground plan—a substituted Mg-tetraporphyrin. However, the nature of the substitutions and of the sequence of conjugated double bonds generate a series of absorption spectra that span from 680 nm for the major absorption peak of chlorophyll *a* in the cyanobacteria to 1,035 nm for the major absorption maximum for bacteriochlorophyll *b* in certain purple bacteria. Thus, the photosynthetic prokaryotes are able to span a broad range of photic zones. The green and purple bacteria usually occupy shallow, aquatic areas, underlying the oxygenic cyanobacteria that filter out the relatively short, visible wavelengths of light and transmit the longer, near-infrared wavelengths. This orientation is consistent with the fact that photosynthesis in the green and purple bacteria is an anoxygenic process and their photosynthesis is obligately anaerobic.

Autotrophic CO_2 Fixation

Carbon dioxide is an abundant and available source of carbon, but it must be reduced to cellular organic carbon at approximately the level of CH_2O, a process that requires reducing power and usually requires energy. Organisms that use CO_2 as their primary carbon source are autotrophs and serve as primary producers in ecosystems. Autotrophic carbon dioxide fixation in eukaryotes is represented solely by the Calvin cycle, though among the prokaryotes there are several distinct pathways of autotrophic CO_2 fixation: 1) the Calvin cycle; 2) the reverse TCA cycle; 3) acetogenesis; and 4) the hydroxypropionate pathway.

The Calvin cycle, which was discovered initially in the green algae, is also found among many of the photolithotrophic and chemolithotrophic Bacteria, where it serves as the major mechanism for carbon assimilation (Fig. 25). The first step of CO_2 fixation is the ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) reaction, resulting in the conversion of one molecule of ribulose-1,5-bisphosphate and CO_2 to two molecules of 3-phosphoglyceric acid. These are then reduced to glyceraldehyde 3-phosphate, followed by several rearrangements to regenerate ribulose-1,5-bisphosphate. Rubisco from the Bacteria has been classified into two types. Type I is found in plants, cyanobacteria and several other prokaryotes and has a subunit structure consisting of eight large and eight small subunits. Type II Rubisco is found in certain purple nonsulfur bacteria and a few other organisms and has been found to be a dimer of large subunits. The phylogenetic tree for Rubisco shows many branching orders considerably different from that of the 16S rRNA tree, and this has been considered strong evidence for rampant genetic transfer of this gene (Delwiche and Palmer, 1996). Moreover, genes resembling those encoding Rubisco have been found in archaeal genomes, and it has been shown that the corresponding proteins have Rubisco activity (Maeda et al., 1999; Watson et al., 1999). These Rubisco homologues form yet another phylogenetic cluster, and the metabolic role of these enzymes in their host organisms has yet to be determined because most evidence indicates that CO_2 in methanogenic archaea is fixed via the acetogenic pathway (see below).

The Chlorobiaceae, known colloquially as the "green sulfur bacteria," were shown not to use the Calvin cycle for CO_2 fixation. Instead, they run the tricarboxylic acid (TCA) cycle in the reverse, reductive direction, using it to fix CO_2 eventually into acetyl-CoA and pyruvate, rather than in the conventional oxidative direction (Fig. 26). Most, but not all of the enzymes will catalyze the reactions in the reverse direction. Thus, the Chlorobiaceae have replaced succinic dehydrogenase with fumarate reductase, substituted an α-ketoglutarate dehydrogenase-ferredoxin oxidoreductase for the conventional α-ketoglutarate dehydrogenase complex, and replaced the irreversible citrate synthase with an ATP-citrate lyase. Since its discovery in the Chlorobiaceae, the reductive TCA cycle has also been found in Desulfobacter hydrogenophilus in the δ-subphylum of the Proteobacteria, in members of the

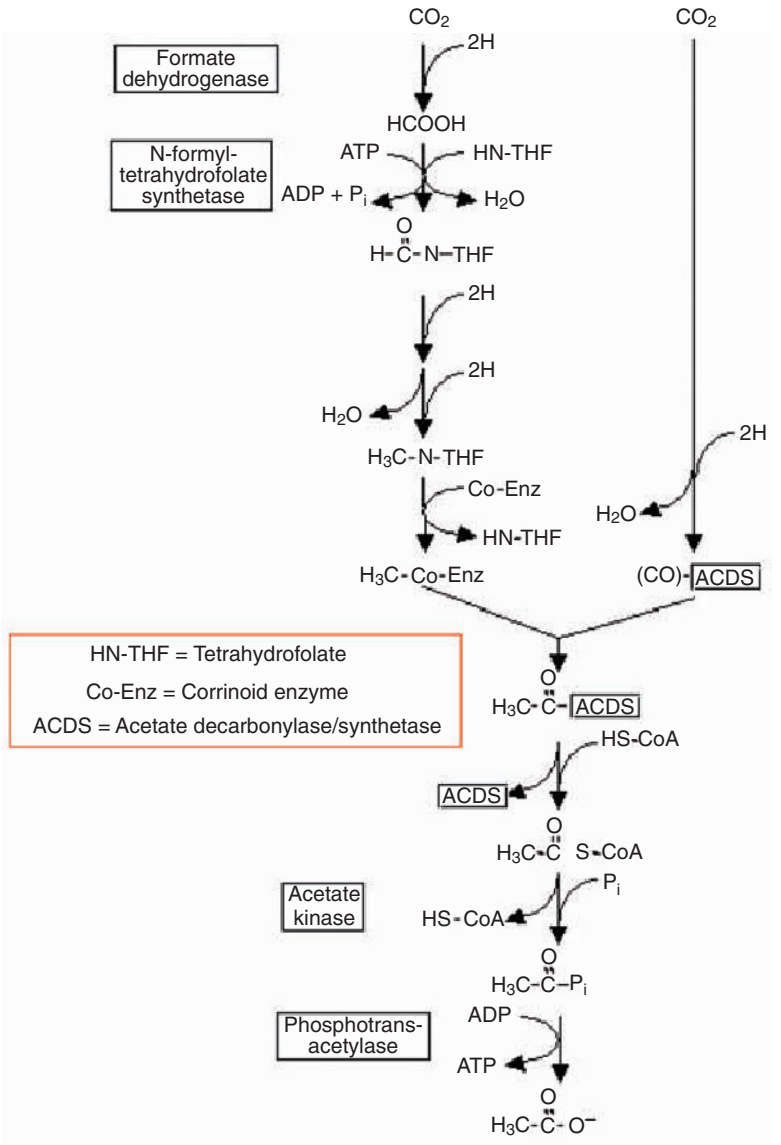

Fig. 27. The acetogenic pathway.

Aquificae, a deeply branching hyperthermophilic phylum in the Bacteria, and in anaerobic members of the Crenarchaeota. It was thought to be present in some aerobic Crenarchaeota, but recent results indicate that a different pathway functions in those organisms (see below).

As mentioned previously in the discussion of anaerobic respiration, acetogenic bacteria can convert H_2 and CO_2 into acetate, the equivalent of fixing CO_2 into organic matter. Indeed, many acetogens can grow in mineral medium using CO_2 as a carbon source and are therefore autotrophs. The pathway, shown in Fig. 27, leads to the fixation of two moles of carbon into acetate. The methyl group of acetate is synthesized by reducing one-carbon units to methyltetrahydrofolate. This methyl group is transferred to a corrinoid-containing iron-nickel sulfur enzyme complex called "carbon monoxide dehydrogenase" or "acetate synthetase/decarbonylase." The methyl group is transferred to the cobalt of a corrinoid and a CO_2 is reduced to the equivalent of carbon monoxide. These are then assembled into an enzyme-bound acetyl group, which is released as acetyl-coenzyme A (CoA), which can be conserved as ATP in catabolism or can be used for biosynthesis. This pathway costs a cell only one ATP per two carbons fixed to acetyl-CoA. This pathway is also found in certain sulfate reducers in the δ-subphylum of the Proteobacteria (Menendez et al., 1999). A variation of this pathway using methanopterin derivatives rather than folates is found in autotrophic methanogenic Archaea as well as in the sulfate-reducing Archaeoglobus (Menendez et al., 1999). Thus, the acetogenic pathway is responsible for much of the CO_2 fixation occurring in anoxic habitats.

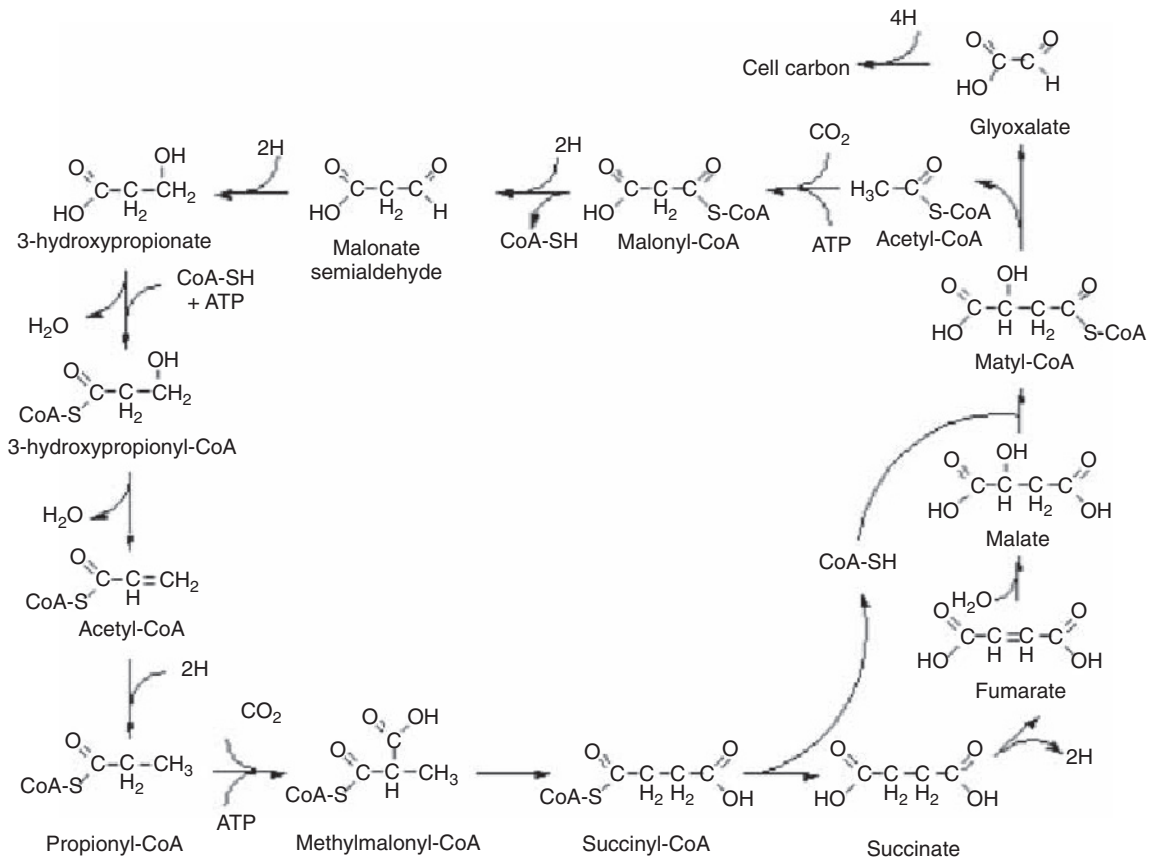

Fig. 28. The 3-hydroxypropionate cycle. (From Menendez et al., 1999.)

Finally, the pathway for CO_2 fixation in the green nonsulfur photosynthetic bacterium *Chloroflexus aurantiacus* was not clear until it was demonstrated (Strauss and Fuchs, 1993) that a novel pathway based on carboxylation of acetyl-CoA and propionyl-CoA (Fig. 28), sometimes called the "3-hydroxypropionate pathway," is responsible for CO_2 fixation to glyoxalate in these organisms. The key enzymes of this pathway are acetyl-CoA carboxylase and propionyl-CoA carboxylase. This pathway has also been found in aerobic lithotrophic Crenarchaeota such as *Sulfolobus* (Menendez et al., 1999). The distribution of these four autotrophic pathways is summarized in Table 4.

Nitrogen Fixation

Fixation of N_2 is carried out solely by prokaryotes. Until the twentieth century, when a large amount of nitrogen was fixed anthropogenically by the Born-Haber process, essentially all nitrogen found in eukaryotes was originally fixed by prokaryotes and transferred to them either indirectly through the food chain or directly in symbiosis, as in the case of the symbioses between legumes and rhizobia found in their root nodules. Nitrogen fixation is found in a variety of physiological types of prokaryotes, occurring in aerobes, microaerophiles, anaerobes, phototrophs and in free-living as well as symbiotic bacteria. Phylogenetically it is widespread in the Bacteria, including members of the phyla Proteobacteria, Firmacutes, Actinobacteria, Chlorobia and Cyanobacteria. In the Archaea, nitrogen fixation has only been found thus far in the methanogens (Lobo and Zinder, 1992).

The enzyme that is responsible for the process, nitrogenase, is a complex of two metalloprotein components. One component usually contains an iron/sulfur/molybdenum cluster that is considered the active site for dinitrogen reduction, as well as an unusual iron/sulfur cluster called the "P cluster" (Dean et al., 1993). The second component is sometimes called the "Fe protein" and contains a single 4Fe-4S cluster per homodimer and transfers electrons to the first component, accompanied by hydrolysis of approximately two ATPs to ADPs per electron transferred. Because this process is so energetically expensive, it is not surprising that most free-living organisms regu-

Table 4. CO_2 fixation pathways found in prokaryotes.

Pathway	Representative organisms	Phylum
Calvin cycle	Plant chloroplasts	Cyanobacteria
	Anabaena cylindrical	Cyanobacteria
	Rhodobacter sphaeroides	Proteobacteria
	Thiobacillus ferrooxidans	Proteobacteria
	Methanococcus jannaschii[a]	Euryarchaeota
Reductive TCA cycle	*Chlorobium limicola*	Chlorobi
	Desulfobacter hydrogenophilus	Proteobacteria
	Aquifex pyrophilus	Aquificae
	Thermoproteus neutrophilus	Crenarchaeota
Reductive acetyl CoA pathway	*Clostridium thermoaceticum*	Firmacutes
	Desulfobacterium autotrophicum	Proteobacteria
	Methanococcus jannaschii[b]	Euryarchaeota
	Ferroglobus placidus	Euryarchaeota
Hydroxypropionate cycle	*Chloroflexus aurantiacus*	Chloroflexi
	Sulfolobus metallicus	Crenarchaeota

Abbreviations: TCA, tricarboxylic acid; and CoA, coenzyme A.
[a]The function of Rubisco found in methanogens and other Euryarchaeota are not presently known.
[b]Pathway uses methanofuran and tetrahydromethanopterin instead of tetrahydrofolate.
Data from Menendez et al. (1999).

late expression of nitrogenase genes (Berger et al., 1994) and activity (Ludden and Roberts, 1988). Alternative nitrogenases exist in which molybdenum (Mo) is replaced by vanadium (V) or in which no metal other than iron has been found (Bishop and Premakumar, 1992). The nitrogenase protein components contain many highly conserved amino acid sequence motifs involved in cofactor binding and subunit interactions. Interestingly, these proteins are homologous to proteins involved in reductive steps of chlorophyll *a* biosynthesis (Fujita and Bauer, 2000), providing a link between the processes of nitrogen fixation and photosynthesis.

Both protein components of nitrogenase are extremely sensitive to oxygen and the bacteria fixing nitrogen aerobically have evolved a variety of strategies to protect the nitrogenase from oxygen poisoning. Among the members of the genus *Azotobacter*, there are three mechanisms for nitrogenase protection. These are respiratory protection, conformational protection, and oxygen regulation of nitrogenase synthesis (Kennedy and Toukdarian, 1987). Respiratory protection occurs because *Azotobacter* can consume oxygen much faster than its rate of entry into the cell. These unusually high rates of respiration thus result in maintaining the nitrogenase in an essentially anoxic environment. Indeed, limiting *Azotobacter* respiration increases their sensitivity to oxygen during nitrogen fixation. Conformational protection is a result of the ability of *Azotobacter* to synthesize another FeS protein that enters into an association with the nitrogenase complex and protects it from O_2 inactivation (Moshiri et al., 1994). During this association, the complex is unable to manifest any nitrogenase activity.

Many organisms are not as adept as Azotobacter at protecting their nitrogenase from O_2 and fix nitrogen only under microaerophilic conditions, even though they otherwise are not microaerophiles. One example of this is the rhizobia (Spaink, 2000). They were not shown to be able to fix nitrogen until 1975, nearly a century after their isolation by Beijerinck. When in the plant root nodule, the rhizobia are protected by the heme protein leghemoglobin, which has an extremely high affinity for O_2 and transports the O_2 necessary for *Rhizobium* growth, simultaneously preventing the access of the O_2 to the nitrogenase (Dilworth and Appleby, 1979).

The nitrogen-fixing cyanobacteria are presented with an even greater challenge than other aerobes because O_2 is one of the main products of their photosynthetic metabolism. Anabaena and other related filamentous, nitrogen-fixing cyanobacteria solve the problem of O_2 poisoning of nitrogenase by segregating the nitrogen-fixing enzymes in a specialized cell called "the heterocyst." The heterocyst insulates the nitrogenase from O_2 in two ways. First, it lacks photosystem II and thus does not generate any O_2; photosystem I is still operative and continues to generate ATP by photophosphorylation. Second, it is surrounded by a laminated structure consisting of a series of unique glycolipids that seem to act as a physical barrier to prevent O_2 from penetrating into the cell. Thus, the cell separates its nitrogenase both from endogenous as well as exogenous O_2. The heterocyst can feed the fixed, reduced nitrogen products to the adjoining vegetative cells, from which it receives the reducing power necessary to convert dinitrogen to amino acids. To add to the elegance of the solution, the heterocysts are interspersed along the filament,

spaced so as to provide an optimum supply of fixed nitrogen to the growing and dividing vegetative cells. A peptide signal, similar to those used for quorum sensing by Gram-positive bacteria, is used to regulate this spacing (Yoon and Golden, 1998). The actinomycete *Frankia*, which fixes nitrogen in nodules in alder trees and several shrubs, utilizes a similar solution, forming specialized cell aggregates called "vesicles" (Benson and Silvester, 1993).

Some of the nonheterocystous cyanobacteria have solved the problem of nitrogen fixation and photosynthetic O_2 evolution by separating the two processes in time rather than in space. Thus, nitrogenase is synthesized and nitrogen fixation takes place in the dark. During the photoperiod, the nitrogenase formed during the previous dark period is presumably destroyed (Stal and Krumbein, 1985). Indeed this was the first evidence for a biological clock in prokaryotes (Johnson and Golden, 1999). It is still not clear, however, how the filamentous nonheterocystous colonial cyanobacterium *Trichodesmium* fixes nitrogen during photosynthesis (Capone et al., 1997).

Finally, it should be mentioned that a thermophilic actinomycete utilizes a nitrogenase enzyme complex in which a modified Mo-Fe protein is coupled to a carbon monoxide dehydrogenase (Ribbe et al., 1997). This system is much more O_2 resistant than the standard nitrogenases, and it is not clear why similar systems have not been found in other aerobes. In summary, the variety of mechanisms devised by the prokaryotes for protecting nitrogenase from O_2 poisoning is an impressive example of the strategic versatility of the prokaryotes.

Adaptation to Environmental Extremes

The prokaryotes not only can tolerate the broadest spectrum of environmental extremes of any group of organisms, but some of their optimum conditions for growth would roast, freeze, acidify or shrivel up most other organisms. Thus, *Pyrolobus fumarii* can grow up to 113°C and survive one hour of autoclaving at 121°C (Blochl et al., 1997), *Halobacterium salinarium* grows optimally at 5.2 M salt (Kushner, 1985), *Ferroplasma* grows at pH 0 (Edwards et al., 2000), and a wide variety of organisms can grow at temperatures below 0°C (Morita, 1975). It should be pointed out that the organisms specifically referred to above are Archaea. While the ability to thrive under extreme conditions is not an exclusive property of the Archaea, they seem to be able to withstand high temperatures, at least partially attributable to their unusual ether-linked lipids.

In most cases, the mechanisms whereby the organisms are able to thrive in an extreme environment have reduced or eliminated the ability of that organism to tolerate the normal or common environment. In other words, the adaptation to the extreme environment has not extended a particular organism's milieu but rather replaced one optimum with another. Thus, the ability to tolerate, indeed the requirement for, a high salt concentration renders *Halobacterium salinarium* fragile in a normal osmotic milieu, *Pyrolobus* cannot grow at below 80°C, and *Ferroplasma* cannot grow at a neutral pH.

The ability to exploit a wide variety of ecological niches and to grow optimally at environmental extremes that are intolerable for higher, more complex organisms is a result of the intense physiological and metabolic specialization among the prokaryotes. In a sense, then, the ability of a complex, multicellular organism to deal with its environment is a compromise among the various specialized and differentiated cells; the extremes that such an organism can tolerate are the lowest common denominator of the properties of its individual cells. That is the price paid for the operational complexity of the multicellular organism. On the other hand, the small size, structural simplicity, and unicellular nature of the prokaryote are admirably suited to permit adaptation to a wide variety of environmental extremes, with each adaptive response narrowly focused on dealing optimally with that particular extreme.

Conclusion

It is appropriate that we end this essay with a quotation from the late mentor of one of us (M.D.), Professor Jackson W. Foster (Foster, 1964):

"The source of the microbiologist's strength, and at the same time, his refuge, is the infinitely large numbers and varieties of microbes known or presumed to be extant. Compounded with those that can be modified artificially, this pool represents an infinitely versatile catalyst. Because, figuratively speaking, it catalyzes innumerable reactions and transformations with virtually any material occurring in nature, the microbe has to be regarded as a prime, natural resource of all men regardless of national boundaries. . . . As a means of emphasizing . . . the diverse, mysterious, and gratifying potential of the microbe, I paraphrase a trenchant saying made famous many years ago by the influential American magazine, the *Ladies Home Journal*. Whereas they were concerned with women, and I with microbes, the small perversion I make does no injustice to either—'Never underestimate the power of the Microbe.' "

CHAPTER 1.8

Cell-Cell Interactions

DALE KAISER

Discovery and Distribution

Roland Thaxter published a time bomb in December 1892. He reported that *Chondromyces crocatus*, before then considered an imperfect fungus because of the morphological complexity of its fruiting body, was actually a bacterium. Thaxter had discovered the unicellular vegetative stage of *C. crocatus*; the cells he found were relatively short and they divided by binary fission, unlike the mycelium of a fungus. *C. crocatus* was, he concluded, a "communal bacterium." Thaxter described the locomotion, swarming, aggregation and process of fruiting body formation of *C. crocatus* and its relatives, which are collectively called myxobacteria, with an accuracy that has survived 100 years of scrutiny. He described the behavior of myxobacteria in fructification in terms of a "course of development" because it was "a definitely recurring aggregation of individuals capable of concerted action toward a definite end" (Thaxter, 1892). These qualities of an integrated multicellular unit clearly implied positive interaction between the cells. Existence of favorable cell-cell interactions is one hallmark of multicellular life and the theme of this essay.

Thaxter's discovery called attention to the transition from single, apparently independent cells to an integrated multicellular unit. There is general agreement that this step has been taken many times in the course of the organic evolution of plants and animals. For example, the sponges are thought to have arisen from solitary cells separately from all other animals; moreover the seed plants, the fungi, and the algae are all believed to have gained their multicellular condition independently (Whittaker, 1969). Given the apparently strong natural selection for multicellular life, it would be surprising if prokaryotes also had not adopted the multicellular condition many times, and perhaps even earlier in time.

One current estimate suggests that more than 99% of the bacteria on earth live as cell masses (Costerton et al., 1995), a condition conducive to cell interactions. As the broader significance of multicellular microbial life has been recognized, the cell interactions that facilitate multicellularity have been revealed.

Evolution of Cell Interactions

To imagine how two partners to a cell interaction could coordinately evolve high, yet complementary, specificity seems difficult. To start with a weak and poorly specific signal would seem to have little, if any, selective advantage. But what other way is there to start? The relative structural simplicity of bacteria belies their metabolic versatility and their sophistication in responding to the environment by their sensory systems. Given current knowledge of bacteria and given some advantage for an interaction, at least two evolutionary scenarios are plausible. 1) The progressive evolution of a cell-cell interaction between dissimilar cells could start with cells of one type feeding on the metabolic products of cells of another type. Mutation and selection on both partners would then optimize syntrophic growth. While this cooperative growth was taking place, the release by one cell type of a metabolic regulator for the other type would constitute a primitive signal, subject to improvement by selection. 2) Instead of metabolic cross-feeding, a cell-cell signaling interaction might evolve from an existing sensory system. The wide variety of two-component sensory, regulatory systems would be ground for such evolution (Hoch and Silhavy, 1995). Bacterial sensory systems are robust, having sensitivity and reliability required for an effective interaction (Barkai and Leibler, 1997). Release or display of a signaling factor by cells could trigger one of the sensory systems. Immediately after this event, selection would need to act only on signal production. Then the specificity of matching between trigger and sensor could be improved, or a higher level of sensitivity could evolve. 3) Bacteria have stimulons. If the output of a sensory system as in 2) or a metabolic regulator as in 1) becomes the input to a stimulon, responses would govern many genes. From cell-cell interactions, the evo-

lutionary path to timed gene expression and a circuit that "develops" in Thaxter's terms is simple. Starting with signal 1 and its response, including expression of a set of genes, let one of those genes encode production of signal 2. Iteration of that process would give something like the signaling pattern of fruiting body development in Myxobacteria Fruiting Body Development signaling. 4) Because haploid bacteria are less insulated from their environment than diploid organisms, natural selection can constantly play a role in shaping and improving the interactions between cells, speeding such evolution. Loss of cell-cell interaction in less than one thousand generations after relaxing social selection indicates experimentally the force of social selection (Velicer et al., 1998).

Types of Cell Interactions

Four kinds of cell interactions can be distinguished: 1) Transfer of a chemical signal from one cell to another. The variety of such transfers is presented in several examples below. 2) Signaling by direct physical contact between two cell bodies, which may involve their surfaces or cell appendages, such as fibrils, pili, or flagella. Direct physical contact is often involved in cell swarming. 3) Syntrophic metabolism. Because syntrophic interactions are the subject of another chapter by Schink (Syntrophism Among Prokaryotes in Volume 2), this essay will focus on the other three types. 4) Gene transfer from one cell to another. Eubacterial gene transfer interactions are widespread. Transfer within the Archaea has recently been observed, and their genetics is being developed (Stedman et al., 1999; Whitman et al., 1999). Prokaryotes have three mechanisms for unidirectional gene transfer from a donor to a recipient. These mechanisms are *transformation* in which naked DNA from the donor is taken up by the recipient, generalized *transduction* in which a phage has packaged a head-full of donor DNA and injects that DNA into the recipient, and *conjugation* in which a specialized apparatus in the donor transfers a long DNA segment directly into a conjugating recipient. The three mechanisms have different qualities: transforming DNA fragments may be 10 to 50 kb in length and are vulnerable to extracellular nucleases. Competence of the recipient to accept DNA may be restricted to certain nutritional states: *Bacillus subtilis* growing in minimal salts with glucose and amino acids develops competence postexponentially (Dubnau, 1991), but growing without amino acids, exponential cells are competent when two peptide pheromones are added (Lazazzera et al., 1999). In *Haemophilus influenzae*, competence is restricted to exponential cells after nutritional downshift in a medium that supports protein synthesis but not cell division (Herriott et al., 1970; Kahn et al., 1983), and *Streptococcus* cells are competent in the presence of a secreted competence peptide (Havarstein and Morrison, 1999). The *Bacillus* and *Streptococcus* peptides may be quorum sensors.

Transduced DNA fragments may range up to 100 kb, a limit imposed by the capsid volume of the transducing phage. Although the DNA is shielded from nuclease attack by the capsid proteins, the host range of the phage limits transduction. That typically narrow range is set by the distribution of the adsorption receptor for the phage among bacteria. Phage P1 is an exception because its receptor is the common lipopolysaccharide (LPS) core lipid (Lindberg, 1973), which suggests that practically all Gram-negative bacteria could be P1 recipients (Murooka and Harada, 1979). Transfer is by syringe-like injection that is triggered by phage adsorption (of P22 or P1, for example), or the virus may enter the cell intact and release its DNA once inside (M13 is an example).

In conjugation, most or all of the donor chromosome may be transferred. Conjugal DNA transfer is mediated by physical contact and a multi-molecular machine, consisting of many proteins. Conjugation mediated by F-plasmids begins when the F-pilus binds to the ompA protein on the surface of an *Escherichia coli* recipient (Manoil and Rosenbusch, 1982). A mating signal is sent back to the donor cell (Kingsman and Willetts, 1978), the donor and recipient are then drawn closely together, and an electron dense junction forms at the cell-cell interface (Durrenberger et al., 1991). DNA is then transferred with synthesis in both cells. After transfer and chromosome segregation, the cells actively separate (Achtman et al., 1978; Durrenberger et al., 1991). More than 15 proteins may be in a conjugation machine, including the pilus proteins. This degree of structural complexity suggests a strong selective advantage for conjugation.

Gene transfer by any of these mechanisms may be lateral (in which transfer is from one cell species to another) as well as vertical (in which the donor and recipient belong to the same species). Whereas transduction is restricted to certain members of particular species, transformation and conjugation may have very wide ranges that facilitate lateral gene transfer. Broad host-range plasmids such as RSF 1010 (Frey and Bagdasarian, 1989) can transfer between a wide variety of bacterial species, and RP4 can even transfer to *Saccharomyces cerevisiae* (Heineman and Sprague, 1989). The transkingdom transfer by RP4 requires its five *tra* genes (*tra FGIJK*)

and ten *trb* genes (*trb BCDEFGHIJ* and *L*; Bates et al., 1998), which include the pilin gene, *trb C*. Moreover, in nature, a sector of the pTi plasmid laterally transfers from *Agrobacterium* to a variety of plant cell species, thereby producing crown gall tumors.

Widespread infectious transfer of drug resistance between bacterial species is circumstantial evidence for lateral transfer (Mazodier and Davies, 1991). But recently, as a consequence of whole genome studies and of the construction of phylogenetic trees based on particular proteins, discrepancies between trees have suggested that lateral transfer may be more general. A strong case for the transfer of the gene for glucose-phosphate isomerase from a plant to *E. coli* has been made (Smith et al., 1992). Pathogenicity islands in, for example, *Salmonella*, are large clusters of virulence genes not present in related but benign organisms, and they appear to have been transferred from another organism(s) (Baumler, 1997; Groisman and Ochman, 1997). Ongoing lateral transfer of the retrons that encode production of multicopy single-stranded DNA is evident in *E. coli* and other enteric bacteria. Ten percent of *E. coli* clinical isolates are found to have them, and most retron isolates in these strains are different (Herzer et al., 1990). The retron Ec107 may be spreading from one strain of *E. coli* to others (Lampson, 1993). By contrast, retrons are ubiquitous in the Myxobacteria, and all members of the myxococcus subgroup have a version of Mx162, while members of the other subgroup lack it (Rice and Lampson, 1995). The retron element Mx162 apparently transferred laterally into the common myxococcus ancestor about 100 million years ago and has subsequently been inherited vertically (Rice and Lampson, 1995).

Lateral transfer requires a mechanism for DNA integration that does not depend on perfectly homologous recombination. Transposons such as Mu, Tn*5*, or Mariner insert within short target DNA sequences, and their transposases are thus present in bacteria. The Mariner target, for example, may simply be the AT dinucleotide (Hartl et al., 1997). Site-specific and other nonhomologous recombination mechanisms are also common in bacteria where they are associated with repair of damage to DNA and help preserve genome integrity.

Chemical Signals and Direct Physical Contact

Some themes recur frequently. Certain small molecules like amino acids and their derivatives are frequently used as signal molecules. Examples are homoserine lactones and peptides shorter than ten amino acids. Multicellular sensing is more accurate than unicellular and may be able to compensate for cell-to-cell variations in metabolism, transcription and translation. One example is the A-factor of *M. xanthus*, which is a mixture of 6 amino acids and is a cell-density signal (Kuspa et al., 1992a). The amount of A-factor released is proportional to the number of cells per unit volume, and a certain minimum quantity of A-factor is required to continue development. Thus the A-signal ensures a cell density sufficient to complete a proper fruiting body (Kuspa et al., 1992b). A-factor, which is released about 2 hours after the beginning of starvation, is also a way for cells to vote their individual assessment of nutritional conditions. Since new proteins must be made during aggregation and sporulation, some protein synthetic capacity must be retained, and the cells must begin to aggregate before they have exhausted all their sources of amino acids and energy. To initiate development or to grow slowly is an important choice on which long-term survival depends. An optimal choice is one that anticipates the future. A decision jointly made by a population of cells rather than by one cell is likely to be more reliable. Multicellular, rather than unicellular, feeding on polymeric substrates is more efficient when extracellular hydrolases are employed for digestion.

One example is the social feeding in myxobacteria. The selective advantage for the evolution of multicellularity in myxobacteria is likely to have been cooperative feeding. Myxobacteria feed on particulate organic matter in the soil by means of extracellular bacteriolytic, proteolytic, cellulolytic, and other digestive enzymes (Reichenbach, 1984). Based on their secretion of lytic enzymes, Dworkin (1973) likened myxobacteria to "packs of microbial wolves." Rosenberg et al. (1977) measured the growth rate when the only source of carbon and nitrogen for *M. xanthus* cells in liquid culture was the polymeric substrate casein and found that proteolysis was required for growth. A two-fold increase in growth rate was observed as the cell density was raised above 104 cells/ml. When intact casein was replaced with hydrolyzed casein, the cells grew independent of cell density at the more rapid rate. Evidently extracellular digestion of protein is enhanced by cooperation between cells, akin to syntrophism.

A swarm may be the unit of efficient cooperative feeding. Reichenbach has shown that a single germinating sporangiole of a *C. apiculatus* fruiting body forms an active swarm that behaves much like a swarm of bees (Bonner, 1952; Kuhlwein and Reichenbach, 1968; Quinlan and Raper, 1965). Forming a multicellular fruiting

body ensures that, when conditions favorable for growth are restored, the myxospores can germinate, and the new phase of growth can start as a pre-formed community of efficiently feeding cells. The success of the myxobacterial design is evident in their distribution; they are common inhabitants of soils drawn from all over the world regardless of climate (Reichenbach, 1984).

Multicellularity and cell density effects are prominent in starvation or nutrition-limiting states. Starvation requires management of scarce resources, and for that reason, requires sharper, more accurate perceptions. Examples include sporulation, biofilms, and fruiting bodies.

Possible Strategies for Detecting Signals

Common themes suggest the following possible strategies for detecting signals: 1) Look for cell-density effects (Lazazzera et al., 1999; Rosenberg et al., 1977). Test the response of low-density cells to high-density conditioned medium. 2) Look for signal-production defective mutants that can be rescued by co-cultivation with wild type cells. Such mutants can be divided into classes by mixing mutants with each other, possibly identifying different signal specificities (Hagen et al., 1978). 3) Isolate signal-response-defective mutants (Gorski and Kaiser, 1998). For this purpose, reporter gene constructs are likely to be useful. 4) Signal molecule bioassays can be built upon the provision of signal molecules in crude form (Hastings and Greenberg, 1999). 5) Starvation survival strategies often involve cell interactions. 6) Interactions are common among cells in biofilm communities (Davies et al., 1998). 7) Two-component sensory systems may perceive intercellular signals.

Examples of Interactions

These include: 1) Autochemotaxis; 2) Vibrio, Squid, Lux, autoinducer; 3) Microbial Biofilms in this Volume; 4) Agrobacterium and crown gall; 5) Rhizobium and nodules; 6) Myxobacteria and fruiting bodies: A-signaling and C-signaling; 7) Pheromone-inducible plasmid transfer in *E. faecalis*; 8) Swarming, type IV pili, twitching and gliding; 9) Heterocysts in filamentous cyanobacteria (Anabaena); 10) Sporulation in *B. subtilis*; 11) Syntrophism Among Prokaryotes in Volume 2.

Aggregation by Autochemotaxis

A striking illustration of the power of a single cell-cell interaction to produce complex cellular patterns is shown in Figure 1. This pattern of aggregates of *E. coli* cells developed in 3 days following a single inoculation made in the center of a plate containing succinate and a small amount of methylaspartate.

Fig. 1. Organized *E. coli* cells in a pattern generated by autochemotaxis. This pattern of cell aggregates developed in 3 days from a single inoculation made in the center of a plate. Color added for contrast. From Budrene and Berg, 1995.

When chemotactic *E. coli* cells are inoculated near the center of a Petri plate containing semi-solid agar, they swarm outward in concentric bands (Adler, 1966; Adler, 1969). The cells swim in semisolid (0.3%) agar almost as if it were water. Concentric bands form because of chemotactic responses to spatial gradients generated by transport and metabolism. As the cells take up metabolizable attractants from a complex medium, they grow, divide, and generate spatial gradients of attractants, which they subsequently chase. This leads them to swarm outward in concentric bands.

In medium rich in amino acids, a leading band of *E. coli* cells consumes most of the aspartate aerobically. The Tar methyl-accepting chemotaxis protein detects aspartate (Macnab, 1987), which binds to the extracellular domain. This binding then triggers the phosphorelay cascade of chemotaxis (che) proteins. The cascade signals the proteins at the base of the flagellum, which cause the cell either to continue swimming in the same direction or to tumble and swim in an arbitrary new direction. That the aspartate ring of a swarm depends on chemotaxis has been shown with a series of mutant strains made deficient in one of four chemotaxis receptors or in one of the cytoplasmic chemotaxis proteins (Wolfe and Berg, 1989). The spreading of chemotactic bands has been shown to require the entire regulatory network for chemotaxis, including desensitization and resensitization of the receptor by methylation and demethylation of its highly conserved carboxy tail located in the cytoplasm.

Formation of concentric bands and spots requires a particular set of metabolic conditions, unlikely to be found in nature, but instructive nonetheless. Growing in minimal medium on one of the more highly oxidized dicarboxylic acids of the tricarboxylic acid (TCA) cycle (e.g., 5 mM succinate), *E. coli* forms into a pattern of small, compact, focal aggregates, like those in the center of Fig. 1. If the concentration of succinate is doubled, the pattern becomes one of concentric rings. The pattern begins to form in the central part of the colony, then spreads sequentially outward.

The pattern depends on chemotaxis toward aspartate: the Tar receptor and all the downstream components in the chemotaxis phosphorelay are necessary (Wolfe and Berg, 1989). Ring formation can be suppressed by adding saturating amounts of chemicals that are sensed by the aspartate receptor (e.g., the nonmetabolizable aspartate analog, a-methyl-aspartate), implying in this case that a (self-generated) gradient of aspartate is involved. Formation of a focal pattern requires a high initial cell density in a ring; these cells then redistribute into foci (Budrene and Berg, 1995). Addition of succinate causes the cells to excrete aspartate. (A secretion of 4×10^{-17} moles of aspartate per cell has been measured.) Succinate would be oxidized by the TCA cycle to fumarate that in turn would be aminated to aspartate, some of which is released from the cell. A swarm ring forms when an aspartate gradient is established at the periphery of the spreading colony. The process of focal aggregate formation from a ring has been observed to continue in both directions around a ring until a complete set of aggregates has formed. Cells in the aggregates can be seen moving around, like a swarm of bees that are held together by their mutual attraction. While appearing to be colonies, they are swarms. By changing substrate concentrations and strains, a series of related patterns have been obtained. The formation of swarm rings and focal aggregates has been subjected to a thorough physical-mathematical analysis (Brenner et al., 1998). Thus, remarkable cellular patterns can be generated by chemotaxis to a single diffusible substance released by the cells themselves.

Autoinducer and Quorum Sensing

One of the earliest cell-cell interactions to be investigated is found in the symbiotic luminous vibrios. In nature they inhabit the light organs of certain marine bony (monocentrid) fishes and the bobtail squids (Nealson and Hastings, 1979). The bacterial light is crucial to the survival of these squid in their coastal water habitat. The squid's usual black ink trick is not very effective at night when the squid forages. Instead they emit light from their cultivated bacteria. This light helps camouflage the squid from their predators, which live below them on the floor of the relatively shallow coastal waters. This emitted light erases the shadow cast by the squid from the moonlight and starlight shining down on them from the night sky. A sophisticated "stealth" technology this, in which the squid by means of an iris and lens adjusts the intensity of light to match the light from above.

Luminous *Vibrio fischeri* release energy when they jointly oxidize $FMNH_2$ and tetradecanal with molecular O_2 (Meighen, 1994). The oxidation energy is emitted as fluorescent light, and luciferase catalyzes the oxidation coupled to light emission.

Light production by *Vibrio* is unusual in that the intensity of light produced per cell increases with cell density (Hastings and Greenberg, 1999). In dilute cultures, each cell is very dim. As their cell density is increased, however, the amount of light produced per cell rises as much as 100-fold. During this density-dependent induction, luciferase protein as well as the enzymes that synthesize the aldehyde substrate for luciferase increases. This augmentation is associated with release into the medium of a small molecule, β-ketocaproyl homoserine lactone, the *V. fischeri* autoinducer, or VAI (Eberhard et al., 1981).

An amide bond links homoserine lactone to an acyl chain, which arises from fatty acid biosynthesis.

Why should cells become bright when they have grown to high density and stay dim at low cell density? Light production requires a large amount of chemical energy to synthesize the fatty aldehyde and to keep FMN reduced. The idea is that the luminescent vibrios live two different lives: one when they are growing in the open sea, another when they are populating the light organ of an animal.

Since luminescence is energetically expensive, energy that could be used for growth in the free-living state would be squandered by emission of light. Life in the ocean is hard; carbon, fixed nitrogen, and energy sources are all difficult to find. Thus, the typical cell density of *V. fischeri* in seawater is low, perhaps 10 cells per ml.

A different economy prevails within the light organ of a squid or fish. There, *V. fischeri* reaches very high cell densities of 10^{10}–10^{11} cells per ml;

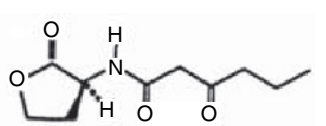

Fig. 2. The structure of *V. fischeri* autoinducer β-ketocaproyl homoserine lactone, or VAI. From Eberhard et al., 1981.

there it is luminescent. The animal pays the energetic cost by feeding its vibrios carbon and fixed nitrogen, allowing them to grow to very high density. The animal pays willingly because in return for food, *V. fischeri* makes the light which allows the animal to escape its predators.

Because of the low density of *V. fischeri* cells in sea water where they are nutrient limited, the extracellular autoinducer concentration never builds up to a significant level, and thus *V. fischeri* is not luminescent in its free-living state. Autoinduction may be viewed as an intercellular signaling system that allows *V. fischeri* to discriminate between a free living, low-density state and a host-associated, high-density state. Accordingly, the luminescence genes are activated only when a host is there to pay the high energy price of light production (Ruby and McFall-Ngai, 1992). The minimum number of bacteria necessary for high level luminescence in the light organ is thought of as a "quorum." This mechanism of regulatory discrimination between low density in the sea and high density in the light organ exemplifies the concept of quorum-sensing (Fuqua et al., 1994).

The autoinducer (VAI) and the regulatory response to its presence in the medium discriminate between the low- and high-density states. Two divergent lux operons, as shown here, have this purpose in *V. fischeri*.

The structural genes responsible for the synthesis and activity of luciferase (*luxA* and *B*), of tetradecanal (*luxC*, *D*, and *E*; Engebrecht and Silverman, 1986), and of the autoinducer synthase (*luxI*) make up one operon in *V. fischeri*. The substrates for autoinducer synthase are S-adenosylmethionine, which donates its methionyl portion, and the appropriate fatty acid conjugated to acyl carrier protein, which is an intermediate in fatty acid biosynthesis. The transcription unit is regulated by *luxR* (Figure 3), which encodes a DNA-binding protein that mediates the effect of autoinducer (Kaplan and Greenberg, 1987; Shadel et al., 1990). Gene *luxR* is divergently transcribed and separated by 155 bp from the *luxI* operon. Between these two transcription units lies a 20 bp inverted repeat, the "lux box," a sequence consensus element which has been found ahead of lux promoters in several organisms. The box is required for activation of both leftward and rightward transcripts and is thought to be the site of LuxR protein binding.

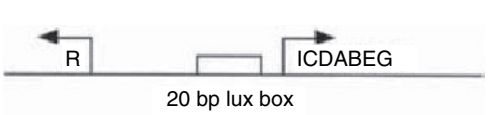

Fig. 3. Map of the two divergently transcribed lux operons. From Stevens and Greenberg, 1999.

The autoinducer is produced at a low constitutive rate during the early stages of *V. fischeri* growth. Once the cell density rises above a critical level, and the concentration of VAI in the medium rises to such a level that its intracellular concentration is high enough to bind LuxR, expression of the lux/CDABEG rises and there is luminescence. Because *luxI* is part of this transcription unit, a positive feedback loop is established which induces higher levels of VAI and locks in the luminescent state (Engebrecht et al., 1983).

Lux R protein is cytoplasmic and has no hydrophobic α-helical regions typical of membrane-spanning proteins. *V. fischeri* cells are freely permeable to acylated homoserine lactone, which is hydrophobic (Stevens et al., 1994). The acylated homoserine lactone (autoinducer) apparently enters and exits cells by passive diffusion through the membrane. Hydrophobic signal molecules have a double advantage: they require neither a specialized secretor nor a specialized transporter for uptake. Then why doesn't a cell signal itself with its own autoinducer? The cell does but the signal is too weak—the cell has no way to retain its "own" autoinducer. A hydrophobic signal molecule that is membrane diffusible in both the signal donor and the signal receiver is a starting point from which a plausible step-by-step Darwinian path could lead to highly specific signal molecules and to cognate and highly specific transmembrane receptors. In addition to the autoinducers of luminescent marine *V. fischeri* and *V. harveyi*, other acylhomoserine lactones are produced by a diverse and growing number (25 could be listed in 1997) of different terrestrial Gram-negative bacteria.

The LuxI homologs in all these organisms direct the synthesis of acylhomoserine lactones (HSL) with saturated or partly unsaturated acyl chains of 4 to 14 carbons, having substitutions at C-3 of either a hydroxyl group or a carbonyl group. Species specificity is provided by the acyl chain—its length, the oxidation state of C-3, and the degree of unsaturation of the hydrocarbon chain. All such acylated HSL compounds are expected to be membrane permeable, as has been demonstrated for β-ketocaproyl homoserine lactone (Kaplan and Greenberg, 1985). Various HSLs regulate diverse physiological processes including bioluminescence, swarming, antibiotic biosynthesis, plasmid conjugal transfer, and the production of exoenzyme virulence determinants in human, animal, and plant pathogens.

Biofilms

In natural aquatic environments, most bacteria are to be found within biofilms, which is the sub-

ject of the chapter by de Beer (Microbial Biofilms in this Volume). Biofilms are polysaccharide-enclosed bacterial masses adhering to a surface, the polysaccharide having been secreted by the bacteria themselves. As the bacteria grow and divide following their initial colonizing adhesion to a surface, the cells may cluster in pillar- and mushroom-like structures (Costerton et al., 1995). A three-dimensional structure, penetrated by anastomosing channels, is believed to provide a circulatory system that brings oxygen and other nutrients in while it flushes metabolic wastes out. Under favorable conditions, a biofilm can achieve a relatively high local density of cells, and the point here is that those cells can interact with each other. Cells within a biofilm are found in different regulatory states from their planktonic siblings, in part due to cell-cell interactions. Cells in the biofilm may be more antibiotic resistant and more exuberant in polysaccharide production and in enzymes for exopolysaccharide biosynthesis, such as alginate (Costerton et al., 1995).

Biofilms form on human epithelia bathed in nutrient-rich fluids. Many human bacterial infections occur in biofilms, such as common dental plaque leading to tooth decay and periodontal disease. *Pseudomonas aeruginosa* can form a biofilm on the skin of burn victims. Such a film tends to shield the bacteria from otherwise protective antibodies. At least one cell-to-cell signal molecule is necessary for the normal development of *P. aeruginosa* biofilms (Davies et al., 1998). The small molecule, *N*-(3-oxododecanoyl)-L-homoserine lactone, is essential for exopolysaccharide production by the Pseudomonad. Initial attachment of cells to a fresh surface requires motility and type IV pili (O'Toole and Kolter, 1998) but not the homoserine lactone. The lactone signal is needed in the subsequent step of biofilm differentiation. Two different acyl-homoserine lactones are produced by *P. aeruginosa*, which are specified by the *lasI* and *rhlI* genes. Only the first is required for biofilm differentiation as shown by specific mutant knockout and by rescue of the mutant with pure *N*-(3-oxododecanoyl)-L-homoserine lactone (see Autoinducer). There is no evidence for chemotaxis; the circumstances of rescue tend to rule out a gradient of the acyl-homoserine lactone. Wild type cells but not *lasI* mutants build a biofilm in which the cells are resistant to the detergent sodium dodecyl-sulfate (SDS). Resistance to SDS can be rescued in the *lasI* mutant by adding pure *N*-(3-oxododecanoyl)-L-homoserine lactone. Thus, cells within a biofilm can be functionally integrated with each other as well as physically attached to a surface. At least one cell-cell signal is required for the multicellular regulatory state of *P. aeruginosa* in a biofilm. The biofilm also integrates metabolic interactions between the cells through the polysaccharide matrix, growth substrates, and waste elimination.

Agrobacterium and Crown Gall

Agrobacterium tumefaciens, a plant pathogen, produces crown gall tumors. Agrobacteria are able to grow within the tumor as a consequence of both genetic and physiologic interactions with plant cells and of genetic interactions among the bacteria.

Virulent agrobacteria harbor a large plasmid called Ti (for tumor inducing). Responding to signal molecules released by wounded plants, a set of virulence (vir) genes on pTi are expressed. The proteins encoded by these genes process and transfer a segment of the Ti plasmid (the T-DNA) from the bacterium to the susceptible plant during infections (Kado, 1998). Following transfer, the T-DNA integrates into the nuclear genome of the plant cell. Expression of some genes on the integrated DNA results in an oncogenic transformation of the plant cell by means of phytohormone induction. The tumor cells also produce novel low-molecular-weight compounds called opines, whose synthesis from normal intermediary metabolites is directed by genes expressed from the T-DNA. Although the genes for opine biosynthesis are present on a bacterial replicon, they are expressed properly only in plant cells, a remarkable evolutionary adaptation (Hong et al., 1997). The genes for opine biosynthesis lack identifiable bacterial promoters but contain 5′ and 3′ sequence motifs characteristic of plant transcriptional signals. In turn, the causative bacteria can utilize the opines produced by the tumors as a source of carbon and energy, and nitrogen in some cases. Thus, *A. tumefaciens* redirects plant cell metabolism to produce specific metabolites which the bacterium can use as growth substrates.

The opine released by the host plant induces production of 3-oxo-octanoyl-HSL (Zhang et al., 1993). In turn, the HSL enhances the transfer of Ti plasmid from *A. tumefaciens* cells that carry the Ti plasmid to any non-carrier *Agrobacteria* within the tumor. The plasmid carries genes for the breakdown of a particular opine; Ti plasmid T-DNA, which encodes plant proteins involved in the biosynthesis of opines in crown gall tumors, is matched by Ti plasmid genes, which confer on the bacterium the ability to take up and utilize the particular set of opines produced by the tumor. For example, tumors that produce octopine, an arginine derivative, contain bacteria that specifically degrade octopine, while tumors that produce agropine contain bacteria that specifically degrade that agropine. Conjugation

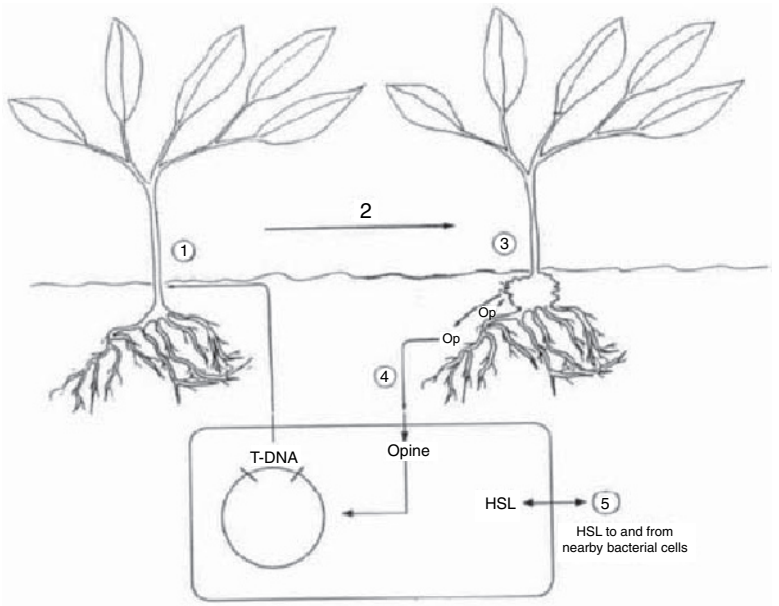

Fig. 4. Diagram showing infection of a plant by *Agrobacterium tumefaciens* and production of a tumor. The pTi plasmid is shown within the bacterium from which T-DNA is transferred to the plant and opine induces homoserine lactone (HSL) production. From Farrand, 1993. Five steps are indicated: 1. Agrobacterial cells enter a susceptible plant. 2. The T-DNA is transferred from the bacteria to plant cell nuclei. 3. Tumor grows, secreting opine (Op). 4. Opine taken up by the bacteria induces production of HSL. 5. The HSL induces conjugation between bacteria and plasmid transfer.

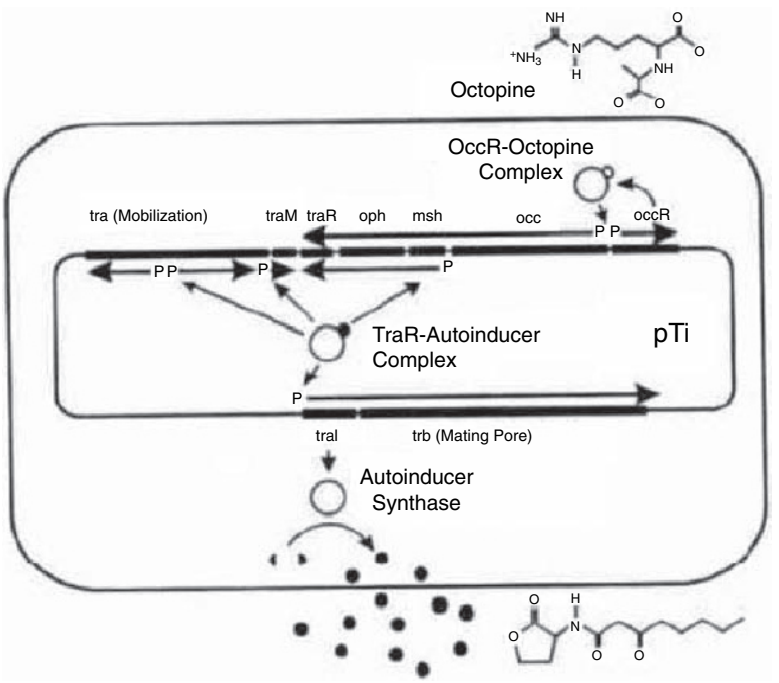

Fig. 5. Quorum-dependent regulation of octopine-type Ti plasmid *tra* and *trb* genes. The octopine-OccR complex elevates transcription of *traR*. The *traR*-autoinducer complex causes a further elevation in *traR* and *traI* expression as well as induces other *tra* and *trb* genes. Modified from Winans et al., 1999.

and plasmid transfer enhance the spread of the appropriate catabolic activity among the bacteria. A high density of donor cells enhances conjugation, and the role of this HSL is to assess the cell density, activate conjugation if appropriate, and spread the plasmid so that the specificity of opine produced by the plant tumor matches the ability of the *Agrobacterium* within the tumor to metabolize it.

Conjugation and plasmid transfer is controlled by a pair of LuxI-LuxR homologs designated *traI* and *traR* (see Fig. 5; Hwang et al., 1994; Piper et al., 1993). An HSL-TraR complex activates expression of transfer (*tra* and *trb*) genes (Piper et al., 1993). One lux box in the *tra* region is located between two divergently transcribed plasmid transfer genes, *traA* and *traC*. In sum, *Agrobacterium* receives chemical signals from its plant host and sends genetic signals to the plant and also to other agrobacterial cells.

Rhizobium

Bacterial signaling is needed to promote nitrogen-fixation within leguminous plants. Members of the genus *Rhizobium* engage in a symbiotic

relationship with peas, soybeans and other legumes to assimilate gaseous nitrogen and incorporate it into cellular material. Fixation is carried out only by a few specialized kinds of bacteria, which include the symbiotic Rhizobia, and these are highly specific for their plant host. Their specificity arises in part through the nature of their cell-to-cell signals.

Rhizobium in the soil invades tiny hairs on the roots of the legume, penetrating into the root tissues. There, the bacteria change their shape and size, becoming rounder and bigger, as they differentiate into bacteroids. Meanwhile, the root cells multiply and give rise to specialized nodules that house and feed the bacteroids. In this mutually beneficial association, bacteroids supply their host with a readily assimilated form of nitrogen (ammonia) and the plant supplies the bacteria with food (carbohydrates).

These developmental changes in both microbe and host result from a reciprocal molecular conversation. Legumes secrete flavonoids into the rhizosphere. When an appropriate flavonoid is recognized by the bacterium, it responds by synthesizing a lipochitooligosaccharide (LCO) signal, known as a Nod factor. Nod factors are major determinants of host specificity. Nod factors have a similar basic structure composed of a chitooligosaccharide (a linear chain of β-1,4-linked *N*-acetylglucosamines) linked to an acyl chain.

This core is modified in a way that is characteristic for each Rhizobium species. Variations include the degree of chitooligosaccharide polymerization (n in the figure), the nature of the fatty acid at R1, and modifications located at one or both ends of the oligosaccharide (R2–R7; Long and Staskawicz, 1993; Mergaert et al., 1997).

The appropriate Nod factor initiates the nodulation program in the plant, triggering the cell divisions that form a nodule, within which the *Rhizobium* differentiates into bacteroids that fix N_2. Thus, a two-way conversation between the bacterium and its plant host instructs them both in the successive steps that build a nodule.

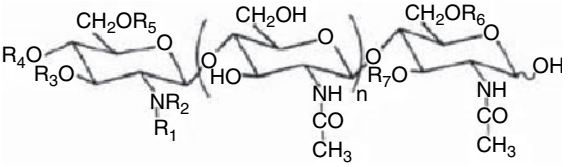

Fig. 6. Generic *Agrobacterium* Nod factor, a modified lipochitooligosaccharide that is synthesized by the bacterium. R1 is a fatty acid; R2 is hydrogen or methyl; R3, R4, or R5 are hydrogen or carbamoyl; R6 or R7 are various glycosyl modifications (Mergaert et al., 1997). The R6 branch may be sulfated (Schwedock et al., 1994). The degree of polymerization, n, may be 3, 4, 5, or 6.

Fruiting Body Development

Myxobacteria have adopted multicellularity as their strategy for survival. When they begin to exhaust their available food supply, they construct fruiting bodies (Reichenbach, 1993). Each fruiting body contains about 100,000 cells differentiated as asexual spores. Multicellular sporulation is thought to improve their long-term survival by enhancing spore dispersion and by providing a high cell density for cooperative feeding when the spores germinate (Reichenbach, 1984). In their vegetative phase, they also feed cooperatively. The figure (7) shows *Myxococcus xanthus*, the "golden" myxobacterium, one of many species of myxobacteria, all of which are phylogenetically related. *Myxococcus* and *Stigmatella*, which has a stalk and multiple sporangioles, have the same size circular genome of 9.5 Mb and common initial steps of their morphological development (Reichenbach and Dworkin, 1981; Shimkets and Woese, 1992).

Using a capacity to move on the surface of other cells, *M. xanthus* builds a fruiting body as shown in Figure 7.

Starting from a uniform sheet of cells (Figure 7, panel 1) a punctate distribution of small asymmetric aggregates appears within a few hours (panel 2). More and more cells enter some of these early aggregates, and after about 10^5 cells (panel 4) have entered, a mound becomes a steep-sided hemisphere. Then the cells differentiate from long rods into spherical spores. Spores have thick walls, are metabolically dormant, resistant to radiation and dessication, and long-lived (White, 1993). A mature fruiting body is entirely filled with close-packed spores (panel 6).

To carry out their program of morphological development, the cells communicate with each other by emitting and responding to extracellular chemical signals. Three signals have been chemically identified: A, E, and C, which are passed between genetically identical cells to coordinate their development. Mutants that are unable to produce the A, C or E signals prematurely arrest the assembly of fruiting bodies (Hagen et al., 1978; Toal et al., 1995); each stops at a stage that corresponds to the time at which the signal is needed (see Figure 8).

These morphologic stages are linked with the developmental expression of sets of genes. Transcriptional fusions of developmentally regulated promoters to *lacZ*, the structural gene for β-galactosidase, report the activity of each promoter as expression of the enzyme. More than nine-tenths of the transcriptional *lacZ* fusion mutants modify development in a limited way, but they are not necessary for its completion

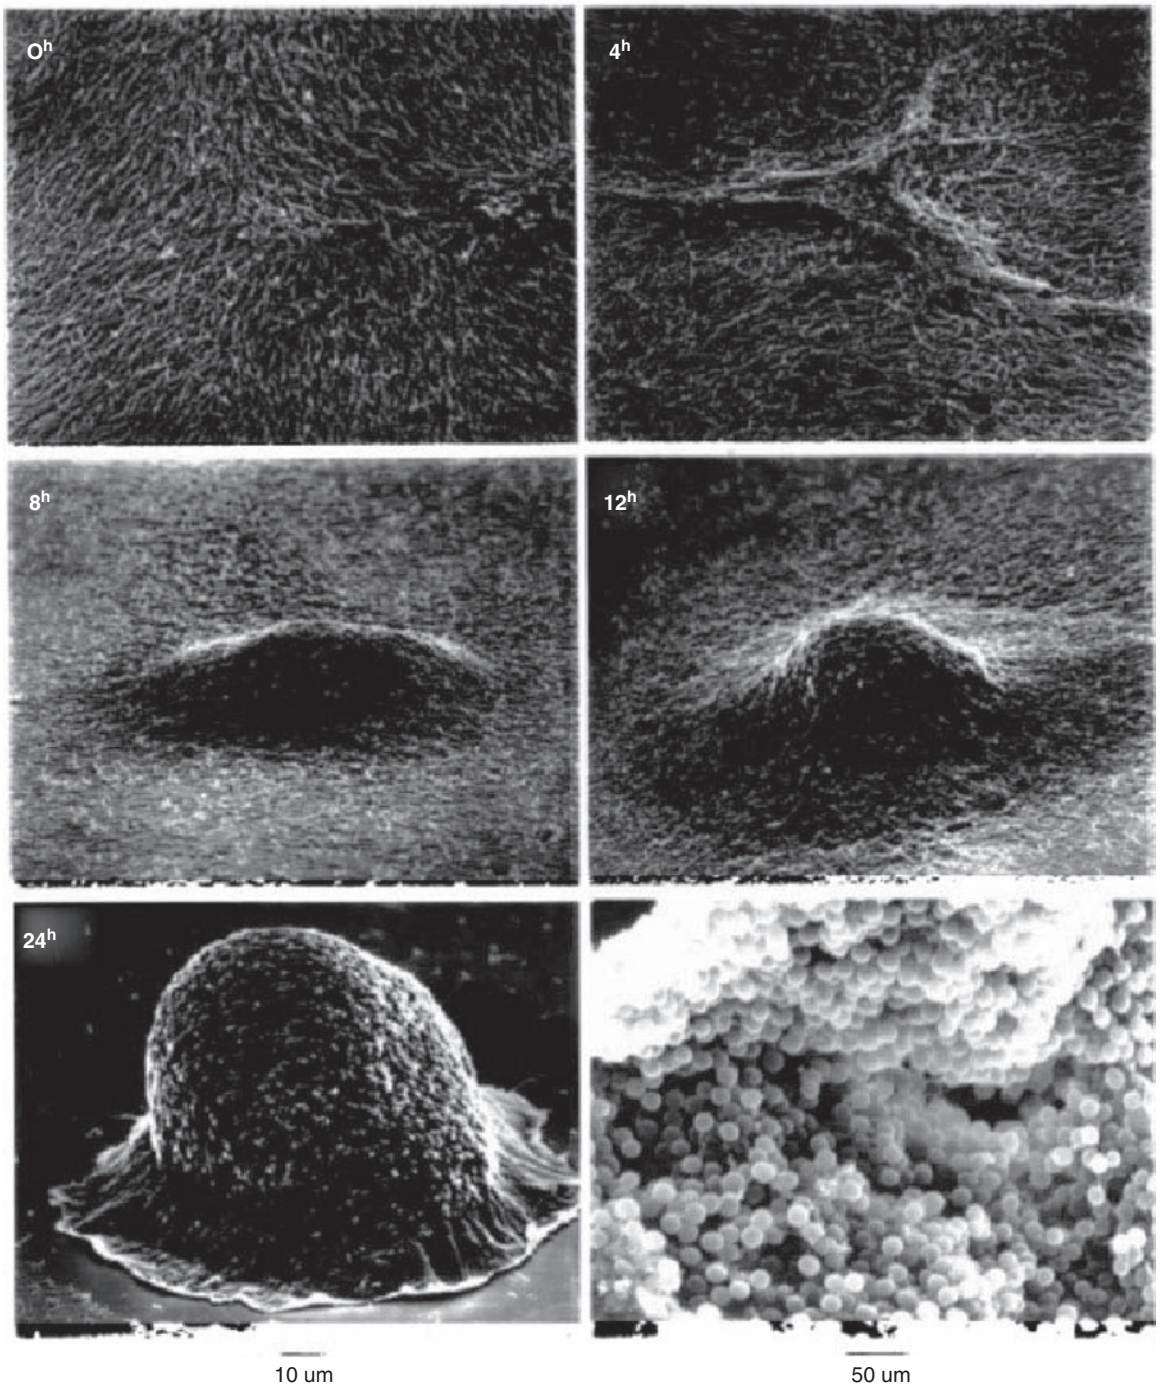

Fig. 7. Fruiting body development in *M. xanthus*. Development was initiated at 0 hours by replacing nutrient medium with a buffer devoid of a usable carbon or nitrogen source. The lower right frame shows a fruiting body that has split open, revealing spores inside. This frame is three times the magnification of the others. Scanning electron microscopy by J. Kuner. From Kuner and Kaiser, 1982.

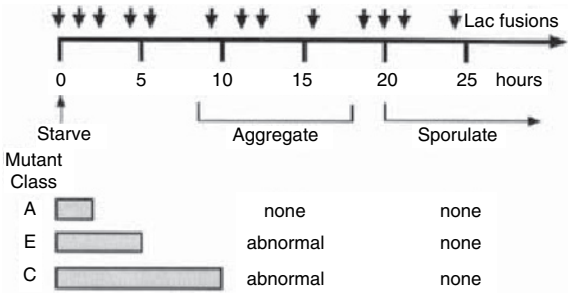

Fig. 8. Three classes of signal-defective developmental mutants of *M. xanthus*. Vertical arrowheads point to the time at which one of the lacZ fusions to a developmentally regulated promoter begins to be expressed. These fusions are reporters of normal development. The horizontal bars indicate the period of normal expression of reporters for each of the indicated mutants. Rightward from the end of the bar, development is defective; expression of the reporters is greatly reduced. The columns to the right show the morphological phenotype with respect to aggregation and sporulation of the indicated mutants.

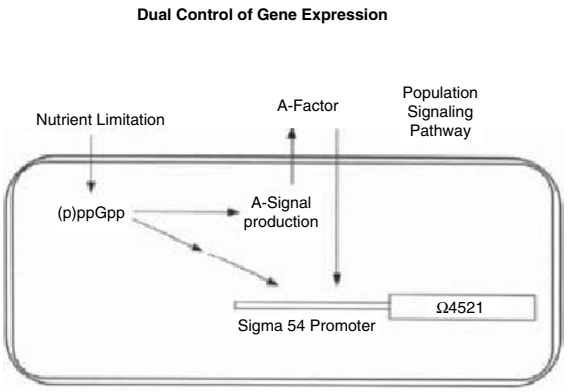

Fig. 9. Dual control of gene expression. As nutrient levels decrease and the protein synthetic capacity of the cell falls, the (p)ppGpp levels increase. Production of A-factor is induced by that increase, and it is released into the medium. Each starved cell releases a fixed amount of the set of A-factor amino acids, which pool in the fluid surrounding the cells. In responding to A-factor each cell perceives the pooled concentration of these amino acids in its vicinity. Promoters of genes that are A-factor and starvation dependent, like Tn5 lac *Ω4521*, receive one input from the cell's (p)ppGpp level and a second input from A-factor; both inputs are necessary for *Ω4521* expression.

(Kroos et al., 1986). Hence the fusions serve as reporters for the various regulatory stages of development without interrupting the overall flow of that program.

Mutants defective in producing extracellular signal A arrest at 1 to 2 hours of development, as a flat film of cells with no sign of focal aggregation (much like panel 1 of Figure 7). A-signal mutants are capable of sensing starvation, however (Singer and Kaiser, 1995), and express several early reporters (Figure 8). Mutants defective in producing extracellular signal E are blocked at 3 to 5 hours, and C mutants arrest after about 6 hours, partially aggregated and having expressed more genes.

A-Signaling

A-signal-production-defective mutants have been found in three genes. One, *asgA*, encodes a protein with a two-component receiver domain followed by a histidine protein kinase domain (Davis et al., 1995; Li and Plamann, 1996; Plamann et al., 1994) and is thought to function as a phosphorelay that, in response to starvation, is required for generation of extracellular A-factor. A-factor is a set of 6 amino acids (trp, pro, phe, tyr, leu and ile), peptides containing these 6 amino acids, or proteases capable of releasing these amino acids from *M. xanthus* cells (Kuspa et al., 1992a; Plamann and Kaplan, 1999; Plamann et al., 1992).

Myxococcus releases small quantities of these amino acids about 2 hours into development, then proceeds to take them back, Figure 9. This release and uptake helps *Myxococcus* choose between two alternative responses to nutrient limitation—on the one hand, entering stationary phase with very slow growth or on the other, fruiting body development with differentiation of spores. At least 30 new proteins are made during fruiting body development (Inouye et al., 1979), so a capacity to synthesize protein must be retained well into the sporulation phase. Accordingly, the cells must make their choice before any nutrient essential for protein synthesis has been totally depleted.

Starvation for any amino acid or starvation for carbon, energy, or phosphorous (Manoil and Kaiser, 1980) but neither starvation for purine or pyrimidine induces fruiting body development (Kimsey and Kaiser, 1991). The set of effective inducing conditions implicates the availability of a complete set of amino-acylated tRNAs. In *Myxococcus*, as in other bacteria, the absence or shortage of any one of the charged tRNAs leads a ribosome, sensing with a codon "hungry" for its cognate amino-acylated tRNA, to synthesize guanosine tetra- (and penta-) phosphate [(p)ppGpp] by condensing ATP and GTP. A rise in this highly phosphorylated nucleotide sets off a stringent response that stops the synthesis of new ribosomes and of the other major polymers of the cell, including DNA, phospholipids, and peptidoglycan (Cashel et al., 1996). Stringent conditions do allow certain genes to be expressed and selected proteins to be synthesized, insofar as activated amino acids are available. In this way, the genes for new fruiting body proteins are expressed and translated.

Accumulation of (p)ppGpp is both necessary and sufficient for fruiting body development. On

the one hand, ectopic production of (p)ppGpp in *M. xanthus* initiates early developmentally specific gene expression (Singer and Kaiser, 1995). The *E. coli relA* gene was introduced into *M. xanthus* for this purpose; its introduction was followed by production of the *E. coli relA* protein and (p)ppGpp accumulation without any prior starvation. Moreover, the rise in (p)ppGpp also induces production of A-factor (Singer and Kaiser, 1995). On the other hand, *M. xanthus* has its own *relA* gene, and either a point mutation or a deletion mutation in that gene blocks starvation-initiated development at the flat biofilm stage of Figure 7 frame 1 (Harris et al., 1998). In fact, these *relA* mutants arrest before expression of any of the developmentally regulated reporters.

A-SIGNALING AND DUAL CONTROL Each starved cell that has accumulated ppGpp releases a fixed amount of the set of A-factor amino acids. Being soluble, these amino acids then pool in the fluid surrounding the cells. In responding to A-factor, each cell perceives the pooled concentration of these amino acids in its vicinity (Kuspa et al., 1992b). Promoters of genes that are A-factor and starvation dependent, like Tn5 lac *Ω4521*, receive one input from the cell's (p)ppGpp level and a second input from A-factor. Both inputs are necessary for *Ω4521* expression (Kuspa et al., 1986). The promoter for *Ω4521* recognizes σ 54 rather than the more common σ 70 (Keseler and Kaiser, 1995). All known σ 54 promoters require an upstream activator protein to initiate open-complex formation and then transcription (Wedel and Kustu, 1995). An activator protein (Gorski and Kaiser, 1998) and the σ-54 holo enzyme are two spatially distinct input sites for controlling transcription of *Ω4521* (see Figure 9). The (p)ppGpp level indicates the level of nutrient currently available, since this nucleotide tracks nutrient changes. A-factor recalls the level of starvation 2 hours previously. The expression of *Ω4521* requires both inputs; very low expression occurs when either input is absent. In this way, the A-factor pool summarizes the votes of all the cells. Thus A-factor belongs to the class of extracellular signals called quorum sensors (Kaiser, 1996). Given the concentration window for an A-factor response, the reliability of the judgment whether to enter stationary phase or to initiate fruiting body development is increased when the whole population of cells has made it.

C-Signal

Primary functions of C-signaling are to bring cells into selected asymmetric foci until they have mounded into hemispheres of about 10^5 cells and to trigger the cells inside a completed hemisphere to differentiate into spores, by transforming the individual motile rod cells into nonmotile spherical dormant cells with tough coats. Null mutants of *csgA*, the gene encoding C-factor protein, form small irregular aggregates (Figure 7, frame 2) and stop developing at this stage. They also do not sporulate; the sporulation frequency of cells with csgA$^+$ is 10^5 fold higher than the mutant. Sporulation requires C-factor to initiate the cell-shape change and for expression of spore genes.

C-factor was purified from whole cells, and a 17-kDa protein was obtained (Kim and Kaiser, 1990d). Antibodies to C-factor reveal its exposure on the cell surface (Shimkets and Rafiee, 1990). Neither an aggregation reporter like the Tn5lac insertion *Ω4499* nor a sporulation reporter like *Ω4435* is expressed in the absence of C-factor. However, both are expressed if purified C-factor is added to *csgA* mutant cells (Kim and Kaiser, 1991). Higher levels of C-factor are needed for sporulation than for aggregation. Both the aggregation and the sporulation reporter were expressed when high levels of C-factor were added; neither was expressed when low levels were added, and only the aggregation reporter was expressed when intermediate levels were added. Whether the amount of C-factor is limited by promoter deletions or by adding variable amounts of purified C-factor, the same gradation of aggregation and sporulation was observed (Kim and Kaiser, 1991; Li et al., 1992).

The amount of C-factor in cell extracts rises between 8 and 18 hours of development, naturally staging aggregation before sporulation (Kim and Kaiser, 1990a). The rise in the concentration of C-factor per cell is a consequence of a positive feedback loop in the C-signaling circuit. Expression of the *csgA* gene is controlled by C-factor itself (Kim and Kaiser, 1991). Once C-signaling has started, *csgA* gene expression begins to rise. Because C-signaling depends on cell contact (Kim and Kaiser, 1991), that rise in C-factor concentration speeds up as aggregation proceeds.

C-Signal Transduction

The C-signal transduction circuit (Figure 10) branches twice, one branch for expression of *csgA* and another for aggregation and sporulation, so that one signal performs 3 tasks (Søgaard-Anderson et al., 1996b). C-factor on the surface of one cell interacts by contact with another cell (Kim and Kaiser, 1990b; Kim and Kaiser, 1990c; Kroos et al., 1988). End-to-end contact is believed to be necessary (Kim and Kaiser, 1990b; Sager and Kaiser, 1994; Wall and Kaiser, 1998). Whether C-factor signals as an enzyme or as a ligand has not been established as yet (Baker, 1994; Lee et al., 1995; Lee and Shimkets, 1994).

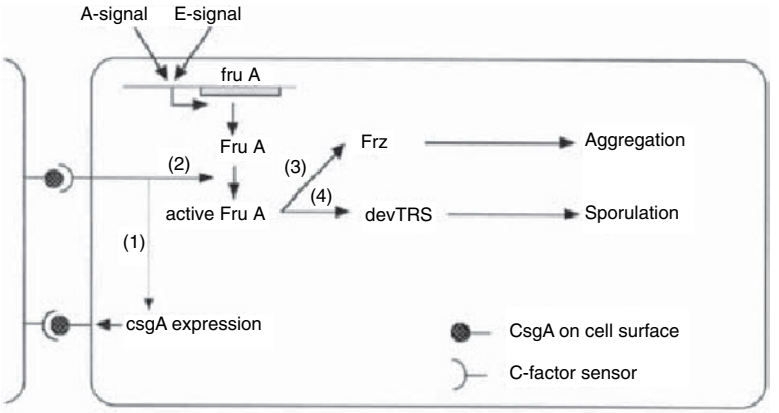

Fig. 10. C-signal transduction pathway. The structural gene *fruA* encodes a basic helix-turn-helix transcription factor. Steps (1), (2), (3), (4) are described in the text. The set of proteins Frz makes up a phosphorelay pathway and *dev* is an autoregulatory operon. The figure shows a pair of rod cells that are C-signaling to each other through their ends.

Following C-signal transmission, step (1) in Figure 10 causes the expression of *csgA* to rise; this is the positive feedback that increases the intensity of signaling once it has started. In step (2) of Figure 10, C-signaling activates FruA protein by a post-translational modification that is evident by its electrophoretic mobility (Ellehauge et al., 1998). The protein FruA is a DNA-binding response regulator with a helix-turn-helix (HTH) motif (Ellehauge et al., 1998; Ogawa et al., 1996). Activated FruA is necessary for aggregation and sporulation; there is no evidence that *csgA* expression is FruA-dependent. Synthesis of FruA protein depends on A-factor and E-factor, but not on C-factor (Figure 10).

The *frz* target of FruA is a phosphorelay, Figure 10 step (3), which modulates the frequency of reversal of direction (Blackhart and Zusman, 1985). In that relay, the FrzCD protein has a domain that resembles the carboxy-end of a methyl-accepting chemotaxis protein (McBride et al., 1989). However, FrzCD protein is not a membrane receptor; it is found in the cytoplasm and has no transmembrane or extracellular domain. Activated FruA sends a signal along the *frz* phosphorelay, as detected by the methylation of the FrzCD protein (Søgaard-Anderson and Kaiser, 1996a), and by a C-factor-induced increase in gliding speed and duration of gliding interval (Jelsbak and Søgaard-Andersen, 1999).

The methylation of FrzCD shifts during fruiting body development (Søgaard-Anderson and Kaiser, 1996a). Starting from a fully nonmethylated state early in development, the FrzCD protein gradually shifts to methylated states, and by 9 hours, the time of symmetrical mound building, all the FrzCD protein is methylated. Extracellular addition of purified C-factor to C-factor-less mutant cells directly and specifically induces the full methylation of their FrzCD protein, paralleling wild-type development (Søgaard-Anderson and Kaiser, 1996a). The cellular mechanism of aggregation, however, has not yet been established.

Both *fruA* and *frz* mutants were found in a screen of Tn5 insertion strains that arrested development in a state of partial aggregation, at the same stage as *csgA* mutants (Søgaard-Anderson et al., 1996b). Unlike *csgA* mutants, however, the targeted mutants are cell-autonomous; they are not rescued by addition of wild-type cells, or by addition of purified C-factor. Comparison of the properties of the *fruA* and *frz* mutants immediately showed that FruA is needed for aggregation and sporulation, but *frz* is only needed for aggregation.

The second target of activated FruA is the *dev* operon, Figure 10 step (4). Operon expression, as measured by the extent and time course of β-galactosidase expression from a Tn5 *Lac* transcriptional fusion to *devR*, depends on FruA in the same manner as it depends on C-factor (Ellehauge et al., 1998). The operon, in turn, is necessary for fruiting body sporulation; null mutants sporulate at 0.1% or less the frequency of wild type cells (Thony-Meyer and Kaiser, 1993). The morphological differentiation of myxospores occurs after aggregation is complete. In *Sigmatella aurantiaca*, another myxobacterium whose fruiting bodies have a more complex morphology (a stalk, branches and multiple cysts containing the spores), the aggregates pass through different intermediate shapes, including a myxococcus-like mound. Nevertheless myxospores do not form until the fruiting bodies are assuming their final branched shape (Qualls et al., 1978).

Activated FruA elevates the transcription of the *dev* operon. This operon has a switch-like quality, evident in the bimodality of operon expression in populations of developing cells (Russo-Marie et al., 1993). The two states may be consequences of the intense C-signaling in the densely packed cells that circulate inside nascent fruiting body aggregates and of little or no C-signaling in cells less densely arrayed in the periphery. Spores are found differentiated inside the fruiting body after its morphogenesis is complete, following intense C-signaling. Hence, the

chemical properties of A- and C-factors match the cell density at which they signal. For A-signaling, the cells are separate, the signal must diffuse between them in a generally aqueous environment, and the A-factor amino acids are water soluble. Quorum sensing A-factor counts the number of votes cast by those cells recommending fruiting body development. For transmitting the cell-bound C-signal, the cells must touch each other. This condition and the requirement for a high level of C-signaling to switch *dev* on test whether the cells have reached the high density characteristic of a nascent fruiting body, ensuring that it has the proper morphology.

Pheromone-Inducible Plasmid Transfer in *Enterococcus faecalis*

Enterococcus faecalis, a nonmotile Gram-positive species, exhibits a highly specific cell interaction to initiate plasmid transfer. Potential recipient cells excrete short peptides that stimulate a mating response by donor cells, which carry the corresponding plasmid. The peptides signal donor cells to synthesize surface adhesins, and mating mixtures form large aggregates of donors and recipients. The cells specifically adhere to one another. The interactions are summarized in the scheme of Figure 11.

At the center of the scheme, a plasmid-free recipient synthesizes two different pheromones, called cA and cB and shown as triangles and squares. The cell carrying plasmid pA (on the left) responds to cA and the cell carrying plasmid pB (on the right) responds to cB. Upon exposure to pheromone, a signal is transduced to the resident plasmid that results in expression of a plasmid gene encoding a surface adhesin (AS) on the donor cells. The adhesin has the capacity to bind to a normal constituent of the cell walls, probably lipoteichoic acid (LTA), the major wall antigen of Gram-positive cells. Once triggered by pheromone, donor cells will bind recipients and other donor cells as well. Chemotaxis toward the pheromones by donor cells is not evident. Within the resulting aggregates, which may be large, plasmid is transferred from donors to recipients by conjugation (see Conjugation in the Introduction).

Several pheromones have been isolated, purified, sequenced and synthesized (Table 1). Typically they are hydrophobic octapeptides. These pheromones are active at concentrations below 5×10^{-11} M, and as few as two molecules per donor cell may be sufficient to induce a mating response (Mori et al., 1988). Their specificity is high: pheromone cAD1 is unable to induce the clumping of cells which carry plasmid pPD1 even at 10^{-6} M, ten thousand times the threshold concentration for pheromone, and pheromone cPD1 is unable to induce the clumping of cells which carry plasmid pAD1. The plasmid also encodes formation and secretion of a competitively inhibitory peptide, which blocks the action of a corresponding pheromone. Several inhibitors have been purified, and they have the same length as their corresponding pheromones, as well as some identical residues. Inhibitors and their sequences also are shown in Table 1.

The plasmid-encoded adhesins, or AS, for pAD1 and pPD1 are large proteins with a proline-rich C-terminal region for cell-wall association, followed by a membrane anchor. The adhesins have been visualized by electron microscopy as dense, hair-like structures on the bacterial cell wall, protruding about 20 nm from

Table 1. *E. faecalis* pheromone amino acid sequences.

Pheromone or inhibitor	Peptide structure
cAD1	LFSLVLAG
iAD1	LFVVTLVG
cPD1	FLVMFLSG
iPD1	ALILTLVS
cCF10	LVTLVFV
iCF10	AITLIFI
cAM373	AIFILAS
iAM373	SIFTLVA
cOB1	VAVLVLGA

Structure of *Enterococcus faecalis* pheromones. The structures are based on work from the laboratories of M. Mori, J. Nakayama, A. Suzucki, and D. Clewell (Clewell, 1999).
L = leucine; F = phenylalanine; S = serine; V = valine; A = alanine; G = glycine; T = threonine; M = methionine; I = isoleucine.

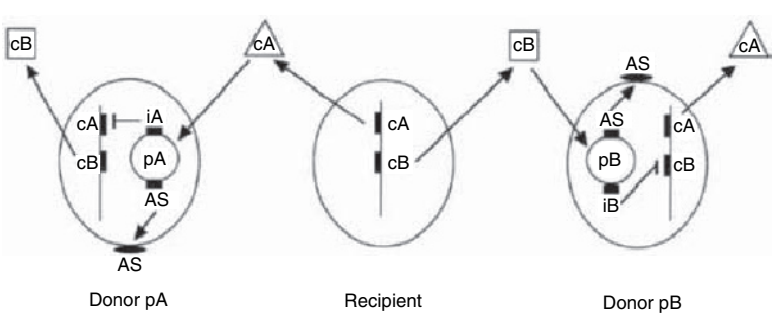

Fig. 11. Conjugal pheromones used by *Enterococcus faecalis*. The cell in the middle is plasmid free, while the cells at either side carry conjugative plasmids pA and pB, respectively. The cA and cB are two different pheromones; iA and iB are their corresponding inhibitor peptides, and AS is aggregation substance.

its surface (Galli et al., 1989). The adhesin molecules are unevenly distributed over the surface of cells, apparently attached only to the cell wall that was present when AS induction by the pheromone began. Such behavior suggests a convenient way for donor cells to dissociate from mating aggregates after plasmid transfer is complete. Growth and cell division would give rise to new donor cells free of the adhesin. These new donors would tend to dissociate from the clumps.

The target for the adhesin on *E. faecalis* cells is thought to be lipoteichoic acid (LTA) because LTA-deficient mutants lose the ability to conjugate with active donor strains. Moreover, a reversal of the normal donor-recipient orientation of adhesin-LTA allowed practically normal conjugation and plasmid transfer (Dunny, 1990).

In the genome sequence of *E. faecalis*, which has been completely determined, three of the pheromones appear in one or another of the recipient protein signal sequences (Clewell, 1999), and a single cell produces at least five different pheromones. The use of signal peptides, which are often released from cells, suggests that the entire pheromone-induced conjugation response may have evolved when potential donors gained a capacity to detect potential recipients by the signal peptides they release. At least 11 different plasmids encode pheromone responses, and the genes that specify their aggregation substances are homologous for 10 of them. Moreover, at least two of these plasmids, pAD1 and pCF10, have a similar organization of pheromone-induced genes and an identity of more than 85% for their structural genes encoding aggregation substance (Galli and Wirth, 1991). The whole set of plasmids may have evolved from a common ancestor plasmid. In conclusion, *E. faecalis* uses sequence-specific peptides to induce the agglutination of plasmid donors and recipients. The plasmid is transferred from donor to recipient within the aggregate; the aggregate then disperses.

Swarming

Swarming cells spread from a point of inoculation radially outward over a solid surface such as agar. Swarming motility, which is cooperative, organized and relatively rapid, is observed in many Gram-negative and some Gram-positive bacteria. Motility depends on interactions between cells that have appendages. However, both flagella and type IV pili promote swarming, whereas other pili do not. Flagella and pili are thought to propel a cell by different means; nevertheless the two cause remarkably similar spreading patterns. Comparison of the two modes may offer insight into the cell-cell interactions that generate swarm behavior. Swarming is inducible in flagellated cells but constitutive in cells with type IV pili.

Swarming Based on Flagella

Among Gram-negative bacteria, swarming with flagella has been found in the genera *Aeromonas*, *Escherichia*, *Proteus*, *Pseudomonas*, *Rhodospirillum*, *Salmonella*, *Serratia*, *Vibrio*, and *Yersinnia* (Harshey, 1994a). Swarming also has been observed in *Bacillus* and *Clostridium*, which are Gram-positive (Harshey, 1994a). All these swarming bacteria possess flagella, which they use for swimming, but swarming requires that the swimming cells change size and physiology. The shape modifications adapt cells to life on a surface, instead of swimming in a liquid environment. The differentiation involves flagella and other gene products that control cell division. In *Vibrio parahaemolyticus*, 40 genes or more are expressed for the swarming state. The differentiation inhibits septation and produces an elongated multinucleated cell (up to 80 μm long in *Proteus*) with a two to fifty-fold higher surface density of flagella, depending on the organism (Harshey, 1994a). *E. coli*, *Proteus*, *Salmonella typhimurium*, and *Serratia marcesens* use the same type of flagellar organelle for swimming and swarming. The structures of the flagella of *E. coli* and *S. typhimurium* are well known, and they are essentially identical (Macnab, 1996).

V. parahaemolyticus is the only swarmer to have distinct organelles for swimming and swarming (Harshey, 1994a). It possesses hundreds of lateral flagella, while undifferentiated swimming cells have but a single polar flagellum. A proton-motive force powers the lateral flagella, while a sodium-motive force drives the polar flagellum (Atsumi et al., 1992). These distinctions have been turned to experimental advantage in the study of swarming.

Signaling (using the chemotaxis phosphorelay) but not chemotactic behavior has been shown to be essential for the differentiation of swarm cells in *E. coli* (Burkart et al., 1998). A quadruple mutant that lacks all four inner membrane chemoreceptor-transducers (Tar, Tsr, Tap, and Trg) fails to swarm, but mutants lacking any one of the four continue to swarm (Burkart et al., 1998). Swarming is rescued in the quadruple mutant by restoring either Tsr or Tar, which happen to be the most abundant chemoreceptors in *E. coli*. However, neither the presence of saturating chemoeffector concentrations or mutations that destroy ligand binding to Tsr or Tar interferes with swarming or with hyperflagellation. In addition, mutants with defects in *cheA*, *B*, *R*, *W*, *Y*, or *Z* elongate, but none

hyperflagellate or swarm (Harshey and Matsuyama, 1994b). Apparently communication of the receptors with the *cheA* kinase is essential. For swarming, it appears that the chemoreceptors signal through the chemotaxis pathway and induce swarmer-cell differentiation, but the receptors are responding to other unknown signals rather than their well-known chemoeffectors (Burkart et al., 1998).

Interference with either the *fla* genes or the functioning of the polar motor results in constitutive expression of lateral flagella in *V. parahaemolyticus* (Kawagishi et al., 1996; McCarter et al., 1988). Transposon insertion within the *lonS* gene of *V. parahaemolyticus*, which encodes an ATP-dependent protease homologous to the *E. coli lon* gene, causes expression of *lafX*, one of the genes high in the pathway of differentiation and cell filamentation—even in the absence of UV irradiation (Stewart et al., 1997). Targets of *lonS* might include a transcriptional activator of *laf* genes and an inhibitor of cell division (Stewart et al., 1997). FlhDC in *P. mirabilis*, an operon known to regulate transcription of the genes of the flagellar hierarchy, has been suggested to control swarmmer differentiation as well since it plays a role in the inhibition of cell division (Furness et al., 1997). The operon also affects cell division in *E. coli* (Pruss and Matsumura, 1996). Transcription of the *flhDC* operon rises during differentiation and decays as the cells dedifferentiate back into swimmers (Furness et al., 1997).

The natural trigger to differentiate *V. parahaemolyticus* swarm cells may be the high medium viscosity which is found on a surface and places a mechanical load on the polar flagellum, thereby signaling and inducing the cell to differentiate (McCarter et al., 1988). A high viscosity medium also triggers hyperflagellation in *Se. marcesans* (Alberti and Harshey, 1990) and *P. mirabilis* (Allison et al., 1993). Swarmer cells of *P. mirabilis* transferred to liquid medium return rapidly to normal vegetative morphology; cells in the center of a swarm colony on a plate also return. Both suggest that swarmer cells must be continuously signaled to maintain the differentiated state (Harshey, 1994a; Shinoda and Okamoto, 1977).

Isolated swarmer cells barely move, suggesting that cells must be close together to swarm, and that flagella from neighboring cells coalesce into shared bundles. Swarm cells of *P. mirabilis* do align closely along their long axis, forming two-dimensional rafts that migrate by coordinate flagellar action. A mutant, *ccmA*, that has an abnormal curved shape loses the capacity to swarm but not to swim, as if, due to its shape, it could not align with other *ccmA* cells (Hay et al., 1997).

Swarming Based on Type IV Pili

Pili have been implicated in the swarming of a wide variety of Gram-negative bacteria, many of which are pathogenic (Henrichsen, 1975). These include *Acinetobacter calcoaceticus*, *Dichelobacter nodosus*, *Eikenella corrodens*, *Kingella denitrificans*, *Moraxella bovis*, *Myxococcus xanthus*, *Neisseria gonorrhoeae*, *N. meningitidis*, *Pseudomonas aeruginosa*, Synechocystis PCC6803 and enteropathogenic *Escherichia coli* (Henrichsen, 1983; Kaiser, 1979; Manning and Meyer, 1997; Strom and Lory, 1993). Remarkably, the swarming pili of all these organisms belong to the structural class known as type IV. Type IV pili (abbreviated Tfp) are distinguished from other pili by their strictly polar origins on cells, by N-terminal sequence conservation of the pilin monomer units, by sequence conservation of a core set of proteins for pilus assembly, and by supporting bacterial motility (Ottow, 1975; Strom and Lory, 1993). A broad collection of reviews on Tfp can be found in Manning and Meyer, 1997, and a recent review on Tfp and motility in Wall and Kaiser, 1999a.

Pilus-Dependent Swarming in Myxobacteria

Myxobacteria move by gliding, which occurs at a solid-liquid, solid-air, or solid-solid interface. Gliding consists of smooth motions in the interfacial plane that are directed along the long axis of the cell, with occasional reversals of direction (Hodgkin and Kaiser, 1979a).

Myxococcus xanthus has two independent gene systems named A and S, which control swarming behavior based on gliding (Hodgkin and Kaiser, 1979b). Mutations in any gene of either system only inactivate that system alone, but cells can still swarm by means of their remaining system, albeit less efficiently. However, no A^- S^- double mutant cell can move more than its length, nor can it swarm. More than fifty A^- S^- double mutants have been constructed which are defective in different A and S genes, and all fail to swarm. While the wild type cells (A^+ S^+) produce large, flat, spreading colonies with a serrate edge, the A^- S^- mutants produce small domed-shaped colonies with sharp, non-serrate edges. Ten mutants have been mapped to the *mglA* (mutual gliding) gene, which encodes a small Ras-like G-protein. This gene is required to complement both A^- and S^- motility defects (Hartzell, 1997; Hodgkin and Kaiser, 1979a).

Pili are essential for S-motility, but not for A-motility (Kaiser, 1979; Wu and Kaiser, 1995). Although wild type cells (A^+ S^+) swarm by combining the A and S swarm patterns, any A^-

S^+ mutant cells swarm by the S swarm pattern, and the role of pili is thereby revealed. Pili are usually found in tufts of 2 to 8 fibers, and always at the poles. The S-motility is lost when pili are shaved off cells by violent shearing action, but reappears as the pili grow back (Rosenbluh and Eisenbach, 1992). The S-motile cells cannot move at all when they are far apart. Nevertheless, individual cells that are separated from their nearest neighbor by less than a cell length do move (Kaiser and Crosby, 1983). Because pili tend to break when cells are washed, it is difficult to determine the length of pili on cells isolated from colonies; nevertheless many pili are roughly the length of cells. The rate at which an S-motile swarm expands depends on the cell density, showing strong dependence on cell interactions (Kaiser and Crosby, 1983). The swarming rate of S-motile cells is highest when the average cell-cell distance is less than about 1.5 μm. The bodies of cells do not have to touch to interact (Kaiser and Crosby, 1983). Spreading is evident in the change in morphology of a young S-motile colony after 2 hours (Figure 12). The colony has spearhead-like clusters of 50 or more cells but almost no single cells.

Non-swarming *M. xanthus* strains, either A^- S^- or *mglA* mutants, are unable to form fruiting bodies (see *M. xanthus* A- and C-signaling). Almost all A^- S^+ and A^+ S^- single mutants delay fruiting body aggregation, reflecting a need for the type IV pilus system (Cheng, Wee, Wu and Kaiser, unpublished). Abnormal fruiting body development is a consequence of the defective swarming when either system is absent (Hodgkin and Kaiser, 1979b; Wu et al., 1998).

UV-irradiation, chemical mutagenesis, or transposon insertion was used to create a library of about 160 independent S-motility mutants to explore the role of TfP in swarming. The S-motile (A^- S^+) colonies are flat and their spreading edges are smoothly serrated, whereas A^- S^- mutants of an A^- S^+ strain have smooth, dome-shaped colonies with sharp non-serrate edges. This library of S-motility mutants is divided into four groups named *pil*, *tgl*, *dsp*, and *frz*.

The largest group of S-motility genes is the *pil* genes. Over 100 mutations have been mapped within a contiguous *pil* gene cluster that contains 17 genes and is shown in Figure 13 (Wall et al., 1999b; Wu and Kaiser, 1995; Wu et al., 1998; Wu et al., 1997b). Products of fourteen of these genes

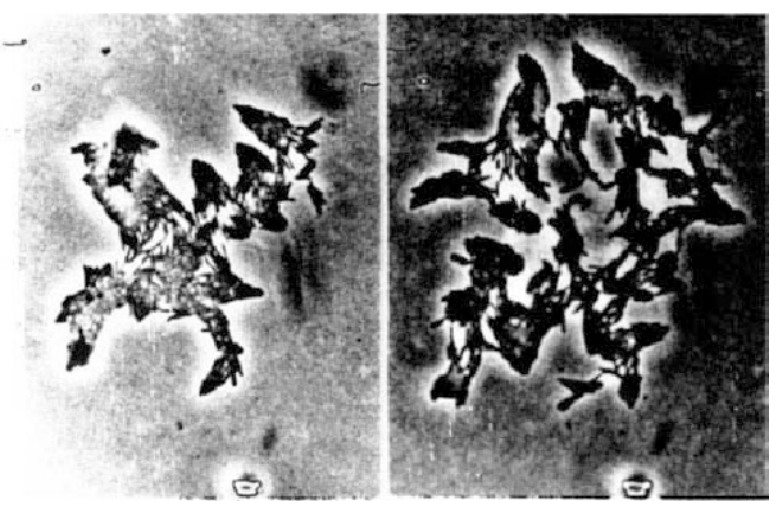

Fig. 12. Expansion of an S-motile microcolony. The two panels show the same colony at 0 (left) and 2 hours (right) at 33°C. Magnification scale: 1 cm is 15 μm. From Kaiser and Crosby, 1983.

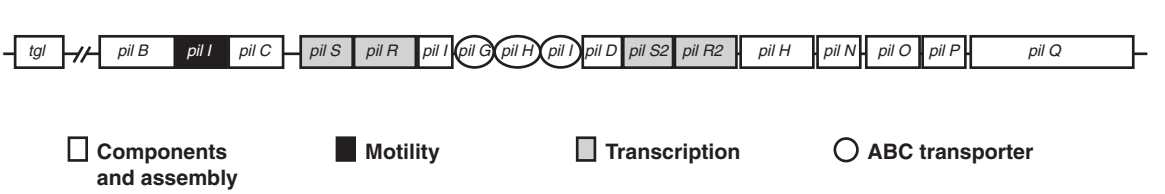

Fig. 13. *M. xanthus* Pil gene cluster and the function of each gene in type IV pilus assembly, motility, and control of gene expression. From Wall and Kaiser, 1999a.

are about 30% identical and 50% similar to proteins in *P. aeruginosa* and *N. gonorrhoeae* that encode their type IV pilin and related assembly proteins. The *Myxococcus pilG*, *pilH* and *pilI* genes have no homologs among other Tfp systems. The *pilH* gene encodes a member of the ABC transporter family with an ATP-binding cassette (Wu et al., 1998). In-frame deletions, transposon insertions and other null mutants reveal the functions of all 17 *pil* genes except *pilD*, for which deletion appears to be lethal. Null mutation in 14 of the 17 genes, including *pilG*, *pilH* and *pilI*, abolishes S-motility. These mutations, with the exception of *pilT*, also abolish the production of pili. Pili remain in a *pilT* mutant; this gene appears to be necessary for pilus function as opposed to pilus assembly. Mutant screening and sequencing left and right of the *pil* cluster shown in Figure 13 revealed no other *pil* homologs or S-motility genes in that vicinity. Clearly, Tfp is essential for S-motile swarming.

The *tgl* mutants lack S-motility and pili, like the *pil* mutants. They are distinguished from the *pil* mutants by their map position (distant from the *pil* cluster) and by their capacity to be stimulated, a process of phenotypic rescue (Hodgkin and Kaiser, 1977; Rodriguez-Soto and Kaiser, 1997a; Rodriguez-Soto and Kaiser, 1997b). It is the only stimulatable gene in the S system, although five stimulatable genes are known in the A system (Hodgkin and Kaiser, 1977; Rodriguez and Spormann, 1999). The *tgl* gene contains a type II signal sequence, suggesting it encodes a lipoprotein. Six tandem but degenerate tetratrico peptide repeats (TPR) follow the signal sequence (Rodriguez-Soto and Kaiser, 1997a). Tetratrico peptide repeats motifs are associated with proteins that interact with other proteins (Das et al., 1998). The Tgl protein may be an assembly factor for the pili, since it is not part of the pilus fiber (Rodriguez-Soto and Kaiser, 1997b).

The third group of S^- mutants is the *dsp*. All 21 *dsp* mutants map in one cluster. Transductional linkage within this group suggests an approximately 10 kb *dsp* region. Unlike wild type cells, the *dsp* mutants grow as *disp*ersed cultures in liquid medium; they neither clump nor aggregate, even though they have pili. Autoaggregation of cells in suspension is common for bacteria that have Tfp (Bieber et al., 1998; Knutton et al., 1999; Manning and Meyer, 1997; Wu et al., 1997b). Like *pilT* mutants, all *dsp* mutants retain pili, yet lack S-motility. The *dsp* mutants are depleted in extracellular fibrils, but do not totally lack them (Chang and Dworkin, 1994; Dana and Shimkets, 1993). Fibrils are peritrichous filaments composed of approximately equal amounts of polysaccharide and protein, and help to hold cells together. In addition to a cohesive function, it has been suggested that fibrils transfer signals, perhaps by ADP-ribosylation (Dworkin, 1999). A chaperone of the HSP70 family encoded by the *sglK* gene is necessary for production of one of the protein components of fibrils, and *sglK* mutants are S^- (Weimer et al., 1998). However, the relationship between S-motility and fibrils could be indirect, because *esg* mutants, which are also defective in fibril production, retain S-motility (Ramaswamy et al., 1997).

The final group of S-motility genes is called *frizzy*. These genes control the frequency of reversal of gliding direction (Blackhart and Zusman, 1985), and possibly speed (Spormann and Kaiser, 1999). The *frz* genes are homologous to the enteric bacterial chemotaxis genes for swimming (McBride et al., 1989). When a *frz* mutation is combined with an A^- mutation, the *frz* genes behave like S-genes (Fontes and Kaiser, 1999). Swarming of A^- *frz* double mutants is greatly diminished. However, it is not eliminated, resembling A^- *dsp* mutants.

It may be useful to think of S-motile swarming as the product of a pathway shown in Figure 14. Blocks at any stage in the pathway would create an S^- mutant. The first stage (pilin synthesis) includes control of *pilA* expression by PilS/PilR, a two-component regulatory system (Wu and Kaiser, 1997a), membrane insertion of a pilin monomer, and finally processing by the bifunctional PilD peptidase/N-terminal methylase. Processed subunits are then polymerized into a pilus fiber. The pili contact other cells and other pili, providing cell interactions that may also involve the fibrils and proteins bound to fibrils. In the last step, pilT and frz proteins may help to control movement behavior. The pili, and possibly the fibrils, are thus essential for social swarming, but their role is not yet clear (Kaiser, 1979; Wu et al., 1998).

Twitching Motility Twitching describes a type of surface translocation that, like gliding, does not depend on flagella, and in which the movements of individual cells appear as small, intermittent jerks (Henrichsen, 1972). Like gliding, twitching depends on humid agar but unlike gliding, twitching is jerky, not smooth (Henrichsen, 1972; Henrichsen, 1975; Henrichsen, 1983). Henrichsen surveyed some 1,000 bacterial

Fig. 14. Steps on the dependent pathway to social swarming in *M. xanthus*.

strains representing more than 50 species, classifying their surface translocations as twitching or gliding. About 20 of his species were found to twitch, and some he demonstrated to have polar pili. All strains of the same species with polar pili exhibited twitching. Moreover, twitching was not found in variants of the strains that had lost their polar pili by mutation, or in strains with pili that were not type IV. Henrichsen concluded from this study that twitching depends on polar pili. Subsequent genetic studies of *P. aeruginosa* and *N. gonorrhoeae* showed that their twitching depends on their Tfp (Strom and Lory, 1993). Behavior, sequence conservation of Tfp genes among *P. aeruginosa*, *N. gonorrhoeae*, and *M. xanthus*, and strong similarities of mutant phenotype clearly connect twitching and social gliding (Mattick et al., 1996; Wall et al., 1999b; Wu and Kaiser, 1995).

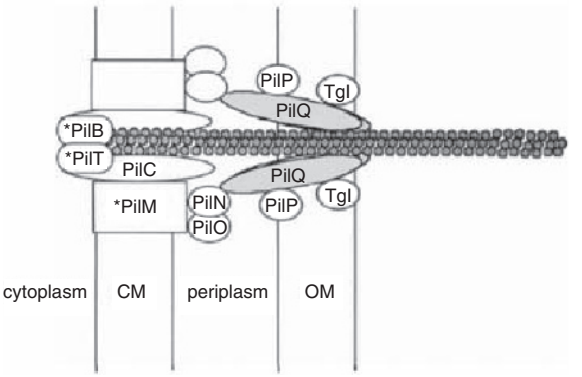

Fig. 15. Model of the type IV pilus in *M. xanthus*, based on genetic studies and on location of the individual proteins. From Wall and Kaiser, 1999a.

Type IV Pilus Fiber Structure

The structure of the pilus fiber and its mode of assembly (and possibly disassembly) are relevant to pilus function in twitching and gliding, as well as to the cell interactions necessary for swarming. The Tfp fiber has a three-layered helical structure of coiled α-helices surrounded by a β-sheet. These two inner layers are covered with the C-terminal regions of adjacent monomers, based on a 2.6 Å resolution X-ray crystal structure of dimers of pilin protein from *N. gonorrhoeae* (Forest and Tainer, 1997; Parge et al., 1995). The *N. gonorrhoeae* fiber has 5 pilin monomers per helical turn, a rise of about 4 nm per monomer, and an outer diameter of about 6 nm. The helix parameters and diameter agree with fiber diffraction data from *P. aeruginosa* Tfp, which suggests that the proposed structure is representative of the Tfp in many organisms. The N-terminal amino acid sequence, which is highly conserved from one bacterial species to another, forms the innermost coil of staggered, hydrophobically packed, parallel α-helices. Hydrophobic packing and the flexibility of α-helices may allow pili to bend and to adopt twisted or bundled conformations. The middle layer of β-sheet is continuous from one pilin monomer to the next in the sense that any crosssection of the fiber would cut through 25 β-strands. The β-sheet hydrogen bonding may provide much of the mechanical stability required for a fiber whose length of up to 4 microns approaches 600 times its diameter of 6 nm. It is generally believed that the pilus is assembled from its base, since there is no channel in the center of the fiber and one would be needed for assembly from the tip. Moreover, a pool of pilin is found in the cytoplasmic membrane, ready to drive assembly. No pool of pilin in the cytoplasm would be required for assembly from the tip, as found in the assembly of flagella from flagellin.

Based on the structure of the pilus fiber, on the genetic studies, and on the localization of pilus proteins, a model of the pilus and its assembly system is presented in Figure 15. This structural model is neutral with respect to theories of pilus retraction by disassembly and reassembly of the fiber as suggested by Bradley and others (Bradley, 1980).

In *conclusion*, swarming is observed only when the cell density is high. The similarities in spreading behavior between flagellar swarming and type IV pilus swarming could arise because both types of cells move in groups, both involve elongate cells which tend to move parallel to their long axis, and both types of cells maintain close contact with other cells.

Heterocyst Differentiation in Cyanobacteria

Cyanobacteria carry out photosynthesis as well as nitrogen fixation. In photosynthesis, atmospheric CO_2 is reduced using water as the primary electron donor and O_2 is generated. This generation of O_2 is a problem for nitrogen fixation because nitrogenase, the enzyme that catalyzes reduction of N_2, is sensitive to O_2. Perhaps, to solve this problem, cyanobacteria of the genus *Anabaena* differentiate specialized cells called heterocysts to house their nitrogenase. The heterocysts have thick walls, which prevent O_2 from penetrating; nitrogenase is thereby permitted to function inside. *Anabaena* forms chains of photosynthesizing vegetative cells, punctuated with an occasional heterocyst.

If *Anabaena* is grown in a medium that provides ample fixed nitrogen as NH_4^+, nitrogen

fixation is not required and no heterocysts are formed, only vegetative cells. But when cells that have been grown with ample NH_4^+ are washed, then resuspended in medium free of fixed nitrogen, they develop heterocysts during the next 24 hours. Since the vegetative generation time under these conditions is also about 24 hours, heterocyst differentiation can be thought of as growing a new cell with a different wall and a somewhat different set of enzymes. The RNA hybridization data suggest as many as 1,000 protein differences between vegetative cells and heterocysts (Buikema and Haselkorn, 1993).

When nitrogen fixation is needed, about one cell in 10 becomes a heterocyst. Nitrogen fixation and respiration in the heterocyst require a supply of reductant and of carbon from the adjacent, photosynthesizing, vegetative cells. Reductant and carbon are provided in the form of maltose, sucrose, or other disaccharides. In return, the heterocyst releases fixed nitrogen in the form of glutamine to its vegetative neighbors.

The intercellular exchange of metabolites illustrates the metabolic interdependence of vegetative cells and heterocysts. These cells are also developmentally interdependent in that the heterocysts differentiate at fairly regular spatial intervals (Wilcox et al., 1973). Chain-breaking experiments show that many more cells have the potential to become than normally become heterocysts (Wilcox et al., 1973). Because all the cells in a chain have received the same environmental cue, the implication is that some kind of local cell interaction underlies the regular spatial pattern of heterocysts. To appreciate this pattern, consider that all cells in a chain of vegetative cells grow and divide, causing the chain to elongate internally. To maintain a fixed ratio of heterocysts to vegetative cells, new heterocysts must differentiate in proportion to the new vegetative cells that form. Moreover, a regulatory system that appropriately selects particular vegetative cells to become heterocysts would seem to be necessary so that fixed nitrogen (glutamine) will be equally available to all the growing cells. Since the levels of hundreds of proteins differ between heterocysts and vegetative cells, the process needs coordination. It is hard to escape the inference that a cell interaction triggers one daughter cell to become a proheterocyst and its sister to remain a vegetative cell.

Each new heterocyst forms very near the center of a segment of vegetative cells. This maintains a stable 1/10 ratio and is clearly the most efficient way to exchange fixed carbon and fixed nitrogen between vegetative cells and heterocysts. But what are the cell interactions and how do they generate the pattern? A promising start to answering this question comes with the discovery of the gene *patS* (Yoon and Golden, 1998).

Overexpression of *patS* blocks heterocyst differentiation, while a *patS* null mutant has an increased frequency of heterocysts clustered abnormally along the chain of cells. This contrast of phenotypes suggests that *patS* encodes an inhibitor of heterocyst differentiation. Moreover, *patS* is expressed in proheterocysts but not in vegetative cells. The *patS* gene can encode a peptide of 17 amino acids, and a synthetic peptide corresponding to its C-terminal pentapeptide has the capacity to inhibit heterocyst development. Yoon and Golden propose that heterocysts synthesize and secrete a *patS* peptide that prevents neighboring vegetative cells from becoming heterocysts.

Sporulation of *Bacillus* Subtilis

Bacillus subtilis usually divides by binary fission, but when the cells are starved for carbon, nitrogen, or phosphorous they differentiate a new type of cell, an endospore. The spore can survive for years without food and retains an ability to germinate and to produce rapidly growing and dividing vegetative cells when food is again available. The developing cell undergoes a rigid sequence of morphological and biochemical changes over a period of about 8 hours as it makes the spore. A program involving the expression of more than 100 genes governs progression through the morphological and biochemical stages. The transcriptional program is controlled by the sequential activation of different subunits of RNA polymerase.

The earliest morphological event in that developmental program is a redirection of septum formation from its usual midcell position to a sub-polar one. An asymmetric septum partitions one copy of the chromosome to the larger mother cell and one copy to the smaller forespore. However, the two cells are held together by a common cell wall. These two cells, each with its own nucleus and cytoplasm, are in a position to interact with each other, and they do. Their interactions can be considered to couple gene expression to morphology. This example will focus on the best understood interaction between the two daughters as they codevelop. There is evidence for more interactions in the sporulation program as well (Kroos et al., 1999; Sonenshein, 1999; Stragier and Losick, 1996).

A different cascade of σ factors is active within each compartment; in the mother cell σ^E is replaced by σ^K, while in the developing spore σ^F is replaced by σ^G. Moreover all four of these sporulation-specific σ factors are inactive at the moment of their synthesis. The σ^E and σ^K factors are synthesized in the mother cell as inactive precursor proteins, while in the developing spore σ^F and σ^G are held in an inactive state by associ-

ation with inhibitory proteins. In particular, σ^K is synthesized as a larger but inactive precursor, pro-σ^K. Activation of σ^K in the mother cell occurs by proteolytic removal of its 20 amino acid N-terminal (Kroos et al., 1989). During sporulation, the activation of σ factors is carefully regulated. Pro-σ^K associates with both the mother cell membrane and the outermost membrane surrounding the forespore after engulfment. The processing enzyme, thought to be the product of *spoIVFB*, is also made in the mother cell and is located in the same membrane as pro-σ^K (Kroos et al., 1999). However, cleavage in the mother cell is not constitutive, but depends on a protein located in the inner membrane of the forespore, the spoIVB protein (Cutting et al., 1991). Concentration or timing changes of this protein, which is synthesized under control of σ^G in the forespore, changes the timing of pro-σ^K, which strongly supports a regulatory role for spoIVB in that processing (Stragier and Losick, 1996). Two other membrane proteins, believed to form a complex with it, block the activity of the spoIVFB protease. This complex is thought to be the target of the spoIVB protein from the forespore. This interaction relieves the inhibition of the protease, and pro-σ^K is processed in response to the forespore signal. Thus, during *B. subtilis* sporulation, the mother cell and forespore interact with each other to activate a stage-specific sigma factor.

CHAPTER 1.9

Prokaryotic Genomics

B. W. WREN

Introduction

Haemophilus influenzae strain Rd became the first free-living organism to have its genome sequenced (Fleischmann et al., 1995). The floodgates have opened with over 100 prokaryotic genomes completely or partially sequenced. However, the acquisition and analysis of sequence data is not an end in itself; instead it is a starting point for generating hypotheses that can be tested in the laboratory. It is clear that knowledge of the complete genome sequence of an organism does not tell us a great deal about the composition or functional capabilities of the organism. Homology, or sequence similarity, provides clues, but it does not prove gene function. Furthermore, a large percentage of genes have no matches to known genes. For example, at the time of sequence release, up to 62% of predicted protein-coding genes in the *Methanococcus jannaschii* genome had no matches with genes from other organisms (Bult et al., 1996). Elucidating the function of these "ORFan" or "FUN" (function unknown) genes is one of the biggest challenges of the post-genomic era.

The avalanche of genome sequence data has coincided with important technological advances in four research areas: bioinformatics, gene mutagenesis, nucleic acid hybridization technology and protein chemistry. These advances will liberate scientific understanding from the piecemeal study of individual genes or operons towards a comprehensive analysis of the entire gene and protein complement of the prokaryotic cell. This new technology will allow a holistic approach to the functional characterization of prokaryotes at the mutational, transcriptional, and protein expression levels (see Fig. 1). The application of functional genomic approaches in the smaller genomes of prokaryotes is the forerunner for the study of functional genomics in higher organisms, including humans. An important exception is the efforts of the *Saccharomyces cerevisiae* research community, which is a shining example of what can be achieved through functional genomics studies (Lashkari et al., 1997; Winzeler et al., 1998; Winzeler et al., 1999a; Winzeler et al., 1999b; Uetz et al., 2000).

Prokaryotic Genome Projects and the Birth of Comparative Genomics

The availability of genome sequences has spawned the new scientific discipline of comparative genomics, which allows the comparison of genome sequence data between strains, species, genera and even kingdoms. Such studies will provide important taxonomic insights and will have far-reaching implications for the study of evolution. The virtual genome center is a useful web-based site (alces.med.umn.edu/VGC.html) for evolutionary comparisons of proteins, protein families, and genome sequences. In the future, comparative analysis of genome sequence data will be facilitated by high-density array DNA hybridization analysis (see section on Applications of High-Density DNA Arrays and Genomotyping in this Chapter).

The salient features of prokaryotic genome sequences are summarized in chronological order of publication. First, *Haemophilus influenzae* strain KW20 (Rd; 1.83 Mb; Fleischmann et al., 1995) was sequenced using the now widely adopted whole genome, random shotgun, sequencing approach. The full complement of genes enabled the deciphering of the polysaccharide structure of the organism. Several iterative sequences (dinucleotide and tetranucleotide) repeats were identified suggesting *H. influenzae* probably uses recombination and slipped-strand mispairing within repeats as a mechanism for antigenic/phase variation and adaptive evolution (Hood et al., 1996).

Mycoplasma genitalium (0.58 Mb; Fraser et al., 1995) has the smallest known genome content of any free-living organism. As a consequence its physiology and metabolic capacity differ from that of most living organisms. *Mycoplasma genitalium* represents an important system for determination of the minimal number of genes required for host-independent existence (Hutchison et al., 1999).

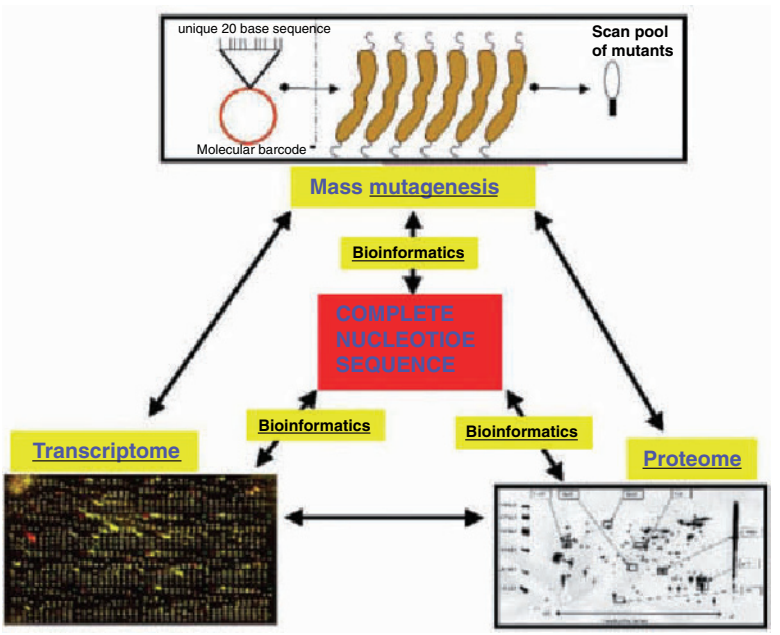

Fig. 1. Schematic showing available complementary functional genomics approaches.

Methanococcus jannaschii (1.66 Mb; Bult et al., 1996) was the first archaeon to be sequenced. In *M. jannaschii* the majority of genes related to cell division, energy production and metabolism are more similar to those found in bacteria; by contrast, most of the genes involved in transcription, translation and replication are more similar to those found in eukaryotes.

Synechocystis sp. strain PCC6803 (3.57 Mb; Kaneko et al., 1996) is a photosynthetic bacterium where 5% of identified open reading frames (ORFs) were dedicated to photosynthetic reactions and 99 ORFs showed similarity to transposase genes, suggesting frequent rearrangement of the genome.

The sequencing of *Mycoplasma pneumoniae* M129 (0.81 Mb; Himmelreich et al., 1996) was the first occasion that two organisms within the same genera were sequenced. A subset of essential genes was identified in both *Mycoplasma* species. Anabolic and metabolic pathways were absent, which is consistent with its obligate parasitic lifestyle.

Sequence analysis of *Helicobacter pylori*, strain 26695 (1.67 Mb; Tomb et al., 1997), demonstrated that a surprisingly large proportion of the genome content was dedicated to DNA restriction modification, motility and sequestration of iron. Similarly, several adhesins and outer-membrane proteins were identified suggesting a complex host-pathogen life style. Surprisingly, few regulatory sequences and σ factors were identified, which is consistent with the restricted ecological niche of the human stomach in which the pathogen resides.

The *Escherichia coli* K-12 (4.64 Mb; Blattner et al., 1997) genome appeared highly organized and contains insertion sequence (IS) elements and phage remnants, indicating genome plasticity through horizontal transfer.

The *Methanobacterium thermoautotrophicum* strain delta H (1.75 Mb; Smith et al., 1997) sequence predicted that most of the proteins involved in DNA metabolism, transcription and translation were of eukaryotic origin, whereas gene structure and organization have features that are typical of bacteria. Comparisons with the *M. jannaschii* genome underline the extensive divergence that has occurred between these two *Methanogens*.

Bacillus subtilis (4.21 Mb; Kunst, 1997) was the first Gram-positive organism to be sequenced. A quarter of the genome corresponds to several gene families that have been greatly expanded by gene duplication, and a significant proportion of the genetic capacity is devoted to the utilization of a variety of carbon sources. The genome contains at least ten prophages suggesting that bacteriophage infection has played an important evolutionary role in horizontal gene transfer.

Archaeoglobus fulgidus VC-16 (2.18 Mb; Klenk et al., 1997) was the first sulfur-metabolizing organism to have its genome sequence determined. A quarter of the genome encodes novel proteins indicating substantial archaeal gene diversity.

Borrelia burgdorferi B31 (1.44 Mb; Fraser et al., 1997) appears unique among prokaryotes as its genome contains a linear chromosome (0.91 Mb) and at least 17 linear and circular plas-

mids (totaling 0.53 Mb). The biological significance of the multiple plasmid-encoded genes is not clear, although it is postulated that they may be involved in antigenic variation or immune evasion.

The complex metabolic machinery needed for *Aquifex aeolicus* (1.55 Mb; Deckert et al., 1998) to function as a chemolithoautotroph is encoded within a genome a third the size of the *E. coli* genome. Metabolic flexibility seems to be reduced as a result of the limited genome size. Although *A. aeolicus* grows at 95°C, the extreme thermal limit of the bacteria, only a few specific indications of thermophily are apparent from the genome.

Pyrococcus horikoshii OT3 (1.74 Mb; Kawarabayasi et al., 1998) is a hyperthermophilic archaebacterium whose genome sequence provided evidence that a considerable number of ORFs were generated by sequence duplication. Eleven ORFs were assumed to contain inteins.

Mycobacterium tuberculosis strain H37Rv, (4.41 Mb; Cole et al., 1998) has a very high G+C content that is reflected in the biased amino acid content of the proteins. *Mycobacterium tuberculosis* differs from other bacteria in that much of its coding capacity is devoted to lipogenesis and lipolysis. Two novel families of glycine-rich proteins are present that have a repetitive structure, which may represent a source of antigenic variation.

In *Treponema pallidum* (1.13 Mb; Fraser et al., 1998), the systems for DNA replication, transcription, translation and repair are intact, but catabolic and biosynthetic activities are minimized. Comparison of the *T. pallidum* genome sequence with that of another pathogenic spirochete, *B. burgdorferi*, identified both unique and common genes and confirms the considerable diversity observed among pathogenic spirochetes.

Although the obligate intracellular pathogen *Chlamydia trachomatis* (1.04 Mb; Stephens et al., 1998) lacks many biosynthetic capabilities, it retains functions for the interconversion of metabolites obtained from their mammalian host cells. The apparent wide origin of chlamydial genes, including a large number of genes of eukaryote origin, implies a complex evolution for adaptation to obligate intracellular parasitic status.

The sequence of *Rickettsia prowazekii* (1.11 Mb; Andersson et al., 1998) revealed surprising similarity to mitochondrial genes. For example, ATP production in *Rickettsia* is the same as that in mitochondria. The *R. prowazekii* genome contains the highest proportion of noncoding DNA (24%) for a prokaryote, and *R. prowazekii* more closely related to mitochondria than any other microbe studied to date.

The sequence of *Helicobacter pylori* strain J99 (Alm et al., 1999) allowed the first genome comparison of two strains from the same species. Prior to the availability of the second sequence, *H. pylori* was thought to exhibit a large degree of genomic and allelic diversity, but the overall genomic organization and gene order appeared quite similar. Between 6 to 7% of the genes are specific to each strain. Almost half of these genes are clustered in a single hypervariable region, termed "a plasticity zone."

Analysis of the *Chlamydia pneumoniae* (1.23 Mb; Kalman et al., 1999) genome revealed 214 protein-coding sequences not found in *C. trachomatis*, many without similarity to other known sequences. Significant comparative findings included conservation of a type-III secretion virulence system, expansion of a novel family of outer-membrane proteins, and three serine/threonine protein kinases.

Aeropyrum pernix K1 (1.70 Mb; Kawarabayasi et al., 1999) grows optimally at 95°C. All genes in the tricarboxylic acid (TCA) cycle were present except for that of α-ketoglutarate dehydrogenase. Sequence comparison among the assigned ORFs suggested that a considerable number of ORFs were generated by sequence duplication.

Of the eubacteria sequenced to date, *Thermotoga maritima* MSB8 (1.86 Mb; Nelson et al., 1999) has the highest percentage (24%) of genes that are most similar to archaeal genes. Conservation of gene order between *T. maritima* and archaea in several clustered regions of the genome suggests that lateral gene transfer may have occurred between thermophilic eubacteria and archaea.

The genome of the radiation-resistant bacterium *Deinococcus radiodurans* R1 (3.28 Mb; White et al., 1999) is, unusually, composed of two chromosomes (2.65 and 0.41 Mb), a large plasmid (0.178 Mb) and a small plasmid (0.045 Mb). Several regions of the genome were identified that allow *D. radiodurans* to survive under conditions of oxidative stress, desiccation, starvation and high amounts of DNA damage.

Campylobacter jejuni (1.64 Mb; Parkhill et al., 2000) was the first foodborne pathogen to be sequenced. The genome is unusual in that there are virtually no IS or phage-associated sequences and very few repeat sequences. A striking feature was the presence of hypervariable sequences commonly found in genes encoding surface structures. The apparently high rate of variation of these homopolymeric tracts may play an important role in the survival strategy of *C. jejuni*. Despite its close phylogenetic relationship to *H. pylori*, strong similarities between these organisms are mainly confined to housekeeping

genes. In most functions related to survival, transmission, and pathogenesis, the organisms have remarkably little in common. This indicates that selective pressures have driven profound evolutionary changes to create two very different pathogens from a close common ancestor.

Neisseria meningitidis serotype B strain MC58 (2.23 Mb; Tettelin et al., 2000) revealed three major regions of horizontal DNA transfer. The sequence revealed insight into the commensal and virulence nature of the organism; in particular, the organism appears to undergo more phase variation than any prokaryote studied to date. In an accompanying paper, over 350 candidate antigens were expressed in *E. coli* and tested for their vaccine efficacy (Pizza et al., 2000). The sequence *Neisseria meningitidis* serotype A strain Z2491 (2.18 Mb) revealed hundreds of repeat elements ranging from short homopolymeric tracts to gene duplications again suggesting extreme genome fluidity, which probably plays a significant role in antigenic variation of this human specific pathogen (Parkhill et al., 2000). Comparison between *N. meningitidis* serotype B and *N. meningitidis* serotype A awaits further analysis.

Bioinformatics

Bioinformatics and the range of new supercomputers are poised to change forever the way in which we tackle prokaryotic research. The unprecedented deluge of sequence data requires processing and rapid access to functional genomics information and is central to the revolution that is taking place in prokaryotic molecular genetics. Bioinformatics is essentially the evolution of computer-based technology dedicated to the analysis of genome sequences. It is a cross-disciplinary activity, including aspects of computer science, software engineering, molecular biology, and mathematics. The past few years have seen vast improvements in the algorithms used to analyze sequence data, and an increasing range of bioinformatics software has been developed and released into the public domain by way of the Internet. Careful and intelligent use of this software can afford important new insights into protein structure and function and allow the generation of testable hypotheses.

Coincident with the availability of genome sequence data, several other factors have meant that it is easier than ever before for scientists to exploit such data. For example, the rise of the Internet and the World Wide Web, coupled with well-supported free software facilities, has made it easier than ever for scientists to use remote computing facilities (see examples on Table 1).

The most common use of bioinformatics is the search for sequence similarity with homologous genes/gene products deposited in the numerous nucleotide and protein databases worldwide. The basic local alignment search tool (BLAST); Altschul et al., 1990) is the most widely used program for such analysis. A simple example of the application of bioinformatics is the rapid identification of iterative nucleotide sequences in a genome sequence. These can act as markers for polymorphic regions important for antigenic/phase variation and in host-pathogen interactions (Hood et al., 1996). Comparative analysis of gene pathways from several complete genome sequences allows more definitive information on components of the pathway. Comparison of the citric acid cycle from numerous genome sequences makes it possible to reason confidently about the absence or presence of the different parts and branches of the cycle and even the overall metabolic scheme of the organisms (Huynen et al., 1999). *The Kyoto Encyclopedia of Genes and Genomes* worldwide (http://www.genome.ad.jp/kegg/kegg2.html) shows many metabolic and regulatory pathways based

on orthologous sequences from databases. Observations on chromosomal organization and gene order have proven useful in identifying recently acquired DNA sequences. This approach has been exploited in the *T. maritima* genome project to suggest that lateral gene transfer has occurred between thermophilic eubacteria and archaea (Nelson et al., 1999). The operon structure of prokaryotes makes it possible to identify coregulations, coexpressions, and more generally, gene clusters that might infer a common function (Overbeek et al., 1999).

The published annotated forms of the genome sequences fall short of being definitive. Generally, narrow sets of analysis programs have been employed, and no doubt, several reanalyses of the sequence data will be undertaken. In addition to the benefits of such static analysis, an ongoing dynamic analysis is needed, constantly reevaluating the sequence data in the light of newly published sequences. One example of such re-analysis software is the protein extraction, description, and analysis tool PEDANT, which is a software system that utilizes modern bioinformatics methods to provide complete functional and structural characterization of protein sequence sets from individual sequences to complete genomes. For other examples, see Table 1.

Sustained improvements in computing speed and in hard-drive capacity mean that even very computationally intensive analyses can be performed on readily available hardware. The availability of supercomputers will trigger a revolution in the complexity of problems we tackle to understand the basic biology and evolution of the prokaryotes (Butler, 2000).

Functional Genomics

In the past, geneticists have assigned gene function by specifically disabling or "knocking out" a single gene, usually by transposon mutagenesis (insertion mutagenesis) or allelic replacement (usually deletion mutagenesis), and then comparing the phenotypes of the mutant strain with the parent strain. This approach is still valid, but with the availability of information at the genome-wide level, a global approach to the study of gene function at the mutational, transcriptional and translational levels is now possible.

Mutational Analysis

The construction of defined mutants by transposon mutagenesis or allelic replacement has proven to be a powerful method for determining gene function in numerous prokaryotes. Information about the biological functions can be inferred by monitoring the fitness of the null mutant under a variety of selected growth conditions. However, in conjunction with the construction of mutants is the potential to label each mutant with a unique DNA-signature tag permitting simultaneous analysis of several hundred mutants for phenotypic features (Fig. 2; Hensel et al., 1995).

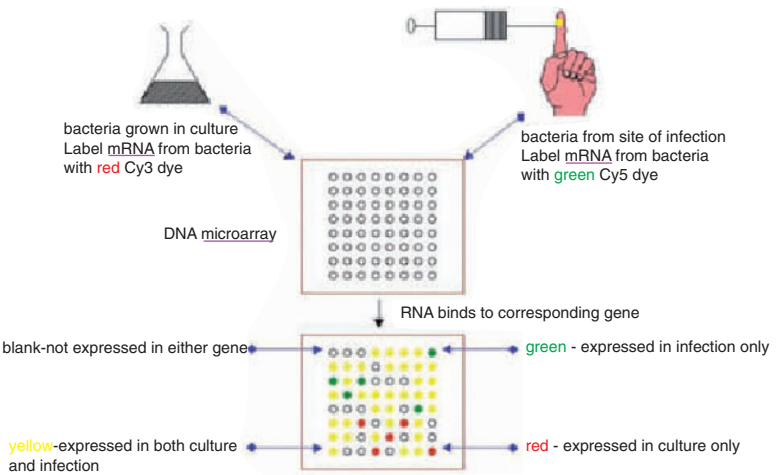

Fig. 2. Schematic showing how differential gene expression of a bacterium at a site of infection or in culture is determined using a DNA microarray.

Signature-Tagged Mutagenesis The use of DNA-signature tags was validated using *Salmonella* and a murine model of typhoid fever (Hensel et al., 1995). In the original design, the tags consisted of a central 40-bp variable region that allows differentiation between tags, flanked by constant 20-bp arms to which primers can bind for DNA amplification. By negative selection, mutants that fail to be recovered from the host following inoculation of a mixed pool of mutants can be identified (Fig. 2). Thus, when the hybridization signals from the tagged input pool of 96 mutants were compared with the respective tagged output pools of mutants, several mutants essential for the in vivo survival of *Salmonella typhimurium* could be identified (see Fig. 2; Hensel et al., 1995). This included the identification, and subsequent characterization, of a novel type III secretion system (SPI 2) in *S. typhimurium* (Shea et al., 1996). Signature-tagged mutagenesis (STM) has since been successfully used in the identification of virulence-associated factors in *Staphylococcus aureus*, *Vibrio cholerae*, *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Legionella pneumophila*, *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, *Proteus mirabilis*, *Mycobacterium tuberculosis*, and *Brucella suis* (Mei et al., 1997; Chiang and Mekalanos, 1998; Claus et al., 1998; Polissi, 1998; Camacho et al., 1999; Darwin and Miller, 1999; Edelstein et al., 1999; Foulongne et al., 2000).

The use of wholescale tagging of bacterial mutants will have its greatest potential impact on in vivo studies, insofar as the number of animal experiments required for the assessment of bacterial virulence can be drastically reduced. A review on how STM can help to identify virulence genes and other applications has been published recently (Shea and Holden, 2000). However, the tagging and analysis of prokaryotes also should be useful to measure the survivability of mutants in other complex environments ranging from biofilms to deep-sea ocean beds.

Exploitation of a DNA array of a given organism (see Macroarrays and Microarrays in this Chapter) may obviate the need to tag transposons and could be used to identify essential genes. Assuming that a transposon can insert randomly into a prokaryotic genome, a single primer reading out from the transposon (Karlyshev et al., 2000) could be used to detect all interrupted genes in a single hybridization to an organism-specific DNA array. Potentially by screening populations of input pools and output pools from a selective environment (e.g., stress), some transposon mutants will drop out of the pool, and those genes required for stress survival will be identified. Additionally, because cDNA will only be synthesized from genes with an integrated transposon, by deduction it should be possible to detect genes essential for the survival of the organism throughout the genome.

Signature-Tagged Allele Replacement Because transposons often fail to integrate (or integrate randomly) into the chromosome of many prokaryotes, transposon mutagenesis is not universally applicable. Allelic replacement is often a useful alternative to the construction of defined deletion mutants. Furthermore, the availability of entire genomic sequences means that the large-scale, systematic construction of defined mutants is now possible. Thus, all genes can be tested methodically under a particular condition. The coupling of the incorporation of DNA tags with allelic replacement has been referred to as signature-tagged allele replacement (STAR). The STAR method does not require the use of transposons, but enables a systematic unbiased genetic analysis of the

genome. As the gene target is predetermined, the need to sequence mutation sites is obviated, and by using a systematic approach, the number of mutants required for screening is minimized. Such an attempt has been made in *S. cerevisiae* (Shoemaker et al., 1996; Winzeler et al., 1999), which was coupled to the quantifying mutants with a specifically designed Affymetrix "barcoding" biochip (see Affymetrix Oligonucleotide Arrays in this Chapter) containing all the complementary DNA sequences of the tags used in mutant construction. The unique tags are based on an algorithm to select a set of over 9,000 maximally distinguishable 20mer sequences with similar Tm values (61 ± 5°C; Shoemaker et al., 1996). The optimized DNA tags increase the sensitivity of probes in complex hybridization reactions and enable the semiquantitative determination of viable bacteria. Thus, the barcoding biochip has the capacity to measure the relative abundance of defined mutants and can measure the growth rate of all tagged mutants simultaneously.

Parallel quantitative assessment of multiple strains significantly decreases labor and material required for screening, and it increases the reliability of data obtained. This approach also removes the need for onerous, hazardous, and repetitive filter-based radioactive hybridizations. Finally, the inclusion of DNA tags is an invaluable way of tracking and validating strains distributed to laboratories worldwide.

Transcriptome Analysis

Cellular processes are governed by the repertoire of expressed genes, in particular by the levels and the timing of their expression. The mRNA complement of a cell reflects the state of a cell, uniquely defining growth, division, stress adaptation and apoptosis. Transcriptome analysis offers the potential for the simultaneous measurement of expression levels for all transcripts (mRNAs) from a genome, giving a "snapshot" of the transcriptional activity of all genes in that genome. Analyses can be performed simultaneously at a given time point in growth or in any environment. This versatility is possible because mRNA expressed under a range of environmental conditions can be extracted and hybridized to a high-density gridded array of an organism's DNA content. The availability of ever-cheaper oligonucleotides, 384-well polymerase chain reaction (PCR) technology, robotics, and complete genome sequence data makes possible the highly attractive option of using gridded libraries of PCR products, constituting a defined and complete set of ORFs and intergenic regions. Such high-throughput analysis allows massive parallel gene expression and gene discovery studies to be undertaken.

High-Density DNA Arrays

There are two main high-density DNA array formats. These are generally referred to as microarrays (or macroarrays), which consist of 100- to 1,000-bp stretches of DNA, and Affymetrix biochips that consist of in situ synthesized oligonucleotides (~20 bases).

DNA Macroarrays and Microarrays High-speed robots assemble DNA arrays on nylon membrane (often referred to as DNA macroarrays) or glass-slide solid supports (DNA microarrays). Pat Browne and colleagues, at Stanford University, have pioneered the construction and application DNA microarrays (Brown and Botstein, 1999; DeRisi and Iyer, 1999), which include the building of a robotic microarrayer from component parts. The principles and an example of the application of a DNA microarray for transcriptome analysis (also referred to as differential gene expression) are shown in Fig. 3.

To measure relative differences in gene expression, sample DNA or RNA is labeled (normally by fluorescence) and hybridized to the array (Fig. 3). For example, mRNA from cells grown under standard culture conditions is labeled with the red fluorescent dye Cy3, and sample mRNA from a site of infection is labeled with the green fluorescent dye Cy5. After cohybridization to the microarray, the fluorescent intensities of each fixed DNA sample are read to determine the relative abundance of mRNA from the two test conditions. A red signal indicates gene expression of cells grown in culture, a green signal indicates gene expression only during infection, and a yellow signal indicates genes expressed in both conditions (Fig. 3). To date, most applications of DNA microarrays have been used on eukaryotic systems (Ross et al., 2000; Scherf et al., 2000). A useful web site for the construction and application of bacterial pathogen DNA microarrays is the (http://www.sghms.ac.uk/depts/medmicro/ {BUGAS website}).

Affymetrix Oligonucleotide Arrays Oligonucleotide arrays are constructed by in situ light-directed combinatorial nucleotide synthesis (Chee et al., 1996), a process termed "photolithography" (Fig. 4; see http://www.genechip.com/). Because Affymetrix DNA arrays (biochips) consist of in situ synthesized oligonucleotide sequences, they offer two major advantages over DNA microarrays: 1) greater sample

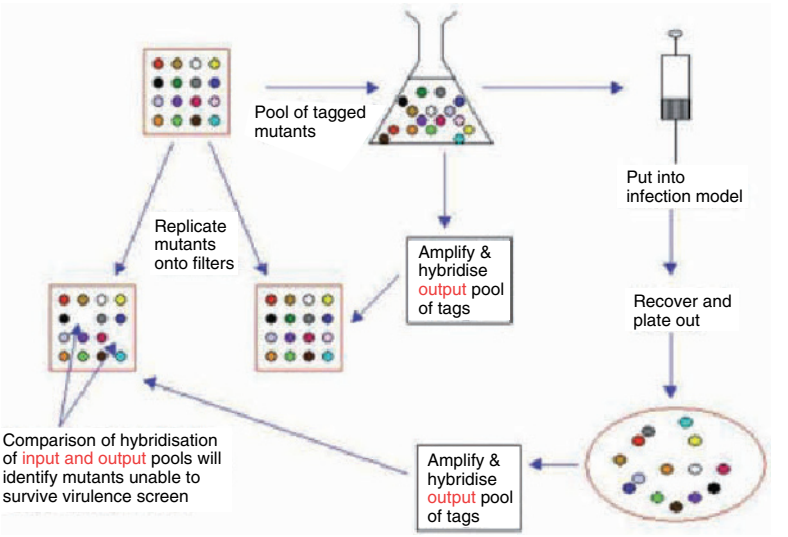

Fig. 3. Schematic illustrating the principles of a signature-tagged mutagenesis screen, which can distinguish virulent from nonvirulent mutants.

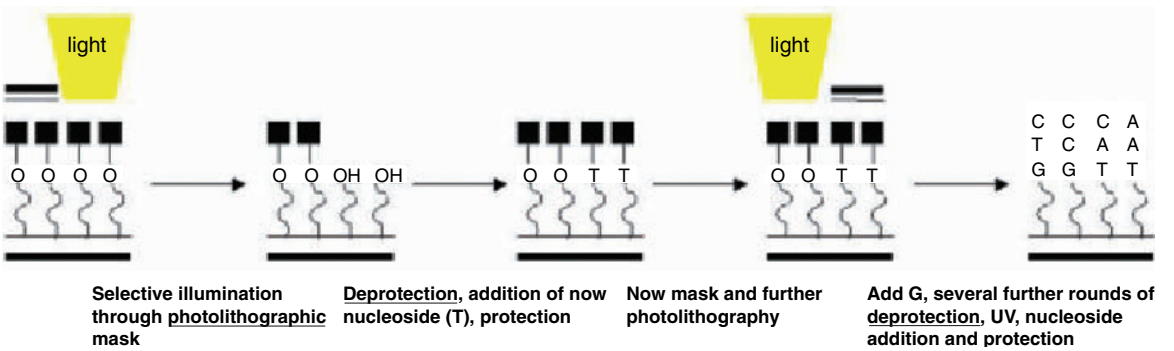

Fig. 4. Schematic showing stages in the in situ synthesis of an Affymetrix oligonucleotide array.

capacity (>50,000 samples per cm^2 compared with 4,000 samples per cm^2 for a typical DNA microarray) and 2) an ability to detect single nucleotide polymorphisms. However, due to cost and selective availability of biochips, Affymetrix technology is beyond the reach of most academic institutes. The large capacity of Affymetrix biochips has meant that their application has been used mainly for eukaryotic systems (Chiang and Mekalanos, 1998; Cho et al., 1998; Cho et al., 1999). However, synthesis of prokaryotic biochips containing several genome sequences (e.g., *E. coli*, *B. subtilis*, *H. pylori*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*) is planned.

Applications of High-Density DNA Arrays and Genomotyping

Perhaps the most straightforward application of DNA microarrays is hybridization test strain DNA (e.g., from clinical or environmental isolates) with the genome of a sequenced strain arrayed on the solid support. Thus, a comprehensive assessment of genome diversity of a large number of strains can be rapidly attained. The use of DNA microarrays to compare the genome complements of several strains has been termed "genomotyping." Among bacterial pathogens, such an approach will be an invaluable molecular epidemiological tool, allowing the sources and routes of transmission of economically and clinically important pathovars to be determined. By assessing correlates of pathogenicity, a basic understanding of the evolution of virulence can be gained. To date, microarrays have been reported in the identification of gene sequences absent in the attenuated *Mycobacterium bovis* strain BCG compared to virulent *M. tuberculosis* strain H37Rv (Behr et al., 1999) and have been applied to *S. cerevisiae* (Winzeler et al., 1999).

Other potential applications of microarrays to prokaryote analysis include: 1) differential gene expression (DGE) by hybridizing mRNA extracted under varying environmental condi-

tions; 2) DGE by comparing mutant to the wild-type strains, particularly to decipher regulatory networks; 3) testing genome plasticity of an individual strain by DNA hybridization; and 4) identifying single nucleotide polymorphisms (SNPs) by use of the Affymetrix DNA array.

Proteome Analysis

The case for global monitoring of mRNA applies equally to proteins, with the added advantage that post-translational modifications, which frequently play key roles in prokaryotic interactions, also can be studied. Proteomics, the study of the complete set of proteins that is expressed and modified by the entire genome in the lifetime of a cell, is an important rapidly evolving discipline, readily applied to prokaryotes.

2-D Gel Electrophoresis Protein Identification

Recent improvements in high-sensitivity biological mass spectrometry have provided a powerful adjunct to traditional 2D-gel electrophoresis (Pappin, 1997; Fernandez et al., 1998). Proteins cut out of a 2D-gel can now be peptide-mass-fingerprinted, and constituent peptides can be sequenced by mass spectrometry. New software takes data from mass spectrometry and uses it to find the best match in a sequence database, allowing one to go from a spot on a polyacrylamide gel electrophoresis (PAGE) gel to protein identification in a matter of hours (Fig. 1). Thus, the entire complement of soluble proteins expressed by a cell (the proteome) can be defined. This kind of approach already has been used to provide insights into the function of an anatomical subset of the proteome (such as the cell envelope; Qi, 1996). Proteome studies are made even more powerful when applied to an organism whose genome has been sequenced. Synergistic interactions between the two approaches maximize information return. For example, ORFan or FUN gene products can be identified as functional proteins. Proteome or partial proteome analysis has been reported for *M. genitalium*, *S. typhimurium*, and *M. tuberculosis* (Wasinger et al. 2000; O'Connor et al., 1997; Sonnenberg and Belisle, 1997; Jungblut et al., 1999; Tekaia et al., 1999). The continued *E. coli* proteome is on the http://web.bham.ac.uk web. A comprehensive web resource for mass spectrometrists is found on Base Peak (basepeak.wiley.com/).

Potential applications of 2D sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDSPAGE)/mass spectrometry analysis for prokaryotes include: 1) characterization of regulons and stimulons; 2) study of posttranslational modifications; 3) study of protein complexes; 4) identification of immunogenic proteins by immunoblotting; and 5) determination of mechanisms of drug action and identifying drug targets.

Protein-Protein Interaction Maps

Interactions between proteins mediate the majority of biological processes, and various biochemical assays have been developed to measure such interactions. The most widely applied is the yeast two-hybrid system. The two-hybrid system exploits the ability of two interacting proteins to fetch a transcription domain into the locality of a DNA-binding site that regulates the expression of an adjacent reporter gene (Fields and Song, 1989; Chien et al., 1991; Fields and Sternglanz, 1994). The system can be used to identify proteins that bind to a protein of interest or to define domains or residues critical for an interaction (Fields and Song, 1989; Chien et al., 1991; Fields and Sternglanz, 1994).

Protein-protein interaction maps of selected components of prokaryotes should provide invaluable data on structural components of the cell. Some recent examples where this has been applied include outer-membrane proteins, secretion systems, and mutation proteins (Williams et al., 1998; Day and Plano, 1998; Hartland et al., 1999; Hall and Matson, 1999).

Once all DNA, RNA, and proteins are known, it should be possible to compile complete interaction maps of the genome. This already has been accomplished for bacteriophage (55 proteins), and it should be possible to tackle prokaryotes. Indeed, a comprehensive analysis of protein-protein interactions in *S. cerevisiae* has been performed recently using exhaustive yeast two-hybrid screens (Uetz et al., 2000).

Studies and Practical Implications

A multidimensional analysis, looking at genome sequences, mutants, transcripts, and proteins, will result in a quantum leap in our understanding of the biology of prokaryotes. In determining the activity of large sets of genes, proteins, and the interactions between them, an important step towards constructing a functional model of the entire organism will be taken. This basic information will provide the framework for future research; for example, in bacterial pathogens, opportunities for vaccine design are unprece-

dented because the complete inventory of genes encoding every virulence factor and potential immunogen is available for selection. The combination of 2D-gel electrophoresis and immunoblot analysis of the whole organism, or a subset such as the cell envelope, should identify all immunodominant proteins. Indeed, in an attempt to identify a *N. meningitidis* vaccine target, over 350 candidate antigens based on the recently completed *N. meningitidis* type B genome sequence were expressed in *E. coli* and tested for their vaccine efficacy (Pizza et al., 2000). By deduction, approaches for the systematic mutagenesis of all genes in a genome will identify genes essential for the viability of the organism. Such genes/gene products are potential targets for drug design. The availability of the genome content of multiple organisms on a DNA microarray or an Affymetrix biochip should allow more accurate identification of organisms and, in a clinical setting, more rapid diagnosis. Exploitation of a database of nucleotide differences among strains should allow the design of a biochip to differentiate subtle differences between strains. Such a universal prokaryote biochip would have profound implications in studying the epidemiology, population genetics, molecular phylogeny and evolution of prokaryotes.

Genomics Glossary

Adapted from the (http://www.phrma.org/genomics/ website).

Affymetrix DNA chip: High-density array of evenly spaced in-situ synthesized oligonucleotides on a silicon support. The company Affymetrix produces these DNA arrays using in-situ, light-directed, combinatorial nucleotide synthesis. An Affymetrix DNA chip the size of a thumbnail can contain up to 50,000 oligonucleotide probes.

allelic replacement: The exchange of a gene via homologous recombination. This method is often used to specifically exchange a wild-type gene with a mutated gene to construct a rationally defined isogenic mutant.

apoptosis: The process by which cells are programmed to self-destruct at an appropriate moment in an organism's life cycle. If the apoptotic process malfunctions in a cell, uncontrolled cell growth may result and can contribute to the development of cancer.

bioinformatics: The science of informatics as applied to biological research. Informatics is the management and analysis of data using advanced computing techniques. Bioinformatics is particularly important as an adjunct to genomics research because of the large amount of complex data this research generates.

cloning vector: A DNA molecule originating from a virus, a plasmid, or the cell of a higher organism into which another DNA fragment of appropriate size can be integrated without loss of the vector's capacity for self-replication. Vectors introduce foreign DNA into host cells, where it can be reproduced in large quantities; examples are plasmids, cosmids, and yeast artificial chromosomes. Vectors are often recombinant molecules containing DNA sequences from several sources.

combinatorial chemistry: A technique for rapidly and systematically assembling a variety of molecular entities, or building blocks, in many different combinations, to create tens of thousands of diverse compounds that can be tested in drug discovery screening assays.

comparative genomics: The study of the degree of relatedness of complete genome sequences from different strains or organisms. Such studies provide important taxonomic and evolutionary insights.

contigs: Groups of clones representing overlapping regions of a genome.

differential gene expression (DGE): Comparative analysis of mRNA levels of individual genes from cells functioning in different environments. This method is frequently performed at the genome level as transcriptome analysis.

directed mutagenesis: A specific alteration of a cloned gene in vitro before the gene is placed back into the organism.

DNA microarray: High-density array of evenly spaced DNA spots of generally 100 to 1,000 bp gridded onto glass slides. Typically, about 4,000 individual gene fragments can be spotted onto a microscope slide.

DNA macroarray: High-density array of evenly spaced DNA spots of generally 100 to 1,000 bp gridded onto nylon membranes. Generally, arrays have a lower density than Affymetrix chips or microarrays and generally they are not amenable to differential fluorescence hybridizaton analysis.

expressed sequence tag (EST): A short strand of DNA (ca. 200 bps), which is part of a cDNA. Because cDNAs correspond to a particular gene in the genome, and ESTs correspond to particular cDNAs, ESTs can be used to help identify unknown genes and to map their position in the genome.

functional genomics: The process of determining the function of individual genes at a genome-wide scale.

gene library: A collection of cloned DNA fragments, which, taken together, represent the entire genome of a specific organism. Such libraries or "gene banks" are assembled so as to allow the isolation and study of individual genes. Gene libraries are produced by first breaking up

or "fractionating" an entire genome. This fractionation can be accomplished either by sonication or other physical methods.

gene expression: The process by which the information in a gene is used to create proteins.

genetic polymorphism: A difference in DNA sequence among individuals, groups or populations. Genetic polymorphisms may be the result of chance processes or may have been induced by external agents (such as viruses or radiation). If a difference in DNA sequence among individuals has been shown to be associated with disease, it usually will be called a genetic mutation. Changes in DNA sequence, which have been confirmed to be caused by external agents, are also generally called "mutations" rather than "polymorphisms."

genetic map: A map of a genome that shows the relative positions of the genes and/or markers on the chromosomes.

genome: All the genetic material in a particular organism; its size is generally given as its total number of base pairs.

genomic library: A collection of clones made from a set of randomly generated overlapping DNA fragments representing the entire genome of an organism.

genomics: The study of genes and their function. Recent advances in genomics are bringing about a revolution in our understanding of the molecular mechanisms of disease, including the complex interplay of genetic and environmental factors.

homologies: Similarities in DNA or protein sequences between individuals of the same species or between species.

hybridization: The process of joining two complementary strands of DNA or one of DNA or of RNA to form a double-stranded molecule.

messenger RNA (mRNA): The DNA of a gene is transcribed into mRNA molecules, which then serve as templates for protein synthesis.

mutation: A change, deletion, or rearrangement in the DNA sequence that may lead to the synthesis of an altered inactive protein or to the loss of the ability to produce the protein.

oligonucleotide: A molecule made up of a small number of nucleotides, typically fewer than 25. Oligonucleotides are frequently used as DNA synthesis primers in sequencing, in PCR, or in Affymetrix DNA arrays.

orthologues: Homologous genes between species.

paralogues: Homologous genes within the same strain/species.

pharmacogenomics: The science of understanding the correlation between an individual patient's genetic makeup (genotype) and their response to drug treatment. Some drugs work well in some patient populations and not as well in others. Studying the genetic basis of patient response to therapeutics allows drug developers to more effectively design therapeutic treatments.

physical map: A map of the locations of identifiable landmarks on DNA (e.g., restriction enzyme cutting sites, genes), regardless of inheritance. Distance is measured in base pairs. For the human genome, the lowest-resolution physical map is the banding patterns on the 24 different chromosomes; the highest-resolution map would be the complete nucleotide sequence of the chromosomes.

pleiotropy: One gene leading to many different phenotypic expressions. An example of a pleiotropic gene is *phoP* in *Salmonella*, which controls over 40 genes associated with virulence and survival inside and outside the host.

proteome: The complete set of proteins that is expressed and modified by the entire genome in the lifetime of a cell.

proteomics: The study of the proteome using technologies of large-scale protein separation and identification.

rational drug design: A process for designing drugs based upon the structure of the protein target of the drug. This approach has been enhanced recently through use of combinatorial chemistry and high-throughput screening.

restriction fragment length polymorphism (RFLP): Variation between individuals in DNA fragment sizes produced after cutting DNA with specific restriction enzymes. Polymorphic sequences that result in RFLPs are used as markers on both physical maps and genetic linkage maps. Almost all RFLPs are caused by mutations in the restriction enzyme recognition site.

sequencing: Determining the order of nucleotides in a DNA or RNA molecule, or determining the order of amino acids in a protein.

shotgun method: Cloning of DNA fragments randomly generated from a genome.

signature-tagged allele replacement (STAR): A modification of STM where mutants are DNA-tagged systematically prior to allele replacement during their construction.

signature-tagged mutagenesis (STM): Mutants generated by transposon mutagenesis are tagged with 20-base sequences, which act as unique identifiers. The pool of tagged mutants allows one to study en masse the relative abundance and survivability of all mutants in any given environment.

single nucleotide polymorphism (SNP): A single nucleotide alteration in a gene, frequently characteristic of a genetic trait. A SNP can be assayed en masse using an Affymetrix DNA array.

telomere: A series of repeated DNA sequences located at the end of a chromosome.

Telomeres serve to assure that a chromosome is replicated properly each time a cell divides. Each time a cell divides, some of the telomere is lost in the process. Eventually little or no telomere remains and the cell dies.

transcriptome analysis: The simultaneous analysis of all transcripts within a cell by hybridizing mRNA to a DNA micro-, macro- or Affymetrix DNA array.

transposable elements: A class of DNA sequences that can move from one chromosome or plasmid site to another. Transposable elements are frequently referred to as jumping genes.

transposon mutagenesis: Insertion of a transposable element into a genome (usually bacterial) to generate a pool of random mutants.

toxicogenomics: A new scientific subdiscipline that combines the emerging technologies of genomics and bioinformatics to identify and characterize mechanisms of action of known and suspected toxicants. Currently, the premier toxicogenomic tools are the DNA microarray and the DNA chip.

wild type: The form of an organism that occurs most frequently in nature.

CHAPTER 1.10

Genomics and Metabolism in *Escherichia coli*

MARGRETHE HAUGGE SERRES AND MONICA RILEY

Escherichia coli as a Model Organism

When did *Escherichia coli* attain the status of a model organism? Over many decades biochemical researchers used *E. coli* as a source of enzymes supplementing the more common sources such as rat liver, pigeon breast and spinach, but that practice in itself did not confer the status of model organism. A giant step was taken in 1955 when the Carnegie Institute of Washington Biophysics group headed by R.B. Roberts published a large monograph reporting its own work and the work of others on the intermediary metabolism of *E. coli* (Roberts et al., 1955).

Model organism status was gained when genetic transfer capabilities were discovered (Wollman et al., 1959; Lederberg and Tatum, 1946). In this same era, Maaloe and colleagues untangled the dynamics of *E. coli* cell physiology by documenting the effects of shifts in growth conditions on macromolecule synthesis (summarized in Maaloe and Kjeldgaard, 1966). Elucidation of the operon theory of regulation of gene expression (by means of a combination of bacterial genetics and enzyme assays; Pardee et al., 1959; Jacob and Monod, 1961) firmly established *E. coli* as a lead microorganism for molecular biology research.

Over 50 years of intense investigation of laboratory strains of *E. coli* have produced a vast amount of experimental information. The unique repository of summarized information on *E. coli* genetics, cell biology, physiology, metabolism, evolution and population biology is the two-volume, 155-chapter, and nearly 3000-page multi-author work coordinated by senior editor F. C. Neidhardt and published by ASM Press (Neidhart, 1996). The object of most of this study has been the nonpathogenic strain K-12. Medical microbiology throughout this time and to the present dealt with entero- and uropathogenic *E. coli* strains, but this essay is about the nonvirulent strain K-12.

Escherichia coli plays a prominent role in the new field of genomics, the study of entire genomes, their chemistry, and the molecular biology of all gene products. Inasmuch as gene cloning allows introduction of genes from any source into *E. coli* (Sambrook et al., 1989), this organism has become a tool for studying its own molecular biology as well as that of other taxa. One of perhaps 25 microorganisms for which an entire nucleotide sequence is known (Blattner et al., 1997), *E. coli* plays a prominent role in reaping biological information from the complete nucleotide sequences of genomes.

The Genomics of *Escherichia coli*

The complete sequence of the 4.7 Mb chromosome of *E. coli* strain MG1655 was announced in 1997 (Blattner et al., 1997). A substantial portion of another K-12 strain W3110 was completed independently (Itoh et al., 1999).

What is the point of having a complete genome sequence of an organism? When we understand how every gene product (protein or RNA) of a genome functions and how those proteins and nucleic acids interact, we will understand how a single-cell organism lives, derives energy and motility from foodstuffs, adapts its processes to changing circumstances, and regularly reproduces itself. The DNA sequence itself does not give this complete knowledge of course, but it does set us in this direction. With the genomic sequence in hand—even one from an organism as well studied as is *E. coli*—much remains to be discovered. At least some, if not all, future work on this organism will be based on the broad platform of knowledge from two sources: decades of experimentation and the sequence of the entire genome.

Complete genomic sequences also may be used to reconstruct evolutionary history (possible events, paths and mechanisms of evolution) from examining minutely the relationships between comparable sequences in many life forms. Sequences of ribosomal RNAs have been particularly successful information sources for

revealing the structure of the tree of life (Woese, 1987). Trees for proteins are presenting complexities difficult to untangle. Determining what proteins are truly comparable among a set of organisms (truly orthologous) is made easier by availability of complete genome sequences. In time with more information on contemporary organisms, reconstruction of the path of the evolution on earth will become more straightforward.

What has the complete sequence of the *E. coli genome* so far revealed about its biology and evolution? The great advantage of assembling information on a model organism is that so much experimental work has been done on its biochemistry, metabolism, cell biology, physiology, and genetics. As a result, detailed information on a major fraction of the total genomic sequence can be understood in terms of the known gene functions and gene products (RNA and proteins). As the databases on gene sequences from many organisms grow rapidly, chances that function by similarity to other known genes can be imputed continue to increase. Thus the fraction of totally unknown genes in *E. coli* is much lower than for other organisms. Table 1 summarizes the kinds of gene products made in *E. coli* K-12 strain MG1655, both known and imputed by sequence similarity (for updates see [{genprotec.mbl.edu}{GeneProtEC database]). About half of the gene products are known from experimental biology, about one quarter are assigned functions imputed from sequence similarity to known gene products, and the remainder are open reading frames of unknown function.

Of known and tentatively known genes, the largest category encodes enzymes, followed by categories that encode transporters and regulators. (Smaller functional categories include cellular structural components, factors, and RNAs.)

Table 1. Numbers of *Escherichia coli* genes of different types.

Category	Experimental	Putative	Total
Enzymes	955	361	1,316
Transport proteins	281	295	576
Regulators	208	121	329
Factors	103	44	147
Structures	93	37	130
RNAs	114		114
Membrane	50	49	99
Carriers	30	17	47
Leaders	12		12
External origin	284		284
Phenotype	117		117
ORFs			1,225
Total	2,247	924	4,396

Abbreviation: ORF, open reading frame.

The number of genes for enzymes is known to be even higher than the current tally because genes have not been identified as yet for 52 enzymes (known biochemically to be present in *E. coli*; Table 2). Information on transporters (http://www.biology.ucsd.edu/~iapulsen/transport/) and regulators (http://www.cifn.unam.mx/Computational_ Biology/regulondb/) (the next largest categories) has been assembled into accessible databases.

A framework for designating functions of gene products was devised (Riley, 1993; Riley and Labedan, 1996) and used to classify the physiological roles of gene products of sequenced genomes. The assignments for *E. coli* have been improved as understanding has increased. Current designations can be accessed at the [{GenProtEC database}{genprotec.mbl.edu}]. However, it has become increasingly apparent that the assignment of just one role to any one-gene product is often artificial. For instance, many enzymes and enzyme subunits as well as transport elements are counted as "enzymes" when in fact they are located in the inner membrane and thereby constitute an important part of the cell structure. Because they are not registered as membrane proteins, the count of total membrane proteins in the cell is artificially low. Other multi-role cases also exist, so the division of function in Table 1 is to some extent artificial.

How densely packed is the *E. coli* chromosome with coding information and regulatory sequences? Some genes abut precisely, such as genes within operons; a few even have an overlap of the stop codon of one protein with the f-Met initiating codon of the next. Two genes are particularly dense in information, giving rise to two polypeptides from each transcript (the DNA polymerase III gamma subunit from the *dnaX* gene and spermidine biosynthesis gene *speD*). How much is there of intergenic DNA, noncoding DNA that falls between coding regions? Rudd finds 11.4% of the genome in intergenic spaces and has analyzed them for presence of repeat sequences (Rudd, 1999).

Some genes clearly have been incorporated into the *E. coli* chromosome from other sources from time to time. Presence and absence of genes and operons in different *E. coli* strains may signal extrachromosomal origins. Genes that come from the outside and vary in number and genetic location from strain to strain are genes of prophages (most no longer viable as independent phages), insertion elements, or transposons that replicate themselves and move within the genome. These constitute 6.4% of the genome of *E. coli* K-12 strain MG1655 (see class of genes of extrachromosomal origin in the {GenProtEC database}({genprotec.mbl.edu}). An early

Table 2. Enzymes purified from *Escherichia coli*, but not as yet identified with genes.

EC[a] number	Enzyme
1.1.1.111	Imidazol-5-yl-lactate dehydrogenase
1.1.1.214	2-Dehydropantoyl-lactone reductase (B-specific)
1.1.1.5	Diacetyl reductase
1.1.1.75	(R)-Aminopropanol dehydrogenase
1.1.3.3	Malate oxidase
1.1.99.14	Glycolate dehydrogenase
1.2.1.16	Succinate semialdehyde dehydrogenase II, NAD-dependent
1.2.1.19	Aminobutyraldehyde dehydrogenase
1.2.7.1	Pyruvate synthase (pyruvate ferredoxin reductase)
1.3.1.10	Enoyl-ACP-reductase, NADPH-specific
1.6.2.5	NADPH-cytochrome-c2 reductase
1.6.99.2	NAD(P)H dehydrogenase (quinone)
1.8.4.2	Glutaredoxin reductase
2.3.1.4	Glucosaminephospho-*N*-acetyltransferase
2.4.2.5	Nucleoside ribosyltransferase
2.6.1.29	Diamine transaminase
2.6.1.31	Pyridoxamine-oxaloacetate transaminase
2.6.1.38	Histidine transaminase
2.6.1.54	Pyridoxamine-phosphate transaminase
2.7.1.121	Phosphoenolpyruvate-glycerone phosphotransferase
2.7.1.23	NAD kinase
2.7.1.24	Dephospho-CoA kinase
2.7.1.7	Mannokinase
2.7.7.18	Nicotinate-nucleotide adenylyltransferase
2.8.1.2	3-Mercaptopyruvate sulfurtransferase
3.1.1.17	Gluconolactonase
3.1.3.-	NADP phosphatase
3.1.2.2	Palmitoyl-CoA hydrolase
3.1.3.27	Phosphatidylglycerolphosphatase C
3.2.1.68	Isoamylase
3.2.2.14	NMN nucleosidase
3.2.2.5	NAD(+) nucleosidase
3.5.1.2	Glutaminase A
3.5.1.2	Glutaminase B
3.5.1.42	Nicotinamide-nucleotide amidase
3.6.1.-	Dihydroneopterin triphosphate pyrophosphohydrolase
3.6.1.-	Dihydroneopterin monophosphate dephosphorylase
3.6.1.21	ADP-sugar pyrophosphatase
3.6.1.22	NAD(+) pyrophosphatase
3.6.1.9	Nucleotide pyrophosphatase
4.1.1.36	Phosphopantothenoylcysteine decarboxylase
4.1.3.9	2-Hydroxyglutarate synthase
4.4.1.1	Cystathionine gamma-lyase/L-cysteine desulfhydrase
4.4.1.15	D-Cysteine desulfhydrase
4.5.1.2	3-Chloro-D-alanine dehydrochlorinase
4.6.1.2	Guanylate cyclase
5.1.99.1	Methylmalonyl-CoA epimerase
5.3.1.13	D-Arabinose-5-phosphate isomerase
5.4.2.3	Phosphoacetylglucosamine mutase
6.3.2.5	Phosphopantothenate cysteine ligase
6.3.4.3	Formate-tetrahydrofolate ligase
6.4.1.3	Propionyl-CoA carboxylase

Abbreviations: CoA, coenzyme A; NAD, nicotinamide adenine dinucleotide; NADP nicotinamide adenine dinucleotide phosphate; NADPH, nicotinamide adenine dinucleotide phosphate reduced form; NMN, nicotinamide mononucleotide.
[a]EC, Enzyme Comission.

approach to identifying such acquired genes was based on comparing genetic maps to find genetic information present in one bacterial genus not in a closely related genus (Riley and Anilionis, 1978). Comparing gene contents of laboratory strains and pathogens identifies "pathogenicity islands" that may have been incorporated by the pathogenic strains (Ohnishi et al., 1999; Perna et al., 1998). Methods of identifying horizontally transferred genes involve differences in base composition and codon usage of genes (Danchin et al., 2000; Lawrence and Ochman, 1998; Medigue et al., 1991; Mrazek and Karlin, 1999; Ochman, 2000). Estimates of the total content of relatively recently acquired genes in the *E. coli* K-12 MG1655 genome are around 17% (Lawrence and Ochman, 1998).

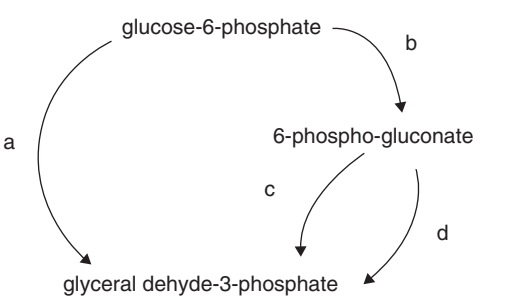
The Versatile Metabolism of *Escherichia coli*

Escherichia coli is a very versatile organism that can exist as an aerobe, anaerobe, or as a facultative anaerobe that can ferment sugars or amino acids (and can degrade proteins, polysaccharides and nucleic acids to provide the low molecular weight material). When oxygen is the ultimate electron acceptor for an oxidative chain, the organism is growing by aerobic respiration, but when nitrate or organic compounds such as fumarate are the final electron acceptors, the organism is growing by anaerobic respiration. Glucose can generate energy in conversion to triose phosphate by glycolysis, the pentose phosphate pathway or the Entner-Douderoff pathway (Fig. 1). Other sugars are converted to glucose or to intermediates in these pathways. When the available carbon source is further down the energy scale, such as acetate or succinate, the gluconeogenesis pathway is invoked to generate necessary precursors for biosynthetic pathways.

Thus many alternate paths from different starting points are available to support the life of *E. coli*, all generating energy and reducing power for biosynthesis, some more efficient than others. Regulatory machinery detects the availability of substrates for catabolism and the presence of suitable electron acceptors for oxidative pathways. Regulation induces or activates the appropriate enzymes for the appropriate pathways.

Escherichia coli can grow on rich media containing digests of proteins and many pre-made organic compounds, or it can make do on a minimal medium that provides one organic carbon source (such as glucose), an organic or inorganic source of nitrogen, and inorganic salts (as sources of K, Na, Cl, P, S, Mg, Fe, and trace elements). The versatility is reflected in the regulation machinery that induces synthesis of enzymes necessary for the available energy source and that turns on biosynthetic pathways when required substances are absent or shuts them down by feedback inhibition or repression when they are present in the environment.

It might be supposed that a chromosome containing over 4,400 genes (about 1,000 coding for enzymes) is necessary for *E. coli* to grow on defined minimal medium (Table 1). However, this is only part of the story. Versatility and a certain amount of redundancy account for some of the genetic capacity. Examples are present in the catabolic metabolism from glucose to glyceraldehyde-3-phosphate (Fig. 1). Also, the early steps of gluconeogenesis provide an example of alternate pathways to generate phosphoenol pyruvate from malate (Fig. 2). After pyruvate,



a. Glycolysis
b. Pentosephosphate pathway, oxidative branch
c. Entner-Doudoroff pathway
d. Pentosephosphate pathway, non-oxidative branch

Fig. 1. Degradation of glucose 6-phosphate via: a) glycolysis; b) pentose phosphate pathway, oxidative branch; c) Entner-Douoroff pathway; and d) pentose phosphate pathway, non-oxidative branch.

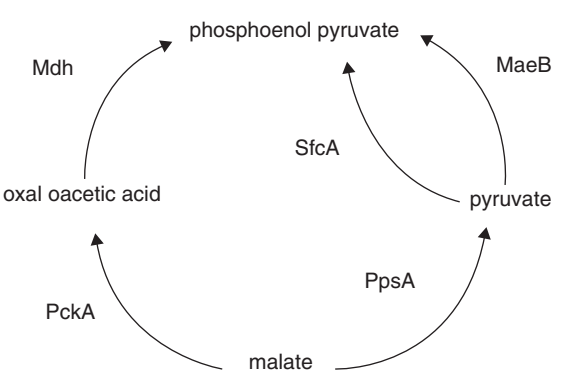


Fig. 2. Synthesis of phosphoenol pyruvate pathway from malate in the gluconeogenesis pathway. Mdh indicates Malate dehydrogenase; MaeB, Maleic enzyme; SfcA, NAD-linked Malate dehydrogenase; PpsA, Phosphoenolpyruvate synthase; PckA, Phosphoenolpyruvate carboxylase.

the path chosen depends on whether conditions are aerobic or anaerobic and what electron acceptors are present. During fermentative metabolism, *E. coli* may reduce phosphoenol pyruvate to a variety of compounds (Fig. 3), and alternatives are available at almost every turn. For instance, many "contingency" pathways evidently are present to deal with circumstances as they come into play. Fitting this description are the many pathways that bring carbohydrates (other than glucose) into glycolysis. Some of these feeder pathways are tailored for aerobic or anaerobic conditions. There are alternate glycerate dehydrogenases that cover this possibility.

In nitrogen metabolism of *E. coli*, inorganic ammonium ion, nitrite or nitrate is sufficient as a source of nitrogen. Should organic sources of nitrogen be available, many transaminases and amidotransferases can harvest amino or amido nitrogen from organic compounds.

Many pathways bifurcate where there are two enzymes available for a given step. In some cases, each one of the pair uses a different cofactor. This allows the organism greater flexibility in case one of the cofactors is not available in the cell. For examples of bifurcations, see Table 3. In the formyl tetrahydrofolate (THF) biosythesis pathway, THF is converted to 5,10-methylene-THF by four alternate paths (1a–d). Two of these paths contain 1 step (1a, b) whereas the other two (1c, d) carry out the conversion in two steps. Purine metabolism provides two examples of bifurcations: 1a, b (5-phosphoribosyl-glycinamide to 5′-phosphoribosyl-*N*-formylglycinamide) and 2a, b (xanthosine-5-phosphate to guanosine monophosphate [GMP]), all of which are one-step reactions. Table 4 lists instances of more than one enzyme known in *E. coli* to carry out the same or almost the same reaction. In some cases the physiological conditions under which each enzyme is active are known, but not all. Some of the multiple enzymes are used in different pathways with different end products and thus could be regulated differently, such as the three diaminohydroxypyrimidine (DAHP) synthetases (2-dehydro-3-deoxyphosphoheptonate aldolase) in aromatic amino acid biosynthesis. The three enzymes are regulated separately by tyrosine, phenylalanine or tryptophan (Pittard, 1996). Some of the enzymes listed in Table 4 are isozymes in that they are closely similar in amino acid sequence as well as reaction mechanism, whereas others carry out the same reaction but have quite different amino acid sequences (see Riley and Serres, 2000 for examples). Clearly *E. coli* possesses far more than a minimum set of enzymes needed to grow at 37°C aerobically on a glucose minimal medium. Many fewer than the 4,400 genes would be needed for that purpose.

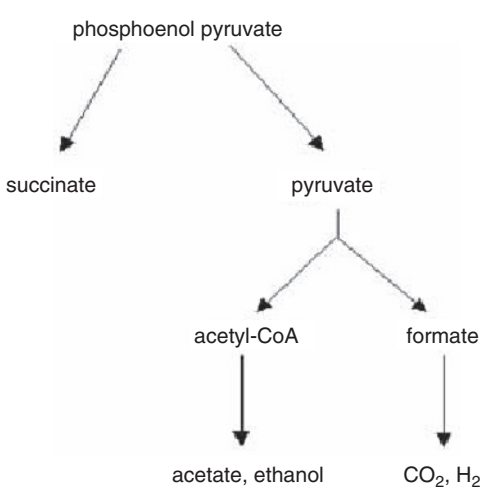

Fig. 3. Fermentative metabolism of phosphoenol pyruvate.

The multiplicity of genetic capacity in *E. coli* is not only present among enzymes but also extends to transporters and regulators. A system has been constructed for classifying transporters (http://www.biology.ucsd.edu/~ipaulsen/transport/) by type (Saier, 2000). *Escherichia coli* frequently has more than one type of transport system for any given compound to be transported. Examples are given in Table 5. As to regulators, action at different levels means that several regulators may act on a single operon to control its expression. The *lac* operon is under the control of the specific *lac* repressor and of the more general cyclic-AMP catabolism regulator, and it is subject to broad controls rendered for switches between aerobic and anaerobic growth.

Because *Escherichia coli* is rich with alternative mechanisms, multiplicity of options and some redundancy, its genome is far from minimal. There have been attempts to define a minimal bacterial genome (Hutchison et al., 1999; Kyrpides et al., 1999). It goes without saying that one must speak of a minimal genome under a stated set of conditions. Is it to allow growth as an intracellular parasite? Or is it to allow growth outside a host but in rich medium of a certain composition? Or is the condition to be growth in minimal medium of a certain composition? Is the intention to describe a genome that gives the organism a certain degree of adaptability or one that simply equips it for survival under only one condition of growth? Evidently there is not just one minimal genome, but rather a set of sparse genomes suitable to sustain life under different circumstances from rich to spare. It may be that the estimates of between 650 and 800 Kb for *Mycoplasma* spp. are at or near the minimum for those organisms.

Table 3. Examples of identical substrate-to-product conversions by multiple pathways.[a]

Pathway	Rx[b]	Gene Prod	EC[c]	Reactions
Asparagine biosynth.	1a	AsnA	6.3.1.1	L-Aspartate + ATP + NH_3 + H_2O = L-asparagine + Pi + AMP
	1b	AsnB	6.3.5.4	L-Aspartate + ATP + L-glutamine + H_2O = L-asparagine + L-glutamate + AMP
FormylTHF biosynth.	1a	Gcv[d]		THF + L-glycine + NAD = 5,10-methylene-THF + CO_2 + NH_3 + NADH + H^+
	1b	GlyA	2.1.2.1	THF + L-serine = 5,10-methylene-THF + H_2O + L-glycine
	1c	MetH	2.1.1.13	THF + L-methionine = 5-methyl-THF + homocysteine
		MetF	1.7.99.5	5-Methyl-THF + NAD = 5,10-methylene-THF + NADH
	1d	FolA	1.5.1.3	THF + NADP = 7,8-dihydrofolate + NADPH
		ThyA	2.1.1.45	7,8-Dihydrofolate + dTMP = 5,10-methylene-THF + dUMP
Glycogen catabolism	1a	AlP	2.4.1.1	Maltodextrins + phosphate = maltotetraose + glucose-1-phosphate
	1b	Isoamylase	3.2.1.68	Maltodextrins = maltotetraose

Abbreviations: DTDP, deoxythymidine diphosphate; FKBP, FK-506-binding protein. Refer to footnotes in Table 3 for all other abbreviations.

[a]1, indicates the N-terminal, and 2, the C-terminal, part of the molecule has the activity.

Table 5. Examples of multiple transporters for the same compound.

Compound	Transporter	Gene(s)	Comments
Galactose	ABC superfamily	*mglA, B, C*	
	MFS family	*galP*	
Gluconate	GntP family	*gntU*	Low affinity transporter
	GntP family	*gntT*	High affinity transporter
	GntP family	*gntP*	Possibly additional "substrates"
	GntP family	*idnT*	Primarily L-idonate transporter
Nitrite	FNT family	*nirC*	Nitrite uptake
	MFS superfamily	*narK*	Nitrite extrusion
	MFS superfamily	*narU*	Nitrite extrusion
Nucleosides	MFS superfamily	*nupG*	
	NUP family	*nupC*	
Phenylalanine	APC family	*pheP*	
	APC family	*aroP*	Also transports tyrosine
Phosphate	ABC superfamily	*pstABCS*	High-affinity transporter
	PiT family	*pitA*	Low-affinity transporter
	PiT family	*pitB*	Low-affinity transporter
Proline	ABC superfamiliy	*proVWX*	Also transports glycine, betaine
	APC family	*proY*	Cryptic
	MFS superfamily	*proP*	Also transports betaine
	SSS family	*putP*	
Putrescine	ABC superfamily	*potFGHI*	
	ABC superfamily	*potDCBA*	Also transports spermidine
	APC family	*potE*	Also transports ornithine

Abbreviations: ABC, ATP-binding cassette; MFS, major facilitator superfamily; GntP, gluconate permease; FNT, formate nitrite transporter; NUP, nucleoside uptake permease; PiT, inorganic phosphate transporter; APC, amino acid polyamine choline; SSS, solute sodium symporter.

Genes and Enzymes

The gene-enzyme relationship can be complex. The insightful doctrine of "one gene-one enzyme," originally set forth by Beadle and Tatum (1941), paved the way for decades of fruitful progress in understanding what a gene does. Later Benzer articulated the relationship of a gene to *trans* complementation. Based on phage studies, he saw that the basic gene component,

which he dubbed "the cistron" (Benzer, 1955), was able to function as an independent complementing unit and encode one polypeptide chain.

Today the extent and sequence of many genes and their products can be known with more precision, i.e., what they do in the cell and the phenotypes brought on by their absence. It can be seen that one functional protein complex may require many genes, and a single polypeptide with many functions may require only one gene. Clearly complex structures such as ribosomes require the coordinated action of several assembly proteins to put together in correct spatial and temporal relationship the many protein and RNA constituents of the structure. Some examples of complex gene-enzyme relationships are listed in Table 6. The stoichiometry of gene : polypeptide : enzyme : reaction can be 3 : 3 : 3 : 1 as for the three isozymes of fumarase, where there are three genes—one for each polypeptide—but only one reaction. For the fatty acid degradation polypeptide FadB there is one gene, one polypeptide, one enzyme, but four separate catalytic reactions. The example of TrpD (a tryptophan biosynthesis enzyme) is more complicated. The C-terminal part of TrpD is a straightforward 1 : 1 : 1 : 1 enzyme for EC reaction 2.4.2.18. In addition the N-terminal glutamine amidotransferase part of TrpD forms a heterotetrameric complex with TrpE to generate anthranilate synthase (EC 4.1.3.27). The TrpDE encoded enzyme uses glutamine or ammonia as a nitrogen donor, though TrpE can carry out the reaction by itself using ammonium as the nitrogen donor. This situation is similar to the reaction carried out by imidazole glycerol phosphate synthase (EC 2.4.2.-) where the histidine biosynthesis (HisFH) enzyme complex uses glutamine as the nitrogen donor and HisF alone uses ammonium as the nitrogen donor.

Succinate dehydrogenase is an example of a multiple subunit enzyme. Many dehydrogenases take this form. The relationships are 4 : 4 : 1 : 1, four genes and polypeptides and one four-subunit enzyme for one reaction. For spermidine biosynthesis gene *speD*, whose transcript is processed to give two different polypeptides that come together as a heterodimer, the ratio is 1 : 2 : 1 : 1, and in a similar case the *dnaX* gene is transcribed into two polypeptides that function as separate subunits in the DNA polymerase III holoenzyme. One of the most complex enzymes in *E. coli* is the large pyruvate dehydrogenase multienzyme complex. With three genes making three independent enzymes that complex together to carry out one overall reaction, the ratio can be expressed as 3 : 3 : 1 : 3. Yet another type of complexity not mentioned in Table 6 follows. The two homodimers PheA and TyrA of phenylalanine and tyrosine biosynthesis, respectively, both have chorismate mutase activity (EC 5.4.99.5). Each has a different second reaction: PheA has prephenate dehydratase activity (EC 4.2.1.51) and TyrA has prephenate dehydrogenase activity (EC 1.3.1.12). Each would need to be described as 1 : 1 : 1 : 2. These and other similar variations illustrate the complexity and variations involved in assembling the elements of enzymes for metabolic functions from the information encoded in the DNA of genes. It now is known that the simple view of one gene making one enzyme is not always the case. Interpreta-

tion of phenotypes of mutants and functions of genes takes this complexity into account.

Molecular Evolution

Multiple Enzymes

The versatility of *E. coli* is seen in the cases of both multiple enzymes used for one reaction and multiple reactions catalyzed by one enzyme that is a single protein used in more than one context. The *lpdA* gene encodes lipoamide dehydrogenase. This enzyme is a necessary component of the two similar dehydrogenase complexes, the pyruvate and oxalglutarate dehydrogenase complexes. It is also a necessary part of the glycine cleavage complex which releases CO_2 from glycine. This kind of multiple use of single proteins has been called "moonlighting" (Jeffery, 1999). Moonlighting also could play a role in molecular evolution. If a gene that has more than one function is duplicated, it is easy to picture that one of the two copies might evolve to better carry out one function while the other copy might concentrate on the other function. In time, three specialized *lpdA* genes and proteins, each especially fitted for one of the three roles, might be seen. This scenario is a variation of the evolutionary mechanism "enzyme recruitment" that pictures cooption of a protein with one function to accomodate to another related function (Ahmad and Jensen, 1988; Jensen, 1976).

Fused Genes

Fused genes also reflect changes over time. Some of the genes of *E. coli* act as if two or more independently functioning genes have fused to give a multimodular gene with two or more independent functions. Such fusions are easiest to find in enzymes, but also exist in regulators (such as those for both sensor and response, which are in the same gene, e.g., *arcB*). In transport, phosphotransferase enzymes IIA, IIB and IIC are found sometimes in one polypeptide (NagE), sometimes in pairs (FrvA = IIA and FrvB = IIBC), or divided into three separate genes and polypeptides (CelC = IIB, CelA = IIC and CelB = IIA).

Multimodular proteins seem to have undergone fusions relatively recently in evolution as is indicated by the different patterns of fusion found in different microorganisms (Crawford, 1975). Multimodularity can cause artifact in procedures that search for sequence similarities among proteins. The separate modules each with a unique evolutionary history must be recognized and separated, if true sequence relationships are to be identified and quantified (Riley and Labedan, 1996; 1997).

Molecular Mechanisms of Change

What other aspects of molecular evolution are brought forward by the study of genomics and comparative genomics? From the point of view of chemistry of DNA, molecular mechanisms of evolution have been proposed for many years. Point mutations and frameshifts predominate at close distances. Comparisons of either DNA or protein sequences of related genes in related organisms often reveal that small insertions and deletions have also occured, resulting in gaps in the alignments. One does not know whether the gaps represent replication errors or incorporation or losses of oligonucleotides from genes. New functions are generally believed to have been created over time first by duplication and then by divergence. Acquisition of DNA from the outside contributes to change when foreign DNA (integrated by recombination into the genome) is retained. Rearrangements of genetic material within the chromosome also occur, changing gene order between genera as between *E. coli* and *Salmonella enterica* (Riley and Labedan, 1997) and among strains of *E. coli*. These rearrangements do not seem to affect integrity of the chromosome or the phenotype of the organism.

Does knowledge of the complete sequence of a genome offer an opportunity to understand the molecular basis of evolution any better? Now with fully sequenced genomes, detailed analysis of chromosomal sequences and comparisons between organisms provide examples of the kinds of changes that can underlie evolutionary change. Comparisons of whole genomes give information on acquisition/loss of genes and occurrence of rearrangements. Construction of trees for comparable sequences among many organisms (orthologous relationships) does not depend on having complete genome sequences. On the other hand, with complete genome sequences true orthologous pairs can be identified with more confidence. In addition, with complete genome sequences, sets of related sequences within any one organism (paralogous relationships) can be studied and give information on families of proteins descended during ancient and recent evolution from common ancestors.

Ancestral Proteins

Ancestors of a family of proteins present in all branches of the tree of life are believed to have arisen early in evolution. Duplication within ancestral organisms provided copies of an ances-

tral gene that could become specialized by divergence. Because the functions of so many *E. coli* proteins are known, the composition and functions of groups of sequence-similar genes and proteins can clarify mechanisms of evolution (Labedan and Riley, 1999). The sequence-similar paralogous groups of earliest origins will have counterparts in all or most other organisms, such as the set of 80 ATP-binding-cassette (ABC) transport proteins. Sequence-similar groups of more recent origin can be identified by the fact that they exist only in some related species.

The paralogous groups (sets of sequence-related proteins) within *E. coli* range in size from pairs to a group of 82 (P. Liang and M. Riley, manuscript in preparation; [{GenProtEC} (genprotec.mbl.edu)]. The smaller groups are mostly enzymes whereas the largest groups are mostly transporters and regulators. Larger groups may contain proteins whose functional requirements limit much change and are therefore still visibly related by sequence, even though divergence was ancient. Smaller groups and single proteins with no known partner evidently diverged widely, so that it is difficult to trace their early evolutionary history. At the present only their closest relatives can still be detected. Most of the proteins of this type in *E. coli* are enzymes.

Mechanisms of Divergence to New Functions

How did metabolic pathways evolve? Did each sequential enzyme in a pathway evolve from the one before by duplication and divergence (Riley and Sanderson, 1990), or did an entire pathway duplicate, changing specificity toward substrates while retaining the same general mechanism of catalytic conversions down the pathway? Coopting one type of enzyme to produce another related type is referred to as "recruitment" (Jensen, 1976). The short-chain dehydrogenase reductase (SDR) family seems be an example.

Only a few examples exist of related enzymes that function in individual pathways, as visualized by Horowitz and Leupold (1951). Table 7 lists cases in *E. coli* (i.e., genes of methionine, histidine and purine biosynthesis pathways and the synthesis of peptidoglycan). There are more examples known of proteins of similar sequence catalyzing similar reactions serving many pathways. Iron-sulfur subunits of dehydrogenases form a big family of sequence-related proteins. The ATP-binding subunits of ABC transporters also form a large family. A family of aminotransferases comprises enzymes for the same type of reaction but each with different substrate specificities. These examples speak to the validity of the recruitment model (Jensen, 1976).

Table 7. Sequence-similar genes of *Escherichia coli* found in the same metabolic pathway.

Pathway	Sequence similar genes
Methionine biosynthesis	*metB, metC*
Histidine biosynthesis	*hisA, hisF*
Purine biosynthesis	*purK, purT*
Peptidoglycan biosynthesis	*murC, murD, murE, murF*

Although most of the proteins in any one sequence-similar group in *E. coli* are closely related in function, there are exceptions. These exceptions may be able to tell us something about the way divergence proceeded in evolution.

Most sets of sequence-similar dehydrogenases of *E. coli* using NAD(P) as cofactor are made up only of proteins that catalyze the dehydrogenase reaction but use different substrates. However, one sequence-similar group of dehydrogenases also contains certain NAD(P) requiring epimerases and dehydratases. These enzymes are known to belong to the SDR class of NAD-requiring enzymes. They are related by binding sites for the NAD coenzyme and they utilize similar mechanisms of reaction that pass through or terminate at an oxidation or reduction step. The SDR group may be an example of how functions can begin to diverge among the progeny of gene duplication events. A common type of dehydrogenase seems to have thrown off variants that have become epimerases, dehydratases, and, in organisms other than *E. coli*, also isomerases. This behavior represents the divergence part of the duplication and divergence process.

Unknown or Unused Genes and Functions

How will the functions of *E. coli* genes that have no sequence match in current databases be learned? Laboratory projects are under way to find the phenotypes of mutants deleted for every *E. coli* gene. Some of these mutants will have no observable phenotype either because of multiple capabilities in *E. coli* that act like redundancies or because the phenotype is subtle or only observable under circumstances different from the laboratory environment. Expression analysis will provide clues. Large grids of unique oligonucleotides will identify by hybridization the transcripts that predominate when the bacteria are grown under specific conditions.

Conclusions

It comes as something of a surprise that in spite of the decades of experimental work on *E. coli* K-12 by many scientists, and in spite of having the complete sequence of the genome in hand, a

great deal is still unknown about the genetic content of *E. coli*, the functions of many of its genes, and all the complex intertwined mechanisms for coordinating gene expression as environmental circumstances change. There is much more work to be done.

CHAPTER 1.11

Origin of Life: RNA World versus Autocatalytic Anabolism

GÜNTER WÄCHTERSHÄUSER

Introduction

The deep past of the earth is unobservable. Therefore, the problem of the origin of life, the emergence of the first evolvable entity, which is the primordial ancestor of all extant organisms, can only be solved by a theory. Theories on the origin of life are scientific rather than myth, if they have empirical significance: empirical biological significance by providing evolutionary explanations for extant facts of biology and/or empirical chemical significance by predicting unknown but testable chemical reactions. Preferably, they also should have geological significance by being compatible with geological theories on the early history of the earth, which themselves, however, need to be scrutinized for their power to explain and predict facts of geology and chemistry. These requirements follow from Popper's methodology of science (Popper, 1959; Popper, 1963; Popper, 1972). They constitute the challenge of the field.

Only two theories on the origin of life are detailed enough for an evaluation by the above criteria:

1) The *RNA world theory* (Joyce, 1989; Gesteland et al., 1999) assumes that the first organism was a "living" RNA-like molecule replicating in a prebiotic broth of activated nucleotides.

2) The *autocatalytic anabolist theory* (Wächtershäuser, 1988; Wächtershäuser, 1990; Wächtershäuser, 1992; Wächtershäuser, 1997; Wächtershäuser, 2000) assumes that life began on minerals with an anabolic metabolism of synthetic, autocatalytic carbon fixation cycles.

These two theories will be discussed here in a comparative manner. For a detailed list of references and for a description of further studies, the readers should consult the available comprehensive reviews (Bengtson, 1994; Brack, 1998; deDuve, 1991; Fry, 2000; Lahav, 1999; Smith and Szathmary, 1995; Zubay, 2000). Given the huge body of literature, the specific references given here cannot be anything but incomplete; the emphasis is placed on references that are extraordinarily relevant for the present discussion, or very recent, or effectively forgotten.

Nutrients and Energy

All organisms require nutrients and energy for growth and reproduction. In the *RNA world theory*, activated nucleotides are required as nutrients. Because these nucleotides are quite complex, the theory is forced to assume a rather protracted "prebiotic chemistry" for generating a prebiotic pool of activated nucleotides. There is some experimental support, most notably the formation of adenine from HCN (Oró, 1960) and the formation of pyrimidines from cyanoacetylene (Ferris et al., 1968).

However, the various reactions reported require different and mutually incompatible reaction conditions (Shapiro, 1986). A further difficulty of this approach resides in high dilution and in the destructive force of hydrolysis, notably in a hot prebiotic broth. As a solution of this problem an adsorption to minerals, like clay, has been suggested. Another difficulty resides in the problem of chemical selectivity. Given the multitude of organic compounds in a presumptive prebiotic broth, any envisioned reaction would be accompanied by numerous competing reactions. It is presently not clear, which mechanism of chemical selection could keep these competing reactions at bay (Shapiro, 1986).

It should further be remembered that the main ingredients in a prebiotic broth, when judged by the composition of meteorites or by electric discharge experiments (Löb, 1908; Löb, 1913; Miller, 1953) are carboxylic acids, notably amino acids. For thermodynamic reasons, free (amino) acids in a dilute aqueous solution cannot combine to form larger compounds. As a remedy, it has been suggested that thioesters are formed by equilibration with mercaptanes under hot, acidic

conditions and subsequently quenched with cold, neutral water (deDuve, 1991). Hydrolysis, however, will occur as soon as aqueous nonequilibrium conditions are established.

The *autocatalytic anabolist theory* requires as nutrients the inorganic volatiles in magmatic exhalations, such as CO_2, CO; H_2S; N_2, NH_3; H_2, and H_2O. They are found in varying proportions in extant magmatic exhalations and must have been ubiquitous in the earliest days of the earth. Additionally, the theory requires mineral or cluster surfaces with catalytic centers of mainly iron, but also nickel or cobalt (notably with a combination of sulfido and CO ligands). At high temperature (e.g., 1,500°C), gaseous exhalations are equilibrated. They are quenched into a state of nonequilibrium when mixed rapidly with cool (e.g., 100°C) aqueous liquid. This provides the chemical potential for synthetic reactions. For example, at low temperatures (e.g., 100°C) H_2 and CO are reductants and FeS and H_2S form a potent reducing agent ($E^{\circ\prime} = -620$ mV):

$$FeS + H_2S \rightarrow FeS_2 + 2H^+ + 2e^-$$

Initiation and Reproduction

The two competing theories give characteristically different answers to the question of primordial reproduction, which chemically speaking is an autocatalysis.

According to the *RNA world theory*, a large variety of RNA-type molecules formed de novo in the prebiotic broth, and by chance one of these was capable of reproducing by replication from activated nucleotides, which started evolution. Strand separation required a temporary elevation of the temperature (Kuhn, 1972), which complicates the theory considerably. This theory was greatly promoted by the discovery of catalytic RNA (ribozymes). It was concluded that the first "living" RNA molecules were not only the carriers of genetic inheritance (genotype), but also the sole carriers of catalytic function (phenotype). All attempts to demonstrate a replication of an RNA-type molecule without enzymes have failed. This result, mainly due to L. E. Orgel and his school, is close to a conclusive falsification, and therefore, a most important scientific achievement in this field. Subsequent attempts to employ *in vitro* evolution to at least show the possibility of an RNA sequence with a polymerase function for its own replication from nucleoside triphosphates have resulted in the conclusion that the minimum RNA with such capability could only have arisen by Darwinian evolution and not in a prebiotic broth (Johnston, 2001).

The *autocatalytic anabolist theory* assumes a primordial reproduction cycle consisting of small, low-molecular-weight organic constituents, like the constituents of extant intermediary metabolism. These are seen as an autocatalytic carbon fixation process in a ligand sphere of catalytic transition metal complexes, clusters, or minerals. The initiation reaction (Fig. 1) involves a reaction sequence from CO and H_2S via methyl mercaptane (CH_3-SH) to activated acetic acid (CH_3-CO-SH and CH_3-CO-SCH_3) in the presence of Fe/Co/Ni-catalysts, e.g., coprecipitated FeS and NiS. This has been experimentally demonstrated at 100°C (Huber and Wächtershäuser, 1997). The reaction is very similar to the reductive acetyl-CoA pathway. This and other experiments have revealed the importance of freshly precipitated sulfide gels (presumably comprising a library of unknown cluster structures ranging from oligonuclearity through multinuclearity to crystal structures) as compared to highly ordered sulfide crystals.

For a primordial reproduction by an autocatalytic feedback mechanism, several possibilities, which may have come in sequentially or jointly by cooperation, have been considered:

1) Feedback by the accumulation of lipids on mineral/cluster surfaces. Lipid accumulation would have the effect of mineral/cluster modification and hydrophobization. This in turn would lower the water activity on the surface and inhibit hydrolytic reactions. At the same time, lipid synthesis would be promoted, which means feedback. The biosynthetic formation of lipids by the condensation of activated acetic acid requires a strong base for forming an anionic intermediate. Under primordial aqueous conditions, such a strong base cannot exist. As a solution, we may consider a hypothetical route (Fig. 1) via metal-bonded HS-CH_2-SH to activated

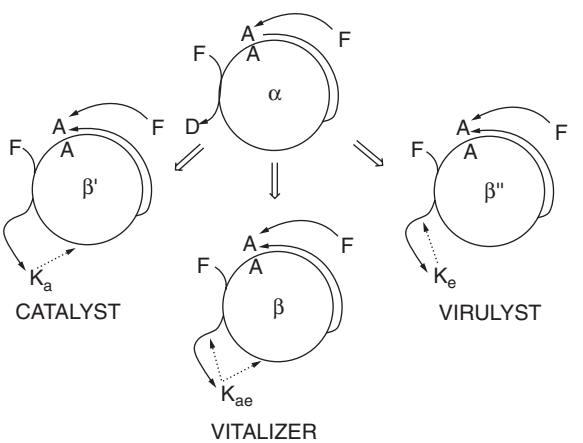

Fig. 1. Hypothetical reaction cascades and feedback effects of a primordial metabolism. (Bold arrows: experimentally demonstrated reactions; dotted arrows: hypothetical reactions; drawn-out arrows: extant enzymatic reactions.)

thioglycolic acid, which in the presence of FeS converts into an anionic species by nucleophilic attack and reductive elimination. Subsequent condensation to activated acetoacetic acid would open the way for formation of isoprenoid acids. It is an important aspect of this suggestion that an accumulation of these first surface-bonded lipids would constitute the common origin of structural and metabolic evolution.

2) Feedback by peptide ligand formation. It has been suggested that peptides bonded to surfaces or to transition metal centers preceded proteins and translation (Woese, 1972). Primordial peptide formation by carbon fixation (Fig. 1) is here seen as including the following steps (each one experimentally demonstrated in dilute aqueous systems around 100°C):

Reduction of CO via HS-CH_2-SH to CH_3-SH by H_2S and FeS/NiS (Huber and Wächtershäuser, 1997);

Double carbonylation of CH_3-SH to keto acids with Fe/Co/Ni catalysts (C. Huber and G. Wächtershäuser, manuscript in preparation);

Reductive amination of keto acids to amino acids with ammonia and Fe catalysts (Hafenbradl et al., 1995; C. Huber and G. Wächtershäuser, manuscript in preparation);

Activation of the amino acids (presumably as oxazolinones) with CO and H_2S on (Fe,Ni)S and conversion of the activated amino acids into peptides, which readily hydrolyze again to amino acids under the same conditions (Huber and Wächtershäuser, 1998).

This suggests the formation of a dynamic peptide library, which continuously scans the peptide sequence space as long as the energy source (CO + H_2S) lasts. Some of the peptides would bind strongly to the metal centers and would thereby be stabilized. Some of these in turn would increase the catalytic activity and/or selectivity for the above steps by ligand modification of the catalytic transition metal centers. This would constitute autocatalysis by self-selecting peptides (Wächtershäuser, 2000). Pressure is highly advantageous, as evidenced by the reported conversion of nonaqueous HCOOH via CO to pyruvate at 200 MPa and 250°C in the presence of FeS (Cody et al., 2000).

3) Reductive citric acid cycle as a primordial feedback cycle. A nonenzymatic archaic version of the reductive citric acid cycle would be autocatalytic and therefore could function on mineral surfaces as the first reproduction cycle, driven by a redox energy source and doubling by cleavage at the level of a thioester (or thioacid) of citric acid or malic acid.

4) Autocatalytic formose cycle as a primordial feedback cycle. It has been suggested that a primordial autocatalytic formose cycle based on CO and operating on mineral surfaces could function as primordial reproduction cycle (L. E. Orgel, 2000, personal communication).

Mechanism of Evolution

The mechanism of evolution is of singular importance for the problem of the origin of life. The *RNA world theory* assumes that evolution has always been based on replication of nucleic acids, on sequence variations, and on selection.

The *autocatalytic anabolist theory* assumes that nucleic acids and replication are a product of evolution. This means that there must have been a primordial mechanism of evolution, which was independent of nucleic acids. Such a primordial mechanism of evolution has been proposed (Wächtershäuser, 1988; Wächtershäuser, 1992). It is based on the by-products of autocatalytic metabolic reproduction (Fig. 2). Normally such by-products are products of decay. If they dominate, the rate of reproduction goes below 1 and the metabolic reproduction ceases to exist. But if such a by-product or a set of such by-products has a positive feedback effect either by being catalytic for at least one step of the pre-existing metabolism or by being converted into a constituent of the pre-existing metabolism, an accelerated or expanded metabolism arises. This positive feedback will persist as long as the production rate of the by-product is greater than its rate of decay. If the rate of decay is very slow, as with lipids, even a slow production will lead to a positive feedback effect by accumulation. For (catalytic) by-products with a high rate of decay, we entertain the following additional consideration: As long as such a (catalytic) by-product or set of by-products is produced solely by the pre-existing chemical conditions (*de novo* synthesis), its concentration changes in synchrony with the changes of the chemical environment. A dramatically different situation exists, however, if a by-product or a set of by-products shows the following "dual feedback" effect: an "altruistic feedback" effect for promoting at least one step of the pre-existing metabolism, and an "egotistic feedback" effect for promoting at least one step of the pathway of synthesis of the by-product. Now, the (catalytic) by-product with this dual feedback ("vitalizer") may persist by virtue of its egotistic feedback even though the chemical conditions for its *de novo* synthesis have vanished. Therefore, with every new autocatalytic dual feedback, the metabolism switches into a new and relatively stable expanded state. This constitutes a memory effect. A catalyst that has a purely egotistic feedback effect (a "virulyst") is strictly parasitic and may be considered the most primitive forerunner of a virus.

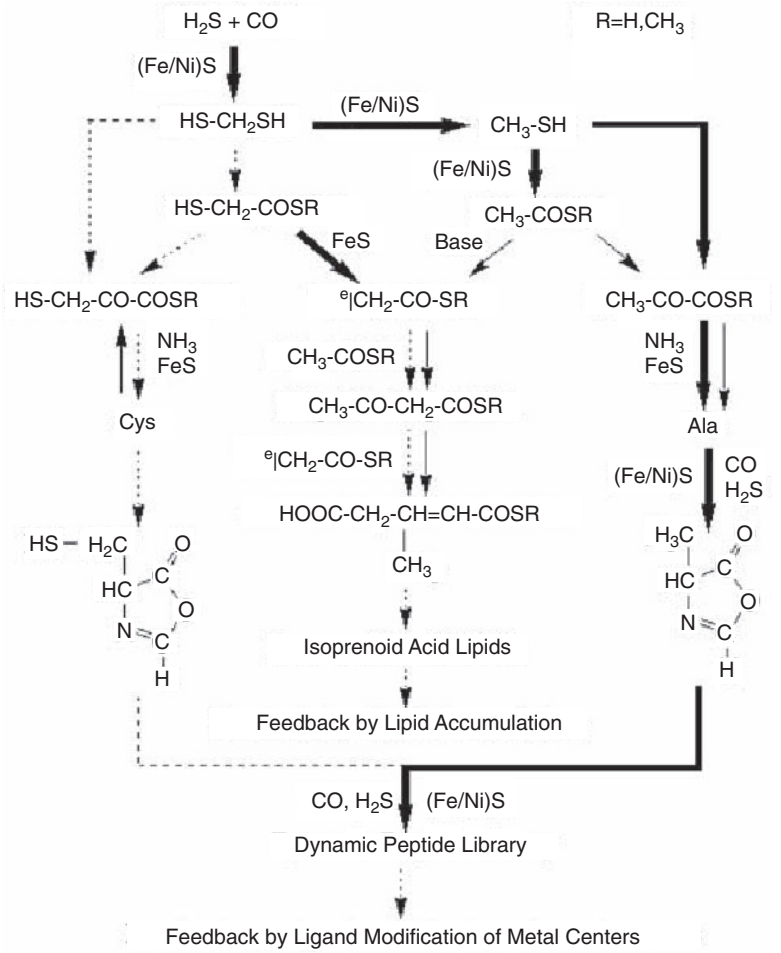

Fig. 2. Generalized mechanism of evolution by catalytic feedback. (Arrows signify expansions of the metabolism from α-stage to β-stage; Abbreviations: F, food; A, autocatalyst; D, product of decay; K_a, catalyst with altruistic feedback; K_e, catalyst with egotistic feedback; and K_{ae}, catalyst with dual feedback.)

Extant cellular organisms are replete with vitalizers: Coenzymes catalyzing a step in their own biosynthesis, ribosomes catalyzing the synthesis of all proteins including ribosomal proteins, translocases catalyzing the introduction of membrane proteins including translocase proteins into the cell membrane, as well as nucleic acids coding for all proteins including polymerases. As candidates for the earliest mutations by vitalizers, we may consider the emergence of new ligands (e.g., new amino acids and sets of peptides) modifying the catalytic metal centers or the emergence of new lipids modifying lipophilicity or lipid membranes.

Cellularization

All extant organisms are cellular owing to lipid membranes. However, primitive lipid membranes without transporter proteins are essentially impermeable for hydrophilic or ionic organic molecules. This creates a major paradox for the *RNA world theory*, which is dependent on the existence of a prebiotic broth. Any increase in barrier effectiveness of the primitive lipid membrane means on the one side an advantage in terms of keeping the constituents inside, but on the other side a disadvantage in terms of keeping the organic broth components outside (isolation/starvation paradox).

According to the *autocatalytic anabolist theory*, cellularization does not give rise to an isolation/starvation paradox. The neutral inorganic nutrients (H_2S, CO, CO_2, N_2 and NH_3) pass freely through a lipid membrane. The catalytic metal ions are provided by the mineral itself, and phosphate ions may be provided as an adsorbate of the mineral surface.

The overall cellularization process is seen as a protracted evolutionary affair. The earliest lipid function is seen in a modification of the inorganic structures (developing from cluster structures through colloidal structures to mineral structures), notably by (surface) lipophilization. This leads to a decrease of water activity and therefore it promotes lipid formation (egotistic feedback effect) as well as pre-existing metabolic

reactions (altruistic feedback effect). Most importantly, however, the accumulation of lipids elicits new kinds of reactions. This effect may be generalized and termed "feedforward effect." It greatly accelerates evolution. Eventually, with the accumulation of lipids, closed membrane vesicles are formed, first supported by the inorganic structures and later self-supporting. Subsequently, translocases and membrane proteins emerge.

An automatic consequence of this development is the possibility of an ion (proton) gradient over the vesicle membrane of a closed membrane envelope. This is the prerequisite for the emergence of Fe/S-dependent electron transport chains and chemiosmosis. Chemiosmosis may at first have been restricted to a combination of exergonic and endergonic electron transport chains. Membrane-bound ATPases would then have been added later (Wächtershäuser, 1997).

The early organisms with a primitive membrane envelope (termed "precells") must have undergone frequent fusions and fissions and thus did not have an effective function of individuation (Kandler, 1998; Woese, 1998). True cells capable of stable organismic individuation emerged as soon as vesicle fusions became inhibited, perhaps by mutually immiscible enantiomeric lipid types, which forced the physicochemical separation of the domains of life (Wächtershäuser, 1988; Wächtershäuser, 1992) and/or by cell walls.

Chirality

Homochirality unites biochemistry and sets it apart from the abiotic world. Therefore, it is a touchstone for any theory on the origin of life.

The *RNA world theory* requires homochiral building blocks for forming well-folded ribozymes. A prebiotic broth, however, can only be racemic (Bada and Miller, 1987). This seems to constitute an insurmountable dilemma. For under racemic conditions, replication is subject to enantiomeric cross-inhibition (Joyce et al., 1984; Schmidt et al., 1997).

According to the *autocatalytic anabolist theory*, the first ligands are small organic compounds, like lipids, amino acids or peptides. Homochirality is not required for a feedback effect by these ligands. It would even be detrimental by impoverishing structural variability. Moreover, optically active amino acids, even if they had come about, would have quickly racemated. It has been experimentally shown that such racemization of amino acids occurs rapidly under the conditions of activation with CO/H_2S, probably due to oxazolinone intermediates. This means that homochirality would have been impossible under primordial conditions. Homochirality would have occurred much later, perhaps only after the takeover of activation by ATP, and perhaps in conjunction with the emergence of homochiral polymers, like nucleic acids (Bolli et al., 1997).

Temperature

The *RNA world theory* of an origin of life in a prebiotic broth requires a cold ocean to avoid decomposition of the thermally sensitive constituents. Therefore, it is incompatible with geological theories of a hot early ocean. The *surface metabolist theory* is compatible with high temperatures because binding to metal centers of minerals or clusters stabilizes the constituents. The theory even requires a hot environment, for otherwise the reaction rates may not be high enough. Hot aqueous local environments exist today and surely must have existed at the dawn of life.

The discovery of hyperthermophilic Bacteria and Archaea, occupying deep and short branches in Woese's tree of life (Woese, 1987) has made room for the previously unthinkable possibility of a hyperthermophilic last common ancestor, and by extension, of a hyperthermophilic origin of life, from which mesophiles would have been derived polyphyletically. This notion contrasts with the conventional notion of a mesophilic or even psychrophilic origin of life and a mesophilic last common ancestor from which hyperthermophiles would have derived polyphyletically by adaptation to high temperatures.

The adherents of a mesophilic origin of life make the implicit assumption of an essential symmetry between thermally upward and thermally downward evolution. This view is not tenable. An adaptation from a mesophilic lifestyle to a hyperthermophilic lifestyle is effectively impossible for the following reason. Unlike any other parameter, temperature is all-pervasive. It influences practically all structures and processes of an organism profoundly. Therefore, an "upward adaptation" of a whole organism to higher temperatures requires a concerted, simultaneous adaptation of all processes and all structures. This is very demanding. For example, an upward adaptation of each polymer structure would require several specific covariations for folding stabilization at high temperatures. The probability of all these changes occurring simultaneously is extremely low. Therefore, the conclusion seems inescapable: an upward adaptation is probabilistically forbidden. It means that evolution proceeded irreversibly from hyperthermophily to mesophily. This must have occurred by

a gradual loss (one at a time) of a few sets of strong covalent bonds, e.g., S-metal bonds, in favor of a gradual appearance of a multitude of weak noncovalent bonds, i.e., by degeneration rather than by adaptation. Such degeneration may take a relatively long time, but its overall probability is not effectively zero. This explains a striking fact concerning many ancient proteins (e.g., aminoacyl synthetases for Val, Ile, Leu, Met, His, Phe and Pro; ribosomal proteins L33, S17, L24, S14, L36, S4, L31, L28 and S18). In hyperthermophiles, these proteins have patterns of sequence signatures with 4n Cys units (n = 1 to 6), which are typical for strong covalent metal (e.g., Zn) bonding. But in mesophiles, these signatures are partially to wholly absent. Their gradual loss is readily possible in a thermally downward evolution, whereas their simultaneous reintroduction at the right places in a thermally upward evolution is highly improbable.

The theory of a hyperthermophilic origin has been contradicted recently by a paper (Galtier et al., 1999), which has attempted a reconstruction of the G+C contents of rRNAs and tRNAs of the universal ancestor. The reconstruction was based on complete extant sequences with conserved as well as variable positions. The projected G+C contents were rather low, which was taken to be indicative for a mesophilic lifestyle of the universal ancestor. Subsequently, however, it has been shown (Di Giulio, 2000) that a reconstruction method that ignores highly variable positions produces very high G+C contents not only for the universal ancestor, but also for the common ancestor of all bacteria, the common ancestor of all archaea, and to a lesser extent the common ancestor of all eukaryotes. This strongly supports a hyperthermophilic origin of life.

It has been demonstrated that random RNAs do not fold well at temperatures of hyperthermophilic organisms. From this it was correctly concluded that the *RNA world theory* and the notion of a hyperthermophilic origin are incompatible. Based on the presumption of truth of the *RNA world theory*, a mesophilic origin was concluded (Moulton, 2000). This latter conclusion, however, is at odds with the simple fact that in hyperthermophilic organisms' RNAs have no trouble folding, owing to a high G+C content. Therefore, on the basis of the *autocatalytic anabolist theory*, we merely have to assume that the earliest RNAs were all bonded to surfaces and that only those with a high G+C content lifted off as well-folded self-supporting structures. Later, after the emergence of enzymes for stabilizing RNAs by secondary modifications, the restriction to a sequence space with high G+C content was relaxed. Similarly, we assume that the earliest peptides and proteins were all bonded as ligands to surfaces of clusters and minerals and that only those with sequence signatures for strong bonding to metal centers turned into self-supporting structures. Later, after the emergence of folding catalysts (chaparones), the sequence space for hyperthermophilic proteins became expanded.

Time Frame

The *RNA world theory* of an origin of life in a prebiotic broth requires a sufficiently long period of time for a slow accumulation of the presumptive constituents of the broth and for playing out the so-called "prebiotic (broth) chemistry" until the onset of replication. Early on, it was assumed that more than a billion years were available for prebiotic chemistry. Two geological findings narrowed the window of time dramatically. First, fossils of bacteria (much like cyanobacteria) were discovered in 3.5-billion-year-old sedimentary rocks in Australia (Schopf, 1993). Moreover, it was discovered that 3.85-billion-year-old, highly metamorphosed sedimentary rocks in Greenland have a C-isotope signature that is characteristic for life (Schidlowski, 1988; Mojzsis, 1996). Second, heavy bombardment with ocean-boiling impactors is calculated to have lasted from the origin of the earth (4.6 billion years ago) until about 3.8 billion years ago. This nearly removes the window of time required for the occurrence of a mesophilic origin of life in a prebiotic broth.

The *autocatalytic anabolist theory* avoids this dilemma. It does not require the preaccumulation of a prebiotic broth or even the existence of a large body (ocean) of water. It only requires enough aqueous fluid for solvating mineral surfaces, colloidal structures or catalytic clusters.

The *RNA world theory* sees the origin of life in a prebiotic broth as a one-time event, never to recur after the first inception of life. By contrast, the *autocatalytic anabolist theory* of a chemoautotrophic origin leads to the conclusion of perpetual or recurrent reactions of origin as long as suitable inorganic conditions prevail. It makes room for the realistic possibility of an origin of life on numerous celestial bodies with magmatic outgassing, including Mars. Moreover, it assumes a rapid succession of synthetic reaction steps giving rise to activated intermediates undergoing further synthetic reactions, which concatenate to pathways and cycles. These reactions must go on at a rate higher than the rate of hydrolysis. Thus this theory assumes a rapid origin of life by metabolic cycles instead of a protracted prebiotic chemistry in a slowly accumulating prebiotic broth.

These considerations are most important for the experimental research programs that transpire from the two theories. Experiments within

the *RNA world theory* can only have the role of demonstrating the principal possibility of certain partial chemical aspects of the theory. By contrast, the experimental program for testing the *autocatalytic anabolist theory* sets its ultimate target beyond such partial plausibility and aims at eventually bringing about an origin and early evolution of life in vitro.

Phylogenetic Connection

Extant organisms are the result of some four billion years of evolution. They are highly complex and far removed from primordial life. There are attempts to employ comparative biochemistry and genomics for reconstructing the last common ancestor to get closer to the origin of life. However, numerous lateral transfers, notably of genes concerning the metabolism, complicate this program of reconstruction considerably (Woese, 1998; Woese, 2000). Therefore, formal sequence comparisons alone cannot resolve major questions of the metabolism of the last common ancestor, e.g., whether it was autotrophic or heterotrophic.

Bacterial and archaeal genomes comprise long and highly conserved clusters of genes concerning the machineries of transcription and translation. These machineries are highly complex, comprising a large number of cooperating components. A lateral transfer of a long cluster of many genes encoding components of such machineries may be expected to lead to hybridized machineries with severely impaired functional competence. Therefore, these clusters are prime candidates when we search for cases of forbidden lateral transfer. By an overlapping alignment of these clusters of different organisms, it was possible to reconstruct a hypothetical segment of the genome of the last common ancestor (Wächtershäuser, 1998). It comprises genes for transcription (polymerases and antitermination factors), translation (ribosomal proteins and elongation factors), and protein translocation. This means that the universal ancestor had already an organized DNA genome, RNA, a closed precell lipid membrane, a genetic code, and sets of bases and amino acids much like in extant cells. This suggests the following broad stages of early evolution, which are not sharply separated, but overlapping.

Stage 1: Anabolic autotrophic surface metabolists with metal catalysts;
Stage 2: Formation of precells and the earliest genetic machinery;
Stage 3: Metabolic takeover by genetically encoded enzymes, perfection of the genetic machinery, emergence of true cells and isolation.

Genetic Machinery

The genetic machinery has the central function in all extant organisms. It is extremely complex. Therefore, it must have arisen in a long evolutionary process with numerous steps. The two theories discussed here give characteristically different accounts of this process.

The *RNA world theory* assumes that the pioneer process of life was replication of RNA or a similar nucleic acid in a prebiotic broth of activated nucleotides, and that RNA was catalytic for this process as a template and perhaps also as a ribozyme with the function of a polymerase. Other ribozyme functions followed, and it is assumed that the set of biocatalysts of the earliest forms of life consisted exclusively of ribozymes. Hence the name "RNA world." One of the later ribozymes was a proto-ribosomal RNA, which had the function of translating preexisting RNA sequences into protein sequences. This was the starting point for an enzymatic takeover, which eliminated almost all ribozymes. Subsequently DNA replication as an extension of RNA polymerization took over the role of information conservation.

The *autocatalytic anabolist theory* assumes that the pioneer process of life was a self-expanding synthetic autocatalytic metabolism. Proto-nucleic acids emerged as a product of this metabolism, the bases having first a catalytic (acid-base) function and the backbone having a surface anchoring function. The earliest nucleic acids may have been homopolymers, and therefore, would have been devoid of sequence information. Nevertheless base pairing could have already been in service of catalyzing the formation of short peptides by positioning amino acids. After the appearance of more and more amino acids, sequence information for genuine translation emerged. Now peptide sequences became more and more determined by the base sequences of the nucleic acids and thus faithful replication began to become important. Now longer and longer protein sequences appeared, and enzymes replaced the short peptide ligands. With the appearance of more and more complex RNA folding, additional ribozymes for catalyzing RNA chemistry emerged by dual feedback. Whether DNA came after RNA or coevolved with RNA is presently not crucial in this theory.

Explanatory Power

Popper has suggested assessing the empirical or scientific merit of a theory by assessing the explanatory power of the theory, i.e., its power to explain many facts by using few assumptions. Theories on the origin of life have to explain

extant facts by linking them to hypothetical primordial functions going back some four billion years. Therefore, the possibility of an explanatory success of a theory on the origin of life is largely dependent on how many radical biochemical takeovers are assumed to have occurred and obliterated the remains of the earliest evolution.

The *RNA world theory* makes several assumptions of different strength:

The strong assumption of an emergence of naked "living" RNA molecules that evolved by replication and selection in a prebiotic broth would be explanatory, if a linkage could be drawn from the presence or absence of constituents of the broth to the presence or absence of constituents of extant RNA.

The theory makes the strong assumption that, early on, ribozymes (RNA) were the sole biocatalysts. It remains to be explained how this strong assumption could be explanatory for extant organisms in which most of the biocatalysts are enzymes.

The much weaker postulate that ribozymes and enzymes had a role in early life is explanatory for the extant coexistence of the catalytic roles of enzymes and ribozymes, like rRNAs and tRNAs.

The postulate that RNA came before DNA has explanatory power for viral RNA genomes, RNA primers of DNA replication, RNA in telomerases, and the biosynthetic conversion of ribonucleotides into deoxyribonucleotides.

For the development of the *autocatalytic anabolist theory* a methodology of biochemical retrodiction has been employed, whereby a common precursor function is postulated for two or more disparate successor functions. This generates explanatory power. At the same time it produces a backward convergence toward the origin as the ultimate common precursor function. Here are some illustrative examples:

Primordial surface bonding to clusters/minerals is a functional precursor of cell enclosure, enzyme surfaces, catalytic transition metal centers and protein folding.

The requirement of strong surface bonding of anionic bioorganics to cationic metal centers is explanatory for the domination of the central metabolism by anionic carboxylate and thiolate groups and notably for the phosphate groups in sugar metabolism and nucleic acids.

A primordial CO-based metabolism is explanatory for the role of CO in the reductive acetyl-CoA pathway and for the CO ligands in hydrogenases.

A primordial sulfide-based metabolism is explanatory for the central role of SH and sulfido groups in extant enzymes and coenzymes.

A primordial iron-sulfur-based metabolism explains the central role of iron-sulfur clusters, notably in anaerobes; it explains iron-oxo clusters and hemes as later substitutes.

A primordial nickel-based metabolism explains the critical role of nickel in hydrogenases, CO-dehydrogenase, acetyl-CoA synthase and methane synthase as leftovers.

A primordial activation of amino acids as oxazolinones by CO/H_2S as a direct source of energy for peptide formation and prototranslation, and as an indirect source of energy for pyrophosphate or ATP formation, explains the emergence of extant amino acid activation by ATP in synthetases as a reaction reversal.

A general mechanism of evolution by (dual) autocatalytic feedback explains the possibility of an evolution by low-molecular-weight metabolic by-products. It further explains why central components of extant cells (e.g., ribosomes, translocases and coenzymes) exhibit dual feedback. And finally, it explains the takeover by a mechanism of evolution based on high-molecular-weight nucleic acids simply as an extension of the primordial mechanism. Metaphorically speaking, it explains early evolution as a changeover from the analog information of feedback loops to the digital information of nucleic acids and the ribosome as a digital-to-analog converter.

Conclusion

The scientific problem of the origin of life can be characterized as the problem of finding the chemical mechanism that led all the way from the inception of the first autocatalytic reproduction cycle to the last common ancestor. All present theories fall far short of this task. While we still do not understand this mechanism, we now have a grasp of the magnitude of the problem.

Acknowledgements. I express my gratitude to Claudia Huber for years of dedicated and ingenious experimental testing of the *autocatalytic anabolist theory*, which led to significant extensions, deletions and modifications; to Helmut Simon and Adelbert Bacher for generously sharing their laboratory space and facilities, and for providing support for enabling these experiments; to the Deutsche Forschungsgemeinschaft for financing the experiments; to Otto Kandler, the great catalyst without whom none of this would have come about and the theory would not have developed beyond its adolescent stage; and to Dorothy Wächtershäuser for help in formulating this paper.

CHAPTER 1.12

Biotechnology and Applied Microbiology

EUGENE ROSENBERG

Introduction

There is no agreed upon definition of biotechnology. Definitions vary from the most noble—the use of biology for the benefit of man—to the most prosaic—the use of biology to make money. A balanced definition might be the use of living organisms (or materials from living organisms) to perform defined processes for industrial application. Applied microbiology is a large part of biotechnology because microorganisms have a broadly diverse synthetic and degradative potential, which is easily manipulated genetically, and they can readily grow under controlled conditions in large fermenters. The so-called "new biotechnology" generally refers to the use of recombinant DNA technology to construct useful new strains. However, a considerable amount of "new biotechnology" does not use recombinant DNA technology but rather structural biology as a basis for rational drug design, monoclonal antibodies as biosensors, and enzymes from extremophiles to facilitate industrial production. In addition, conventional industrial microbiological processes apply many of the new biotechnologies.

This edition of the Prokaryotes contains an entire section dealing with the following specific biotechnology and applied microbiology topics: bioremediation, bioleaching, microbial biofilms, biodeterioration, bacterial enzymes, bacteria in food and beverage production, organic acid and solvent production, scale-up of bacterial fermentations, amino acid and vitamin production, recombinant DNA protein production in bacteria, bacterial pharmaceutical products and bioemulsifiers. In addition, each chapter dealing with a particular genus (or a group of genera) has a section on applications. In this introductory chapter, I will attempt to put applied microbiology and biotechnology into an historical perspective and give an overview of some of the general principles related to the biotechnology of prokaryotes. It should be emphasized at the outset that both applied and basic microbiology have been and always will be intertwined. Applied microbiology without basic microbiology is lame and limited. A major driving force of basic microbiology is the solution of applied problems.

The Fermentation Controversy

For thousands of years, microbiological processes (such as those for producing wine, beer, vinegar, bread, pickles, sauerkraut and various milk products such as yogurts, cheeses and butter) were developed by trial-and-error, without any understanding of the underlying principles. During the last half of the nineteenth century, the controversy regarding the causative agent of fermentation stimulated experimentation that serves as the scientific basis of today's applied microbiology and biochemistry.

For centuries fermentation had a significance that was almost equivalent to what we would now call a chemical reaction, an error that probably arose from the vigorous bubbling seen during the process. The conviction that fermentation was strictly a chemical event gained further support during the early part of the nineteenth century. French chemists led by Lavoisier and Gay-Lussac determined that alcoholic fermentation could be described as the chemical conversion of one molecule of glucose ($C_6H_{12}O_6$) into two molecules of ethanol (C_2H_5OH) and two molecules of CO_2. It was, of course, known that yeast must be added to the glucose solution to ensure a reproducible and rapid fermentation. The function of the yeast, according to the chemists, was merely to act as a chemical catalyst. Then, in 1837, Theodor Schwann and Charles Cagniard-Latour independently published studies that indicated yeast was a living microorganism. Prior to their publication, yeast was considered merely as a proteinaceous chemical substance. One reason it was difficult to ascertain whether yeasts were alive was that, like most other fungi, they are not motile. The cellular nature of yeast was discovered only when improved microscopes became available, and it is most likely that improved microscopes enabled the two workers to come up with the

same observation at approximately the same time. Schwann and Cagniard-Latour also observed that alcoholic fermentation always began with the first appearance of yeast, progressed only with their multiplication, and ceased as soon as their growth stopped, so both scientists concluded that alcohol is a by-product of yeast growth.

The biological theory of fermentation advanced by Cagniard-Latour and Schwann was immediately attacked by the leading chemists of the time. The eminent Swedish physical chemist, Jons Jakob Berzelius, reviewed the papers of Cagniard-Latour and Schwann in his *Jahresbericht* for 1839 and dismissed microscopic evidence as of no value in what was obviously a purely chemical problem. According to Berzelius, nothing was living in yeast. "It was only a chemical substance which precipitated during the fermentation of beer and which had the usual shape of a non-crystalline precipitate." In addition, Liebig published a paper containing several important arguments against the biological theory of fermentation. Liebig's two major points can be summarized as follows:

1. Certain types of fermentation such as the lactic acid (souring of milk) and acetic acid (formation of vinegar) can occur in the complete absence of yeast.
2. It is not necessary to conclude that, even if yeast were a living organism, fermentation is a biological process. Yeast is a remarkably unstable substance, which, as a consequence of its own death and decomposition, catalyzes the splitting of sugar. Thus fermentation is essentially a chemical change catalyzed by breakdown products of the yeast.

Liebig's views were widely accepted, partly because of his powerful influence in the scientific world and partly because of a desire among chemists to avoid conceding an important chemical change to the domain of biology.

In 1857, Pasteur published his first paper in the field of fermentation. The publication dealt with lactic acid fermentation, not alcoholic fermentation. Utilizing the finest microscopes of the time, Pasteur discovered that souring of milk was correlated with the growth of a microorganism, but one considerably smaller than the beer yeast. During the next few years Pasteur extended these studies to other fermentative processes, such as the formation of butyric acid and lactic acid. In each case he was able to demonstrate the involvement of a specific and characteristic microorganism; alcoholic fermentation was always accompanied by yeasts, lactic acid fermentation by nonmotile bacteria, and the butyric acid fermentation by motile, rod-shaped bacteria. Thus Pasteur not only disposed of one of the opposition's strongest arguments, but also provided strong circumstantial evidence for the biological theory of fermentation. Pasteur then attacked the crucial problem, alcoholic fermentation. Liebig had argued that the proteinaceous material, released from yeast during its decomposition, catalyzed the splitting of sugar. Pasteur countered this argument by developing a protein-free medium for the growth of yeast. He found that yeast could grow in a medium composed of glucose, ammonium salts and some incinerated yeast. If this medium was kept sterile, neither growth nor fermentation took place. As soon as the medium was inoculated with even a trace of yeast, growth commenced, fermentation ensued, and the quantity of alcohol produced paralleled the multiplication of the yeast. In this protein-free medium, Pasteur was able to show that fermentation took place without the decomposition of yeast. In fact, the yeast synthesized protein at the expense of the sugar and ammonium salts. Thus, Pasteur concluded in 1860 that "Fermentation is a biological process, it is the subvisible organisms which cause the changes in the fermentation process. What's more, there are different kinds of microbes for each kind of fermentation. I am of the opinion that alcoholic fermentation never occurs without simultaneous organization, development and multiplication of cells, or continued life of the cells already formed. The results expressed in this memoir seem to me to be completely opposed to the opinion of Liebig and Berzelius" (Dubos, 1950).

Pasteur argued effectively and, more importantly, all the data were on his side. Thus, the so-called vitalistic theory of fermentation predominated until 1897, when an accidental discovery by Eduard Buchner finally resolved the controversy and threw open the door to modern catalytic biochemistry based on enzymes.

Buchner was attempting to obtain from yeast an extract that might have medicinal value. After several unsuccessful trials, he discovered that mixing yeast cells with fine sand and grinding the mixture in a mortar and pestle disrupted the cells. After filtering the mash to remove the sand and any unbroken cells, a clear yeast juice was obtained. The juice, however, soon became contaminated with bacterial growth. Since the extract was for human consumption, Buchner could not utilize ordinary antiseptics to prevent the spoilage. Therefore, he attempted to preserve the yeast extract by adding large quantities of sugar. The yeast extract began to bubble soon after the sugar was added. Careful analysis revealed that the sugar was decomposing to carbon dioxide and ethyl alcohol. Fermentation had proceeded *in the absence of living cells*. Buchner's achievement inaugurated a new era in the study of alcoholic

fermentation and other metabolic processes. Reactions that normally took place only in vivo could now be studied in vitro. The agents which are present in cell extracts and which catalyze these reactions were called enzymes, from the Greek en zyme, meaning "in yeast." In 1907 Eduard Buchner received the Nobel Prize in Chemistry "for his biochemical researches and his discovery of cell-less fermentation."

Classical Applied Microbiology (1900–1940)

After it was demonstrated that living yeast was the causative agent for the alcohol fermentation, rapid progress was made in isolating and identifying the microorganisms responsible for other fermentations. As a result, considerable practical knowledge was gained, commercial media developed, producer strains improved, and the fermentation industry grew and diversified (Table 1). As an example, commercial bio-production of citric acid was begun in New York in 1923, and by 1940, over 10-million kgm were produced per annum. Much of this early work on industrial fermentations has been reviewed by Prescott and Dunn (1940).

With the advent of World War I, it became necessary to develop a fermentation method for making acetone, used for the manufacture of explosives. The United States government purchased two large distilleries in Indiana and established the Weizmann process, which made acetone from maize by *Clostridium acetobutylicum* fermentation. After the war, the Weizmann process was used mainly to produce butyl alcohol needed in the manufacture of automobile lacquers. During the development of the Weizmann and other industrial fermentation processes, several important and general aspects of applied microbiology became established.

Isolation of Cultures

Isolation of a pure culture of the desired microorganism is often the first step in an applied microbiology project. Selective media and growth conditions developed for the isolation and cultivation of specific groups of Bacteria and Archaea are described throughout this book. In addition, microorganisms that carry out a specific selectable function can be isolated by enrichment culture procedures (Krieg, 1981; Veldamp, 1970; Jones and Krieg, 1984). For example, if the applied goal is to obtain a xylanase that is active at pH 9.0 and 70°C, then an enrichment culture that contains xylan as the sole carbon and energy source would be adjusted to pH 9.0 and incubated at 70°C. Also, the preferred inoculum would be a soil sample taken from a high temperature and pH site that contains decaying plant material. After several transfers in the same medium, the mixed culture is streaked onto an agar medium containing the same nutrients. The resulting colonies of microorganisms must contain an extracellular xylanase that is active at 70°C and pH 9.0. Enrichment cultures of this type have been successfully employed to obtain a wide variety of useful strains. The power of the enrichment culture technique depends on the enormous metabolic diversity of microorganisms and on the ingenuity of the investigator to establish proper restrictive growth conditions.

Screening Procedures

The enrichment culture technique is valuable only when growth conditions select for the desired strain. The selection is usually based on the degradation of a particular substrate or the resistance to a particular environmental parameter, e.g., high and low temperature, salt and pH

Table 1. Production of industrial chemicals by fermentation.[a]

Fermentation	Microorganism	Commercial Use
Ethyl alcohol	*Saccharomyces cerevisiae*	Industrial alcohol
Acetone-butanol	*Clostridium acetobutylicum*	Synthetic rubber, explosives, lacquers and solvents
Acetone-ethanol	*Bacillus acetolyticus*	Solvents
Acetic acid	*Acetobacter*	Vinegar
Lactic acid	*Lactobacilli, Streptococci*	Textile and leather industries
Propionic acid	Propionic acid bacteria	Solvent
Citric acid	*Aspergillus niger*	Medicines, food and beverages
Gluconic acid	*Penicillium chrysogenum*	Pharmaceutical industry, cleaning
Gallic acid	*Penicillium glacum*	Dye industry
Fumaric acid	*Rhizopus*	Food and beverages
Mannitol	White *Asperg*	Resin production, food and beverages
Dihydroxy acetone	*Acetobacter*	Artificial tanning and chemical industry

[a]See chapter on Organic Acid and Solvent Production.

values, antibiotics and toxic metals. However, it is generally not possible to select directly for microorganisms that produce or overproduce useful chemicals, such as fermentation products, antibiotics and other drugs. In such cases, screening procedures have to be employed. The success of the Weizmann process for producing acetone and butanol depended on screening a large number of microorganisms for a strain (*C. acetobutylicum*, Weizmann) that produced high levels of these solvents. In recent years, many new screening procedures have been developed and automated for the discovery of new products (White et al., 1986). Screening procedures are based on either chemical or functional assays, using intact cells or subcellular preparations. An example of a functional assay that uses intact cells is antibacterial screening by the agar plate diffusion assay (Gerhardt, 1981). The lambda prophage induction assay for screening anticancer drugs is an example of an assay that uses subcellular preparations (Price et al., 1964).

Strain Improvement

Microorganisms freshly isolated from nature have highly regulated metabolic systems designed to prevent the overproduction of biochemicals. Genetically altering the strain so that it overproduces a desired product is an important step in industrial microbiology. Three such general procedures have been used successfully: mutation, genetic recombination, and gene cloning. Each technique has its advantages and disadvantages. Often two or three of these techniques can be used in tandem to obtain a stable improved strain. Success in bringing a fermentation product to market and consequently competing in that market depends on continuous strain improvement programs. Screening and selection methods for strain improvement have been reviewed by Elander (1966), Aharonowitz and Cohen (1981), Queener and Lively (1986), and Silverman et al. (1998).

Historically, mutant screening was the first systematic method to improve industrial strains. The lineage of strain improvement for penicillin production is shown in Table 2. After an exhaustive screening of natural *Penicillium* strains, one isolate (NRRL-1951) was obtained that produced ten times more penicillin than the initial isolate of Fleming. Starting in 1944, strain NRRL-1951 was used as the parent strain for a program of mutation and selection by several groups of investigators. The results were remarkable: strain X-1612, an x-ray-induced mutant of NRRL-1951, produced 0.3 g of penicillin per liter; strain Q-176, an ultraviolet light-induced mutant of X-1612, yielded 0.55 g per liter; and descendants of strain Q-176 (e.g., strain 49-133) in turn produced 1.2 g; and currently used commercial strains yield more than 7 g per liter. The significance of this strain improvement program is that today it is possible to produce enough penicillin at a low cost to treat anyone who needs the antibiotic, whereas before only a few serious cases could be treated at a high cost.

Genetic recombination of advantageous mutations from several mutant strains is a useful procedure for strain improvement. It allows one to combine advantageous mutations from different sources. Also, genetic recombination makes possible the removal of deleterious secondary mutations. For example, when a culture is mutagenized and then a bacterium is selected which overproduces the desired product, the bacterium may also contain mutations that interfere with growth. By backcrossing the mutant strain into the wild type, it is possible to screen for strains that contain the useful mutation without the deleterious one. This procedure of "cleaning up" the strains is particularly important when multiple mutation steps are employed.

Gene manipulation is the third and most recent technique of strain improvement. This method requires a good understanding of the molecular genetics and biochemical pathway that is involved in the biosynthesis of the desired product. Gene manipulation can be used to overcome rate-limiting reactions by increasing the production of specific enzymes. This can be obtained by cloning the gene and increasing its copy number, by altering promoter strength and

Table 2. Strain improvement in penicillin production.

Year	Penicillin strain	Origin	Yield (g/l)
1929	Penicillium (Fleming)	Chance contamination	0.01
1941	NRRL-832	Isolated in Belgium	0.04
1943	NRRL-1951	Isolated from a melon	0.15
1944	X-1612	X-ray mutant of NRRL 1951	0.30
1945	Q-176	UV mutant of X-1612	0.55
1949	49–133	Spontaneous mutants of Q-176[a]	1.2
1990	Commercial strains	Nitrogen mustard mutants of 49–133[a]	>7.0

[a]Several steps of mutation and selection were used to obtain this overproducing strain.

ribosome binding sites, and eliminating undesirable properties such as product inhibition. In addition, gene manipulation can be used to generate new products by combining genes from different microorganisms. This latter technique—combinatorial genetics—has been used successfully to produce new macrolide antibiotics (Hutchinson and Fujii, 1995).

Biochemical Engineering

To commercialize the production of fermentation products by microorganisms, it was necessary to scale-up productions from flasks to large fermentation tanks. This requires a combination of microbiological and engineering skills. The first problem that had to be overcome was the need for sterilization and prevention of contamination by undesirable microorganisms. The fundamental principles of sterilization, developed by Pasteur and others, had to be modified considerably when going from flasks and Petri dishes to very large stainless steel tanks. Not only did engineering techniques have to be applied to sterilize the medium, but techniques had to be developed for the sterile introduction of the inoculum, maintenance of pH and temperature, and the introduction of large quantities of oxygen (air) under sterile conditions.

Understanding and controlling a fermentation process depends on the data obtained from biosensors and instrumentation. The most important parameters to measure and control are pH, temperature, and concentrations of dissolved oxygen and substrate. If these parameters are not maintained within a narrow range, the synthesis of the desired product will decline and in the worst case, the culture will die. Each of these parameters must be measured on-line. In modern fermenters, the information obtained by the sensors is fed into computers that then automatically adjust the conditions of the fermentation broth to a predetermined value. Dissolved oxygen can be regulated by increasing air flow into the broth or agitation speed of the rotors, pH can be adjusted by pumping in acid or base, and temperature can be controlled by heating or cooling with circulating cold water. Additional parameters of biological significance that can be measured include culture turbidity, exit O_2 and CO_2, and product concentration. Instrumentation for measuring and regulating fermentation parameters and for computer control of microbial processes has been reviewed by Wang (1981) and Guerreiro et al. (1997).

Scale-up of fermentation processes generally proceeds from flasks to small fermenters to large fermenters (Gaden, 1981). Certain physiological parameters can be determined in flask experiments, such as optimum temperature for growth and product formation, growth rates, growth yields, changes in pH values during growth, and nutrient requirements. Since the cost of producing a fermentation product is often influenced largely by the costs of the nutrient feed stocks, it is important to examine inexpensive commercial sources of nutrients, such as corn syrup and casein hydrolysates, even in the flask experiments. Small fermenters (1 to 50 liters) are used to determine the optimum biochemical engineering parameters that are required in large-scale industrial fermentations, e.g., oxygen demand. Many economic evaluations can not be performed accurately using laboratory equipment and, therefore, pilot plants must sometimes be built. Scale-up of fermentations has been reviewed by Trilli (1981) and Reisman (1993).

The series of steps used to concentrate and purify the desired product is referred to as the downstream process. Each downstream process is tailored to fit the specific properties of the desired product. The first step is usually the separation of the cells from the broth by continuous centrifugation or hollow fiber filtration. If the product is in the cells, then the cells are disrupted and the product purified by specific biochemical procedures. If the product is in the cell-free broth, then the next step is concentration of the product by removal of the water. Depending on the molecular size and charge of the product, the water can be removed by ultrafiltration, precipitation, or distillation of the product. Again, the final purification of the fermentation product depends on its specific biochemical properties. Typical procedures include liquid-liquid extractions, adsorption chromatography, ion-exchange chromatography and gel filtration.

The Antibiotic Era

(See chapter on Bacterial Pharmaceutical Products.)

The Discovery of Penicillin and Aftermath

The discovery and development of antibiotics is one of the great scientific achievements of the twentieth century. Like many events of major historical significance, the contributing factors were varied and complex. Microbiologists, chemists, fermentation engineers, medical doctors, businessmen, industrialists, lawyers and government officials played major roles. The motivating forces ranged from pure scientific curiosity and the desire to alleviate suffering to economic gain and the pressures of the Second World War.

The story, which has been told many times, begins in 1928 with a fortuitous observation by Alexander Fleming, a bacteriologist working in St. Mary's Hospital in London. Fleming was growing a disease-causing staphylococcus in Petri dishes containing nutrient agar. An airborne fungal spore fell inadvertently onto the agar and began to multiply. As the contaminating mold grew, a halo, or clear area, developed around the mold colony. Such accidents must surely have happened to hundreds of bacteriologists before Fleming, but the ruined agar plates were simply discarded in disgust. Fleming, however, realized the significance of the clear area around the mold colony. The fungus must have secreted something into the medium that inhibited the growth of the staphylococci. He therefore isolated the fungus and repeated the experiment, this time intentionally adding the fungus to the bacterial culture. Again the fungus secreted a product that killed bacteria in the neighborhood of the mold colony. Fleming went one step further. He grew large batches of the mold and then separated the mycelial mass from the culture medium. The mold-free juice he prepared was still lethal to the bacteria. Since the mold was a species of *Penicillium*, Fleming called the antibacterial material in the juice penicillin. Shortly thereafter he attempted to concentrate and purify penicillin, failed, and abandoned the project. There followed a period of ten years during which there were no significant developments in penicillin research. Several suggestions have been put forth to explain this ten-year lag between the discovery of penicillin and its development as a potent chemotherapeutic agent. Although Fleming wrote in 1929 that penicillin "may be an efficient antiseptic for applications to, or injection into, areas infested with penicillin-sensitive microbes," he failed to convince the scientific community. Fleming gave up because he was not a good enough chemist to purify the unstable molecule and lacked the money necessary to hire chemists to help him. With the millions of dollars being spent today on medical research, it is difficult to comprehend how an established scientist like Fleming could not then obtain the $5000 per year that he needed. Finally, it should be mentioned that scientists are not always the best promoters of their own ideas. Fleming represents the classic example of a scientist whose original findings were subsequently rediscovered, developed, and exploited by others.

As a consequence of the rise of fascism in the 1930s, many outstanding scientists were forced to flee from Hitler's Germany. One of these refugees was the biochemist Ernst Chain. Shortly after arriving in England, Chain joined with Howard Florey, a pathologist at Oxford, in a systematic search for antibacterial substances. A careful library study led Chain to select penicillin as the target of research. A relatively short time after receiving the penicillin-producing mold from Fleming, the team of Chain and Florey succeeded in developing techniques for the purification of penicillin. The first animal experiment with the partially purified penicillin was extremely encouraging. Subsequent studies demonstrated that penicillin was not toxic to mammals, including humans. Preliminary tests with humans suffering from incurable bacterial infections showed that penicillin was a miraculous drug. By 1941, the pressing problem was how to produce enough penicillin for general clinical use. With the outbreak of World War II, the need for drugs effective against battle wounds became even more urgent. Florey and Chain went to the Ministry of Health for help. A decision was made at the highest level of government to assist the Oxford group in making more penicillin. Florey was sent to Peoria, Illinois, the headquarters of the newly established Fermentation Division of the U.S. Department of Agriculture. The laboratory in Peoria was ideally suited for the project. The proper equipment was available and, more importantly, the research staff was experienced in mold fermentations. After a few days of intense discussions, Florey returned to England, leaving his trusted assisstant, Norman Heatley, to teach the Americans what was then known about growing *Penicillium* and measuring the quantity of penicillin produced. Progress was rapid. As described above, strain improvement by mutation and selection yielded strains that produced higher and higher levels of antibiotic (Table 2). By 1943, the major bioengineering problems had been resolved by a cooperative effort of the Peoria laboratory, universities and industry, and the first aerated stainless steel tank for penicillin production was put into operation.

One of the ironies of the penicillin saga is that England, where the drug was first discovered and shown to be effective, had to pay United States' companies royalties after the Second World War for the technical know-how to produce penicillin. Fleming, of course, never attempted to patent penicillin. It is unfortunate but true that even if he had, the patents would have expired before the drug was produced commercially. The Oxford group, on the other hand, could have obtained considerable financial reward for developing the penicillin extraction procedure, but instead they gave their knowledge freely to the world. The pioneering research on penicillin, however, did not go unrecognized: The 1944 Nobel Prize in medicine was shared by Fleming, Chain and Florey. For the immigrant biochemist Chain, there was the added pleasure of knowing that he was a major contributor to the develop-

ment of a drug that saved the lives of thousands of young men who fought to liberate his former homeland—sweet justice.

Limitations of Penicillin and the Development of Other Antibiotics

There are at least three serious limitations to the chemotherapeutic use of penicillin. First, it cannot be taken orally. The molecule is rapidly decomposed in the acid of the human stomach. Second, it is not effective against several bacteria, including a number of Gram-negative pathogens. Third, a significant number of people are allergic to it. At least three approaches have been used by applied microbiologists and chemists to overcome these limitations: 1) synthesis of chemical derivatives of penicillin (semisynthetic penicillins) that are more resistant to acid and penicillinase and inhibitory to a wider range of bacteria than the natural penicillin G, 2) use of natural inhibitors of penicillinase, such as clavulanic acid, that can work synergistically with β-lactam antibiotics to extend their range, and 3) development of many other antibiotics for clinical use.

The great success of penicillin encouraged microbiologists to search for other antibiotics. A key figure in this search was the soil microbiologist Selman Waksman of Rutgers University in New Jersey. Between 1939 and 1945, Waksman and his associates examined thousands of microbes for their ability to produce antibacterial substances. A major conclusion that emerged from the Rutgers study was that spore-forming bacteria in the soil, especially the *Streptomyces*, were a rich source of antibiotics. From the thousands of antibacterial substances tested, Waksman isolated, characterized and patented several important antibiotics, including streptomycin, neomycin and actinomycin. Streptomycin, first reported in 1944, quickly emerged as a valuable treatment for tuberculosis and other infections caused by penicillin-resistant Gram-negative bacteria. With Waksman pointing his finger to the soil, the "gold rush" was on for new and better antibiotics. Thousands of active compounds have been found, identified chemically, and screened for potential clinical use. Although most of the active compounds were shown to be too toxic for general use, about 50 of them have proven therapeutic value and are currently produced commercially for medical and veterinary use. A partial list of important antibiotics is shown in Table 3.

What are the common characteristics of antibiotics? 1) From the chemical point of view, they are an extremely diverse group of organic molecules. The only chemical feature antibiotics seem to share is their relatively small size. Molecules have fewer than 40 carbon atoms. 2) Ecologically, antibiotics are produced almost exclusively by spore-forming soil microorganisms. Furthermore, antibiotics are synthesized at precisely the time the cells are sporulating. Because of these correlations, some microbiologists have hypothesized that the natural role of antibiotics is to regulate the formation of spores in microbes. However, many mutants do not produce antibiotics yet sporulate normally. It is, therefore, reasonable to conclude that antibiotics have no single function, playing different natural roles in different microorganisms. 3) Medically, the most important trait of an antibiotic is high therapeutic index, an indicator of selective killing and low toxicity. Each antibiotic interferes with an essential and specific microbial function.

The Role of Antibiotic Research in the Development of Microbial Biochemistry, Molecular Genetics and Biotechnology

Much of what we now know about the bacterial cell wall and biopolymer synthesis has come from studies using specific antibiotics to inhibit synthesis. Furthermore, antibiotics were key tools in the development of microbial genetics. For example, most auxotrophic mutants were obtained using the penicillin selection method (Davis, 1948). Antibiotic resistance continues to be the most important selection marker for genetic recombination. The discovery of plasmids was initially connected to research on multi-drug resistance or R factors. Even today most of DNA recombinant technology relies heavily on the use of antibiotics and antibiotic-resistance genes to construct useful strains. Antibiotic research is an excellent example of how applied and basic research overlap, interact and mutually benefit each other.

The New Biotechnology: Applications of Genetic Engineering

(See chapter on DNA Recombinant Protein Production in Bacteria.)

Cloning genes in bacteria is already a valuable technology in both basic biological research and practical applications (Glazer and Nikaido, 1995). In basic research, genetic engineering in bacteria has been used to examine the underlying mechanisms of DNA replication, gene recombination, and gene expression of viral, bacterial and eukaryotic genes. The number of commercial applications of gene engineering continues to grow (Table 4). Recombinant DNA technology can be used to more efficiently carry

Table 3. Antibiotics used in chemotherapy.

Antibiotic	Source	Used medically in treating	Mode of action
Penicillin	Fungus (Penicillium)	Gram-positive infections	Blocks bacterial cell-wall synthesis
Ampicillin (Penbritin)	Semi-synthetic pencicillin	Gram-positive and gram-negative infections	Blocks bacterial cell-wall synthesis
Cephalosporins	Fungus and *Streptomyces*[a]	Gram-positive and gram-negative infections	Blocks bacterial cell-wall synthesis
Streptomycin	*Streptomyces*	Tuberculosis; gram-negative intestinal tract infections	Inhibits protein synthesis in bacteria
Oxytetracycline (Terramycin)	*Streptomyces*	Most bacterial infections	Inhibits protein synthesis in bacteria
Chlortetracycline	*Streptomyces*	Most bacterial infections	Inhibits protein synthesis in bacteria
Chloramphenicol (Chloromycetin)[b]	*Streptomyces*	Typhoid fever; Rocky Mountain spotted fever	Inhibits protein synthesis in bacteria
Polymyxin (Aerosporin)	*Bacillus*	Gram-negative wound infections	Destroys bacterial cytoplasmic membrane
Bacitracin	*Bacillus*	Topical infections of eye and skin; burn infections	Blocks bacterial cell-wall synthesis
Novobiocin	*Streptomyces*	As penicillin; also penicillin-resistant staphylococci	Blocks bacterial nucleic acid synthesis
Erythromycin	*Streptomyces*	As penicillin; also penicillin-resistant staphylococci	Inhibits protein synthesis in bacteria
Griseofulvin	Fungus and *Streptomyces*[a]	Fungal infections (taken orally)	Destroys fungal cytoplasmic membrane
Polyenes (Nystatin)	*Streptomyces*	Systemic fungal infections	Destroys fungal cytoplasmic membrane

[a]Initially discovered as a fungus, now known also to be produced by *Streptomyces* species.
[b]Initially discovered in a *Streptomyces*, now made chemically.

Table 4. Some of the commercial applications of recombinant DNA technology.

Applications	Examples
Production of mammalian proteins in bacteria	Insulin, blood proteins, interferons, growth hormones and tumor necrosis factor
Vaccines	Hepatitis B, rabies, measles, polyvalent vaccines and DNA vaccines
Fermentation products	Increased yields of antibiotics, restriction enzymes, proteases, xylanases, amino acids and vitamins
Diagnostics	Diagnosis of pathogenic microbes and genetic diseases
New antibiotics	Hybrid polyketides
Transgenic plants and animals	Herbicide, insect and microbial disease resistant plants; cows that produce pharmaceutical products in their milk
Gene therapy	Introduction of cloned adenosine deaminase (ADA) into immune deficient patients lacking ADA
Environmental biotechnology	Cloning and overexpression of genes involved in the degradation of pollutants

out an existing process or develop entirely new products. One of the first examples was the production of human insulin in *Escherichia coli*. After the insulin gene was chemically synthesized and inserted downstream from a suitable *E. coli* promoter, the cell was able to synthesize a fusion protein, which was then split into the separate insulin peptides. These peptides, once connected by disulfide bonds, were the final product that is identical to human pancreatic insulin and now commercially available. Microbially produced human insulin is not immunogenic and is purer and less expensive to produce than porcine or bovine insulin, which was previously used. Several other human protein pharmaceuticals are now produced in microorganisms including anticancer agents, such as α- and β- interferon; human growth hormone for the treatment of dwarfism; nerve growth factor; lysozyme for the treatment of inflammations; and several blood proteins, such as hemoglobins used as blood substitutes (Kumar, 1995), erythroprotein to treat anemia, urokinase to assist in blood clotting, and tissue plasminogen activator to dissolve clots.

Safe and highly effective vaccines can be produced by recombinant DNA technology. Instead of using killed or attenuated pathogenic bacteria or viruses, subunit vaccines are produced by cloning part of the protein that is on the outer surface of a bacterium or virus. The subunit protein vaccine is then produced in a microorganism, usually *E. coli*. The subunit vaccines produce a rapid and high level of protective immunity with no possibility of transmitting the infection. Furthermore, vaccines can be produced against microbes that are difficult to grow in vitro. The first recombinant subunit vaccine approved for use in humans was against hepatitis B virus. Recombinant vaccines are also available for animal diseases, such as Newcastle's and fowl pox diseases in poultry. Several trials are currently being carried out with polyvalent (subunits from more than one protein) vaccines against acquired immunodeficiency syndrome (AIDS). A new approach is to use specific, cloned DNA itself as the vaccine. The DNA is taken up by the animal cell and then transcribed and translated into an active immunogenic protein. If successful, these DNA vaccines would be safe and inexpensive.

The fermentation industry has benefited greatly from recombinant DNA technology. The technology is used in strain improvement programs to obtain not only more efficient processes but also new products. Most of the DNA restriction enzymes used in biotechnology are produced in *E. coli* from cloned DNA that has been put into high expression vectors. Similarly, many of the commercial enzymes (such as proteinases used in the detergent and food industries, xylanases and amylases used in the textile and paper industries, and glucose isomerase used to make high fructose corn syrup) are produced in bacteria that are easy to grow in fermenters, e.g., *E. coli* and *Bacillus* species (Godfrey and West, 1996). An interesting approach to the production of new antibiotics is to place selected genes from two different polyketide antibiotic-producing bacteria into a recipient bacterium that can then synthesize a new polyketide antibiotic (McDaniel et al., 1993). Another important application of recombinant DNA technology is the construction of transgenic plants and animals. Such organisms have great potential for enhancing agricultural productivity and improving the nutritional and storage properties of meats and vegetables. Also in development are crop plants, used for the production of recombinant vaccines, including edible vaccines against cholera and enteric diarrhea. In many of the plant engineering constructs, *Agrobacterium tumefaciens* is used to introduce desired genes into the plant. Monsanto Company (St. Louis, MO) is presently marketing a transgenic soybean plant that has an *Agrobacterium-derived* gene

that confers resistance to Roundup, a glyphosate herbicide. Genetic engineering also has been used to protect plants from viral diseases. Calgene Corporation (Davis, CA) produces a transgenic tomato that spoils more slowly than normal tomatoes because it contains an inhibitor of pectinase transcription. Transgenic animals are used extensively in research as well as for the commercial production of proteins of pharmaceutical value, such as α-1-antitrysin in sheep and tissue plasminogen activator in goats. Biotechnology is also involved with human genes and, in the long run, recombinant DNA technology will probably have its most dramatic effect on the human genome. As Robert Sinsheimer stated thirty years ago:

"For eon after eon, creature has given rise to creature upon this earth—blindly, each generation usually like the former, occasionally—by accident—a little different. Of all the creatures that have lived upon this earth we are the first to understand this process. . . . The ultimate significance of this understanding of the very basis of heredity is incalculable. It will change all the eons to come" (Rosenberg, 1991).

Already, PCR technology is widely used in forensic medicine to determine parentage, to analyze evolutionary relationships between modern man, early man, and pre-man, and so forth. In one of the largest biological research programs ever conducted, the human genome project, the entire nucleotide sequence of the human genome will soon be determined. By comparing the DNA sequence of healthy and diseased individuals, the precise position and aberration in the "bad" gene may be found. Gene therapy, through genetic engineering, offers the hope of replacing disease-causing genes with healthy ones, thereby providing preventive medicine in the most profound sense.

Applied Environmental Microbiology: Bioremediation

(See chapters on Bioremediation and Bioemulsifiers.)

Albert Einstein defined the environment as "anything which is not me." This definition is interesting for two reasons: it has enormous scope, and it points the finger away from each of us. Individuals, industries and societies have assumed incorrectly that if the environment is not "them," they do not have to be responsible for it. The result is world-wide pollution, which degrades the quality of our lives and threatens our very existence.

When considering pollution, one must focus on the turnover of matter, which is fundamentally a series of microbial processes. It is primarily by microorganisms that waste products, including most pollutants, are broken down. Microbes have enormous biodegradation potential. They occupy all possible ecological niches, from deep in the earth to high in the atmosphere, and collectively are able to grow over a wide range of temperatures, pH values, salt concentrations and oxygen tensions. There is not a single natural organic compound that cannot be degraded by one or more microbial species.

If microbes have such enormous degradative power, why do we have pollution? For two fundamental reasons: 1) man-made conditions are unfavorable to rapid degradation and 2) certain man-made synthetic compounds are resistant. The former is dictated by the "law of the minimum," i.e., growth is limited by one essential component. For example, if a large amount of petroleum is dumped into the sea, biodegradation may not be at an appreciable rate because utilizable forms of nitrogen and phosphorus are not available—even if many hydrocarbon-degrading bacteria are at the site. Nitrogen and phosphorus are, of course, essential components for all living cells. Another condition, which is unfavorable for biodegradation, is high concentration of organic material. Two good examples of this are whiskey and jam in which ethyl alcohol and sugar are respectively at levels that resist breakdown. One of the reasons that organic matter is degraded so slowly in garbage dumps is that the consolidation and concentration of materials make biodegradation difficult. In the above examples, natural bacteria can completely degrade (mineralize) these materials, whether they are hydrocarbons in crude oil or cellulose in newspaper, if the conditions are favorable. However, several man-made unnatural compounds, such as certain halogenated aromatics and plastics, are not biodegradable in any circumstances. They simply have not been on the planet long enough for bacteria to have evolved degradative mechanisms.

Bioremediation is the use of living organisms, usually bacteria, to prevent or clean-up pollution. Bioremediation is a large and growing area of applied microbiology (Bitton, 1994). Hundreds of companies around the world are involved in treating water and soil that is polluted with industrial wastes, such as petroleum products, herbicides, pesticides, explosives like TNT, toxic metals, dioxenes and polychlorinated biphenyls (PCBs). There are two general approaches to bioremediation. The first and most successful method is to optimize conditions so bacteria native to the polluted site can more rapidly degrade the pollutants. The second method, which has had limited success to date, is to introduce more efficient degraders to the polluted

site, or in the case of nonbiodegradable synthetic pollutants, to construct genetically engineered microorganisms (GEMs) that can degrade the pollutant. The following examples will illustrate these two approaches.

Petroleum Pollution and Bioremediation

During the twentieth century the demand for petroleum as a source of energy and as a primary raw material for the chemical industry has increased world production to about 3,500 million metric tons per year. Approximately 1% or 35 million tons finds its way to soils, lakes and seas. The toxicity of petroleum to microorganisms, plants, animals and man is well established. The polycyclic aromatic hydrocarbon (PAH) fraction of petroleum is particularly toxic and is on the United States Environmental Protection Agency priority pollutant list (Cernilia, 1992).

It has been known for over 80 years that certain bacteria are able to degrade petroleum hydrocarbons and use them as a sole source of carbon and energy. Effective bioremediation of petroleum pollution relies heavily on a fundamental understanding of the requirements for petroleum biodegradation (Table 5). Generally, the presence of hydrocarbon-degrading microorganisms is not the limiting factor in petroleum bioremediation. Hydrocarbon-oxidizing bacteria have been isolated from a wide variety of natural aquatic and terrestrial environments (Rosenberg, 1991), including hydrothermal vent sites (Baylinski et al., 1989). Furthermore, the addition of oil causes a rapid shift to increased numbers of hydrocarbon degraders. For example, Song and Bartha (1990) demonstrated that the number of hydrocarbon-degrading microorganisms increased from 410^4 to 310^{10} per g of soil 4 weeks after addition of jet fuel and inorganic nutrients. The practical conclusion from this and other studies is that seeding an oil-polluted area with microorganisms is generally not necessary, and GEMs are not required for petroleum bioremediation.

In addition to having the biochemical potential for degrading one or more classes of hydrocarbons, an efficient hydrocarbon degrader must be able to adhere to and desorb from water-insoluble hydrocarbons. The role of cell surface hydrophobicity, adhesins, and bioemulsifiers in the growth process has been reviewed (Rosenberg and Ron, 1996).

The most important factor determining the success of a petroleum pollution bioremediation project is the ability to provide the optimum conditions for the hydrocarbon-degrading bacteria. The major requirements are adequate sources of oxygen, nitrogen and phosphorus. Oxygen can be added to soils by frequent plowing and to underground reservoirs by pumping aerated water through them. Soils can be amended with utilizable nitrogen and phosphorus salts. However, no satisfactory method exists that provides the nitrogen and phosphorus necessary for bioremediation of oil spills in open systems, such as the sea. The ideal nitrogen and phosphorus source should adhere to the oil, rather than be diluted with water. An example of bioremediation of beach sand by addition of nitrogen and phosphorus is shown in Table 6. Overall, the bioremediation treatment resulted in the degradation of 88% of the oil after 4 months. During the same period, there was virtually no change in the oil concentration of the untreated control plot.

The Use of GEMs in Bioremediation

The first GEM to be patented in the United States was a Pseudomonas that was designed for degrading different hydrocarbons and constructed from genes derived from different bacteria (Chakrabarty and Gunsalus, 1971). The great potential of GEMs for bioremediation was publicized by the news media, which referred to them as "superbugs." Unfortunately, the potential of GEMs in bioremediation has not been

Table 5. Requirements for biodegradation of petroleum.

A. Microorganisms with:
   1. Hydrocarbon-oxidizing enzymes
   2. Ability to adhere to hydrocarbons
   3. Mechanism for desorption from hydrocarbons
   4. Emulsifier-producing potential
B. Water
C. Oxygen
D. Relatively large amounts of utlizable nitrogen and phosphorus
E. Iron, magnesium, and other essential elements

Table 6. Bioremediation of hydrocarbon-contaminated sand at an Israeli beach.

	Hydrocarbon degradation (%)	
Day	Control (untreated)	Experimental (N_3P added)[b]
10	10	20
20	20	41
30	22	50
40	18	60
50	20	65
70	10	70
90	0	75
120	0	88

[a]Data from Rosenberg et al. 1996.

[b]Approximately 30,000 m^2 of heavy oil contaminated beach were treated with 15 g fertilizer (containing utilizable N and P) per kg sand. The area was plowed twice weekly.

realized as yet for several reasons. 1) Safety regulations have restricted the release of GEMs into the environment; in fact, most of the research carried out on GEMs and bioremediation has been diverted to studying the fate of GEMs in the environment. 2) Genetically engineered microorganisms do not appear to have any significant advantage over a mixture of existing bacteria for the in situ degradation of natural pollutants, such as crude oil. 3) Also, to construct GEMs that effectively degrade recalcitrant synthetic pollutants has proved difficult. In spite of these problems, progress is being made in constructing GEMs for degrading haloaromatic compounds (Reineke, 1998; Timmis et al., 1994) and other pollutants (Chen et al., 1999). When enhanced biodegradative pathways are combined with the genetic potential to catabolize these pollutants in the natural environment, then mineralization rates will likely improve. One possible approach is to clone genes for biosurfactant production into GEMs that have good catabolic potential.

Health-Related Applied Microbiology

(See chapter on Bacterial Pharmaceutical Products.)

Drug Discovery

One of the most exciting areas of applied microbiology involves the discovery of new drugs for human and animal health. Secondary metabolites produced by microorganisms provide a vast array of potentially useful drugs. While the search for new drugs from *Streptomyces* and other spore-forming bacteria continues to be productive, new sources of bacteria are now being exploited, such as marine bacteria (Fenical, 1993, 1997). In addition to expanding the pool of microorganisms in the search for novel pharmaceuticals, researchers are now employing new technologies for drug screening (Steele and Stowers, 1991; Lloyd, 1998; Schmid et al., 1999). These include robotic techniques for plating test bacteria and delivering dilutions of bacterial extracts, use of monoclonal antibodies and fluorescent techniques and combinatorial biosynthesis (Hutchinson, 1998), and screens based on specific enzymatic reactions. These new techniques allow for a more rapid and comprehensive screening for new drugs.

Diagnostic Microbiology

Detecting, classifying and enumerating microorganisms in drinking water, foods and beverages, and human tissues and fluids is a large area of applied microbiology that is constantly undergoing improvements. During most of the twentieth century, microbiology laboratories developed many dependable approaches for detecting microorganisms, especially pathogens, using microscopy coupled to staining techniques, culturing in selective media, and immunoserology (Koneman et al., 1992). This field of diagnostic microbiology has proved invaluable to physicians treating patients, food producers controlling the quality of their products, and health officials monitoring water supplies and consumer products. However, many of these diagnostic tests are slow, expensive and insensitive. For example, culturing bacteria from urine or blood and then testing them for antibiotic sensitivity can take several days. During this time the patient may be at risk, or in the case of a water supply or consumer product, many people could be infected during the diagnosis period. Therefore, it would be advantageous to have more rapid and sensitive techniques.

During the last ten years, many new biotechnology companies have emerged that have as their major focus the development of specific diagnostic tests that do not depend on culturing microorganisms. Rather, these new biotechnology methods rely on amplification of a species-specific DNA target, of the probe, or of the signal that is generated (Hammes and Higgins, 1995; Whelen and Persing, 1996). In addition to great sensitivity and rapidity, these methods can detect pathogens that are difficult to culture, such as *Tropheryma whippelii* (Relman et al., 1992), *Chlamydia trachomatis* (Chapin-Robertson, 1993) and *Neisseria gonorrhorea* (Hale et al., 1993). Nucleic acid probes have already replaced classical morphology and biochemical tests in clinical laboratories for the definitive identification of mycobacteria (Keller, 1993). Considerable effort is now being employed to develop biotechnology-based detection methods for drug resistance in clinically important organisms (Eron et al., 1992). Advances in approaches to DNA-based diagnostics have recently been reviewed (Whitcombe et al., 1998).

Food Microbiology

(See chapter on Bacteria in Food and Beverage Production.)

Food microbiology, one of the traditional areas of applied microbiology, is changing dramatically. Microorganisms play a direct role in producing and processing the healthy foods we eat and drink. Meat and milk are available to us only because microbes, in symbiotic relationships with certain animals, are able to digest cel-

lulose. Different microorganisms convert milk to a variety of yogurts, cheeses and butter. Still other microbes preserve plant materials in the form of tasty products such as pickles and sauerkraut. Alcoholic fermentation by yeast is needed for bread as well as all alcoholic beverages. Hagedom and Kaphammer (1994) have reviewed the role of microbial biocatalysis in the generation of flavor and fragrance chemicals.

An interesting recent development in food microbiology is the use of "probiotic bacteria" to improve animal and human food (Bengmark, 1998; Holzapfel, 1998; Guarino, 1997). Probiotic bacteria are generally isolated from the mouth, stomach and upper and lower bowel of healthy humans and animals. These normal resident bacteria are beneficial, providing vitamin K, helping to process nutrients, preventing colonization of transient bacteria (nonspecific defense mechanism), developing the immune system, and stimulating phagocytic activity. The future of probiotics will depend upon the development of safe strains that are well adapted to occupy specific niches in the body and promote health. When added to food or used as starters in food fermentations, these strains can provide the beneficial effects of probiotics to man and animals.

Biosafety and Legal Protection in Biotechnology

The safety of research microbiologists and legal protection for their discoveries are two subjects which have become more important in recent years in applied microbiology and biotechnology. Unfortunately, most microbiologists do not get an adequate education in these topics. Many laboratory techniques create aerosols, which can lead to the inhalation of undetected infectious agents and the occupational illnesses among laboratory workers who handle infectious materials. Based upon available data, preventative measures have been developed which provide safeguards for scientific personnel and the environment. These safeguards are collectively called containment practices. Leiberman et al. (1986) have written a concise review on biosafety in biotechnology, which should be studied by all practicing microbiologists.

To derive financial benefit from an original and potentially useful discovery in biotechnology, it should be patented. This is particularly important for research scientists at universities because once a patent application has been filed, it is possible to disclose the invention (scientific publications, grant applications, seminars, etc.) and still have legal protection. In the United States it is possible to file a patent within one year of the publication date. The culture of science demands free exchange of ideas and data. Patenting makes this possible, while still protecting the rights of the scientist. Another reason for patenting a discovery is that it allows the owner of the patent to more safely market the invention. An applied microbiologist at a university or research institution cannot generally convert his discovery into a commercial product. It is therefore necessary for the institution to find a partner or sell the patent and know-how. The procedures for obtaining a patent have been outlined by Saliwanchik (1986).

Outlook

The border between basic and applied microbiology, which has always been tenuous, is disappearing. The period in which a discovery in basic microbiology becomes an applied project is often very short. Some of the most basic discoveries in microbiology are now made by scientists working on applied problems in universities, research institutions and biotechnology companies. The rapid progress taking place in applied microbiology and biotechnology, made possible by almost a century of fundamental work on microbial biochemistry, physiology and genetics, makes it difficult to predict which areas will develop most rapidly in the next few decades. Clearly, the use of bacteria in DNA-based technologies will continue to grow and find new applications. Already, a large percentage of the corn grown in the United States contains cloned *Bacillus thuringiensis* protein as an endogenous insecticide. In addition, I predict the following three general subjects will soon emerge as highly significant in applied microbiology and biotechnology.

Environmental Microbiology

The rapid increase in human population and technological developments is degrading our environment at an alarming rate, causing a lowering of the quality of life and serious health problems. Since microorganisms are largely responsible for the turnover of matter on this planet, applied environmental microbiology will become more important. Not only will bioremediation develop further scientifically, technologically, and commercially, but also selected microbes will be used under controlled conditions to recycle waste and to prevent pollution by replacing pollution-producing chemical processes. The so-called "green revolution" will be carried out by microorganisms supplied by a new generation of applied microbiologists.

An outcome of research in environmental microbiology will be the emergence of new prin-

ciples of ecology. For the same reasons that microbes were ideal organisms to study the principles of biochemistry and genetics, they will be used to develop fundamental principles of ecology. The use of higher animals and plants for deriving general ecological principles is limited by our inability to carry out controlled experiments. Animal and plant ecologists can make accurate observations, ask interesting questions and present hypotheses, but the microbial ecologist can obtain quantitative data in controlled experiments, using molecular probes and other tools of modern microbiology. The combined effort of animal, plant and microbial ecologists should lead to a better understanding of how organisms interact with their environment.

Microbial Associations with Animals, Plants and Humans

It is clear that natural bacteria play a key role in maintaining the health of animals, plants and humans by providing nutrients and conditions that deter pathogens (Falk et al., 1998). As we learn more about these interactions, use of selected and improved bacterial strains will grow: in agriculture, for improving yields and preventing spoilage; in animal husbandry, for improving yields and nutritional value of meat, milk and eggs; in humans, for maintaining health and deterring diseases. The use of probiotics in animal food and milk products for human consumption is just the beginning of this development.

Microbial Enzymes

Microbial enzymes are currently being used commercially, primarily for degradative reactions, e.g., proteinases, cellulases, amylases and lipases. This area will be further developed with the introduction of more efficient enzymes and enzymes from extremophiles with increased heat tolerance and extended pH range. However, the commercial potential of microbial enzymes used to synthesize drugs and other fine and bulk chemicals is even greater. With the accumulating data on biosynthetic pathways and the ability to overproduce specific enzymes, it should be possible to mix and match enzymes both in vivo and in vitro to efficiently produce existing valuable products as well as new materials. In this regard, bacterially produced polyhydroxybutyrate and its copolymers have attracted considerable attention as environmentally degradable plastics for a wide range of agricultural, industrial and medical applications (Anderson and Dawes, 1990).

This short list is certainly not comprehensive; many other subjects of applied microbiology will expand and new areas will be created. In short, the future of applied microbiology and biotechnology is bright.

CHAPTER 1.13

The Structure and Function of Microbial Communities

DAVID A. STAHL, MEREDITH HULLAR AND SEANA DAVIDSON

Introduction

For the greater part of its history, microbiology has been a science of the single cell. The cell has dominated thought and experiment. So much so that discussion of other forms of organization, if addressed at all, was most often the subject of hallway speculation rather than a serious question of investigation. It is heartening that within the last decade or so the science of microbiology has begun to address the dimensions of organization that transcend the single cell. For example, the study of biofilms as organized systems is now more acceptable, and several high profile publications have emerged that examine the physiological basis of structure and function at a multicellular level of monospecific biofilm communities (Fuqua et al., 1994; Fuqua et al., 1996; Hastings and Greenberg, 1999; Whiteley et al., 2001). Although there remains an essential reductionism to these studies, they have demonstrated the importance of intrapopulation, and possibly interpopulation, communication systems in controlling the structure and activity of multi-species microbial systems.

A decade ago one of the authors contributed a short article to the American Society for Microbiology (ASM) News (Stahl, 1993), noting a fundamental variance between microbiology and general biological sciences. Microbiology was not built upon a foundation of natural history, for lack of tools to observe and categorize microbes in the field. Morphology was of little utility—the simple shapes of microorganisms conceal their remarkable diversity. Culture-based studies provided only a sketchy census of natural diversity, and conventional biochemical tests did not serve a phylogenetically based system of classification. It was only through comparative sequencing, first of proteins and later of nucleic acids, that inferences of phylogenetic relationship among microorganisms could be made (Zuckerkandl and Pauling, 1965; Jukes and Cantor, 1969). Today we see a field transformed by comparative analyses of genes and more recently of complete genomes. The metric provided by a molecular clock introduced an evolutionary perspective and phylogenetic dimension most forcefully represented by a universal tree of life (Woese, 1987; Woese et al., 1990). This single phylogeny revealed the vast diversity of microbial life, reducing the plants and animals to a peripheral branch (Fig. 1). This has fueled more general recognition that the primary biology of our planet is microbial and provided an essential framework to conduct a census of diversity (Stahl et al., 1984; Olsen et al., 1986; Ward et al., 1990; DeLong et al., 1994; Amann et al., 1995). Within that framework, both cultured and uncultured organisms could be related through a common metric based on the sequence divergence of common biopolymers (e.g., DNA encoded RNA and protein components of the cellular translational and transcriptional machinery). As environmental surveys were initiated, and today continue, microbiologists are confronted with a natural diversity that far exceeds that represented in pure culture, revealing major lines of descent (kingdom and phylum level) that were previously unrecognized. The astounding implication is that we are only now beginning to explore significantly the biological diversity of our planet.

This introduction must include a disclaimer. Although our subject is microbial community structure, the accepted unit of community structure, the species, remains poorly conceptualized. Complete genome sequences and expansive molecular diversity surveys have not provided much illumination on the "species problem." For example, comparative analyses of different strains of *Escherichia coli* have revealed a remarkable plasticity in genome sequence among organisms coherent by traditional phenotypic criteria (Wren, 2000; Hayashi et al., 2001; Perna, 2001; Pennisi, 2001; Dobrindt et al., 2003). Microbial geneticists were startled by the large fraction of genes of unknown function revealed in the genome sequence of *E. coli*. Each newly sequenced genome contains a similarly high fraction of unknowns (20–30%). Nonetheless, clinical labs would assign *E. coli* strains differing by as much as 30% to the same species without difficulty. In contrast, strains of other well

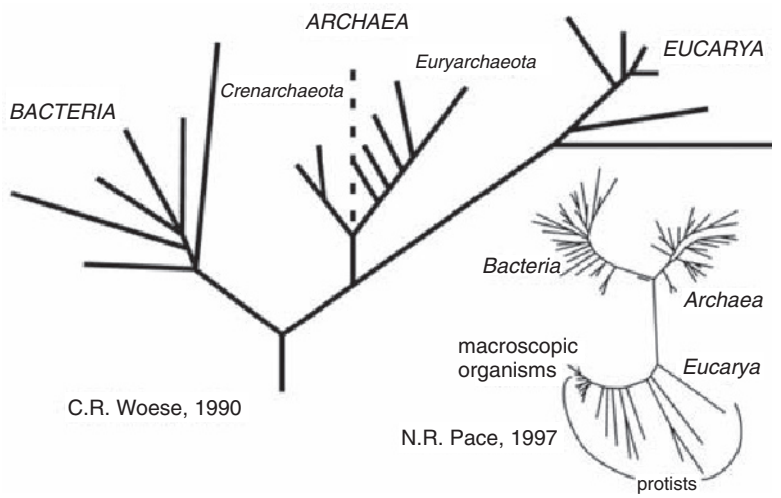

Fig. 1. Universal phylogenetic tree in rooted form shows the three domains. Branching order and branch lengths are based upon rRNA sequence comparisons (Woese et al., 1990). Inset tree illustrates elaborations of existing branches (Pace, 1997) but maintenance of the fundamental framework determined in the earlier phylogeny.

described genera and species are much more uniform in genome sequence and organization. For example, the genome sequence of *Mycobacterium bovis* is greater than 99.95% identical to *M. tuberculosis*, having no genes that uniquely distinguish it from *M. tuberculosis* (Garnier et al., 2003). This apparent incongruity illustrates one of the limitations of characterizing microorganisms in populations of clonally derived cells—the pure culture—and of emphasizing selected features (such as host range or pathogenicity) in formal descriptions. Here, we emphasize that the laboratory culture is not an appropriate context for fully appreciating any organism—divorced from a native habitat of which we have little understanding. The high proportion of genes of unknown function in every completed genome is another reflection of the pure culture paradigm. The environment is the context in which genomes evolved, function, and continue to evolve. It is the only context in which they can be fully understood.

The habitat in which microbial communities reside includes the interplay between biotic and abiotic factors. Microbiologists, again largely because of the pure culture paradigm, have tended to emphasize the abiotic features of habitat (electron donor, electron acceptor, salinity, temperature, pressure, etc.). These are the standards by which organisms have been defined. However, these factors are in most instances only a thin slice of the parameter space defining their ecology and evolution. As was long ago expressed by Darwin, "... the most important of all causes of organic change is one which is almost independent of altered physical conditions, namely, the mutual relation of organisms to organisms. If some of these many species become modified and improved, others will have to be improved in a corresponding degree or they will be exterminated." Thus, more complete understanding of any organism must encompass the features of higher order organization that have shaped the organism's evolution and contemporary "niche."

A recent retrospective by Moselio Schaechter suggests that we have so far experienced two golden ages in microbiology (Schaechter, 2003). The first age followed recognition of microorganisms in general terms—as examples of the unity of biochemical processes, as agents of disease and spoilage, and the primary engines of biogeochemical transformations. The technological development that heralded the beginning of this first golden age was the pure culture method. Advances in molecular biology and associated methods of genetic analysis introduced the second golden age. We are now poised at the beginning of a third golden age which will develop a more complete understanding of systems of organization (ecology), their origins, and mechanisms of change (evolution). This age will be fostered not only by the rapid advances in technology (e.g., high throughput sequencing, proteome and transcriptome analyses, nanotechnology, and bioinformatics) we now see influencing research in all areas of inquiry where life intrudes, but also by the coalescing of disciplines needed to address the complexity of systems-level organization. An empirical observation has been that predictions of higher levels of organization in biological systems are not readily derived from understanding gained at lower levels (Mayr, 1982). Thus, at least for biological systems, it is essential that the tools of analysis accommodate the complexity encountered at higher organizational levels. Advances in technology in concert with disciplinary coalescence will foster investigations that move far beyond the study of clonal lines in laboratory culture to studies of natural systems comprised of diverse interacting populations. This will continue to be

true and the final section of this chapter is devoted to limited discussion of the changing landscape of technology.

Structure and Function of Microbiological Systems

Microbiological systems can be characterized in three general ways: 1) the historical (considering system origins and evolution), 2) the proximate (characterizing the immediate structure and function of a system), and 3) the temporal (addressing the interplay of biotic and abiotic elements that shape a system over diel and annual temporal periods). No one way of characterization provides complete understanding—all three must be considered. In turn, each characterization must incorporate the different dimensions of structure and function. These dimensions encompass both the biotic (phylogenetic, evolutionary, and metabolic) and the abiotic (chemical and physical). We have organized this chapter by considering both the different ways microbiological systems are characterized and the multiple dimensions of structure and function that serve characterization.

The Historical System

The Phylogenetic Dimension

The evolution of our planet is intertwined with the evolutionary history of its microorganisms. Neither the planet nor any one organism is fully intelligible apart from that ancestry. Today, a reasonable representation of the phylogenetic relationships among all life is available (Woese et al., 1990; Woese, 2000). The "universal tree," inferred by comparative sequencing of the small ribosomal subunit rRNA, remains the canonical structure (Fig. 1). Although it is recognized that horizontal gene transfer may have eroded some of the fine detail of structure (Doolittle, 1999), there is an emerging consensus that microorganisms display an organismal genealogy and that many genes are phylogenetically informative (Ochman et al., 2000; Daubin et al., 2003).

Recognition that a microbial genealogy could be inferred from comparative analysis of appropriate gene homologs (orthologs) had significant impact on our perspective and understanding of the structure and function of microbiological systems. The most immediate impact derived from recognition that our census of biological diversity was incomplete; the several thousand named species of microorganisms scattered among thinly branched parts of a tree was not an adequate representation of diversification spanning the greater part of the evolutionary history of this planet. Subsequent application of molecular methods to directly describe environmental microbial diversity has confirmed that the greater part of biological diversity is microbial and that the greater part of microbial diversity has yet to be described (Amann, 2000a; DeLong and Pace, 2001; Torsvik et al., 2002a; Torsvik et al., 2002b).

The phylogenetic dimension embodies the connection between the diversification of life represented in the canonical tree and the emergence of functional groups (e.g., methanogens, acetogens, sulfate reducers, and nitrifiers) in both an evolving and contemporary biosphere. If microorganisms have diversified to fill both general and specific niches, the record of this diversification will be captured by their genealogy. However, there is considerable confusion concerning the ability to infer physiology from phylogenetic affiliation. There are many examples of close phylogenetic relationship between organisms that have remarkably different physiological attributes, for example, close relationships between phototrophs and autotrophs, and between autotrophs and heterotrophs (for examples, see Lane et al., 1992). Conversely, there are also examples of phylogenetically defined groups that are remarkably coherent in physiological characteristics. The *Desulfovibrio* (Devereux et al., 1989; Devereux et al., 1990), methanogenic groups (Raskin et al., 1994), and nitrifiers (Head et al., 1993; Teske et al., 1994) are notable examples of phylogenetic and physiological coherence. Part of this apparent discordance almost certainly derives from failure to recognize ecologically significant features. This is a consequence of using the pure culture phenotype to infer environmental activity outside of the context of the complex environment and interactions between organisms of a microbial community. As we develop methods for direct observations of populations within an environmental setting, we anticipate that many additional phylogenetically cohesive characters will be revealed.

A general relationship between habitat and taxonomic groups has long been recognized. However, molecular tools are refining the characterization of that relationship. An early observation of direct correspondence was made in a microbial mat community in which the depth distribution of different sulfate-reducing populations corresponded with members affiliated with discrete phylogenetic clades (Risatti et al., 1994). A similar correspondence between phylogenetic affiliation and aquatic habitat has been noted. The ubiquitous (SAR11) group, first identified by Giovannoni et al. (1990), appears to be exclusively marine (Morris et al., 2002). However, the

greater assemblage of organisms to which the marine SAR11 belongs includes more distantly related freshwater representatives (Bahr et al., 1996; Field et al., 1997; Morris et al., 2002). *Prochlorococcus* appears to be an exclusively marine assemblage of unicellular cyanobacteria. An early suggestion that genetic variation among *Prochlorococcus* isolates corresponded to different light adapted populations was subsequently confirmed (Moore et al., 1998). The population structure and thus phylogeny of planktonic bacterial communities are associated with general features of habitat (marine versus freshwater, and depth-associated changes in physical and chemical variables).

Although a correlation between closely related populations and habitat is not unexpected, we also ask the more general question—how are the most ancient of evolutionary divergences (domain and division level; Hugenholtz et al., 1998) related to the structure and activities of contemporary systems? If the emergence and diversification of a new lineage were primarily explained by a key evolutionary innovation, then retention of that innovation among contemporary representatives would serve to characterize the lineage and the defining evolutionary innovation. A few notable examples support this, suggesting a centrality of the phylogenetic dimension (Fig. 2). The first example is one of remarkable biochemical innovation, the invention of oxygenic photosynthesis. There is good support that this innovation was a consequence in part of horizontal gene transfer between early anoxygenic phototrophs, each having distinct photosystems. The melding of those photosystems into a two-photosystem apparatus defined the emergence of the cyanobacteria (Buttner et al., 1992). This ancestral metabolic innovation defines all contemporary representatives of the group. In contrast, the spirochetes provide an example of structural innovation. The spiral body form combined with axial flagella offered advantage for moving in viscous environments, and today they are abundant residents in many such habitats, including microbial biofilms and mats. A final example of both structural and physiological innovation is the endospore of named species of *Bacillus* and *Clostridium*. The bacterial endospore was apparently invented only once and likely in large part defines both the origin and successful radiation of major Gram-positive lineages.

The Evolutionary Dimension

The reflections of past innovations in microbial phylogeny raise immediate questions about mechanism and context of innovation. Complete genome sequencing is beginning to reveal the contribution of horizontal gene transfer as a mechanism of biological innovation. However, it

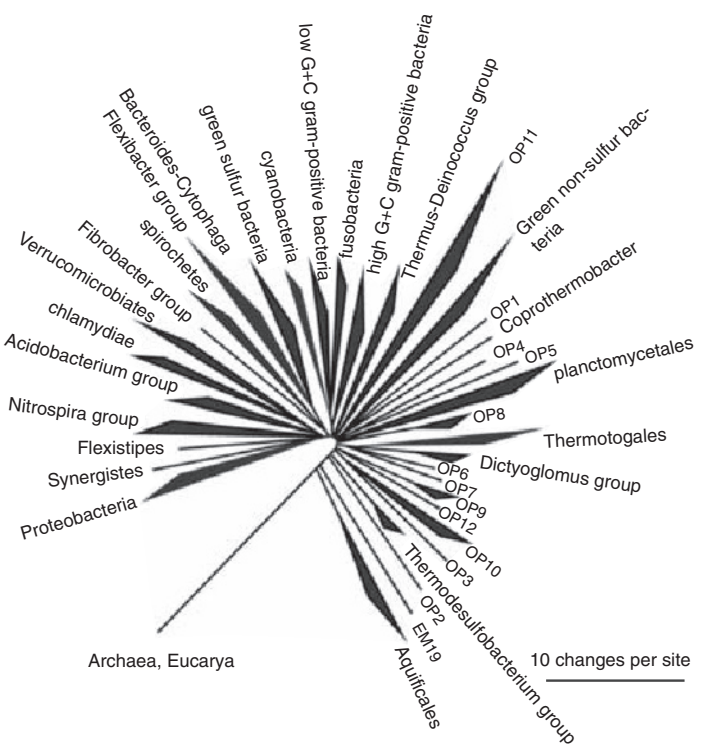

Fig. 2. Evolutionary distance tree of the bacterial domain shows currently recognized divisions and putative (candidate) divisions. The tree was constructed using the ARB software package (with the Lane mask and Olsen rate-corrected neighbor-joining options) and a sequence database modified for the March, 1997, ARB database release.

is too early to constrain its contribution to major innovations in the microbial world since the genomic data sets are still quite sparse in coverage of the major prokaryotic lineages. The context, or environment, in which innovation is fostered can't be separated from mechanism. If horizontal gene transfer is an important mechanism, then the fodder of innovation (genetic diversity) will be determined by opportunities for interaction among contributing populations. Microbial mat communities provide a specific example of this point. Microbial mats are highly active, highly compact, and highly diverse microbial communities providing ample opportunity for intimate interactions among genetically diverse populations. If some early mat communities were based on anoxygenic photosynthesis, this community would be a plausible context for the development of oxygenic photosynthesis via horizontal gene exchange among intimately associated phototrophs. If early mats provided viscous habitats rich in organic substrates produced by phototrophs, this would also have been an ideal context for the emergence of spirochetes. These primarily heterotrophic organisms are adapted to move rapidly in highly viscous environments like microbial mats and biofilms.

Novelty can also arise through isolation limiting genetic exchange and contributing to genetic drift and local adaptation. The degree to which this phenomenon occurs in bacteria is contentious. The prevailing opinion has been that bacterial species are cosmopolitan and exhibit a worldwide distribution. Indeed, surveys using the 16S rRNA suggest a global distribution of many species that can be poles apart (Fuhrman et al., 1992; Fuhrman, 1993; Giovannoni and Cary, 1995; Staley and Gosink, 1999). The adage "Everything is everywhere and nature selects" (Beijerinck, 1913) suggests that geographic barriers do not restrict bacterial dispersal. In this view, bacterial distribution is solely determined by the global dispersal of pre-adapted populations. This view is primarily based on the 16S rRNA gene divergence, which may not be representative of changes in other genes that define specific adaptive traits. The alternative, a biogeography in part determined by evolutionary adaptation to the local environment, is now receiving some support. Several studies have shown that geographically separated populations sharing identical or very similar16S rRNA sequences differ at other genetic loci (Moore et al., 1998; Casamayor et al., 2002; Rocap et al., 2002b). A recent study by Whitaker et al (2003) found that strains of the extremophile *Sulfolobus* clustered geographically rather than by environmental variables that characterized different hot springs. Their multilocus analysis revealed that the genetic distances between populations increased proportionally with geographic distance, suggesting that dispersal of populations and exchange of genetic material between geographically distant groups was limited. Using the 16S rRNA gene as a marker, Papke et al. (2003) also observed genetic differences among thermophilic cyanobacteria from different geographic regions. Their distribution patterns were also ascribed to biogeographic isolation. These and other cumulative data suggest that global distribution patterns reflect both endemic and cosmopolitan groups. This is also supported by recent studies of pure cultures maintained over many generations in the laboratory, demonstrating the capacity for continued adaptive change within a single clonal line of descent (Elena and Lenski, 2003).

Although specific examples are limited, available data point clearly to the importance of contingency in metabolic innovation and adaptive radiation of microorganisms. For example, widespread dispersal may follow major metabolic innovations that derive from interspecies horizontal gene transfer within a complex community, whereas adaptive radiation reflected by biogeographic patterns may arise from more restrictive mechanisms of genetic change. A less speculative discussion of the evolutionary dimension of microbial community structure and function must await more comprehensive descriptions of natural communities.

The Proximate System

Chemical and Physical Dimensions

A central consideration in discussing the structure of microbial communities concerns the interplay between physical and biological controls of organization. Microorganisms are small and experience low Reynolds numbers—viscosity and diffusion dominate their world rather than the mixing and turbulence more familiar to us. Only the fastest and largest bacterium known, *Thiovulum majus*, is able to significantly increase substrate availability by generating advective flow through the entire colony via coordinated communal organization (slime veil formation) and motility (Fenchel and Glud, 1998; Schulz and Jørgensen, 2001; Thar and Fenchel, 2001). More generally, diffusive delivery of nutrient solutes is more important than advective transport (Purcell, 1977; Blackburn and Fenchel, 1999), and diffusion determines structure at both microscopic and macroscopic scales. At microscopic dimensions, a diffusive "sphere" surrounds every metabolically active prokaryotic cell such that substrate concentrations only approach that of the bulk solution several cell diameters away from the microbe's surface.

Microorganisms have developed a variety of strategies to enhance nutrient recovery including the production of siderophores, exoenzymes, smallness and motility (Button, 1994; Blackburn et al., 1998; Blackburn and Fenchel, 1999). Directed movement along a concentration gradient gives the prokaryotic cell a mechanism to move towards regions of higher nutrient concentration, and by doing so increases the flux of nutrient through the cell's diffusive sphere. A recent publication (Fenchel, 2002) suggests that even in a turbulent water column, "nutrient micropatches" derived from cell lysis and excretion by protozoa have life spans sufficiently long to increase nutrient availability to bacteria, not to mention the occurrence of particles or marine snow. The implications for global processes are significant; motile bacteria converging transiently on microscale nutrient patches act to accelerate nutrient uptake and secondary production on a global scale. The ability of microorganisms to utilize available substrates in a competitive manner, and the distribution of these substrates, governs the structure of the microbial communities.

In environments experiencing limited mixing, diffusion and light attenuation contribute to stable architecture at the macroscopic dimensions of millimeters to meters. These systems are layered both chemically and biologically. We briefly discuss several types of layered communities common to aquatic habitats, although we recognize there are terrestrial layered communities as well.

SEDIMENTS. Within a sediment, in the absence of significant advection or bioturbation, mass transport occurs primarily through molecular diffusion. Sediments vary in coarseness and porosity, but in general the sediment matrix limits or prevents water to advect through it. Gradients are formed whenever the production or consumption of a product or nutrient (reactant) exceeds the diffusion of that product or reactant. Substrate concentration reaches a minimum (a boundary condition) at a depth at which the rate of diffusion from the bulk phase matches the consumption rate needed to sustain the minimum free energy required for maintenance. Under these conditions, substrate-concentration gradients reach steady state, yielding characteristic profiles (Nealson and Stahl, 1997; Brusseau et al., 1998; Fig. 3). A key variable is the amount of organic substrate received via sedimentation of organic matter derived from primary produc-

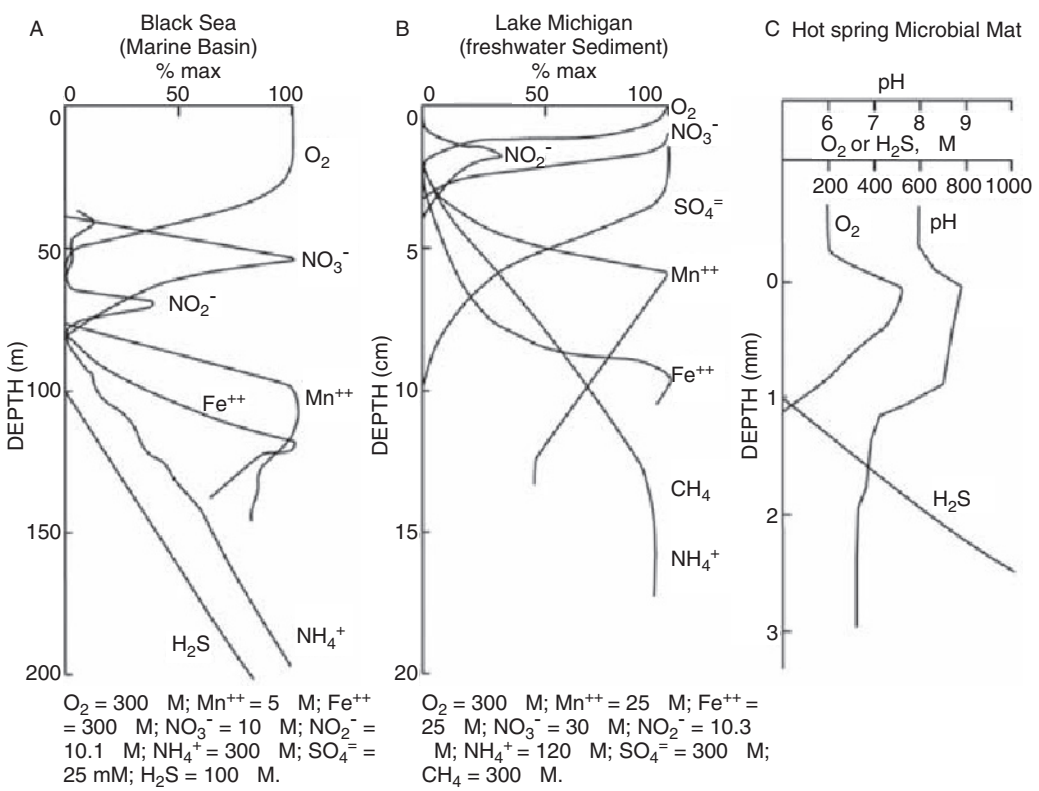

Fig. 3. Chemically stratified freshwater sediment from Lake Michigan and chemically stratified water column of the Black Sea. Although the distributions of the chemicals are similar, the scales over which the chemicals are distributed vary from centimeters in lake sediment to meters in the Black Sea water column.

tion in the water column or from terrestrial input or sediment surface photosynthesis in shallow systems that allow light penetration to the bottom. The observed depth-related changes in chemical composition correspond to a progression of thermodynamically predictable redox changes. Given a variety of possible respiratory modes, those that yield the greatest free energy prevail at each depth under steady state conditions. This begins near the surface with oxygen depletion and typically ends with the reduction of sulfate (in marine environments) to produce sulfide or the reduction of CO_2 (in freshwater environments) to produce methane.

THE WATER COLUMN. The water column of marine and freshwater systems may also exhibit similar depth related chemical structure, most comparably when oxygen depletion extends into the water column. This is observed in small eutrophic lakes and in the permanently stratified Black Sea (Nealson and Stahl, 1997; Taillefert et al., 2002). In addition to diffusion-controlled structure characteristic of sediments, the water column is divided by changes in density, temperature and light. The attenuation of light in the world's oceans provides the most easily resolvable of gradients along which different bacterial populations distribute. For example, as previously noted, different "ecotypes" of *Prochlorococcus* are adapted to different light intensities (Moore et al., 1998; West and Scanlon, 1999; Rocap et al., 2002). Physiological analyses have shown that one ecotype is adapted to the higher light intensities of the upper water column, having a low chlorophyll (Chl) b/a_2 ratio, and the other (higher Chl b/a_2) to life deeper in the euphotic zone. Genome sequence comparisons have also pointed to specific adaptive differences (Rocap et al., 2003). For example, the ecotype adapted to the lower euphotic zone has lost the photolyase gene which is involved in the light-driven enzymatic catalysis of DNA damage repair, presumably because there is little selective advantage to maintain this function under low light conditions.

Variables other than light also contribute to depth-related structure of oceanic provinces. Unlike the relationship to thermodynamic preference observed in chemically stratified lakes and sediments, the controlling variables in the marine water column have yet to be fully resolved. For example, the archaeal phylotypes common in the open ocean vary in depth-related abundance patterns (Massana et al., 2000). Studies of the Antarctic Peninsula showed that planktonic euryarchaeotes were most abundant in surface waters (Masanna, 1998). Increasing archaeal abundance with depth (ca. 25% of total rRNA) was associated with a shift in dominance from euryarchaeal to crenarchaeal rRNA (Massana, 1998). A more recent study at the Hawaii Ocean Time-series (HOTS) station examining the depth-related abundance of these archaeal groups (pelagic euryarchaeota versus pelagic crenarchaea) revealed a similar depth-related pattern of abundance (Karner et al., 2001). Pelagic creanarchaea comprised a large fraction of total picoplankton below the euphotic zone (>150 m), approaching 39% of total DNA-containing picoplankton detected. These groups are surely physiologically distinct, as suggested by a time series study in the Santa Barbara Channel that showed the abundance patterns of these two archaeal groups correlated with general environmental variables (Massana et al., 1997). Other abundant marine picoplankton such as the clade defined by *Pelagibacter ubique* (SAR11) and SAR211 and SAR203 marine clusters also show characteristic depth-related abundance patterns (Giovannoni et al., 1996; Field, 1997; Wright et al., 1997; Morris et al., 2002). Recent success in culturing representatives of the SAR 11 cluster suggests that temperature, not light (Rappe et al., 2002; Zengler et al., 2002), may be an important factor in the growth and distribution of members of this assemblage. The soon to be available genome sequences for these abundant marine picoplankton will undoubtedly provide insights into their physiology and likely provide some explanatory basis for the patterns of structure observed in the open oceans.

MICROBIAL MATS. Microbial mats are among the most visibly conspicuous of layered communities (Fig. 4). Built by photosynthetic or chemolithotrophic bacteria, they share features of structure similar to sediment and water column communities, in that population distribution is governed by light availability and diffusive flux of substrates and metabolites. However,

mats provide for much closer physical and metabolic interactions among contributing populations. The most abundant and versatile photosynthetic mat builders today are the oxygen-producing cyanobacteria (Cohen et al., 1989). The most common types of chemolithotrophic mats are comprised of filamentous sulfur-oxidizing bacteria, generally occurring on sediment surfaces at the interface between gradients of reduced sulfur species and the oxidants oxygen or nitrate (Jørgensen and Revsbech, 1983; Jannasch et al., 1989; Sassen et al., 1993).

The cyanobacterial mats are complete microbial ecosystems, comprised of primary producers (cyanobacteria) and populations of consumers that together mediate all key biogeochemical cycles (Fig. 5). Remarkably, this ecosystem can be represented by a fragment of microbial mat only several centimeters on a side. Although this general type of microbial community is thought to have existed for over 3.5 billion years (Cohen and Rosenberg, 1989), the evolution of metazoan grazers, competition with macrophytes, and changing oceanic carbonate chemistry triggered the decline of the extensive mat communities (represented by stromatolithic fossils) at the end of the Proterozoic (Grotzinger and Knoll, 1999). Today's mats develop conspicuously only in aquatic environments where environmental stress limits or excludes grazing, most commonly in hypersaline or thermal habitats. These are among the best studied of microbial communities and have provided a superb context for studies relating structure and function (Cohen and Rosenberg, 1989).

Hypersaline cyanobacterial mats are characterized by intense oxygen production during the day in the photic surface layer and by highly active sulfate reduction throughout the mat. These gradients virtually disappear at night when the entire mat turns anoxic and sulfidic (Revsbech and Jørgensen, 1983; Canfield and DesMarais, 1993). Both molecular and cultivation studies of the oxic surface layer of cyanobacterial mats have revealed high numbers of sulfate-reducing bacteria (SRB; Risatti et al., 1994; Teske et al., 1998; Minz et al., 1999a; Minz et al., 1999b). Although SRBs are classical anaerobes, oxygen supersaturation apparently does not interfere with the activity of near surface populations in these mats (Jørgensen and Cohen, 1977; Canfield and DesMarais, 1991; Canfield and DesMarais, 1993; Fründ and Cohen, 1992; Jørgensen, 1994; Teske et al., 1998). As yet, there is no physiological or ecological basis to explain these unexpected patterns of distribution.

The chemolithotrophic *Thioploca* mats on the Chilean and Peruvian continental shelf are the most extensive microbial mats on earth (Gallardo, 1977; Fossing et al., 1995). Abundant *Thioploca* populations residing in the upper centimeter of these mats participate in an intense sulfur cycle. The high rate of sulfate reduction (up to 1500 nmol $\cdot$ cm^{-3} $\cdot$ d^{-1}) is balanced by the oxidation of sulfide by *Thioploca* such that sulfate is not appreciably depleted (Thamdrup and Canfield, 1996; Ferdelman et al., 1997). This highly efficient sulfur cycle has been attributed to a close physical association between sulfate-

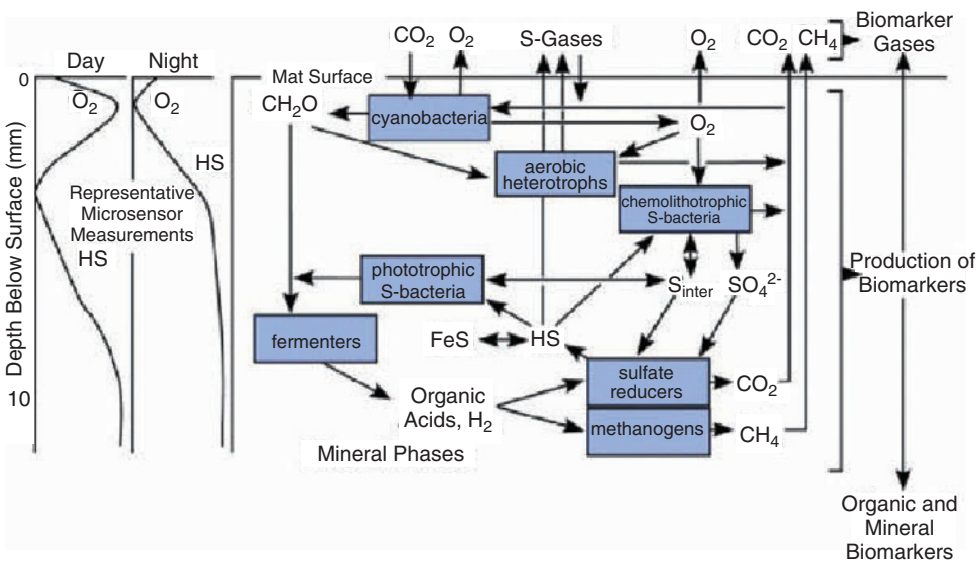

Fig. 5. The distribution and conversions of oxygen, sulfur, hydrogen and carbon dioxide within a layered cyanobacterial mat community.

reducing and sulfur-oxidizing bacteria. Filamentous sulfate reducers of the genus *Desulfonema* were observed growing within the *Thioploca* sheaths, suggesting a complete cycle of sulfate reduction and re-oxidation within individual *Thioploca* bundles, representing an example of syntrophy (Fukui et al., 1999).

Some mat populations rely on motility to follow shifting chemical gradients. Microbes such as the filamentous microaerophilic sulfide-oxidizing bacterium *Beggiatoa* monitor local chemical and physical dimensions of habitat, using that sensory input to relocate to environments better suited to their physiology. *Beggiatoa* in the cyanobacterial mats of Guerrero Negro follow the diel up-and-down movement of the oxygen-sulfide interface closely (Garcia-Pichel et al., 1994). Other organisms have developed a strategy to bridge spatially separated resources. This is exemplified by the recent discovery that *Thioploca* species use large internal vacuoles to store high concentrations of nitrate for anaerobic respiration. Much like a scuba diver fills diving tanks with oxygen to dive in an oxygen limited water environment, *Thioploca* migrate to the sediment surface, partially emerge from their sediment-embedded sheaths to partially enter the water column, and charge internal vacuoles with high concentrations of nitrate (Hüttel et al., 1996). They then return ("dive") to the anoxic depths of the sediment (gliding at a speed of 3–5 $mm \cdot h^{-1}$) to use their stored nitrate for sulfide oxidation (Maier et al., 1990; Fossing et al., 1995).

BIOFILMS. The term "biofilm" is the generally accepted term for microorganisms attached to a solid surface in a relatively thin film. Biofilms pervade virtually all environments and surfaces, often dominating the microbial activity distributed between the individual planktonic and aggregated habitats (Van Loosdrecht et al., 1990). Characklis and Marshall (1990) have generally defined biofilms as systems displaying the following four features: 1) cells immobilized at a substratum and frequently embedded in an organic polymer matrix of microbial origin, 2) a surface accumulation, which is not necessarily uniform in time or space, 3) a significant fraction of inorganic or abiotic substances held together by the biotic matrix, and 4) transport and transfer processes are rate limiting and play a much more important role than in the suspended growth microbial systems. The fourth characteristic highlights the importance of diffusion and reaction in controlling population structure and associated metabolic processes. As for the previously described layered communities, gradients form in response to the balance between microbial synthesis and consumption of diffusible substances, creating niches distinct from the proximal bulk water. Similar to mat communities, natural biofilm systems provide for a spectrum of stable habitat types. Thus, a biofilm community of thickness less than 1 mm can have a diverse and stable microbial ecology amenable to study. For example, the biofilms produced by oral microbiota colonizing tooth surfaces provide a model system for experimental study and are receiving increasing attention (Kolenbrander, 2000).

The microbial populations colonizing suspended particles demonstrate many attributes of biofilms. Suspended organic particles, marine and lake "snow," conspicuous in aquatic habitats provide hot spots of nutrients and carbon sources for bacterial growth (Alldredge and Silver, 1988; Byung and Azam, 1988; reviewed in Turner, 2002). High densities of multiple microbial populations are embedded in a mucoid extracellular polysaccharide (EPS) matrix, providing opportunity for interaction. Reduced diffusion and high activity serve to create localized concentration gradients. Depletion of oxygen towards the center of larger aggregates supports the coexistence of aerobes and anaerobes (Alldredge and Cohen, 1987), as revealed by the presence of sulfate-reducing bacteria (DeLong et al., 1993) and possibly nitrogen fixation (Paerl and Prufert, 1987). Because microorganisms are the only biota having the capacity to utilize the dilute carbon and energy in many aquatic habitats, the colonization and transformation of these particles by microorganisms represents an important portion of secondary production and may play an important role in food web energetics, atmospheric CO_2 exchange, and flux of nutrients to the deep-sea ecosystem through sedimentation of colonized particles (Decho and Herndl, 1995; Turley et al., 1995). Microbial aggregates provide a link between the dilute dissolved carbon and higher trophic levels as food for larval species and protozoa (Pomeroy, 1974; Karl, 1994) and serve to transfer surface water nutrients to the benthos via sedimentation (Passow, 2002; Turner, 2002).

Interactions among microbial populations in aggregated communities are also modulated by regulatory processes that alter gene expression in relationship to population density. Regulated processes are those that are adaptive only when the population density reaches a critical threshold number (the "quorum"). These sensing mechanisms are addressed in the following section on the metabolic dimension.

The Metabolic Dimension

The previous sections emphasized the role of diffusion and reaction in regulating the chemical structure of a microbial system. The metabolic

dimension underlies the chemical reactions governing the flux of energy and matter through the system. Each microbial population must derive sufficient free energy of reaction for maintenance and growth. The biochemical explanation for how the total free energy available is parceled out among the populations is the metabolic dimension. This dimension encompasses factors regulating the biochemical response and activity of populations in any system. We now have only a sketchy understanding of the metabolic dimension and limit our discussion to selected examples of how quorum sensing, syntrophy, and symbiosis govern the metabolic dimension to shape microbial structure and function.

QUOREM SENSING: A LANGUAGE FOR INTER- AND INTRAPOPULATION COMMUNICATION. It is increasingly apparent that specific signalling molecules modulate reactions within microbial communities (Fuqua et al., 2001; Fuqua and Greenberg, 2003; Xavier and Bassler, 2003). The term "quorum sensing" was introduced to describe signaling systems mediated by diffusible molecules (autoinducers, primarily different forms of peptides and homoserine lactones [HSLs]) that regulate expression of genes that are most beneficial when a critical number of microorganisms (the quorum) is present in a locale. The peptide and HSL types of autoinducers primarily control reactions within a single population, for example, in the production of extracellular hydrolases during tissue invasion or in light generation when colonizing particles or inhabiting specialized light organs of certain marine animals (see the subsection Symbiotic Associations). However, a recently described furanone autoinducer (AI-2) has been implicated in signaling between disparate species of bacteria (Xavier and Bassler, 2003). A role of AI-2 in interspecies communication is receiving experimental support, such as a recent study by McNab et al. (2003) showing that interspecies autoinduction is required for the coordinated development of a biofilm comprised of two species of oral microbes, *Porphyromonas gingivalis* and *Streptococcus gordonii*.

Recognition of the widespread occurrence of quorum sensing among microbial species suggests there is frequently an active and rich dialogue between cells comprising one or more populations (Fuqua et al., 1994; Fuqua et al., 1996; Hastings and Greenberg, 1999). To date, most examples have been defined in the context of disease or symbiosis, and they include such diverse processes as bioluminescence, antibiotic biosynthesis and resistance, production of EPS, swarming, plasmid conjugal transfer, and the production of a variety of virulence determinants. Recent studies have revealed the significance of quorum sensing in regulating the formation of biofilms (Davies et al., 1998; Huber et al., 2001; Fuqua and Greenberg, 2002; Fig. 6). An especially fruitful lab model for understanding the possible role of quorum sensing has been the genetically tractable pathogen, *Pseudomonas aeruginosa*, which forms biofilms in the lungs of cystic fibrosis patients, marking the advancement of a serious and recalcitrant infection of the host. Mutations in the HSL receptors and gene regulation have shown that an active quorum sensing pathway is required for the proper development of the characteristic *P. aeruginosa* biofilm comprised of columns of cells embedded in a polysaccharide matrix with open channels between them. This biofilm structure is likely important for nutrient exchange with the bulk liquid phase. The induction of biofilm formation is also asso-

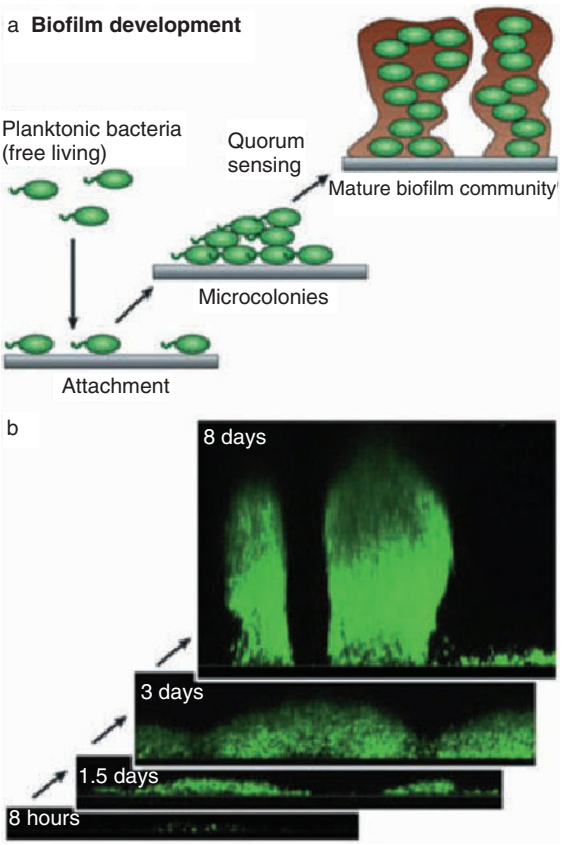

Fig. 6. Biofilm development and quorum sensing. a) The steps involved in a biofilm development. b) Confocal microscope images of a *P. aeruginosa* biofilm developing over time on a microscope slide. The cells are producing green fluorescent protein. The mushroom- and tower-like structures that appear by 8 days are 100 μm high. (The images in b) were kindly provided by M. Welsh, P. Singh, and E. P. Greenberg [University of Iowa, United States].)

ciated with an increase in resistance to antibiotics. Mutants deficient in the production of the specific HSL formed a flat, undifferentiated biofilm.

Although there have been few studies of the possible environmental functions of quorum sensing, there is a growing consensus that this and other chemical signaling systems are a fundamental element of community structure and activity (Fuqua et al., 1996; Fuqua et al., 2001; Hastings and Greenberg, 1999; Xavier and Bassler, 2003). Aggregated microbial communities, regulated in part through quorum sensing, are increasingly viewed as highly adaptive and resilient systems of organization.

SYNTROPHIC ASSOCIATIONS. The metabolic connections among different populations can range from highly specific to generic. An example of a generic association may be simply the use of a vitamin or growth factor released by several other cohabiting populations. This type of interaction would not be expected to exert as much control over the organization of a microbial system or community as connections that specifically link energy recovery between two metabolic pathways. The best examples of systems structured by the parceling of available free energy among interacting populations are found in anaerobic habitats such as the sediment and mat systems described earlier. The anaerobic decomposition of organic material is carried out by the cooperation of several general physiological groups of microorganisms (Schink, 1988). Although a variety of other functional assemblages are present in anaerobic habitats, for the purposes of discussing syntrophic associations in the metabolic dimension, only four main groups are considered here. In the absence of electron acceptors used for anaerobic respiration (e.g., oxyanions of sulfate and nitrate, and oxidized metals), the following four microbial groups are generally recognized to participate synergistically in the anaerobic degradation of organic matter: 1) hydrolytic and fermentative bacteria, which degrade complex biopolymers (e.g., plant cell wall components), and monomers (sugars), and oligomers into acetate, hydrogen, carbon dioxide, and a mixture of short chain fatty acids, alcohols, succinate, and lactate; 2) proton-reducing acetogenic bacteria, which convert fatty acids, alcohols, succinate, and lactate to acetate, hydrogen, and carbon dioxide; 3) hydrogen-oxidizing methanogens, which convert hydrogen and carbon dioxide (as well as other quantitatively less important compounds) to methane and water; and 4) acetoclastic methanogens, which convert acetate into methane and carbon dioxide.

The complete mineralization of organic matter is dependent upon the cooperative growth of all four groups and is sustained by the microbially mediated (via methanogens groups 3 and 4) removal of hydrogen (and acetate). Interdependent growth (syntrophy) was first observed by Bryant and associates (Bryant et al., 1967; Bryant et al., 1977; Wolin and Miller, 1982). Notably, this discovery was a consequence of a failure of the pure culture technique! An organism thought capable of methanogenic growth on ethanol (*Methanobacillus omelianskii*) was found to be a syntrophic association of two species of prokaryotes. One bacterium oxidized ethanol to hydrogen, acetate, and CO_2 (group 2 type). The second was a hydrogenotrophic methanogen (group 3 type). Neither organism was capable of growth on ethanol alone. The energetic basis of this obligate association is the relationship between free energy and hydrogen concentration. The fermentation of ethanol is only favorable at low hydrogen concentrations (negative free energy). Thus, although the ethanol-oxidizing bacterium could initiate fermentation in a closed system (the test tube), hydrogen accumulation soon made this reaction energetically unfavorable. Enter the methanogen—its consumption of hydrogen permitted a continuous fermentation of ethanol. The methanogen was later formally described (*Methanobacterium bryantii*), but its syntrophic bacterial partner has since been lost.

Although interspecies hydrogen transfer was discovered in a closed system, the test tube, it is now recognized to determine higher order structure and activity in both natural and engineered systems. One dramatic example is the granule structure that develops in anaerobic reactors designed to treat industrial waste streams (Sekiguchi et al., 1999). Within upflow anaerobic sludge blanket (UASB) reactors, the four functional assemblages promote the anaerobic degradation of organic industrial waste. These microbiota are retained in the reactor by formation of dense granules of millimetric size, their size controlled by balancing sedimentation with metered upward fluid flow in the reactor. Initial studies of the USAB granules using molecular probes to resolve the distribution revealed fine layering of population types, suggesting tight metabolic connections. The general architecture of each granule consists of a methanogenic core (Archaea), serving to consume hydrogen, CO_2, and acetate, surrounded by outer shells (layers) of fermentative bacteria (groups 1 and 2) that sustain the oxidation of the waste stream components such as propionate, sucrose, and acetate (Fig. 7).

Anaerobic methane oxidation (ANME) is another example of a layered syntrophic association of an inner core of Archaea surrounded by sulfate reducing bacteria (*Desulfosarcina-Desulfococcus* group; Boetius et al., 2000;

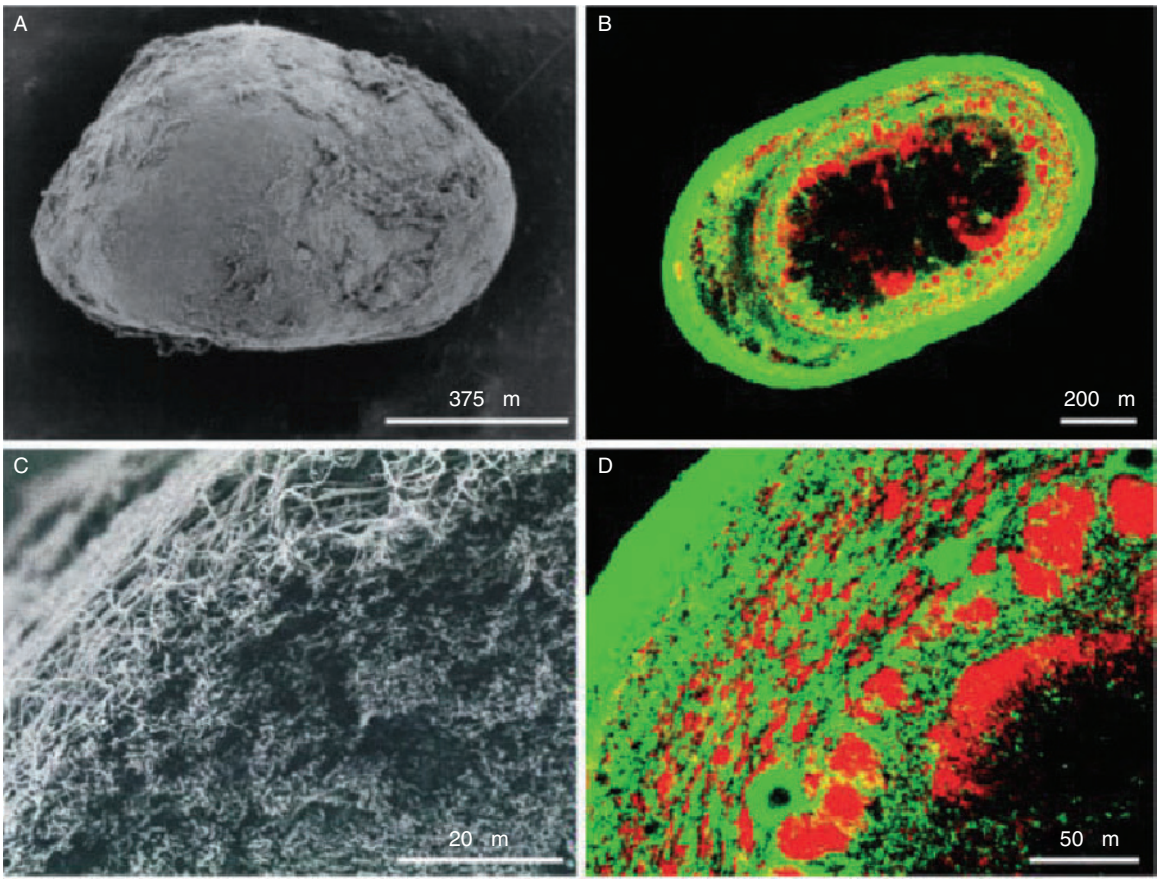

Fig. 7. Sections from mesophilic and thermophilic granules viewed by scanning electron microscopy (SEM) and confocal laser scanning microscopy (CLSM). A) SEM of the surface of granules, B) SEM of internal structure illustrating filaments and rods within layers of the granule, C) and D) are sections simultaneously hybridized with Cy-5-labeled bacterial-domain probe (EUB338; green) and rhodamine-labeled archaeal-domain probe (ARC915; red). (From Sekiguchi et al. [1999].)

Orphan et al., 2001; Teske et al., 2001; Michaelis et al., 2003). It has been hypothesized that this association (like the layered granules above) involves methane oxidation to hydrogen and carbon dioxide. If the concentration of hydrogen remains low, this conversion is energetically favorable, although the energy yield is the lowest known to fuel a microbial metabolism. Removal of the hydrogen is accomplished by hydrogen oxidizing sulfate reducers. Kruger et al. (2004) have isolated from microbial mats a nickel-containing protein, which is similar to methyl-coenzyme M reductase from methanogenic Archaea, the enzyme catalyzing the final step in the production of methane. The metabolic reactions between the Archaea and sulfate reducers result in the formation of $CaCO_3$ reefs that measure 1 m wide by 4 m high in the anaerobic regions of the Black Sea (Fig. 8).

SYMBIOTIC ASSOCIATIONS. Multicellular eukaryotes originated in a microbial world. Thus, a complete understanding of the multicellular condition cannot be separated from pervasive and intimate associations with prokaryotes. These associations have influenced the evolution, development, and physiology of all multicellular life forms (reviewed in McFall-Ngai [2001] and McFall-Ngai [2002]). The phenomenon of symbiosis has been known and studied since De Bary (1879) defined it as two dissimilar organisms living in close association and ranges from the beneficial to the pathogenic. Since then the study of prokaryotic contributions to the evolution, development and functioning of plant and animal systems has become a highly active area of investigation (Seckbach, 2002; Bourtzis and Miller, 2003). In medicine there is growing awareness that the so-called "normal flora" is important to both health and disease (Rook and Stanford, 1998; Relman and Falkow, 2001; Hooper et al., 2002; Hooper, 2004). In response to the need for microbiologists and animal and plant biologists to work in concert to enable progress in understanding the details of these interactions, a discipline of Cellular Microbiology was suggested in 1996 to encompass research

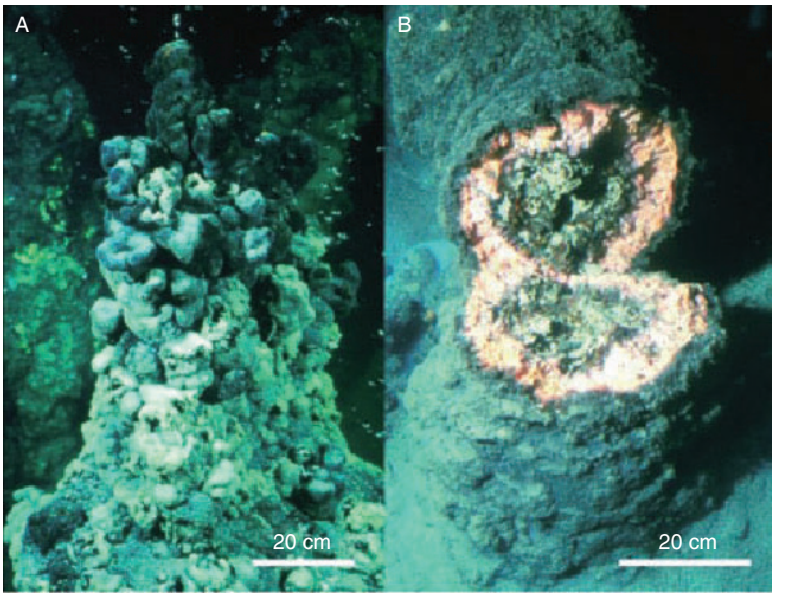

Fig. 8. Image of microbial reef structures. A) Tip of chimney-like structure. B) Broken structure at about 1 m height. devoted to characterizing bacterial interactions with eukaryotic cells (Cossart et al., 1996). Although the initial focus was on understanding pathogens, the field has expanded its scope to include the benign and beneficial associations of bacteria with host cells. Here we focus our discussion only on the beneficial bacterial associations and emphasize that examples presented here are by no means the only or the most important associations but are fairly well studied systems that have provided insights into mechanisms.

All multicellular eukaryotic organisms, including humans, harbor bacteria that serve some function and range in complexity from hundreds of species comprising the populations of the mammalian gut to the simplified monospecific cultures in specialized organs such as root nodules of legumes and light organs of marine animals. The potential for cooperative association provides an evolutionary driving force for both the host and the symbiont. Bacterial symbionts of eukaryotes often confer unique abilities that enable their host to survive on resources that would otherwise be unavailable. Examples include: chemoautotrophs (within the large worms, nematodes, bivalves and shrimp) living on sulfide or methane in a variety of marine habitats (Cary et al., 1997; Deming et al., 1997; Streams et al., 1997; Polz et al., 1998b; Fisher, 1990; Fujiwara et al., 2001); the production of toxins and antibiotics by bacteria (Kobayashi and Ishibashi, 1993; Faulkner et al., 1994; Walls et al., 1995; Kaufman et al., 1998; Currie, 1999; Davidson et al., 2001); the production of light (Hastings et al., 1987; Haygood, 1993); bacteria that degrade cellulose and fix nitrogen in shipworm bivalves and terrestrial termites to allow the hosts to live on wood (Breznak, 1982; Waterbury et al., 1983; Lilburn et al., 2001; Distel et al., 2002); and the associations of cyanobacteria with a variety of fungi to fix carbon and nitrogen (lichens). The activities of certain microbe-host associations, such as gut flora of termites and the nitrogen-fixing *Rhizobium* spp. of legumes, influence the structure and function of entire ecosystems.

The host environment in turn impacts the adaptations of the bacterial partner, which may live, divide and grow either extracellularly (usually associated with specific tissue or organ systems) or intracellularly. There is a continuum of dependence on the partnership ranging from bacteria that are free-living and opportunistically colonize the host (i.e., *Vibrio fischeri* and *Rhizobium*) to obligate intracellular symbionts that are unable to live outside of host cells, having lost a variety of genes as a result of their lifestyle (Baumann et al., 1995; Douglas, 1997; Werren, 1997; Tamas et al., 2002). The severe reduction of the genome sizes in *Buchnera* of aphids is a well-studied example (Ochman and Moran, 2001; Wilcox et al., 2003). The smallest genomes (0.6–1.5 megabases [Mb]) among bacteria are found in obligate intracellular parasites and symbionts (Casjens, 1998). Similarly, the host may be able to live without the symbiont under certain conditions (legumes where there is sufficient nitrogen), or they may lose independence altogether. One of the most dramatic examples of symbiotic dependence is the loss of the entire digestive system of hydrothermal vent-associated tubeworms, *Riftia* spp., which rely entirely on their bacteria for sustenance.

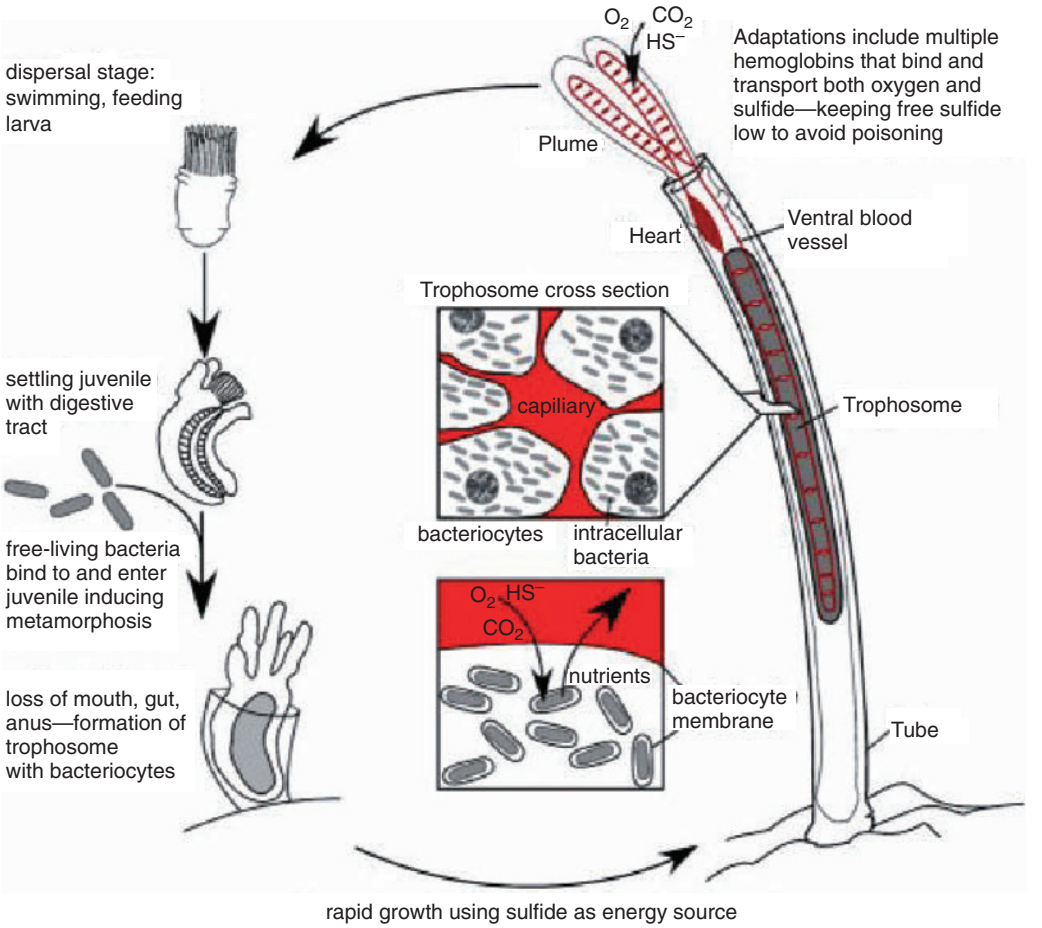

Fig. 9. Bacterial induction of morphological and biochemical adaptations in animals: *Riftia pachyptila* as an example. The dispersal stage resembles other annelid larvae, but upon acquisition of bacterial symbionts, the juvenile loses the digestive tract to form a specialized organ, the trophosome, that houses bacterial cells within host bacteriocytes. In addition to obvious morphological changes, the worm has evolved hemoglobin specialized for transport of both oxygen and sulfide (Childress et al., 1987; Southward, 1999; Bright and Sorgo, 2003; Bright, personal communication).

The vent annelid *Riftia pachyptila* has been profoundly modified from its ancestral form to take advantage of the capabilities of its bacterial partner. This annelid has given up its entire digestive system (no mouth, gut or anus), replacing it with a specialized organ (the trophosome) harboring carbon-fixing sulfide-oxidizing bacteria (reviewed in Fisher [1990] and Fisher [1995]; Fig. 9). Early development of *Riftia* is similar to other marine annelids; a swimming larva locates and settles in an appropriate location near a hydrothermal vent. The developing worm must then recruit appropriate free living bacteria capable of collaborating in an ensuing metamorphosis that results in the loss of the digestive tract to form the trophosome, highly vascularized and packed with intracellular gamma proteobacterial symbionts. A multihemoglobin system found in the red blood and coelomic fluid of these worms accomplishes the delivery of both oxygen and sulfide in a manner that keeps free sulfide levels low but supplies enough to maintain the demands of the symbiont (Fisher et al., 1988; Goffredi et al., 1997a; Zal et al., 1998). The free-living bacteria have not been characterized, and the roles they play in the ecosystem's nutrient cycling outside of the tubeworms, or how they transition to an intracellular lifestyle, are not known.

The early recruitment and colonization of a bacterial symbiont presents a challenge to both partners. The bacteria must evade, or tolerate, host immune defenses and then persist without overgrowth. In turn the host must selectively recruit and encourage growth of its necessary partner without compromising its own health. Several model systems have served to provide detailed understanding of the multiple levels of interaction involved in forming and sustaining a symbiotic association. These systems share the following characteristics that render them more

amenable to study: 1) the bacterial partner can be cultured separately from the host, 2) the host can be studied without the symbiont, 3) genetic manipulation of the bacteria is possible, and 4) the intact lifecycle (or at least early colonization events) can be maintained in the lab (reviewed in McFall-Ngai [2002] and Seckbach [2002]). Notable examples of such systems include the *Vibrio*-squid and *Rhizobium*-legume symbioses (McFall-Ngai, 1999; Ruby, 1999; Stougaerd, 2000; Lum and Hirsch, 2003). These have yielded insight into the biochemistry and genes involved in the initiation, negotiations, colonization, and persistence of the bacterial cells in the host. Key sets of characters that are important for colonization of metazoan and metaphytan hosts include motility, chemotaxis, adhesion, biofilm formation, and quorum sensing (Ruby, 1999; Hirsch and McFall-Ngai, 2000). Many of these are also important in pathogenic associations. In *Euprymna scolopes*, modes of defense against colonization by the wrong bacteria include oxidative stress produced by the host and surface adhesins enabling only specific bacteria to enter and bind to host tissue (Weis et al., 1996; Small et al., 1999; Aeckersberg et al., 2001). Furthermore, to avoid overgrowth, the squid has evolved a behavior of ejecting most of the bacteria at the end of the night, when light is no longer needed, and then allowing the remaining 5% to grow up again during the day while the squid is concealed in the sand. The influence of localized increase in numbers of *Vibrio fischeri* in the water column is not known (Lee and Ruby, 1994; Ruby and Lee, 1998).

We anticipate that this nascent field will be greatly enriched by development of additional model systems, offering comparative framework to study theme and variation in symbiotic systems. Recently developed systems that have proven amenable to dissection of the association in the lab include *Xenorhabdus*-nematode, *Aeromonas*-leech, and *Acidovorax*-earthworm associations. Genetic examination of *Xenorhabdus* spp. and *Photorhabdus* spp. (nematode symbionts; Vivas and Goodrich-Blair, 2001; Heungens et al., 2002; Ffrench-Constant et al., 2003; Martens et al., 2003) and *Aeromonas* sp. (leech symbiont; Graf, 1999; Braschler et al., 2003) has identified genes important for the association. Initial characterization of a specific association between *Acidovorax* spp. bacteria and Lumbricid earthworms suggests that this association is amenable to laboratory study (Fig. 10). Not studied until recently (Schramm et al., 2003), these bacteria have been brought into culture, are vertically transmitted, and likely contribute to nitrogenous waste processing.

Key features that enable bacteria to associate stably with a eukaryotic host are still elusive. The more complete understanding of the complex genetic and metabolic systems of interaction is a central challenge in symbiosis research. With complete genome sequences becoming available, comparisons are possible that may reveal commonalties between bacteria able to associate with hosts and those that do not. To date, the majority of the genomes sequenced are from pathogens of humans or symbionts dependent on close interaction with a eukaryotic host (Ochman and Moran, 2001). Although this is a bias reflective of the human desire to understand disease, it offers comparative opportunities to examine which genes confer the ability to associate stably with a eukaryotic host. Certainly there are pathogenicity islands, sets of genes that confer virulence to normally nonpathogenic bacteria such as *E. coli*. However, there are also examples of symbiosis islands that confer the ability to invade and associate with the host in a positive way, as in the rhizobium-legume interaction (500 kb inserted at a tRNA locus in the plant symbiont *Mesorhizobium loti*; Sullivan and Ronson, 1998). A recent review examining these issues suggests that lineages are either parasitic or symbiotic and do not switch, such that the deep branching pattern of clades indicates one or the other lifestyle (Moran and Wernegreen, 2000a).

The Temporal System

Diel, Seasonal, and Annual Variation in Structure and Activity

The temporal dimension of microbial community structure and activity is determined by a complex interaction of the physical environment on regular daily, seasonal, and annual cycles that influences biology across local, regional and global scales. In aquatic habitats, changes in the stability of the water column related to temperature-mediated changes in water density influence nutrient distribution that ultimately alters microbial activity, community structure, and interactions with higher trophic levels. How the community is shaped by these changes varies and ultimately influences the productivity of the microbial community. Since prokaryotes are the only biota capable of recovering the dilute organic substrates generally present in aquatic systems ("the microbial loop;" Fig. 11), their responses to predictable diel, seasonal, or annual variables are fundamental parameters governing the flux of energy in aquatic habitats (Pomeroy, 1974; Azam et al., 1983; Williams, 2000). The most obvious environmental variables that change on a diel cycle are light (>400 nm) and temperature. Light positively influences primary

production among cyanobacteria but also inflicts UV radiation damage and creates oxidative stress that reduces both primary and secondary production (Garcia-Pichel et al., 1994; Herndl et al., 1994; Ramsing et al., 1997; Pakulski et al., 1998; Booth et al., 2001b). Examples of variables influencing the seasonal distribution of bacterial species are light (Moore et al., 1998; Casamayor et al., 2002), temperature (Murray et al., 1998; Pernthaler et al., 1998; Crump et al., 2003), nutrients (LeBaron et al., 2001; MacGregor et al., 2001; Ovreas et al., 2003; Simek et al., 2003), changes in organic matter quantity and quality (Van Hannen et al., 1999a; Van Hannen et al., 1999b; Crump et al., 2003), abundance of grazers (Pernthaler et al., 2001; Simek et al., 2001a; Simek et al., 2003), and episodic viral lysis (Van Hannen et al., 1999b; Suttle, 2000; Fuhrman, 2001; Hahn and Hofle, 2001). Interannual climatic changes also impact the physical structure of the oceanic water column, which influences nutrient cycling and leads to shifts in the microbial community structure. We present a few examples from aquatic systems that illustrate the complex interaction of physics and biology on diel, seasonal, and annual time scales that influence microbial community structure and activity.

DIEL FLUCTUATIONS IN MICROBIAL GENE EXPRESSION. Here we present a few examples of regulation of gene expression governing responses to regularly changing conditions. During daily fluctuations in light, temperature and other physical parameters, there is potential for damage as well as the need to take advantage of optimal conditions for nutrient and energy acquisition. The ability to anticipate diel cycles of these parameters and adjust gene expression on a regular schedule may have an adaptive advantage. Recent comparative analyses of complete genomes have revealed that homologues of the key genes involved in circadian regulation (*kai* genes) are widely distributed among bacteria and archaea, implicating a more general adaptive significance among prokaryotes of the ability to anticipate regularly changing environmental circumstance (Dvornyk et al., 2003). Autotrophic and heterotrophic prokaryotes exhibit diel shifts in activity regulated by *kai* genes, which belong to the RecA superfamily of DNA binding proteins (Mori et al., 2002), including nitrogen fixation, cell division, and other metabolic processes, although the clocking mechanism is not yet understood (Dvornyk et al., 2003). Synchrony of the endogenous clock and the environmental temporal cycle has been shown to increase the fitness of cyanobacteria (Ouyang et al., 1998).

Diel changes in expression also occur in direct response to an environmental variable rather than being governed by a circadian gene. For example, RecA expression occurs on a diel cycle but in response to DNA damage in the form of cyclobutane pyrimidine dimers (CPD)resulting from absorbance of light in the ultraviolet wavelength (as reviewed in Holm-Hansen et al. [1993], Mitchell and Karentz [1993], Moran and Zepp [2000b], and Jeffrey et al. [2000]). The number of CPD lesions increases over the course of a day, causing mutations if not repaired. In response, bacterioplankton have coordinated RecA-mediated DNA repair and replication over the diel cycle (Herndl et al., 1994; Pakulski et al., 1998), with RecA protein induction peaking at dusk (Booth et al., 2001b). Since the efficiency of DNA repair varies among bacterial species (Arrieta et al., 2000), diel fluctuation in UV is expected to influence the population structure of microbial communities in the euphotic zone of aquatic systems. These are just two examples of strategies employed by bacteria in response to environmental change on a diel scale, and they emphasize that activities and structure oscillate over time in often predictable patterns.

SEASONAL FLUCTUATIONS IN MICROBIAL POPULATIONS. The potential impact of extreme seasonal changes in chemical and physical variables on a microbial system is well illustrated by a study of the high mountain Lake Gossenkollesee (Pernthaler et al., 1998). Changes in light, temperature, nutrients, and organic matter quantity and quality resulted in bacterial populations that were annually recurrent and seasonally variable. Stratification of the water column occurred from June through September with warming of the surface layers, followed by thermal mixing as temperatures cooled in November and then by ice cover throughout the winter and spring. Algae demonstrated a seasonal peak in productivity from December through February as an under-ice bloom (Fig. 12A). This bloom correlated with bacterial productivity (Sommaruga et al., 1997). During autumnal thermal mixing, the total microbial biomass declined (Fig. 12A) followed by a peak during December, once ice formation had occurred. In contrast, *Alcaligenes* sp. showed an annual maximum in November indicating that total biomass estimates often mask fluxes in individual populations (Fig. 12B). Following ice cover, succession continued to occur beneath the ice at temperatures ranging from 0 to 4.2 °C. For example, *Rhodoferax* spp. decreased at the onset of the under-ice algal bloom and then increased after the under-ice algae declined (Fig. 12B). During the ice cover melt, bacterial populations responded to associated inputs of organic carbon from the melting ice, thermal mixing of the water column, and increased temperature. The tight coupling of seasonal variables and microbial population succession in these lake systems

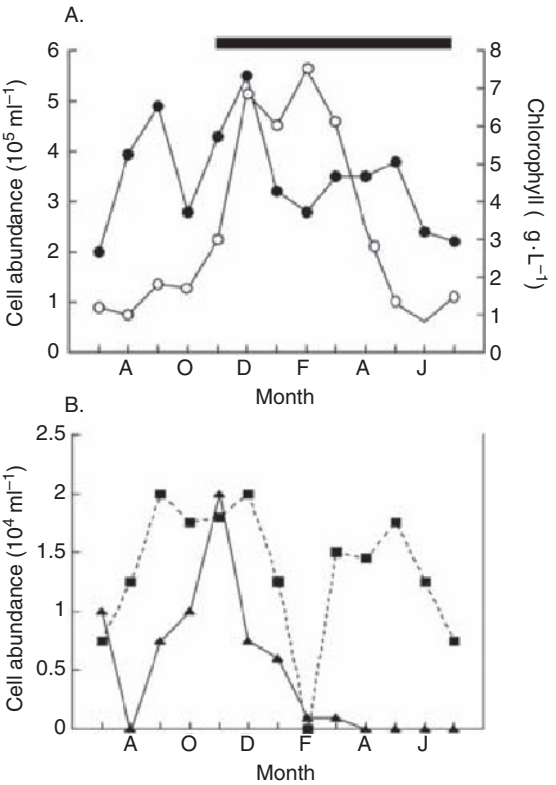

Fig. 12. Seasonal dynamics of primary producers and bacteria at 4 m in Lake Gossenkollesee, an oligotrophic high mountain lake in the Central Alps of Austria. A.) Seasonal fluctuation in chlorophyll a (m) and bacterial cells stained with 4',6'-di-amidino-2-phenylindole (DAPI) (l) at 4 m. The horizontal bar indicates the period of ice cover. B.) Population dynamics of cells hybridizing with probes GKS16 (*Rhodoferax*) (n) and GKS98 (*Alcaligenes*) (s). (From Pernthaler et al. [1998].)

offers opportunities to analyze and better resolve the dynamic interactions between biology, chemistry, and physics in natural systems. Seasonal changes in microbial composition and activity have been investigated and found in other systems including soil, lake sediment, the Mediterranean Sea, and a few oceans (Cannavo et al., 2004; Gallagher et al., 2004; Hasegawa and Okino, 2004; Short et al., 2004; Tanaka and Rassoulzadegan, 2004).

Interaction with higher trophic levels through grazing also influences the seasonal distribution of bacterial species in aquatic systems (as reviewed by Strom, 2000). For example, a seasonal change in nutrient inputs can stimulate a rapid increase of heterotrophic microbial populations which in turn stimulates grazing and growth of protists in aquatic systems (Simek et al., 2003). Grazing by nanoflagellates and protists can be responsible for changes in morphological structure, physiological status of the bacteria (Posch et al., 1999), and taxonomic shifts in the bacterial populations (Hahn, 1999; Simek et al., 2001b), affecting overall cell number and secondary productivity (Simek et al., 2001b; Simek et al., 2003).

Seasonal fluctuations in predation on bacteria by viruses can also alter the distribution of bacteria in a community (as reviewed by Suttle [2000] and Fuhrman [2000]). Since viruses require contact with a host cell, the density of the bacterial cells affects the probability of infection. This implies that since the dominant competitive bacteria is reduced and the rare bacteria are not lysed, viral dynamics in bacterial communities may influence the number of bacterial species that can co-exist in a resource limited environment (Fuhrman, 1999). While viral infections don't lead to extinction, they do shift the relative abundance and growth rates of bacteria on a seasonal timescale. For example, Van Hannen et al. (1999b) showed that the bacterial community structure in freshwater mesocosms was constant until viral lysis of a spring cyanobacterial bloom. The reduction in cyanobacteria was followed by transient blooms of *Cytophaga* and *Actinomycetes* suggesting that these bacterial populations grew on organic matter generated from lysed spring cyanobacterial bloom.

ANNUAL VARIATIONS IN MICROBIAL POPULATIONS. With the awareness that global warming may indeed be altering climate, there is growing interest in how this will influence longer time scale oscillations in climate patterns, and how, in turn, this alters the microbial activities in the oceans and soils globally. An example of a well-studied climatic oscillation, called "El Nino-Southern Oscillation" (ENSO), occurs every 2–7 years (Fiedler, 2002). In non-ENSO years, the trade winds blow in a westerly direction along the equator resulting in increased sea surface height in the west (about 0.5 m). In the eastern equatorial Pacific, water upwells from the deep ocean, causes a decrease in sea surface temperature (about 8°C), and inputs nutrients (NO_3) that fuel algal blooms in an otherwise nutrient limited sea.

During ENSO, the trade winds relax, reducing upwelling, nutrient enrichment (NO_3), and primary productivity (Le Bourgne et al., 2002). These change then influence secondary productivity and food web structure. The warming of the upper surface waters enhances thermal stratification, decreasing the influx of inorganic nutrients (NO_3 and Si) and selecting for N_2-fixing cyanobacteria (as opposed to Si-dependent diatoms). Studies in the North Pacific subtropical gyre suggest that altered nutrient fluxes associated with climate variation have contributed to a shift from eukaryotic primary producers to an array of autotrophic (Karl et al., 2001) and photoheterotrophic prokaryotes (Beja et al., 2000; Beja et

al., 2001; Beja et al., 2002) that now dominates the upper water column in the North Pacific Subtropical Gyre. Thus, the gradual increase in sea and atmospheric temperatures has the potential to alter the time scale and intensity of the ENSO, along with other climatic cycles, influencing the oscillations in microbial ecosystems controlling major biogeochemical cycles (Herbert and Dixon, 2003; Luo et al., 2003; Philander and Fedorov, 2003).

Emerging Technologies Will Enable Characterization of Structure and Function Methodological advancements continue to refine our understanding of microbial communities within an ecological context. Molecular analyses, often based on comparative 16S rRNA sequencing, are now commonly used to explore patterns of diversity and to a lesser extent abundance. These studies have revealed a remarkable diversity of life previously obscured by the limitations of established culture-based descriptions. Continued refinement of methods to enable more comprehensive measurements of microbial populations will begin to illuminate the relationships between population dynamics, physical variables, and the flux of energy and nutrients (carbon, nitrogen, phosphorus, sulfur or other elements).

We anticipate that two analytical developments will greatly enable this research. First, devices or methods capable of making rapid multiple measurements of genotypic and cellular activities (e.g., DNA microarrays) will provide high resolution mapping of temporal and spatial variations in population genotypes and expression patterns. Second, the development of devices or methods capable of measuring the activities at the level of individual cells will define the variability of cellular activity under given conditions and advance culture capabilities. Advances in nanotechnology and microfluidics will likely be key to realizing this second analytical need (Lidstrom and Meldrum, 2003; Hong et al., 2004).

We are now at the leading edge of a revolution in analytical methods that will inform at the level of populations and the single cell. Since this level of resolution will ultimately allow microbiologists to "see the world as microbes see it," this technology will have a profound impact on all aspects of microbiology. Here we highlight only a few promising areas of development for the study of prokaryotes in a more natural context.

MICROAUTORADIOGRAPHY AND FISH. A common indirect measurement of microbial activity has been based on thymidine incorporation into DNA (Fuhrman and Azam, 1980; Fuhrman and Azam, 1982). This and similar approaches (Kirchman et al., 1985) provide an estimate of growth rate averaged over many bacterial groups (see Kirchman and Ducklow, 1993). The contribution of specific populations to bulk processes has been partially revealed by combining the established methods of microautoradiography (MAR) and fluorescence in situ hybridization (FISH; Lee et al., 1999; Ouverney and Fuhrman 1999; Cottrell and Kirchman, 2000; Cottrell and Kirchman, 2003). MAR is based on the incorporation of a specific radioactive substrate added exogenously to an experimental system or environmental sample under controlled conditions. Substrate is generally selected with some understanding of processes intrinsic to a community. Most commonly, cells are fixed to a standard microscope slide, coated with a photographic emulsion, and cells that have assimilated added substrate scored by counting silver grains that develop following an appropriate period of exposure (Brock and Brock, 1966). Currently available imaging devices (e.g., phosphoimagers and beta-emission imagers), although offering wide dynamic ranges, as yet lack the resolution of photographic emulsion (Anderson et al., 1997; Andreasen and Nielsen, 1997; Laniece et al., 1998). FISH using oligonucleotide probes that target varying taxonomic levels from species to higher order phyla are then used to identify which taxa have assimilated added substrate. For example, a general probe for the bacterial domain was used to demonstrate that the capacity to assimilate thymidine is broadly distributed among bacteria inhabiting different ecosystems (Bouvier and del Giorgio, 2001; Cottrell and Kirchman, 2003).

Combined MAR and FISH now provides a method to link novel populations (those identified by rRNA sequence alone) with specific physiological attributes (Nielsen et al., 1998; Lee et al., 1999). Processes and organisms investigated so far include nitrification (Daims et al., 2001a), phosphate accumulation (Nielsen and Nielsen, 2002), sulfate reduction (Ito et al., 2002), and in situ physiology of *Thiothrix* in activated sludge (Nielsen et al., 2000). Recently MAR-FISH has been combined with the redox dye 5-cyano-2,3-ditolyl tetrazolium chloride (CTC) to identify actively respiring cells in filaments of *Thiothrix* (Nielsen, 2003). An important caveat of interpretation is that the method detects uptake of a substrate but does not necessarily imply growth. Microorganisms accumulating certain substrates or compounds (such as phosphate) for storage can be mistaken for actively growing populations.

ISOTOPIC ANALYSES. Stable isotope analysis of microbial communities has been used to identify sources of organic carbon that support bacterial growth in a variety of aquatic systems (Coffin et al., 1989; Hullar et al., 1996). The use

of molecular methods together with stable isotope analysis has served to develop links between phylogenetic affiliation and metabolism of specific populations (Coffin et al., 1989; Kelley et al. 1998; Boetius et al., 2000; Radajewski et al., 2000; Radajewski et al., 2002; Radajewski et al., 2003; Orphan et al., 2001; Whitby et al., 2001; Boschker and Middleburg, 2002; MacGregor et al., 2002; Michaelis et al., 2003). An exemplary method is stable isotope probing (SIP) of nucleic acids (Radajewski et al., 2000). As described for MAR-FISH, these analyses are constrained by the requirement to incubate an environmental sample with substrate (labeled with a heavy isotope) in an enclosed system. Following incubation, DNA (or RNA) is extracted and separated on a density gradient, the heavy fraction derived from populations having incorporated the labeled substrate into their nucleic acids. Functional and taxonomic gene markers are then used to characterize those populations contributing to the heavy (or light) DNA fractions. Recent studies have used 16S rRNA sequence analyses of the heavy DNA fraction to demonstrate consumption of ^{13}C-labeled methanol by members of the *Acidobacterium* division and Alphaproteobacteria (Radajewski et al., 2000), incorporation of ^{13}C -labeled CO_2 by autotrophic nitrifiers (Whitby et al., 2001), and incorporation of ^{13}C -labeled phenol by populations metabolizing phenol in bioreactors (Manefield et al., 2002). SIP has also been used in conjunction with other biomarkers, such as fatty acids, to identify general assemblages of microorganisms contributing to specific activities in the environment (as reviewed in Boschker and Middleburg, 2002). The method has primary utility in assessing assimilatory reactions in contained environmental samples that allow for significant enrichment with the labeled substrate and require relatively short incubation periods. Substrates for dissimilatory reactions (e.g., denitrification of nitrate) cannot be directly measured via incorporation into nucleic acids, and long incubations may contribute to indirect labeling of populations via leakage of labeled metabolites from primary consumers (cross feeding). Genomic studies combined with SIP have the potential to elucidate functional diversity in relation to microbial community structure (Wellington et al., 2003).

More recently, FISH has been combined with secondary ion mass spectrometry (SIMS) to measure isotopic composition of individual cells (Orphan et al., 2001) involved in anaerobic methane oxidation. Another recently described rRNA-based approach used biotin-labeled DNA probes to selectively recover specific rRNA populations for isotopic characterization (MacGregor et al., 2002). In combination with radiotracer approaches, this technique can be used to measure biogeochemical fluxes through specific microbial populations.

DNA MICROARRAYS. DNA-based methods are now commonly used for more direct analysis of community structure. Even so, no study has yet to fully resolve the population structure of a natural microbial community. This is primarily because available formats for nucleic acid-based characterization are not suitable for extensive or intensive analyses. Fingerprinting methods such as denaturing gradient gel electrophoresis (Muyzer et al., 1996) and terminal restriction fragment length polymorphisms analysis (Liu et al., 1997) provide a relatively rapid overview of changing community structure but do not serve to either resolve or identify all contributing populations, and interpretations suffer from the limitations of polymerase chain reaction (PCR) biases (Suzuki and Giovannoni, 1996; Polz and Cavanaugh, 1998a). An alternative format based on hybridization of complex nucleic acid mixtures to dense arrays of DNA probes (DNA microarrays) offers the potential for rapid and high-resolution analysis of sequence composition. Each array element is comprised of a specific DNA probe (an oligomer or PCR amplification product) designed to hybridize to a specific target sequence. Microarrays were initially developed for expression analysis as a natural outgrowth of genomics—the DNA probes designed to target all genes in a specific target organism. Microarrays also provide a format suited to more holistic analyses of microbial communities (Guschin et al., 1997; Gibson et al., 2002).

Initial applications of microarrays in microbial ecology have been primarily demonstration studies, using probes targeting a selected set of conserved genes to evaluate population structure (e.g., ribosomal RNA genes) or potential activity (e.g., nitrification, denitrification, and methanotrophy; Loy et al., 2002; Bodrossy et al., 2003; El Fantroussi et al., 2003; Taroncher-Oldenburg et al., 2003). Most have relied on PCR amplification to generate sufficient target for hybridization and therefore suffer from the recognized limitations of PCR amplification of mixed environmental gene targets—not all genes are equally amplified. However, the greater challenge is interpretation of hybridization events. Unlike expression analysis of a single organism, characterization of an environmental sample may be confounded by far greater and undefined genetic complexity (Torsvik et al., 1990). Environmental studies have therefore relied upon independent assessments, generally by limited sequence analysis of the amplification products applied to the microarray, to confirm hybridization results (Cho and Tiedje, 2001; Koizumi et al., 2002; Bodrossy et al., 2003). Since different envi-

ronments present different compositions of nontarget populations, independent validation would be required for each application. Thus, before DNA microarrays will become robust tools for analysis of environmental systems, validation must become an integrated design feature. For example, on-chip thermal dissociation analysis (El Fantroussi et al., 2003) provided an additional criterion for assessing whether hybridization originates from a target or closely related nontarget sequence. We anticipate that future developments will allow hybridization of DNA and RNA isolated directly from environmental samples, and thus avoid the biases of PCR amplifications.

The Future

This is only a selected sampling of the rapidly changing technology landscape that will enable high-resolution analyses of microbial community structure and function. In discussing these few technical advances, we have also omitted many important developments in high throughput methods for culturing environmental organisms (Connon and Giovannoni, 2002; Zengler et al., 2002). Recent development here suggests that the isolation of microorganisms that have "resisted" cultivation in the past will soon be commonplace. This exciting development will place tremendous demands on microbial physiologists, and we anticipate that high throughput methods of physiological and genetic characterization will naturally develop as the number of microorganisms in culture dramatically expands. The development of nanotechnology promises to provide tools to study the physiology of single cells and the measurement of fluxes on scales that are relevant to the microbial cell. Although applications of current methods are associated with many limitations of format and interpretation, continued advances in technology will largely determine the future of environmental microbiology as we continue to resolve the structure and function of complex communities that sustain our biosphere.

CHAPTER 2.1

Cyanobacterial-Plant Symbioses

DAVID G. ADAMS, BIRGITTA BERGMAN, S.A. NIERZWICKI-BAUER, A.N. RAI AND ARTHUR SCHÜßLER

Introduction

Cyanobacteria are unique in the wide range of symbiotic associations they form with eukaryotic hosts including plants, fungi, sponges and protists (for reviews, see Adams [2000], Rai et al. [2000], Rai et al. [2002b], and Bergman et al. [2003]). Cyanobacteria are photoautotrophs, and in many cases facultative heterotrophs and nitrogen fixers, and can provide nonphotosynthetic hosts with both nitrogen and carbon. Even if the benefit to the host is clear, that to the cyanobacteria is less obvious. They often receive carbon from photosynthetic hosts, but they are capable of carbon fixation themselves. Perhaps a more likely advantage is protection from predation and from environmental extremes, such as high light intensity and desiccation, in the enclosed environment provided by the host.

The cyanobacterial symbionts of plants all possess at least two essential characteristics—the ability to differentiate heterocysts, which are specialized nitrogen-fixing cells (for a review, see Adams and Duggan, 1999), and hormogonia, which are short, gliding filaments that lack heterocysts and provide a means of dispersal (Campbell and Meeks, 1989; Meeks, 1990; Meeks, 1998; Johansson and Bergman, 1994; Bergman et al., 1996). The hormogonia serve as the infective agents in most plant symbioses; some plants enhance their chances of infection by producing chemical signals that stimulate hormogonia formation and also chemoattractants that direct hormogonia into the plant tissue. Cyanobacteria are not restricted to the roots of plants but can infect thalli, stems and leaves. The major hosts are bryophytes (see the section Cyanobacteria in Symbiosis with Hornworts and Liverworts in this Chapter), the angiosperm *Gunnera* (see the section Interactions in the Nostoc-Gunnera Symbiosis in this Chapter), the aquatic fern *Azolla* (see the section The Azolla-Anabaena Symbiosis in this Chapter), fungi (forming lichens; see the section Cyanolichens in this Chapter), the fungus *Geosiphon* (see the section The Geosiphon Pyriformis—Nostoc Endocyanosis and its Relationship to the Arbuscular Mycorrhiza (AM) in this Chapter), and cycads (for a review of cycad symbioses, see Costa and Lindblad, 2002).

SECTION I: Cyanobacteria in Symbiosis with Hornworts and Liverworts

Bryophyte Symbioses

The division Bryophyta consists of the Hepaticae (liverworts), the Anthocerotae (hornworts), and the Musci (mosses), all of which are small, nonvascular terrestrial plants, some of which form epiphytic or endophytic associations with cyanobacteria, primarily of the genus *Nostoc*. Only the liverwort and hornwort associations will be dealt with here, but the cyanobacteria-moss associations have been well reviewed recently (Solheim and Zielke, 2002). In their natural habitat the liverworts and hornworts grow as a prostrate gametophyte thallus a few centimeters in length, attached to the substratum by primitive roots known as "rhizoids." Mature symbiotic colonies can be seen as dark spots 0.5–1.0 mm in diameter within the plant tissue (Fig. 1). Of the more than 340 liverwort genera, only four are known to develop associations with cyanobacteria: two (*Marchantia* and *Porella*) forming epiphytic associations and two (*Blasia* and *Cavicularia*) forming endophytic associations (Meeks, 1990). Four of the six hornwort genera (*Anthoceros*, *Phaeoceros*, *Notothylas* and *Dendroceros*) form endophytic associations (Meeks, 1990). Although possibly more common than once thought, the epiphytic associations are poorly understood (Dalton and Chatfield, 1985; Brasell et al., 1986), whereas the endophytic associations have been well studied because of their ease of growth in the laboratory. *Anthoceros*, *Phaeoceros* and *Blasia* can all be grown conveniently in shaken liquid culture (Fig. 2), with or without their symbiotic partners, and can be readily reinfected with their original partner or with cyanobionts

Fig. 1. The liverwort *Blasia pusilla* showing the prominent midribs of the thallus surrounded by the dark spots of *Nostoc* colonies. From Adams (2000), with permission.

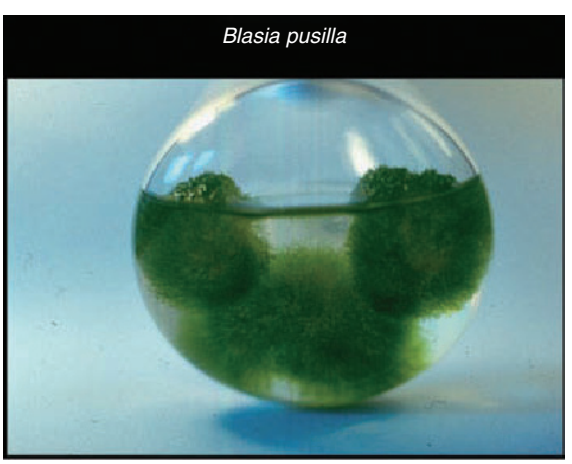

Fig. 2. *Blasia pusilla* grown in liquid medium and viewed from beneath a 250-ml Erlenmeyer flask. Three large masses of thallus are shown here, but for experimental purposes the thallus would be periodically fragmented to maintain a large number of smaller pieces. From Adams (2002), with permission.

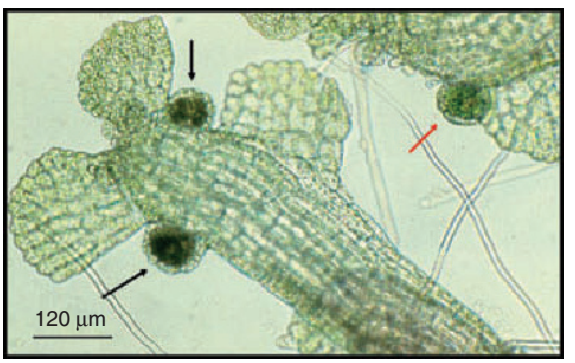

Fig. 3. Part of a *Blasia pusilla* thallus infected in the laboratory with two different cyanobacteria. The two darker colonies (black arrows) contain a different *Nostoc* strain from the paler one (red arrow). Photo courtesy of S. Babic. From Adams and Duggan (1999), with permission.

from *Gunnera*, cycads, lichens and even some free-living strains (Enderlin and Meeks, 1983; Meeks, 1988; Kimura and Nakano, 1990; Meeks, 1990; Babic, 1996; West and Adams, 1997; Adams, 2002; Fig. 3).

The Symbionts

For a cyanobacterium to establish a successful plant symbiosis it must possess at least two essential characteristics—the ability to differentiate both heterocysts, which are specialized nitrogen-fixing cells (for a review, see Adams and Duggan, 1999), and hormogonia, which are short, gliding filaments that lack heterocysts and provide a means of dispersal (Campbell and Meeks, 1989; Campbell and Meeks, 1990; Campbell and Meeks, 1998; Johansson and Bergman, 1994; Bergman et al., 1996). Heterocysts fix dinitrogen for both partners, and the motile hormogonia, which are a transient phase of the lifecycle, enable the otherwise immotile cyanobacterial filaments to gain entry to the plant host (see the section Bryophyte Structures and Their Infection in this Chapter). The symbiotically competent cyanobacteria are hormogonia-forming strains of mostly the genus *Nostoc*, although *Calothrix* and *Chlorogloeopsis* strains have been shown to reconstitute the symbiosis with *Blasia* and *Phaeoceros* (West and Adams, 1997). In the field, a single liverwort or hornwort thallus can become infected by many different *Nostoc* strains (West and Adams, 1997; West et al., 1999; Costa et al., 2001).

Hormogonia differentiation is triggered by environmental stimuli, including the dilution of liquid cultures, or their transfer to solid medium, or exposure to red light (Herdman and Rippka, 1988; Tandeau de Marsac, 1994). Their formation can also be triggered by exudates from plants

such as *Anthoceros* (Campbell and Meeks, 1989), *Blasia* (Knight and Adams, 1996), *Gunnera* (Rasmussen et al., 1994), and wheat roots (Gantar et al., 1993; Knight and Adams, 1996).

Bryophyte Structures and Their Infection

In the bryophyte-cyanobacteria symbioses, the symbionts infect existing plant structures. In the liverwort *Blasia*, the cyanobacteria occupy roughly spherical structures, known as auricles, on the underside of the thallus (Figs. 4 and 5). The thallus of the hornworts *Anthoceros* and *Phaeoceros* is much thicker than that of *Blasia* and the cyanobacteria are found in slime cavities, within the thallus, that open to the ventral surface via slit-like pores (Fig. 6). *Blasia* auricles have two slime papillae, one of which (the inner slime papilla) partly fills the auricle cavity, and the other (the outer slime papilla) arises from the thallus adjacent to the auricle (Figs. 4 and 5). The cyanobacteria enter *Blasia* auricles, and presumably hornwort slime cavities, as hormogonia (see the section on The Symbionts in this Chapter), whereupon they lose motility and differentiate heterocysts (Kimura and Nakano, 1990; Babic, 1996).

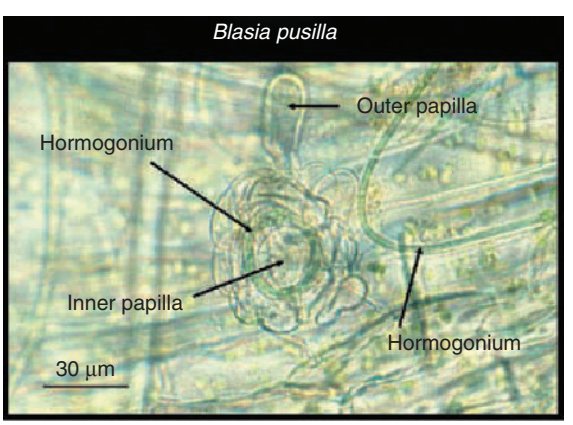

Fig. 5. Photomicrographs of a *Blasia pusilla* auricle infected with cyanobacteria in the laboratory. This auricle has just been infected by a hormogonium which is still motile (and hence out of focus) within the space between the inner papilla and the auricle wall. Another motile hormogonium is present just outside the auricle. Photo courtesy of S. Babic. From Adams (2002), with permission.

Bryophyte-Cyanobacterium Signal Exchange

Anthoceros punctatus releases an unidentified, low molecular mass, heat-labile product that stimulates hormogonia formation in *Nostoc* strains (Campbell and Meeks, 1989). This hormogonia-inducing factor (HIF) seems to be produced as a result of nitrogen starvation, as it is not present when the hornwort is cultured in medium containing excess NH_4^+. Compounds with similar activity to HIF are found in *Gunnera* stem gland mucilage (Rasmussen et al., 1994), wheat root exudates (Gantar et al., 1993), and *Blasia* exudates (Babic, 1996; Watts et al., 1999; Watts, 2001). Combined nitrogen-starved *Blasia* releases factors that trigger hormogonia formation (Babic, 1996) and serve as very effective chemoattractants (Knight and Adams, 1996; Watts et al., 1999; Watts, 2001).

As a symbiotic colony develops, filamentous protrusions grow from the host plant into the colony, possibly to enhance nutrient exchange between host and symbiont (see the section Morphological Modifications to Bryophyte and

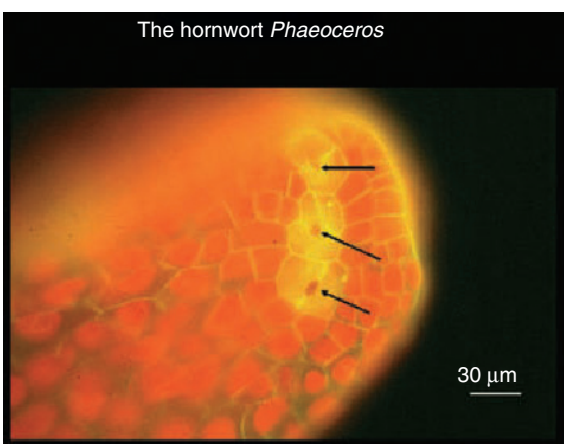

Fig. 6. Fluorescence photomicrograph of the hornwort *Phaeoceros* sp. showing the slit-like entrance (arrow) to the slime cavity. Sample stained with calcofluor white. Photo courtesy of S. Babic. From Adams (2000), with permission.

Symbiont in this Chapter). What signal induces these changes in the host is not known; however, arabinogalactan proteins (AGPs) are released by many cyanobacteria (Bergman et al., 1996), and such AGPs are thought to have important roles in plant growth and development (Pennell, 1992). Liverworts also produce AGPs (Basile, 1990), the inner and outer slime papillae of *Blasia* and the slime cavity of *Phaeoceros* stain with Yariv reagent, which is specific for AGPs, and with anti-AGP monoclonal antibodies (Watts, 2001).

Another group of potential signalling molecules in cyanobacteria-plant symbioses is the flavonoids; these are secreted by legumes and are involved in the initial signalling in the symbiosis with *Rhizobium*, by binding to the transcriptional activator NodD (Fisher and Long, 1992). Seed rinse from *Gunnera*, an angiosperm that forms symbiosis with *Nostoc*, can induce expression of *nod* genes in *Rhizobium* (Bergman et al., 1996; Rasmussen et al., 1996; Rai et al., 2000), and the flavonoid naringin induces expression of *hrmA* (see the sections Cell Division Control and Hormogonia Formation and The Hrm Operon in this Chapter) in *Nostoc punctiforme* (Cohen and Yamasaki, 2000). Expression of the *N. punctiforme hrmA* gene is also induced by a combination of components, including deoxyanthocyanins, found in extracts of the water-fern *Azolla* which forms symbioses with *Anabaena* (Cohen et al., 2002).

Host-Cyanobiont Interactions Post-Infection

Cell Division Control and Hormogonia Formation In symbiosis with *Anthoceros* the doubling time of *Nostoc* can be 240 h, compared with 45 h in the free-living state (Meeks, 1990). This slowed growth of the cyanobiont ensures that its growth rate matches that of the host plant. The mechanism of this growth control is unknown, but it seems not to be nitrogen limitation, even though the host takes most of the nitrogen fixed by its partner (see the section Nitrogen Fixation and Transfer of Fixed Nitrogen in this Chapter).

As well as controlling the growth rate of the cyanobiont, the host must control hormogonia formation. Prior to infection the host plant stimulates the development of hormogonia in potential partners by releasing HIF (see the section Bryophyte-Cyanobacterium Signal Exchange in this Chapter). However, once infection has occurred, the plant must prevent hormogonia differentiation within the developing colony because hormogonia lack heterocysts and so cannot form a viable, nitrogen-fixing colony. A hormogonia repressing factor (HRF), found in aqueous extracts of *Anthoceros* tissue (Cohen and Meeks, 1997; Meeks, 1998), inhibits HIF-induced hormogonia formation in wild-type *N. punctiforme*. The expression of two genes, *hrmA* and *hrmU*, is induced by HRF but not by HIF. These observations imply that the gene products of the *hrmUA* operon block hormogonium formation, perhaps by the production of an inhibitor or by the catabolism of an activator (Cohen and Meeks, 1997; see the section Genetic Analysis of the Nostoc-Anthoceros Association in this Chapter).

Morphological Modifications to Bryophyte and Symbiont In free-living cyanobacteria, heterocyst frequency is typically 4–10% of cells, whereas in symbiosis with hornworts and liverworts frequencies are usually considerably higher (Adams, 2000; Table 1). Although, in at least *Anthoceros*, some heterocysts seem to be senescent or dead (Meeks, 1990), increase in heterocyst frequency is still correlated with elevated rates of nitrogen fixation. Because heterocysts are unable to fix CO_2, this elevated heterocyst

Table 1. Summary of morphological and physiological changes in cyanobacteria symbiotically associated with hornworts and liverworts.

Characteristic	Hornworts	Liverworts
Plant structure infected	Slime cavities	Auricles
Cyanobiont	*Nostoc*	*Nostoc*[a]
Location of cyanobiont	Intercellular	Intercellular
Heterocyst frequency (%)[b]	30–50	30–50
Nitrogenase specific activity[d]	443	n.d.
Glutamine synthetase		
Amount of protein[c]	~86	n.d.
Specific activity[c]	~38	n.d.
Form of combined N released	NH_4^+	NH_4^+
Light-dependent CO_2 fixation (%)[d]	12	n.d.
Rubisco		
Amount of protein[d]	100	n.d.
Specific activity[d]	12	n.d.

Abbreviations: Rubisco, ribulose bisphosphate carboxylase/oxygenase; and n.d., not determined, though likely to be similar to hornwort data.

[a]The symbionts are *Nostoc* spp. in almost all cases; there have been rare reports of *Calothrix* spp. as symbionts (The Symbionts).

[b]Heterocyst frequencies are expressed as a percentage of total cells. Typical values for free-living cyanobacteria are 4–10%.

[c]Values are for the symbiont as a percentage of the same cyanobacterium in the free-living state.

[d]Values are expressed as a percentage of those for the free-living cyanobacteria.

From Steinberg and Meeks (1989, 1991), Meeks (1990), Rai (1990), and Bergman et al. (1992).

frequency results in a loss of CO_2-fixing capacity, which can be compensated by the supply of carbon skeletons by the host. In *Anthoceros*, and presumably all endophytic bryophyte associations, nitrogenase gene expression and heterocyst development in the symbiotically associated *Nostoc* appear to be controlled by plant signals (Campbell and Meeks, 1992).

Morphological changes are also observed in the bryophyte following infection. In both *Blasia* and *Anthoceros*, branched, multicellular filaments grow from the wall of the symbiotic cavity and invade the colony, increasing the surface area of contact between the cyanobacteria and the bryophyte (Rodgers and Stewart, 1974; Rodgers and Stewart, 1977; Duckett et al., 1977; Renzaglia, 1982; Kimura and Nakano, 1990; Gorelova et al., 1996). In *Blasia* these filaments are derived from the inner slime papilla and possess transfer cell morphology, implying an involvement in nutrient exchange.

Nitrogen Fixation and Transfer of Fixed Nitrogen The elevated rate of nitrogen (N_2) fixation in bryophyte-associated cyanobacteria broadly correlates with the increased heterocyst frequency in symbiosis (Table 1). The N_2 fixation rate of the *Anthoceros-Nostoc* association is 4- to 35-fold higher than that of free-living *Nostoc* (Steinberg and Meeks, 1991). Such a high rate of N_2 fixation cannot be supported by the reduced photosynthetic capacity of the cyanobiont and must rely on reduced carbon derived from the plant.

Nitrogen fixed by the cyanobiont is released to the plant as ammonia (Table 1) in both *Anthoceros* (Rodgers and Stewart, 1974; Stewart and Rodgers, 1977a; Meeks et al., 1985a; Meeks et al., 1985b) and *Blasia* (Rodgers and Stewart, 1974; Stewart and Rodgers, 1977a), and initial uptake of the ammonia occurs via the glutamine synthetase-glutamate synthase (GS-GOGAT) pathway of the host (Meeks et al., 1983; Meeks et al., 1985b; Meeks, 1990; Rai, 1990). In *Anthoceros* the cyanobiont retains as little as 20% of the nitrogen it fixes (Meeks et al., 1985a) yet shows no signs of nitrogen deprivation. Ammonia is released by the cyanobiont as a consequence of decreased activity of glutamine synthetase, the first enzyme in the GS-GOGAT pathway, which is the primary route of ammonia assimilation in cyanobacteria. In *Anthoceros* the decreased activity of GS appears to be the result of an undetermined posttranslational modification of the enzyme, because the amount of GS protein differs little in filaments of free-living and symbiotically-associated *Nostoc* (Joseph and Meeks, 1987; Lee et al., 1988; Meeks, 1990; Table 1).

Carbon Dioxide Assimilation and Transfer of Carbon The Calvin cycle is the primary route of CO_2 fixation in free-living and symbiotically-associated cyanobacteria, with ribulose-1, 5-bisphosphate carboxylase/oxygenase (Rubisco) as the primary carboxylating enzyme (Tabita, 1994). The rate of light-dependent CO_2 fixation in the *Nostoc* symbiont of *Anthoceros*, immediately after its separation from symbiosis, is eightfold lower than that of the same cyanobacterium in the free-living state (Steinberg and Meeks, 1989; Meeks, 1990; Table 1). However, the level of Rubisco protein is similar in the two cases (Rai et al., 1989; Steinberg and Meeks, 1989; Meeks, 1990), implying that activity is regulated by an unidentified posttranslational modification of the enzyme (Steinberg and Meeks, 1989; Meeks, 1990). The cyanobiont therefore grows photoheterotrophically, receiving fixed carbon from its photosynthetic host, probably in the form of sucrose (Stewart and Rodgers, 1977a; Steinberg and Meeks, 1991). In at least *Anthoceros*, the presence of glycogen granules in the cells of symbiotically associated *Nostoc* implies that the symbiont is not starved of carbon (Meeks, 1990).

Genetic Analysis of the Nostoc-Anthoceros Association

Meeks and coworkers have developed genetic techniques, including transposon mutagenesis, for the analysis of the symbiotically competent cyanobacterium *Nostoc punctiforme* strain ATCC 29133 (Cohen et al., 1994; Cohen et al., 1998), and have used these techniques to identify a number of genes involved in the initial infection of *Anthoceros*. This has been aided by the availability of the complete genome sequence of *Nostoc punctiforme* {DOE Joint Genome Institute website} (see http://www.jgi.doe.gov).

The Hrm Operon In a transposon mutant of *Nostoc* 29133, characterized by an increased rate of initial infection of *Anthoceros* (Cohen and Meeks, 1997; Table 2), Meeks et al. (1999) identified two open reading frames (ORFs), *hrmU* and *hrmA*, flanking the site of transposition (Fig. 7). *hrmA* has no significant similarity to sequences in major databases, whereas *hrmU* has similarity to the sequences of mannonate oxidoreductase genes and 2-keto-3-deoxygluconate dehydrogenase genes. Expression of *hrmUA* is induced by an aqueous extract of *A. punctatus* but not by the hormogonium inducing factor, HIF. The aqueous extract appears to contain a hormogonium repressing factor (HRF) because it suppresses HIF-induced hormogonia forma-

Table 2. Effect of insertion mutations on the symbiotic infectiveness and effectiveness of *Nostoc* 29133 strains in association with *Anthoceros punctatus*.

Strain (gene)	nmol C_2H_2 reduced per min per: Colonies per mg dry wt per µg Chl *a*	g of fresh weight	Colony ($\times 10^{-3}$)	Gene induction factor(s)
ATCC 29133 (WT)	0.21	6.3	12.4	n.d.
UCD 328 (*hrmA*)	1.6	6.1	8.6	HRF
UCD 398 (*sigH*)	1.2	8.0	10.1	HIF
UCD 400 (*tprN*)	0.49	10.4	6.7	HIF and HRF

Abbreviations: Chl *a*, chlorophyll *a*; HRF, aqueous extract of *A. punctatus* containing hormogonium repressing factor identified as inducing the *hrm* operon; WT, wild type; HIF, exudate of *A. punctatus* containing hormogonium inducing factor; and n.d., not determined.
From Meeks et al. (1999). The standard deviations and number of replicates have been omitted for simplicity.

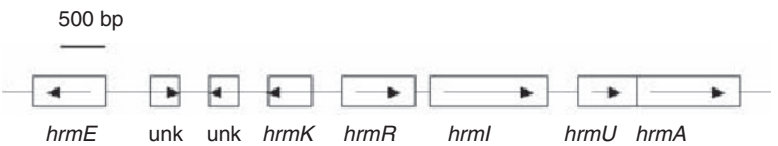

Fig. 7. Map of the open reading frames in the *hrm* locus of *Nostoc punctiforme*. The direction of transcription is indicated by the arrows. Unk are unknown proteins. Sizes are approximate. Adapted from Campbell et al. (2003).

tion in the wildtype but not the mutant. Whereas HIF is released into the growth medium, HRF is probably released into the symbiotic cavity, suppressing further hormogonium formation and permitting heterocyst differentiation.

At the 5′ end of *hrmUA*, three other ORFs (*hrmI*, *hrmR* and *hrmK*) are followed by two ORFs coding for unknown proteins, followed by *hrmE*, which has similarity to an aldehyde reductase (Fig. 7). HrmI shows similarity to uronate isomerase, HrmR to the LacI/GalR family of transcriptional repressors, and HrmK to gluconate kinases. HrmR is a DNA binding protein that binds sugar ligands and represses transcription of *hrmR* and *hrmE* (Campbell et al., 2003). Galacturonate abolishes in vitro binding of HrmR to DNA, implying that the in vivo inducer may be a sugar molecule similar to, or containing, galacturonate. These observations led Meeks and coworkers to propose the following model for the way in which the HRF external signal is transduced into *Nostoc*. HRF enters the *Nostoc* cell and it, or a derivative similar to galacturonate, binds to HrmR, rendering it incapable of binding to the *hrmR* and *hrmE* operator regions; this derepresses transcription of these genes, leading to inhibition of hormogonia formation (Campbell et al., 2003).

sigH AND *ctpH* Mutation of the *Nostoc* 29133 *sigH* gene, which encodes an alternative RNA polymerase sigma subunit, produces no obvious phenotype in filaments grown in medium with or without combined nitrogen but results in an increased infection phenotype when they are cocultured with *A. punctatus* (Campbell et al., 1998; Meeks et al., 1999; Table 2). Transcription of *sigH* is induced by *Anthoceros* HIF, but not by HRF, and *hrmA* transcription is not altered in a *sigH*$^-$ mutant. Thus, although the *hrmA*$^-$ and *sigH*$^-$ mutants both have an increased infection phenotype, it seems likely that increased infection has a different basis in the two strains (Meeks et al., 1999).

The gene *ctpH* lies immediately 5′ of *sigH* and encodes a protein with significant similarity to carboxy-terminal proteases of the cyanobacterium *Synechocystis* PCC 6803 (Meeks et al., 1999). In *Synechocystis* 6803, this gene is required for processing the carboxy-terminal portion of the photosystem II D1 protein in the thylakoid lumen (Anbudurai et al., 1994). However, in *Nostoc* 29133, *ctpH* seems to have a different physiological role because it is not transcribed under vegetative growth conditions, but transcription is induced by *Anthoceros* HIF. The significance of this is not understood.

tprN Lying 3′ of the gene *devR*, expression of which is essential for heterocyst maturation, is the gene *tprN*, which encodes a protein with similarity to tetratricopeptide repeat proteins (Campbell et al., 1996). These proteins have been studied primarily in eukaryotes in which they are required for a variety of functions from cell cycle control to transcription repression and protein transport (Lamb et al., 1995). Inactivation of *tprN* in *Nostoc* 29133 has no apparent phenotypic effect in the free-living growth state, but the mutant infects *Anthoceros* at about twice

the level of the wildtype (Table 2). Transcription of *tprN* occurs during vegetative growth but increases in the presence of both HIF and HRF (Meeks et al., 1999). The significance of this in the infection process is not known.

ntcA, *hetR*, AND *hetF* *Nostoc punctiforme* (*Nostoc* 29133) strains unable to develop heterocysts because of mutations in either *hetR* or *hetF* can still infect *Anthoceros* at a rate similar to that of the wildtype, despite being incapable of forming a functional nitrogen-fixing symbiosis (Wong and Meeks, 2002). *hetR* is thought to be the primary activator of heterocyst development (Wolk, 2000), and the HetF protein seems to be a positive activator of heterocyst differentiation, enhancing transcription of *hetR* and ensuring that HetR is localized to developing heterocysts (Wong and Meeks, 2001).

In cyanobacteria, NtcA functions as a nitrogen-dependent global regulator and controls the transcription of a number of genes, including *hetR* (Fiedler et al., 2001; Herrero et al., 2001). The *Nostoc punctiforme ntcA* mutant, UCD 444, forms motile hormogonia with wildtype morphology but at only 5–15% of the wildtype frequency (Wong and Meeks, 2002). However, rather than infecting *Anthoceros* at a reduced frequency, as might be expected, the *ntcA* mutant fails to infect at all. This noninfective phenotype can be complemented with copies of *ntcA*.

SECTION II: Interactions in the Nostoc-Gunnera Symbiosis

The Nostoc-Gunnera Symbiosis

Although cyanobacterial-plant symbioses are the most widespread of the nitrogen-fixing symbioses, with hosts throughout the plant kingdom, those symbioses with angiosperms (flowering plants) are presently restricted to one monogeneric family, the Gunneraceae. This contrasts with the more recently evolved rhizobia- or *Frankia*-angiosperm symbioses, which involve a considerably wider angiosperm host range. The scarcity is also unexpected as angiosperms form the ecologically most successful plant division on earth. In addition, cyanobacteria are globally widespread with a morphological variation surpassing most other prokaryotes. In spite of this, the cyanobacterial range is narrow, with only one cyanobacterial genus, *Nostoc*, functioning as microsymbiont in *Gunnera*. However, as the Gunneraceae is one of the oldest angiosperm families and with *Gunnera* and cyanobacterial fossils dating back some 90 million years ago (Ma) and 3 billion years ago (Ba), respectively, this symbiosis may have persisted for a long time. Prior to that, however, the same cyanobacterial genus may also have given rise to chloroplasts by entering other ancestral eukaryotic cells. The chloroplast genome of *Arabidopsis* is indeed more similar to that of *Nostoc* than to the unicellular cyanobacteria tested (Martin et al., 2002). As this ca. 400 million-year-old endosymbiotic event (or series of events) was the origin of all plants and algae, such endosymbiosis has, at least once, totally revolutionized our biosphere.

A UNIQUE ENDOSYMBIOSIS Although the symbiosis was first described by Reinke in 1873 (Reinke, 1873), understanding of the infection mechanism in this unique angiosperm symbiosis is incomplete. In contrast to the other cyanobacterial-plant symbioses, the *Gunnera* symbiosis is exclusively intracellular. Still, being a facultative symbiosis, the cyanobiont is easily separated from the plant and may be grown independently, and the symbiosis can be reconstituted under laboratory conditions. This makes the *Nostoc-Gunnera* symbiosis an excellent model for identifying mechanisms involved in plant endosymbioses and indirectly in plastid evolution. Also, since it is the only plant endosymbiosis, the symbiotic development in *Gunnera* may have evolved further than that in the other plant symbioses in which the cyanobacterium remains extracellular.

The Symbionts

The genus *Gunnera* was named by C. von Linné in honor of the Norwegian bishop Gunnérus, a person Linné admired. The approximately 30–50 *Gunnera* species are mostly subtropical to tropical perennial herbs, the exception being the smallest, *G. herteri*, which is annual (Wanntorp et al., 2001; Osborne and Sprent, 2002b). The *Gunnera* plants are composed of large compound spikes and are rhizomatous, or more seldom stoloniferous, and have rhubarb-like leaves. Plant sizes vary considerably; some are gigantic and may be the largest herbs on earth, such as species in South America, Hawaii and Asia, whereas others are small and creeping, such as the stoloniferous species in New Zealand. In nature, *Gunnera* spp. seem to be invariably infected by cyanobacteria (Wanntorp et al., 2001; Osborne and Sprent, 2002b).

Ever since the discovery of this peculiar symbiosis (Reinke, 1873), cyanobacteria of the genus *Nostoc*, which are filamentous and differentiate heterocysts, have been identified as the most frequent cyanobionts (see Meeks et al. [2001], Meeks and Elhai [2002], and Bergman et al. [2003]). The phenotypic range of the cyanobiont

of *Gunnera* is wide in terms of morphology, pigmentation, and colony shape and size, which is obvious when isolates are cultivated (Bergman et al., 1992; Rasmussen and Nilsson, 2002). A genotypic variation has also recently been verified using genetic fingerprinting of 45 cultured isolates originating from 11 *Gunnera* species (Nilsson et al., 2000; Rasmussen and Svenning, 2001) and natural cyanobacteria freshly collected from different *Gunnera* growing in Chile (Guevara et al., 2002). One specific *Gunnera* plant may also occasionally be infected with more than one *Nostoc* strain (Nilsson et al., 2000), while no variation within one plant was found in cyanobionts of *Gunnera* spp. sampled from the natural stands in Chile (Guevara et al., 2002) using the same fingerprinting technique. Recent 16S rRNA analyses also demonstrate that all *Gunnera* isolates examined belong to the genus *Nostoc* (Rasmussen and Svenning, 2001).

Specificity and Recognition Although all *Nostoc* strains form hormogonia per definition, still only certain strains of *Nostoc* are accepted as symbionts, which suggests the existence of other selective recognition mechanisms (see Rasmussen and Nilsson, 2002). The intracellular position of the cyanobiont in *Gunnera* may also impose more severe restrictions on the symbiotic partners than in the other intercellular, and possibly less intimate, plant symbioses. On the other hand, cyanobacterial isolates from cycads and bryophytes readily invade *Gunnera* cells and vice versa.

Host Structures and the Infection Process

The Site of Gunnera Infection—the Gland Infection occurs via a peculiar bright red gland (Fig. 8), already clearly visible at the developing cotyledon (see Bergman [2002a], Bergman and Osborne [2002b], and Bergman et al. [2003]).

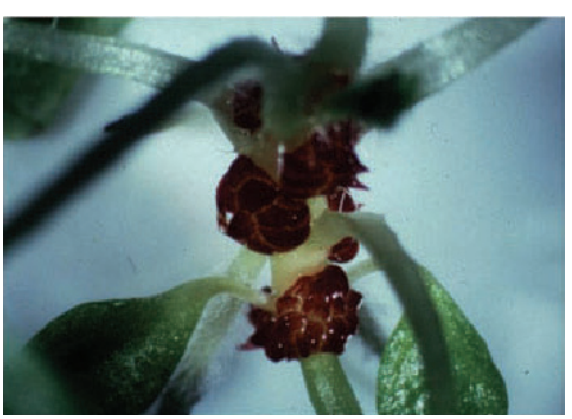

Fig. 8. *Gunnera* seedling with red stem glands.

The glands secrete a carbohydrate rich mucilage (Fig. 9) when noninfected, and new glands continuously develop at the base of each new leaf petiole, i.e., near the growing stem apices, which also become covered by the mucilage. Cyanobacterial infected glands are closed and do not release mucilage. Although root primordia were earlier suggested to be the point of entry (Schaede, 1951), the present consensus is that glands are the sole cyanobacterial entry point (Silvester and McNamara, 1976b; Bonnett and Silvester, 1981; Towata, 1985; Johansson and Bergman, 1992). It has been proposed that these modified glands should be termed "nodules" (Silvester and McNamara, 1976b), and indeed a distinct and well-functioning symbiotic "organ," however restricted in time and space, develops below the gland surface on infection. Each gland, and possibly also each channel, functions as an independent infection unit, which would explain why several cyanobionts may be found inside one individual gland (Johansson and Bergman, 1992; Nilsson et al., 2000).

The involvement of other microorganisms in the establishment of the *Gunnera* symbiosis, as proposed by Towata (1985), is not likely; this can be demonstrated by, for instance, reconstitution experiments under sterile laboratory conditions (Silvester and McNamara, 1976b; Johansson and Bergman, 1992). In addition, some cells of the gland have heavy tannin depositions, which have been suggested to prevent the invasion of noncompatible or unwanted microorganisms (fungi and bacteria), which often reside together with cyanobacteria in the channel mucilage (Towata, 1985).

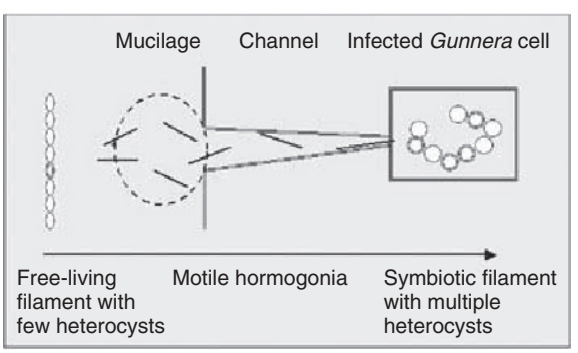

Fig. 9. Schematic illustration of the *Nostoc* infection process in *Gunnera*. Vegetative cells of *Nostoc* with a low frequency of heterocysts are attracted to the mucilage pouring out of the *Gunnera* stem and stolon gland. Motile hormogonia are induced by the mucilage and the cyanobacterium proceeds towards the interior of the gland. At the bottom of the channel the cyanobacterium penetrates *Gunnera* cells. After internalization, a cyanobacterial phenotype with larger cells and supernumerous heterocysts (up to 80%) develop. The arrow indicates the direction of infection.

THE INFECTION PROCESS The focus has so far primarily been on morphological and adaptive changes in the cyanobiont. The plasticity held by *Nostoc* in these respects, utilized by the plant throughout the infection process, is likely a key factor contributing to its success as a *Gunnera* symbiont. A typical feature of the *Nostoc-Gunnera* symbioses is the tight regulation by the plant of cyanobacterial cell division, cell differentiation, and physiological performance.

Hormogonium Differentiation A terrestrial cyanobacterium like *Nostoc* would (under normal free-living conditions) primarily occur as nonmotile, vegetative filaments with heterocysts at regular intervals (about 5–10% of the total cell number; Fig. 9). On contact with *Gunnera*, the gland and the plant apex are, however, soon covered by a cyanobacterial "biofilm" composed of tightly packed hormogonia (Osborne et al., 1991; Johansson and Bergman, 1992; Johansson and Bergman, 1994). Differentiation of these small-celled motile hormogonia is essential for the whole *Gunnera* infection process; they act as a means for the cyanobacterium both to reach and to invade the *Gunnera* organ (the gland; Fig. 9). The mucilage has a pivotal role during this process (Rasmussen et al., 1994). It is composed of highly glycosylated arabinogalactan proteins (AGPs; Rasmussen et al., 1996) and stimulates not only growth, but also hormogonium differentiation. A low molecular weight (<12 kDa), heat-labile protein, not yet characterized, which acts as hormogonium inducing factor (HIF), has been identified in the mucilage (Rasmussen et al., 1994). Molecular mechanisms behind the induction and differentiation are still largely unexplored.

Preliminary studies, using subtractive hybridization and proteomics (two-dimensional [2-D] gel electrophoresis coupled to mass spectrometry) of soluble *Nostoc* proteins treated with *Gunnera* mucilage, show that the induction of hormogonium differentiation is also reflected in a differential expression of genes and proteins, whose expression is either up- or down-shifted or both. For instance, three mucilage induced *hie* (host induced expression) genes have been identified, including a putative precursor of a pheromone-like signaling peptide (HieA), an outer membrane or secreted glycoprotein (HieB), and a protein probably involved in adaptation to acidity (HieC; Liaimer et al., 2001). The latter may be important as the *Gunnera* mucilage has a pH of 4–5 (Rasmussen et al., 1994). Another set of proteins was also identified as being differentially expressed in hormogonia (Klint et al., 2003). These proteins, which were predominantly surface associated, may have roles in motility, recognition, adhesion, as well as in communication with host plants. The mucilage therefore appears to have important functions at earlier stages of the *Gunnera* infection process.

Entrance and Penetration The *Gunnera* glands are composed of a set of up to nine papillae surrounding a central papilla (Johansson and Bergman, 1992; Uheda and Silvester, 2001). Between the papillae, deep invaginations lead into the stem tissue, through which the mucilage is released. The hormogonia use these narrow channels to enter the dark interior of the *Gunnera* stems (Fig. 9). As this is against the normal positive phototactic behavior of *Nostoc*, a potent attractant must be released by the plant, possibly carried by the mucilage. Motility is crucial at this stage, as the direction of infection (Fig. 9) is opposite to that of the flow of mucilage. Upon reaching the bottom of the gland channels, the cyanobacterium penetrates the thin walls of smaller meristematic and dividing cells lining the channel (Silvester and McNamara, 1976b; Johansson and Bergman, 1992; Johansson and Bergman, 1994; Uheda and Silvester, 2001). A delimited tissue of *Nostoc*-infected *Gunnera* cells is formed within a few days of inoculation. The mechanism(s) involved in the actual host cell penetration is still unknown, although Towata (1985) suggested the occurrence of pectolytic or cellulolytic activities in the mucilage of *G. kaalensis*. Also lining the channel are the thick-walled secretory cells releasing the mucilage (Towata, 1985).

Signal Exchange Between the Cyanobacterium and the Host

Besides HIFs, the plant signals involved in hormogonium differentiation still await genetic identification and chemical characterization, as do the cellular response signaling cascades in *Nostoc*. In this context, a highly interesting question is whether the differentiation of hormogonia resulting from a biotic stimulus (such as *Gunnera* mucilage) triggers specific genes (such as those involved in "symbiotic competence") but not those triggered by any abiotic stimulus (such as red light). Also interesting are mechanisms involved in the initial rapid cell division and the machinery behind motility. All studies do, however, verify that the plant influences cyanobacterial morphology and behavior at all stages of the infection process, and that this includes several fundamental cyanobacterial processes such as growth, cell division, cell differentiation, ammonia assimilation, and phototactic behavior. The question is whether this is triggered by plant compounds or by the environment within the plant. For instance, the symbiotic tissue is low in

oxygen and light, which may have consequences for gene expression.

Another open question is to what extent the release of the auxin IAA (indole-3-acetic acid) by *Nostoc* (Sergeeva et al., 2000) acts as a signal or influences the development of the symbiotic *Gunnera* tissues. Indeed, cyanobacteria seem to have the potential to produce all major phytohormones (Liaimer and Bergman, 2003) and also to release "AGP-like" proteoglucans, which may also influence plant development (Bergman et al., 1996).

Host-Cyanobacterial Interactions Post Infection

Internalization of the cyanobiont elicits novel, dramatic modifications of cyanobacterial morphology and function (Fig. 9). Because hormogonia lack heterocysts, they are unable to fix nitrogen. Thus, the hormogonium stage is lethal under free-living conditions (unless combined nitrogen is available), and hence is, of necessity, transient. Redifferentiation into vegetative filaments with heterocysts occurs after 1–2 days. The maintenance of a continuous vegetative stage with heterocysts is a prerequisite for the symbiosis to persist as an efficient provider of combined nitrogen. Repression of hormogonium differentiation in *Gunnera* may be achieved by homologues to the hormogonium repressing factor(s) (HRFs) identified in the bryophyte symbiosis (see Meeks and Elhai, 2002).

When inside the *Gunnera* cells, the cyanobacterial cells enlarge and cell division is restricted (Söderbäck and Bergman, 1992b). In addition, the often shorter filaments remain surrounded by the host cell plasmalemma through the pinocytosis process. This membrane, like the peribacteroid membrane in *Rhizobium*-legume symbioses, acts as the barrier between the symbionts but allows exchange of metabolites. The *Gunnera* cells eventually become filled with cyanobacterial filaments, which soon start to differentiate an abnormally high frequency of heterocysts (Fig. 9). Once infection is complete, the host must tightly control cyanobiont growth to avoid being outgrown, and this may explain the enlargement of cyanobacterial cells so typical for the endosymbiotic stage (see Rai et al. [2000] and Bergman [2002a]).

The dramatic morphological transitions seen in *Nostoc* on entering *Gunnera* cells are also reflected in the transcription of genes (and the corresponding proteins) related to heterocyst differentiation and nitrogen fixation (see Table 1 in Bergman, 2002a). For instance, the expression of the *hetR* gene (the master gene for heterocyst differentiation) correlates positively with the increase in heterocyst frequency, as does the expression of the nitrogen-responsive transcription factor encoded by *ntcA*, whereas *nifH* expression is (as expected) already high close to the growing apex. By contrast, the expression of the *glnB* gene, encoding the signal transduction protein P_{II}, decreases along the same symbiotic profile (Wang et al., 2004). Such overexpression of both *hetR* and *ntcA* and the contrasting downregulation of *glnB* are features indicating important regulatory differences between the symbiotic and free-living life stages. The significance of these findings in relation to cyanobacterial cell differentiation and the establishment and maintenance of an efficient nitrogen-fixing cyanobacterial-plant symbiosis now needs to be explored further. Akinetes have never been detected, not even in older parts of the symbiosis (glands at the base of the rhizome or stolon), though *hetR* is suggested to be involved in akinete differentiation (Zhou and Wolk, 2002). This suggests that conditions in *Gunnera* are never harsh enough or that *hetR* expression for some reason is solely devoted to heterocyst differentiation in symbiosis.

Cross-sectioning of rhizomes of mature plants reveals the final outcome of the symbiosis (i.e., distinct and bright blue-green pigmented but restricted and delimited cyanobacterial colonies seen scattered in the rhizome or along the stolons; Osborne et al., 1991). However, the sites of infection comprise only a small proportion of the total plant biomass, particularly in the large species.

Nitrogen Fixation and the Transfer of Nitrogen

As with most other plant symbioses, the main function of the cyanobacterium in *Gunnera* is to cover the total combined nitrogen requirement of the host via nitrogen fixation (Silvester and Smith, 1969; Silvester, 1976a; Bonnett and Silvester, 1981; Osborne et al., 1992). The heterocysts act as the nitrogen-producing entities, holding all the nitrogenase (Söderbäck et al., 1990; Söderbäck, 1992a), and are capable of supporting the entire symbiosis with combined nitrogen. In addition, the cyanobacterium attains enhanced nitrogen fixation capacities compared to its free-living relatives (Silvester, 1976a; Bonnett and Silvester, 1981). This may be due to the high heterocyst frequency, or to an enhanced nitrogen starvation caused by the continuous N-drainage from the cyanobiont.

Up to 90% of the nitrogen fixed is exported from the cyanobacterium to the host (Silvester et al., 1996). This is likely to be due to downregulation of the glutamine synthetase protein levels, specifically in heterocysts, as well as activities

in symbiosis (Söderbäck, 1992a). As in most nitrogen-fixing plant symbioses, the nitrogen fixed is primarily released as NH_4^+ (Silvester et al., 1996). The *Nostoc*-infected *Gunnera* tissues are always well invested with vascular strands that facilitate exchange of metabolites such as nitrogen (see Fig. 8 in Bergman et al., 1992). Multiple vascular strands persist (polystele) in *Gunnera*, which may be reminiscent of an aquatic ancestry (Osborne et al., 1991). Stock and Silvester (1994) showed, using pulse chase labeling with ^{15}N, that the nitrogen fixed was efficiently transported from mature to young parts (with lower heterocyst frequencies) of *G. monoica* stolons, and that N-translocation occurs via the phloem.

Carbon Assimilation and the Transfer of Fixed Carbon As *Nostoc* inside the *Gunnera* cells is excluded from light, the host must supply the cyanobiont with fixed carbon via its photosynthesis. Hence, the cyanobiont must adapt to a heterotrophic mode of life to generate enough reductant and ATP to support the demanding nitrogen fixation process (Söderbäck and Bergman, 1992b; Söderbäck and Bergman, 1993; Black et al., 2002). Nevertheless, total pigment and ribulose-1,5-bisphosphate carboxylase levels remain constant along the developmental sequence, from young to old parts, although their values show a decrease if related to cell volume because cell volume increases considerably in older cells (Söderbäck and Bergman, 1992b). The high frequency of heterocysts also drastically diminishes the number of vegetative cells, but the use of gas chromatography with mass spectrometry (GC-MS) has shown that still only the vegetative cells are actively taking up C (Black et al., 2002). Following ^{14}C translocation in *Nostoc*-infected *Gunnera* stolons reveals that the *Nostoc*-infected tissues at the apex of *G. magellanica* stolons are particularly efficient sinks for newly fixed plant carbon (Söderbäck and Bergman, 1993). The phloem of *Gunnera* has the unusual capacity to contemporaneously transport N outwards and C inward towards the symbiotic tissue (Stock and Silvester, 1994). A tight interaction of nitrogen and carbon metabolism in the *Gunnera* symbioses is also suggested. *hetR* expression in symbiotically competent *Nostoc* (PCC 9229) is negligible in the absence of a carbon source in darkness but pronounced in the presence of exogenous fructose (Wouters et al., 2000).

Ecological Importance

Our understanding of the ecology and significance (e.g., as a nitrogen-fixer) of this ancient plant and its cyanobiont is still rudimentary. For a detailed review of the ecology of *Gunnera*, the reader is referred to Osborne and Sprent (2002b). The geographic range of *Gunnera* was considerably wider in the past when the climate was more favorable (Osborne et al., 1991; Osborne and Sprent, 2002b). Today, *Gunnera* typically grows in super-humid habitats and often at high elevations or on steep cliffs. The genus is found in all continents, except in Europe and polar regions (see Wanntorp et al. [2001] and Osborne and Sprent [2002b]). Some large *Gunnera* species were introduced into Europe as ornamental plants at the end of the ninteenth century, and eventually some plants escaped and became invasive, e.g., in western Ireland, the Channel Islands, and the Azores (Osborne et al., 1991; Osborne and Sprent, 2002b).

The genetics (*rbcL* and *rps*16 introns) of *Gunnera* plant species have recently been analyzed (Fig. 10). The large species in South America and

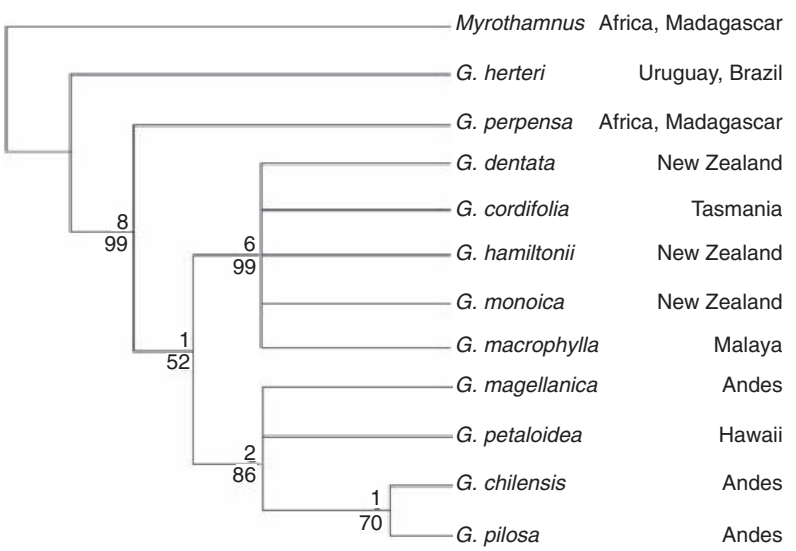

Fig. 10. Phylogram of 11 *Gunnera* species representing varying sizes and geographical origin. *Myrothamnus* is an African shrub-like plant growing in dry areas, as opposed to *Gunnera* species that prefer wet environments characterized by high humidity and high rainfall. From Wanntorp et al. (2001).

Hawaii distinctly group together in one clade, the often smaller species of New Zealand and Southeast Asia group in another, while *G. perpensa* (the first *Gunnera* to be described by Linné) and *G. herteri* (with the smallest size) are sister groups, representing Africa and Brazil, respectively (Wanntorp et al., 2001).

Conclusions

From a cyanobacterial perspective the *Nostoc-Gunnera* symbiosis may on the one hand seem wasteful; the cyanobiont merely functions as a N-producing entity with highly suppressed growth, and is possibly deprived of generating a new generation of cyanobionts. On the other hand, it may be beneficial; the cyanobiont no doubt extends its ecological niche to also include symbiotically competent cells of an angiosperm. In this way, the cyanobacterium not only gains access to plant leaves and roots and their nutrient acquisition capacities, but it also finds shelter from all possible predators, being the sole organism in this "golden cage."

The data obtained so far clearly show that cyanobacterial morphology and protein and gene expression patterns are drastically affected prior to, during, and after the establishment of the *Nostoc-Gunnera* symbiosis, although no symbiosis-specific genes and proteins, equivalent to the *nod* genes and Nod-factors in the *Rhizobium*-legume symbioses, have yet been discovered. However, it seems logical to assume that equally advanced molecular mechanisms must persist in a cyanobacterial-angiosperm endosymbiosis to generate this well coordinated and successful interaction.

SECTION III: The *Azolla-Anabaena* Symbiosis

Introduction

Taxonomy and Distribution The *Azolla-Anabaena* symbiosis is a mutualistic association among the aquatic fern *Azolla*, the filamentous, heterocystous, nitrogen-fixing cyanobacterium *Anabaena*, and endosymbiotic bacteria. The genus *Azolla* contains seven extant species that are divided into two sections on the basis of spore morphology. Section *Azolla* (New World species) includes *A. caroliniana*, *A. mexicana*, *A. filiculoides*, *A. microphylla* and *A. rubra*. Section *Rhizosperma* (Old World species) includes *A. pinnata* and *A. nilotica*. Geographically, *A. pinnata* is found in Australia, New Zealand, Japan, Asia and Africa, and *A. nilotica* is primarily found in Africa (Saunders and Fowler, 1993). Species from the section *Azolla* are more widely distributed around the world and are found in Europe, Asia, Africa, Australia and America. However, the distribution of *A. rubra* is restricted to New Zealand and Australia (Large and Braggins, 1993). The distribution of some species has been impacted by human effects (Janes, 1998a).

Morphology The plant's shape, color and size change significantly under different growth conditions (Janes, 1998b). The rhizome is branched, bearing alternate leaves that are bilobed. The ventral lobe is transparent and serves to float the plant on the surface of the water, whereas the dorsal photosynthetic lobe contains a leaf cavity in which the symbionts are found. The roots are adventitious. The shedding of roots and branches is related to environmental and physiological factors and enables the plant to reproduce via vegetative fragmentation. Factors affecting the growth of *Azolla* include genotype, temperature, light (intensity, quality and photoperiod), water chemistry (including pH, salinity and nutrients), and influence of pests and diseases (see Singh and Singh, 1997).

General Characteristics The association has been most frequently used as an alternative nitrogen fertilizer in rice fields, as well as a supplemental animal fodder. *Azolla* provides the cyanobiont with nutrients, including fixed carbon, and the cyanobiont provides the host with combined nitrogen (via nitrogen fixation). The exact role of the endosymbiotic bacteria in the association remains unclear; however, some possible functions have been suggested.

The Symbionts

Cyanobacterial Symbionts

Identification The filamentous, heterocystous, nitrogen-fixing cyanobacterial symbionts in the *Azolla* association have been extensively studied using both traditional and modern molecular techniques. In addition to characterization of the cyanobionts after they have been directly extracted from the association, there have been a number of studies in which cyanobacteria were isolated and cultured, in attempts to study the cyanobacterial symbionts in a free-living state. While numerous researchers have reported success in isolation and cultivation of the symbiotically associated cyanobacteria (Newton and Herman, 1979; Tel-Or et al., 1983; Gebhardt and Nierzwicki-Bauer, 1991; see Braun-Howland and Nierzwicki-Bauer, 1990), molecular studies (primarily based on restriction fragment length polymorphism [RFLP] analyses) have indicated

that none of the isolates represent the major cyanobacterial symbionts in the association (Gebhardt and Nierzwicki-Bauer, 1991). Though not conclusively demonstrated, major as well as some minor cyanobacteria may be present in the association, with the more readily cultured cyanobacteria representing minor symbionts (Gebhardt and Nierzwicki-Bauer, 1991). The other possible explanation is that the isolates presumably obtained from the association are actually epiphytes. Regardless, based on molecular studies it has not been conclusively demonstrated that the major cyanobacterial symbiont from the association can be cultured in a free-living state.

Given the challenge of studying the cyanobacterial symbionts in a free-living state, direct molecular studies have been used for accurate identification. Restriction fragment length polymorphism (RFLP) analyses (Gebhardt and Nierzwicki-Bauer, 1991), polymerase chain reaction (PCR) fingerprinting (Zheng et al., 1999), random amplified polymorphic DNAs (RAPDs; Van Coppenolle et al., 1995), as well as fluorescence in situ hybridizations (FISH) (Bushnell, 1998) have been used to examine the identity of the symbiotic cyanobacteria (Fig. 11). Regardless of the approach used, the cyanobiont referred to as "*Anabaena azollae*" has in most instances been described as being somewhat related to *Anabaena* or *Nostoc* (Plazinski et al., 1990c; Gebhardt and Nierzwicki-Bauer, 1991). A recent study (Baker et al., 2003) using comparisons of sequences of the phycocyanin intergenic spacer and a fragment of the 16S rRNA gene, places the *Azolla* cyanobiont in the order Nostocales but in a separate group from *Anabaena* or *Nostoc*. Additionally, near full-length (1500 bp) 16S rRNA sequencing and phylogenetic analysis of major cyanobionts from a variety of *Azolla* species yielded similar results (Milano, 2004). In 1989, Komarek and Anagnostidis placed the *Azolla* cyanobiont in a revised genus named "*Trichormus*," on the basis of morphology (Komarek and Anagnostidis). This is not inconsistent with the most recent molecular based findings.

The taxonomy of the cyanobionts is generally in agreement with the taxonomy of the host plant (Plazinski, 1990a; Van Coppenolle et al., 1993; Zheng et al., 1999). These findings, taken in conjunction with the continuous maintenance of the symbiosis throughout the lifecycle of the plant (see the section The Infection Process in this Chapter), suggest co-evolution of the cyanobionts and the host plant.

Developmental Profile Along the Main Stem Axis The growth of the endophyte is coordinated with the growth of the plant. In the apical meristem and younger leaves, the cyanobacterial vegetative cells are smaller than in older leaves and undergo frequent cell divisions. Increases in leaf age are accompanied by a decrease in cell division and increased size of the cyanobacterial vegetative cells, as well as increased heterocyst frequencies (Hill, 1975). The number of heterocysts and nitrogen fixation rates varies in leaves of different ages, as well as in different *Azolla* species (Hill, 1977). Heterocyst frequencies can reach up to 20–30% of the cells within a filament in the symbiotically associated *Anabaena*. These are much higher than the typical 10% heterocyst frequency in free-living *Anabaena* species.

Bacterial Symbionts The presence of bacteria residing within the leaf cavity of *Azolla* has been recognized for many years (Carrapico, 1991), yet still unclear is the specific function(s) of most of the bacteria in this symbiosis. Initial attempts to

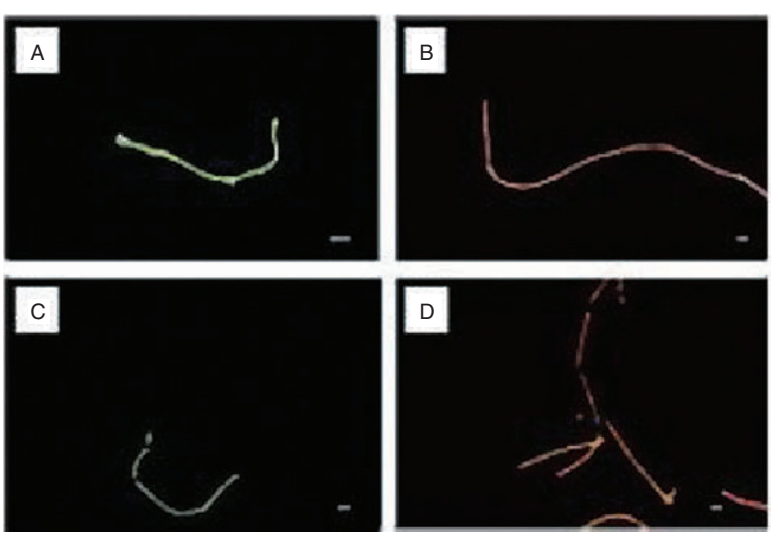

Fig 11. Fluorescent in situ hybridization (FISH) results, using Newton's isolate and different fluorescein isothiocyanate (FITC)-labeled 16S rRNA oligonucleotide probes, demonstrate that this isolate is not the same as the major cyanobiont of *A. caroliniana*. A) 16S rRNA universal probe, B) cyanobacterial group-specific probe (cells treated first with RNAse), C) Newton's isolate-specific 16S rRNA probe, and D) *A. caroliniana* major cyanobiont species-specific 16S rRNA probe. Bars represent approximately 25 μm (Bushnell, 1998).

study the symbiotic bacteria employed traditional microbiological, biochemical and physiological techniques for the identification of bacteria isolated from a variety of *Azolla* species. Utilizing these approaches there were many reports of *Arthrobacter* spp. (most frequently *A. globiformis*) occurring in symbiotic association with *Azolla* (Gates et al., 1980; Wallace and Gates, 1986; Forni et al., 1989; Forni et al., 1990; Nierzwicki-Bauer and Aulfinger, 1991; Shannon et al., 1993). *Agrobacterium* has also been reported to be isolated from different *Azolla* species (Plazinski et al., 1990b; Shannon et al., 1993; Serrano et al., 1999). Other bacteria, such as *Staphylococcus* sp., *Rhodococcus* spp., *Corynebacterium jeikeium* and *Weeksella zoohelcum* were identified by BIOLOG and API tests as being in association with *Azolla* (Serrano et al., 1999). A detailed review of the identification of bacteria isolated from *Azolla* species is provided in Lechno-Yossef and Nierzwicki-Bauer (2002b). Molecular techniques, in particular 16S rDNA gene amplification, cloning, screening, sequencing and phylogenetic analysis, have recently provided more detailed information on the identity of the symbiotic bacteria (Lechno-Yossef, 2002a; Milano, 2003). In the accessions studied, sequence similarity found that the most abundant bacterial symbionts in *A. caroliniana* and *A. filiculoides* were *Frateuria aurantia* and *Agrobacterium albertimagni*, and in *A. mexicana*, *Agrobacterium tumefaciens* (Lechno-Yossef, 2002a).

Host Structures and the Infection Process

The Leaf Cavity In the association, the symbionts reside in a leaf cavity, an extracellular compartment in the dorsal lobe of the leaf. In mature leaves, the symbionts (cyanobacteria and bacteria) are located in the periphery of the leaf cavity in mucilaginous material between internal (Nierzwicki-Bauer et al., 1989) and external envelopes (Uheda and Kitoch, 1991). Electron microscopic analysis combined with specific staining showed that the inner envelope does not have a tripartite structure typical of a membrane and is rich in lipids (Nierzwicki-Bauer et al., 1989). The external three-layered envelope is believed to contain cutinic and suberic substances, as revealed by response to chemical treatments of degradation using hot alkali methanol (de Roissart et al., 1994).

The adaxial epidermis of the leaf cavity contains a pore that is surrounded by two cell layers (Veys et al., 1999; Veys et al., 2000). One layer inside the pore is composed of teat-shaped cells that are extended from the adaxial epidermis. The other layer corresponds to the inner epidermis, which lines the inside of the cavity. Three to four tiers of teat cells form a cone-like pore with an average diameter at the base of 80 μm. The pore opening is larger in younger leaves, and the morphology of the teat cells suggests that their function is as a physical barrier to prevent particles and organisms from entering the cavity and the symbionts from exiting (Veys et al., 2002).

The Infection Process *Azolla* is a heterosporous water fern that is capable of both sexual and asexual reproduction. Unlike any of the other cyanobacterial symbioses, the host is in continual association with the symbionts. Thus, rather than reinfect *Azolla*, the symbionts retain coordinated growth in association with the host throughout its lifecycle. Descriptions of the processes involved in maintaining the continual association during sexual and asexual reproduction are described briefly below.

Sexual Reproduction Sporulation is the sexual reproduction process in *Azolla*. During sexual reproduction the host produces both mega- and microsporocarps. The partitioning of the cyanobacterial filaments into the developing sporocarps and the re-establishment of the symbiosis following embryogenesis in *A. mexicana* have been described (Perkins and Peters, 1993; Peters and Perkins, 1993). The symbionts that are used as inoculum to the developing sporocarps come from the dorsal lobe of the same leaf in which the sporocarps are developing.

The cyanobiont akinetes (which function as spores) and the bacterial symbionts (which do not always show ultrastructural characteristics of spore envelopes; Aulfinger et al., 1991) found in the megasporocarps are transferred to the developing spores and sporelings. After separation of the megasporocarp from the plant, part of the indusium is shed, and the proximal half becomes the indusium cap. The symbionts reside in a space called "the inoculation chamber" (Peters and Perkins, 1993), located between the indusium cap and the apical membrane of the megasporocarp. Following fertilization and the beginning of embryogenesis, the symbionts resume metabolic activity. With the assistance of cotyledonary hairs, the symbionts are introduced into the embryonic leaf, before it displaces the indusium cap (Peters and Perkins, 1993). Leaves, which grow from the meristem, are initially unlobed but contain a structure similar to the leaf cavity that contains the symbionts. As the frondling continues to grow, the symbionts are distributed into the developing leaf cavities by a mechanism similar to the transfer mechanism used during asexual reproduction via vegetative fragmentation (see the section Asexual Reproduction in this Chapter).

Asexual Reproduction The main form of reproduction in *Azolla* is vegetative fragmentation. The apical meristem of each branch contains a colony of undifferentiated cyanobacterial cells. Cyanobacterial filaments from the apical colony are introduced into the leaf primordium before the development of the leaf and leaf cavity are complete. The partitioning of the endophytes into the developing leaves is facilitated by entanglement around primary branched hair (PBH) cells of *Azolla* (Calvert and Peters, 1981). The leaf cavity starts to develop and engulf the cyanobacterial colony in the fourth or fifth leaf along the stem axis. In this way symbionts are inoculated into every leaf cavity that is formed. The development of the leaf cavity is also accompanied by the formation of simple hair cells by *Azolla* (Peters and Calvert, 1983).

"Artificial" In Vitro Infection of Cyanobacteria In sporulating *Azolla*, sexual hybridization between different *Azolla* species, as well as the formation of new combinations of *Azolla* and *Anabaena*, has been somewhat successful (Watanabe, 1994; Watanabe and Van Hove, 1996). For example, *Anabaena* from *A. microphylla* (MI4031) was successfully introduced into *A. filiculoides* (FI1034) by exchange of the indusium cap of the megaspore (Lin et al., 1989). Successful sexual hybridizations between *A. microphylla* (megasporocarp) and *A. filiculoides* (microsporocarp; Wei et al., 1988; Do et al., 1989), between *A. filiculoides* (megasporocarp) and *A. microphylla* (microsporocarp; Watanabe et al., 1993), and between *A. mexicana* and *A. microphylla* (Zimmerman et al., 1991) have also been reported. The key to these successes has been having the cyanobacteria at the appropriate stage of development (during akinete germination and vegetative cell growth) that mimics what naturally occurs in situ.

Host-Symbiont Signal Exchange

The recognition between *Azolla* and *Anabaena azollae* is facilitated by lectins in both the plant (Mellor et al., 1981) and the cyanobionts (Kobiler et al., 1981; Kobiler et al., 1982). Additionally, bacteria isolated from *A. pinnata* and *A. filiculoides* have been shown to contain lectins (Serrano et al., 1999). The presence of Rhizobiaceae symbionts in association with different *Azolla* species and cultures examined would suggest that this group of bacteria has a role in the symbiosis. Plazinski et al. (1991) showed that the *nodL* and *nodABC* genes gave hybridization signals to a plasmid and the chromosome of the isolate AFSR-1 from *A. filiculoides*. These authors suggest that the *nod* genes, if active in the bacterial symbionts of *Azolla*, play a regulatory role in the development of the symbiosis or in the maintenance of bacterial association with the plant.

Host-Cyanobiont Interactions Post-Infection

Morphological Modifications to Host and Cyanobacteria The leaf cavity and inner and external envelopes of *Azolla* do not appear to be present only when it is symbiotically associated with the cyanobionts. These structures are present in both *Anabaena*-free and *Anabaena*-containing *Azolla* (Nierzwicki-Bauer et al., 1989). This evidence excludes the involvement of the cyanobionts in the formation of these structures. However, given that the cyanobiont-free plants examined still contained symbiotic bacteria, a possible role of bacteria in the synthesis of the leaf cavity envelopes cannot yet be excluded.

Nitrogen Fixation and Transfer of Fixed Nitrogen Nitrogen fixation is carried out by the heterocysts of *Anabaena azollae*. In leaf cavities of different ages along the stem axis of *Azolla*, the heterocyst frequencies and nitrogen fixation rates vary. Nitrogen fixation, as determined by the acetylene reduction assay, occurs in the apical (younger) leaves but not in the stem apex, increases and reaches a peak in leaves of middle age, and then decreases in the older leaves (Canini et al., 1990). Ammonium, the product of nitrogen fixation, is released from heterocysts and assimilated by *Azolla* into glutamate using the glutamine synthetase (GS)-glutamate synthase (GOGAT) system (Peters and Calvert, 1983). Nitrogenous compounds in the form of glutamate, glutamine, ammonia and other glutamate derivatives are transferred from the mature leaf cavities to the stem apex (Peters et al., 1985). In *Anabaena azollae*, the activity and protein content of GS are only 5–10% of that of free-living *Anabaena* (Orr and Haselkorn, 1982). However, the nitrogen fixation activity is much higher because of the increased number of heterocysts. Some of the bacteria found in this association can fix nitrogen. Immunoelectron microscopy studies using antibodies against the Fe and FeMo protein subunits of nitrogenase revealed that a subset of the bacteria in the *A. caroliniana* and *A. filiculoides* associations contained these nitrogenase subunits (Lindblad et al., 1991). The potential nitrogen-fixing contribution of the bacteria in the association separate from that of cyanobacterial symbionts could not be measured because they coexist in the leaf cavities and, once removed, are likely to have altered capabilities.

Carbon Assimilation and Transfer of Fixed Carbon The cyanobiont, *Anabaena azollae*, has photosynthetic capabilities; however, in the symbiotic state it is believed to contribute less than 5% of the total CO_2 fixed in the association (Kaplan and Peters, 1988). Pulse-chase studies have shown that sucrose from the plant is supplied to and accumulated by the cyanobiont (Peters et al., 1985). Simple hair cells of *Azolla* are involved in the transport of sugars from the photosynthetic mesophyll cells to the leaf cavity. Simple hair cells have ATPase activity in their plasmalemma and some accumulation of starch in their chloroplasts (which do not possess ribulose 1,5 bisphosphate carboxylase, RuBisCO), suggesting active transfer of sugars from the simple hairs to the leaf cavity (Carrapico and Tavares, 1989). Additionally, primary branched hair cells, having the morphology of a transfer cell, are believed to be involved in nutrient transfer from the plant to *Anabaena* (Peters et al., 1985).

Ecological Importance—Friend or Foe?

The *Azolla-Anabaena* symbiosis is of tremendous ecological importance, having both positive and negative impacts. On the positive side, the association has been extensively used as a biofertilizer, providing a source of combined nitrogen in the form of ammonium, thereby reducing or eliminating the need for the addition of chemical fertilizers. This role has been most extensively used in conjunction with rice paddies or fertilization of fields. The growth of *Azolla* into thick mats also makes it effective in suppressing weed growth. Owing to its high protein content, *Azolla* is used as a fodder for sheep, pigs, ducks, etc. The ability of *Azolla* to remove nitrates and phosphorous from water has resulted in improvement of water quality. Additionally, *Azolla* has been used to remove heavy metals from water. Ten useful characteristics attributed to this association have been described (Van Hove and Lejeune, 1996; Lejeune et al., 1999), with the capacity to fix atmospheric nitrogen, high productivity, high protein content, and a depressive influence on both aquatic weeds and NH_3 volatilization, being considered unquestionably useful.

The same characteristic feature that makes *Azolla* useful for weed suppression and biofertilization of fields (namely, the ability to grow in thick mats) also results in a number of negative ecological impacts. For example, growth of *Azolla* mats in streams in Zimbabwe has been shown to have a negative impact on animal biodiversity (Gratwicke and Marshall, 2001). In many regions where *Azolla* is an invasive species it has overgrown many native species. In efforts to control *Azolla* growth, biological controls such as the introduction of a frond-feeding weevil (McConnachie et al., 2004) or the flea beetle (Hill and Oberholzer, 2002) are being explored. Thus, the overall ecological impact of the *Azolla-Anabaena* association continues to expand and may reach even to Mars, since *Azolla* is currently being used in studies examining possible bioregenerative life support on Mars (http://www.highmars.org/niac/niac04.html, The Caves of Mars Project website).

SECTION IV: Cyanolichens

Introduction

Lichens are associations of symbiotic fungi and green algae (bipartite lichens) or symbiotic fungi, green algae, and cyanobacteria (tripartite lichens). A lichen thallus is quite distinct in appearance from either of its symbionts, and its name refers to the dominating fungal partner (the mycobiont). Lichen thalli represent an integration of the mycobiont's heterotrophic metabolism and the autotrophic metabolism of the photosynthetic partners (the photobionts: green algae and cyanobacteria). In tripartite lichens, the cyanobacterial partner (the cyanobiont) is also referred to as the "secondary photobiont," whereas the green algal partner is referred to as the "primary photobiont." All lichens having a cyanobiont, either as the sole photobiont or as a secondary photobiont, are called "cyanolichens." For lack of space, this review on cyanolichens is brief. The reader can find further details in books and reviews elsewhere (Galun, 1988; Ahmadjian, 1993; Nash, 1996; Rai et al., 2002b; Rikkinen, 2002a). The journal *Bryologist* regularly lists recent literature on lichens, and a literature search is also possible at Mattick's Literature Index website (http://www.toyen.uio.no/botanisk/bot-mus/lav/sok_rll.htm).

There are approximately 1550 known species of cyanolichens, representing roughly 12–13% of all known lichens. Among these, two thirds are bipartite and the rest tripartite species. Lichen symbioses are thought to have arisen independently on several occasions. An estimated 100 lichenization events have occurred during diversification of extant fungi (Aptroot, 1998; see also Rikkinen, 2002a).

The Symbionts

Mycobionts The current classification of fungi is in transition, and molecular approaches are being used to fine-tune it (Tehler et al., 2000; see also Rikkinen, 2002a). Approximately 13,500

species of lichen-forming fungi presently belong mostly to the Ascomycetes (98%) and very few to the Basidiomycetes (1.6%) and Fungi Imperfecti (0.4%). About 15–18 Orders of Ascomycetes (nearly 130 genera from 50 families) include lichen-forming taxa (see Rikkinen, 2002a). Most are from two Orders, the Lecanorales and Lichinales. Nearly 1700 species of fungi associate with different types of cyanobacteria. A fairly comprehensive list of these has been provided earlier (Rikkinen, 2002a).

Cyanobionts A variety of heterocyst-producing and unicellular cyanobacteria occur as cyanobionts in cyanolichens where the mycobiont is an ascomycete. Among heterocystous forms, *Nostoc* is the most common. Others are *Scytonema*, *Calothrix*, *Dichothrix* and *Fischerella* (including *Hypomorpha*, *Stigonema* and *Mastigocladus*). Unicellular forms that occur as cyanobionts in cyanolichens include *Gloeocapsa* (also *Chroococcus*), *Gloeothece*, *Synechocystis* (also *Aphanocapsa*), *Chroococcidiopsis*, *Hyella* and *Myxosarcina* (see Rai et al. [2000] and Rikkinen [2002a]). The range of cyanobionts in cyanolichens where the mycobiont is a basidiomycete is rather limited. Only two cyanobacteria (*Chroococcus* and *Scytonema*) are reported as cyanobionts in basidiolichens (see Schenk, 1992).

In recent years, analyses of $tRNA^{Leu}$ (UAA) introns and 16S rDNA sequences have been used as genetic markers to study the diversity of *Nostoc* cyanobionts (Paulsrud and Lindblad, 1998a; Paulsrud et al., 1998b; Paulsrud et al., 2000; Paulsrud et al., 2001; Lohtander et al., 2002; Rikkinen et al., 2002b). These studies have shown that genetic variation among lichen-forming *Nostoc* strains is considerable. Within symbiotic *Nostoc* strains, there seem to be several subgroups. For example, one subgroup of *Nostoc* strains seems to occur only in epiphytic cyanolichens, whereas another includes strains that occur as cyanobionts in terricolous cyanolichens and other symbiotic systems (Rikkinen, 2002a; Rikkinen et al., 2002b).

The Lichen Thallus Lichen thalli have a stable and organized structure quite distinct from any of their symbionts. The thalli appear to be crustose (small lobes and scales; e.g., *Collema*), foliose (flat and dorsiventral lobes; e.g., *Peltigera*), or fruiticose (round or flat thalli, upright or hanging down from the substratum; e.g., *Stereocaulon*). In foliose or fruticose thalli, the fungal hyphae form an outer pseudoparenchymatous zone (the cortex) that covers or encloses a more loosely interwoven medulla. Within the thallus, the partners remain extracellular to each other and can be isolated and grown in culture, but the symbiosis is fairly stable in nature because of the balanced and synchronized growth and development of the symbionts. Thinner cell walls (less sheath material) and specialized hyphae and haustoria, showing transfer cell ultrastructure, enable close contact between the mycobiont and the cyanobiont. Since the bulk of the thallus consists of the heterotrophic mycobiont, the thallus interior is microaerobic (see Rai et al., 2000).

In bipartite lichens, cyanobionts either are dispersed throughout the thallus (e.g., *Collema*) or occupy a distinct layer below the upper cortex (e.g., *P. canina*). In tripartite lichens, the cyanobiont is located in cephalodia, which occur at the upper surface of the thallus (external cephalodia; e.g., in *P. aphthosa*) or inside the medulla (internal cephalodia; e.g., in *Nephroma arcticum*). In some cases internal cephalodia are found close to the lower surface of the thallus (e.g., in *P. venosa*). In tripartite lichens, direct contact between the cyanobiont and the phycobiont (green algal partner) is never direct.

Lichen symbioses perpetuate by direct transmission of the cyanobiont from one generation to the next, and as a result of the acquisition, by the mycobiont of fresh cyanobiont from the environment. For example, a lichen thallus can develop from propagules (phyllidia, isidia, soredia and hormocystangia) of a pre-existing thallus (direct transmission) or from fresh synthesis (fresh acquisition of cyanobiont from the environment). The former mode of transmission allows prolonged continuity of the partners. Similar modes of cyanobiont acquisition also apply to the development of cephalodia (see Rai et al., 2000).

Cyanobionts are essential for the formation of thalli or cephalodia in cyanolichens. They may stimulate thallus morphogenesis but do not determine the kind of thallus formed. The mycobiont determines the structure and chemistry of a cyanolichen. Different lichen fungi form different lichen thalli even if associating with the same cyanobiont (see Rai [1990], Rai et al. [2000], and Rai et al. [2002b]).

Because they are slow growing, the initiation and development of lichens is difficult to study in nature. Development of a lichen thallus afresh involves germination of the mycobiont spore, development of the hyphal mat, contact, recognition and acquisition of the cyanobiont, and structural-functional integration of the symbionts. While a thallus may result within months when starting from propagules, it takes years when starting from isolated partners. During laboratory synthesis of lichens, the partners initially form undifferentiated aggregates that later differentiate into thalli (see Rai et al., 2000). Fresh synthesis in nature may also start from myco-

biont hyphae that become detached and acquire fresh cyanobiont (Smith and Douglas, 1987).

Development of each cephalodium is a new event. External cephalodia develop on the main thallus by entrapment of a cyanobiont by hairs on the thallus surface, followed by involvement of medullary hyphae immediately below. Internal cephalodia may develop in a similar fashion starting with cyanobiont entrapment by cortical hyphae or rhizines. The cyanobiont, enmeshed by a thick layer of mycobiont, is pressed into the thallus where the cephalodium eventually develops. New cephalodia may develop from hormogonia released by earlier cephalodia (Stocker-Wörgötter, 1995), ensuring cyanobiont homogeneity among cephalodia of a thallus. In laboratory synthesis however, cephalodia developed by attachment of hyphae from primordia (containing cyanobiont and mycobiont) to the green thallus (Stocker-Wörgötter and Turk, 1994). The latter mode of cephalodia development, if prevalent in nature, should cause considerable heterogeneity among symbiont populations within a single thallus, but this is not the case. Occasional reports of different cyanobionts (see Rai, 1990) or different strains of a cyanobiont (Paulsrud et al., 2000) among cephalodia of a single thallus may, however, indicate instances of cephalodia development by capture of a fresh cyanobiont in some lichens. Entry of the cyanobiont for development of internal cephalodia is from the lower surface of the thallus, but occasionally, when the cyanobiont enters from above, the phycobiont layer is pressed deep into the medulla.

Recognition and Signal Exchange Between Partners For the right symbionts to enter into a lichen symbiosis, signal exchange must occur between the partners. Transformation of *Nostoc* colonies into the symbiotic state occurred without the necessity for direct contact with the mycobiont during resynthesis of *Peltigera praetextata* (Yoshimura and Yamamoto, 1991). This suggests that the substance responsible for *Nostoc* transformation may be a diffusible soluble substance from the mycobiont. The exact identity of such a substance is not known, but lichen-forming fungi do produce a large number of unique secondary metabolites and compounds, and their possible roles in signal exchange need to be investigated.

Lectins (glycoproteins) of mycobiont origin have been implicated in the recognition of the cyanobiont by a mycobiont (Rai, 1990; Kardish et al., 1991; Lehr et al., 1995; Lehr et al., 2000). Cyanobiont cell surfaces possess specific sugars, fimbrae (pili), and in some cases, lectins, which may have a role in recognition and adherence (Stewart et al., 1983; Kardish et al., 1991; see Rai et al., 2000).

Direct observations, lectin binding experiments and $tRNA^{Leu}$ intron analysis all indicate a broader cyanobiont-mycobiont specificity in lichens than that in other cyanobacterial symbioses. Different lichen species can have the same cyanobiont, and different cyanobionts have been reported among cephalodia of a single lichen thallus. Different *Nostoc* strains have been found in different lichen species from the same site, while different lichen species from distant places had the same *Nostoc* strain. In chimeroid thalli, both bipartite and tripartite morphotypes are reported to have the same cyanobiont strain (Paulsrud et al., 1998b; Paulsrud et al., 2000; Paulsrud et al., 2001). Overall, there is a great deal of cyanobiont diversity among the lichens, and much of it might be contributed by the mode of cyanobiont acquisition during the development of the lichen thallus and cephalodia (Rai et al., 2000).

Many cyanolichens share similar environmental requirements and may depend on a common pool of cyanobionts. Many cyanolichen species having identical cyanobiont strains co-occur in a particular habitat, forming characteristic communities or "guilds" (Rikkinen et al., 2002b). Within a guild, the cyanobionts of all lichens are closely related, but the mycobionts are not. While some guilds include different mycobiont genera or even families, some closely related mycobionts belong to different guilds (associate with different types of cyanobionts).

Structural-Functional Changes Cyanobionts undergo structural-functional changes in the symbiosis that permit a close interaction and development of nutrient exchange between the partners. These changes include increased cell size, altered cell shape, lack of polyphosphate reserves, fewer carboxysomes, less sheath material, and slower growth and cell division (Rai et al., 2000).

The cyanobionts are photosynthetically active and fix CO_2 via the C_3 pathway. In addition, there is a significant level of dark CO_2 fixation (15–20% of that in the light) via the C_4 pathway (Rai et al., 2000; Palmqvist, 2002). However, CO_2 fixation by cyanobionts in internal cephalodia, particularly those on the lower surface (e.g., *Peltigera venosa*), may be minimal due to low light and Rubisco. In the tripartite *Nephroma arcticum*, the *Nostoc* cyanobiont has 70% fewer carboxysomes compared with that in the bipartite *P. canina* (Bergman and Rai, 1989).

In free-living cyanobacteria, heterocysts are regularly spaced and represent about 5–10% of the cell population. There is a change in the spacing pattern of heterocysts and an increase in their frequency in the cyanobionts in tripartite lichens

(heterocyst frequency 15–35%) but not in bipartite lichens. Heterocyst frequency correlates with the status of fixed carbon in the cyanobiont; in bipartite lichens the cyanobiont bears the burden of providing both fixed nitrogen and fixed carbon to the mycobiont, whereas in tripartite lichens it provides fixed nitrogen only. Indeed heterocyst frequency increases when *Nostoc* isolates are grown in the dark with sugars. In many cyanobacterial-plant symbioses, where the cyanobiont receives fixed carbon from the plant host, heterocyst frequencies of up to 80% can occur (see Rai et al., 2002b).

In free-living cyanobacteria, glutamine synthetase (GS) is the primary ammonia assimilating enzyme and GS levels in heterocysts are twofold higher than those in vegetative cells (Bergman et al., 1985). In cyanobionts, the GS activity and protein levels decrease by over 90% and the remaining GS is uniformly distributed among heterocysts and vegetative cells (Bergman and Rai, 1989; Rai, 2002a). GS activity is undetectable in the mycobiont, but mycobiont hyphae in contact with cyanobiont cells show high levels of nicotinamide adenine dinucleotide phosphate ($NADP^+$)-dependent glutamate dehydrogenase (GDH) activity.

Nitrogen fixation occurs in all lichens containing heterocystous cyanobionts. The rates are higher in tripartite lichens owing to the higher heterocyst frequency of the cyanobiont (see Rai et al. [2000] and Rai [2002a]). In contrast to free-living forms, cyanobionts in bipartite lichens and in excised cephalodia continue to fix N_2 even in the presence of nitrate or ammonia (Stewart and Rowell, 1977b; Rai et al., 1980). However, nitrogen fixation by the cyanobiont in cephalodia attached to the main thallus of the tripartite lichen *P. aphthosa* was repressed by nitrate and ammonia. The effect was obviously mediated via the phycobiont. Significant levels of N_2 fixation have also been reported in darkness and under these conditions ammonia has an inhibitory effect (Rai et al., 1981a; Rai et al., 1983b). As in the free-living forms, nitrogenase is located only in the heterocysts, despite the microaerobic conditions in lichen thalli (Bergman et al., 1986).

The extent of the changes described above varies from young to older, more mature parts of the thallus. While growth rate gradually declines, cell division and GS levels, the levels of N_2 fixation, CO_2 fixation, and heterocyst frequency of the cyanobiont increase. There is a parallel increase in the GDH activity in the mycobiont (Rowell et al., 1985; Hill, 1989; Rai, 2002a). Still undetermined is whether these changes are caused by the mycobiont or by endogenous regulation due to special environmental conditions offered by the host in the symbiosis.

NUTRIENT EXCHANGE Most studies on nutrient exchange relate to carbon and nitrogen transfer from the cyanobiont to the mycobiont in foliose lichens, particularly *Peltigera* species. Such nutrient transfer is biotrophic in nature and varies along the lichen thallus. From young to mature parts of the lichen thallus, the cyanobiont increases fixation and release of nitrogen and carbon. Specialized mycobiont hyphae and haustoria showing transfer cell ultrastructure (TCU) may play an important role in the nutrient exchange (see Rai et al., 2000).

In bipartite cyanolichens, 70–80% of the CO_2 fixed is released by the cyanobiont to the mycobiont. The transfer of fixed carbon occurs mostly in the light and in the form of glucose. Cyanobionts in tripartite lichens transfer little (<5% of CO_2 fixed) or no fixed-C to the mycobiont. Their primary role seems to be the provision of fixed nitrogen. It would be interesting to know whether the cyanobionts in internal cephalodia occurring deep in the medulla or on the undersurface of a lichen thallus actually receive any fixed carbon from the phycobiont (either directly or via the mycobiont). The glucose transferred to the mycobiont is converted to mannitol, which serves as both a C source and a physiological buffer. Mannitol production by lichenized fungi could be an effective way of sequestering the fixed carbon since other partners cannot use it. The mechanism underlying glucose transfer is not fully understood, but the glucose is thought to originate from a glucan pool rather than directly from CO_2 fixation. Altered cell wall synthesis may lead to a diversion of sugars from cell wall synthesis to simple release. Release of glucose declines sharply and stops soon after the isolation of the cyanobiont, indicating the influence of mycobiont and symbiotic conditions in the thallus on this process (Smith and Douglas, 1987; Meindl and Loos, 1990; Rai, 1990; Palmqvist, 2002).

^{15}N tracer studies in *P. aphthosa* (tripartite) and *P. canina* (bipartite) have concluded that fixed-N is transferred from cyanobiont to the mycobiont as ammonia (Rai et al., 1981b; Rai et al., 1983a). Over 90% of the N_2 fixed in *P. aphthosa* (and about 50% in *P. canina*) is released by the cyanobiont because GS in heterocysts is repressed. The partitioning of fixed-N among the partners is proportionate to their contribution to the thallus composition. In *P. aphthosa*, the ammonium released by the cyanobiont is primarily assimilated by the mycobiont in cephalodia, and the phycobiont receives fixed-N via the mycobiont. The mechanism of ammonia release by the cyanobiont and its uptake by the mycobiont at the cyanobiont-mycobiont interface has not been investigated. However, diffusion of NH_3 from heterocysts can occur in the absence

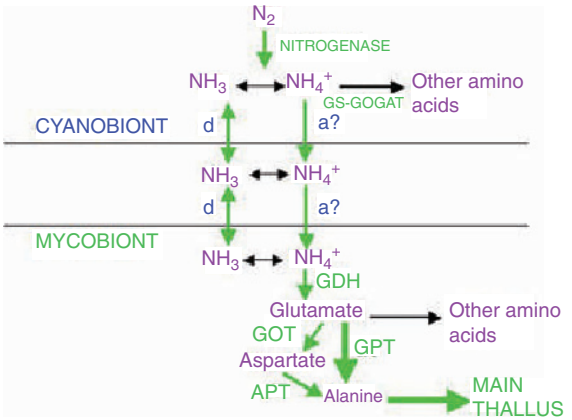

Fig. 12. Pathways of N-metabolism in *P. aphthosa*. a, active transport; and d, diffusion. GS, glutamine synthetase; GOGAT, glutamate synthase; GOT, glutamate-oxaloacetate transaminase; GPT, glutamate-pyruvate transaminase; GDH, glutamate dehydrogenase; and APT, aspartate-pyruvate transaminase.

of ammonia assimilation by GS. Ammonia assimilation in the mycobiont occurs via GDH followed by aminotransferases. In pulse-chase experiments, much of the ^{15}N label accumulated as alanine in the mycobiont of *P. aphthosa* cephalodia. Alanine could be the principal compound transferred to the rest of thallus (Fig. 12).

Ecological Significance Lichens are ubiquitous, occurring in terrestrial as well as aquatic habitats from the equator to the highest latitudes, at sea level to 9000 m altitude, and in the wettest to driest habitats. They are excellent colonizers of nutrient poor habitats (sand dunes, rocks, forest floors, and the surfaces of other vegetation), form dominant vegetation in tundra and arctic-alpine regions, and contribute significantly to the N-economy of these ecosystems. Lichens are good bioindicators of air pollution.

Cyanobionts endow mycobionts with N and C autotrophy and thereby widen their potential habitats. In a lichen thallus, cyanobionts gain a safe habitat and protection from uncertainty of fluctuating nutrient availability and climatic conditions in nature.

Outlook Many interesting aspects of the lichen symbioses remain to be elucidated. These include release and uptake of nutrients at the cyanobiont-mycobiont interface, cyanobiont acquisition, and regulatory mechanisms enforcing synchronized growth and development of the partners. Furthermore, whether the structural-functional changes in symbionts are a result of endogenous regulation due to the symbiotic environment (e.g., microaerobiosis, restricted growth, and cell division) or whether they are directly caused by the mycobiont will need to be resolved.

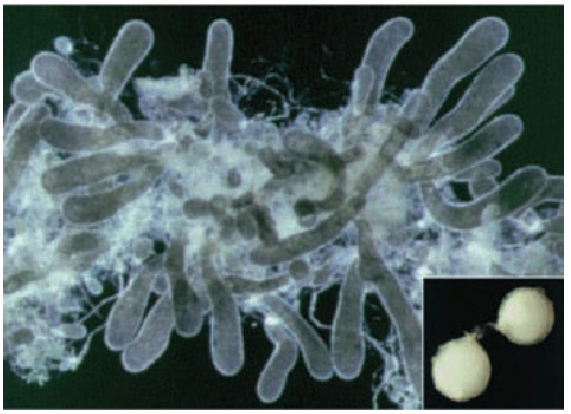

Fig. 13. The *Geosiphon* symbiosis, isolated from a laboratory culture on natural substrate, cleaned, and incubated in liquid medium. The large bladders are about 1.5 mm in length. The insert shows *Geosiphon* spores, which have a diameter of about 250 µm.

SECTION V: The Geosiphon Pyriformis—Nostoc Endocyanosis and its Relationship to the Arbuscular Mycorrhiza (AM)

Introduction

Geosiphon pyriformis (Kütz.) v. Wettstein (v. Von Wettstein, 1915) is presently the only known fungal endocyanosis (endocytobiotic association with a cyanobacterium). The coenocytic *Geosiphon* fungus forms unicellular, multinucleated cells ("bladders") of about 1–2 mm in size (Fig. 13), harboring endosymbiotic filamentous cyanobacteria of the genus *Nostoc*. Only five reports have shown that this symbiosis exists in nature at a range of sites from eastern Germany to Austria. Probably the symbiosis is geographically widespread but, owing to its small size, rarely reported. Presently, locations around the small village of Bieber in the Spessart Mountains (Germany) are the only known natural habitats worldwide (Mollenhauer, 1992; Schüßler and Kluge, 2001).

The species name "*Geosiphon pyriforme*" was used in the past for the fungus as well as for the symbiosis, since this association was often regarded as a "phycomycetous lichen." Nowadays endosymbiotic associations are often excluded from lichen definitions (Hawksworth and Honegger, 1994), and therefore the species name should be used for the fungus only (Schüßler, 2002). Moreover, phylogenetically the *Geosiphon* fungus belongs to the arbuscular mycorrhizal (AM) and related fungi (Fig. 14)

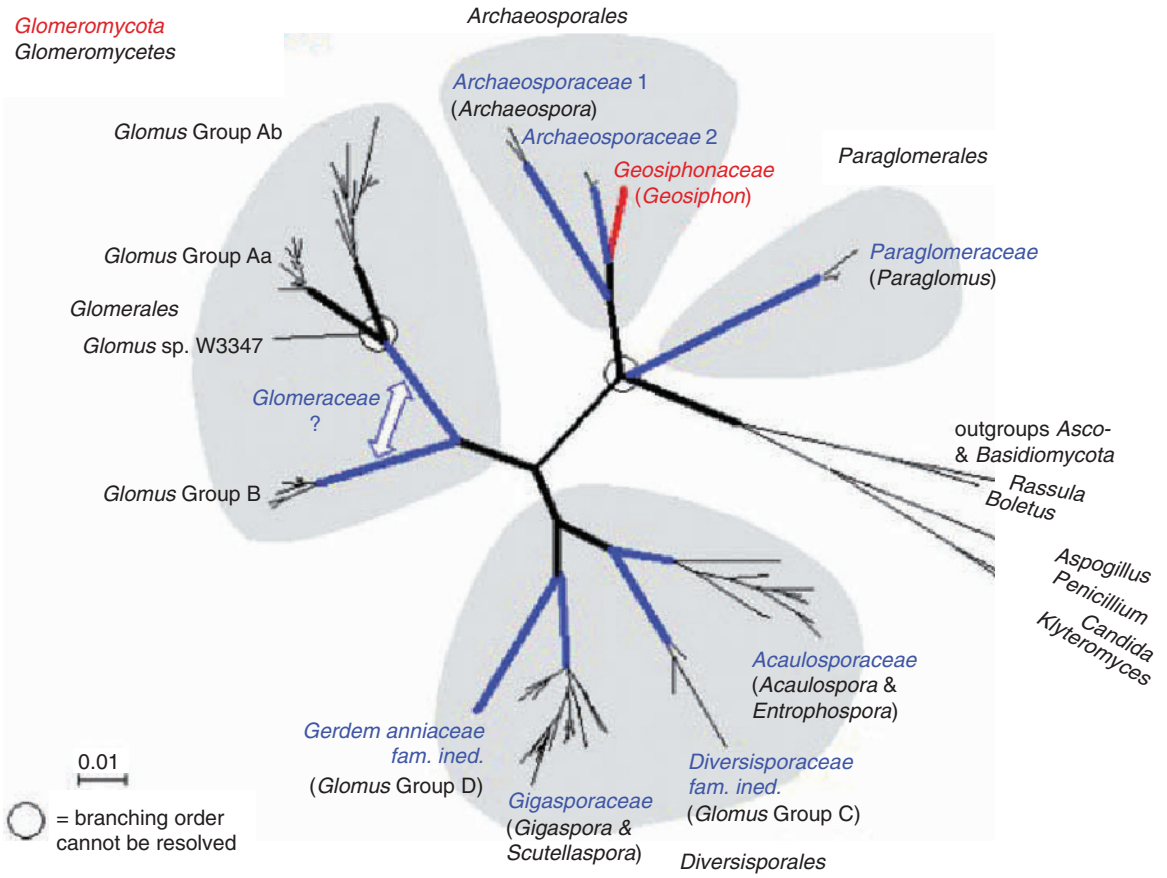

Fig. 14. Phylogenetic (maximum likelihood) tree of AM fungi (Glomeromycota), including *Geosiphon* (see Schüßler et al. [2001], Schwarzott et al. [2001], and Schüßler [2002]). For sequences used, updates, and details, see also (http://www.geosiphon.de) and (http://www.amf-phylogeny.com).

The association between the fungus and cyanobacteria here is referred to as the "*Geosiphon* symbiosis" and the species name of the fungus recently was corrected into its orthographically correct form, *Geosiphon pyriformis* (Schüßler, 2002).

The Symbionts: *Geosiphon pyriformis* and *Nostoc punctiforme*

Analysis of small-subunit ribosomal RNA (SSU rRNA) genes (Schüßler et al., 2001; Schwarzott et al., 2001) and also the morphology and formation of the fungal spores (Schüßler et al., 1994) have shown that the fungal partner of the *Geosiphon* symbiosis belongs to an ancestral branch within the *Glomeromycota*, a new fungal phylum in which the "arbuscular mycorrhizal (AM) and related fungi" (usually referred to as "AM fungi") are placed (Schüßler et al., 2001). In Fig. 14, the molecular phylogeny of the *Glomeromycota*, including *Geosiphon* (Geosiphonaceae and Archaeosporales), is shown. Therefore, the *Geosiphon* symbiosis is also attracting interest from the field of AM research. The AM symbiosis is formed by more than 80% of vascular plants, and moreover, also by lower plants (Read et al., 2000; Schüßler, 2000), where it is also called "AM," though these plants do not possess roots. This huge number of plants forming AM indicates that the AM is one of the most important factors in land ecosystems (Smith and Read, 1997).

The endosymbiont of *Geosiphon* is *Nostoc punctiforme*. Various strains of *Nostoc punctiforme* from other symbiotic systems (e.g., *Anthoceros*, *Blasia* and *Gunnera*) are capable of forming this symbiosis (Mollenhauer, 1992). In the field, *Geosiphon* was always found together with *Anthoceros* and *Blasia*, and its cyanobionts can infect the bryophytes and vice versa. In laboratory cultures, a *Nostoc punctiforme* strain is used that was originally isolated from the *Geosiphon* symbiosis by Mollenhauer.

Geosiphon also harbors another prokaryotic endosymbiont, the so-called "BLOs" ("bacteria-like organisms;" Fig. 15), which are not surrounded by a host membrane (Schüßler at al. 1996; Schüßler and Kluge, 2001). These endosymbiotic bacteria show the typical ultrastructure of those living in most AM fungi. Since these

bacteria are found in diverse branches of the *Glomeromycota*, they have to be considered as ancient symbionts, which are horizontally transferred and have probably lived as symbionts within these fungi for many hundreds of million years. Not much is known about these bacteria. The BLOs of fungi belonging to one glomeromycotan family, the Gigasporaceae, are better investigated. However, these BLOs are enclosed by a host membrane, seem to be a distinct type of bacteria, and may be unique for this branch within the *Glomeromycota*.

The *Geosiphon* symbiosis is facultative for one of the partners—*Nostoc* can be cultivated without the fungus—and obligate for the other one—*Geosiphon*. However, the fungus is, conceivably, not necessarily restricted to the cyanobacteria as symbiotic partner. Likely, *Geosiphon* forms symbiotic associations not only with *Nostoc* but also with plants to form AM (Kluge et al., 2002; Fig. 16). However, this assumption is still speculative.

In any case, because it belongs to the Glomeromycota and has functional as well as structural similarities to the AM, the *Geosiphon* symbiosis probably can play a role in the future as a model system for the hard-to-investigate but extremely important AM symbiosis (Schüßler and Kluge, 2001; Schüßler, 2002).

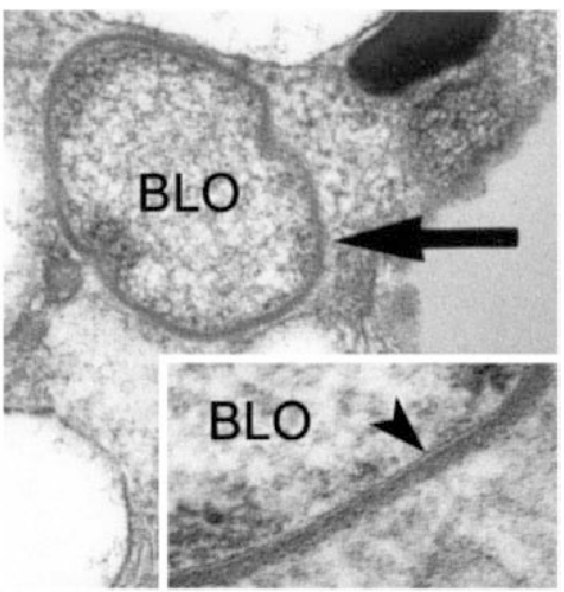

Fig. 15. Electron micrograph of a bacteria-like endosymbiont (BLO) in *Geosiphon*. The BLOs have a diameter of about 0.5 µm and are not enclosed by a host membrane (arrow). The insert shows the plasma membrane of the BLO (arrowhead), as well as its cell wall. The ultrastructure indicates that the BLOs are Gram-positive.

Infection Process, Development and Structure of the Symbiosis

THE INFECTION PROCESS Both symbiosis partners live in the upper layer and on the surface of humid soil, where they can contact each other. The specificity of the interaction between the partners is illustrated by two observations: 1) only certain *Nostoc punctiforme* strains are capable of entering into this symbiosis, and 2) before a successful interaction with the fungus can occur, *Nostoc* has to be at a specific stage of its lifecycle. This is represented by an early immobile stage of the cyanobacterial developmental cycle called a "primordium" (Mollenhauer et al., 1996). The motile filaments (hormogonia) of *Nostoc* and later developmental stages are not recognized by the fungus. When contacting *Nostoc*, the tip of the fungal hypha bulges out and surrounds a part of a cyanobacterial filament, thus incorporating the *Nostoc* cells (Fig. 17). Usually about 5–15 *Nostoc* cells are taken up by this process; exceptions are the heterocysts, which are cut off by the fungus when enclosing the filament. These events are also documented in a scientific film available in German and English (Mollenhauer and Mollenhauer, 1997).

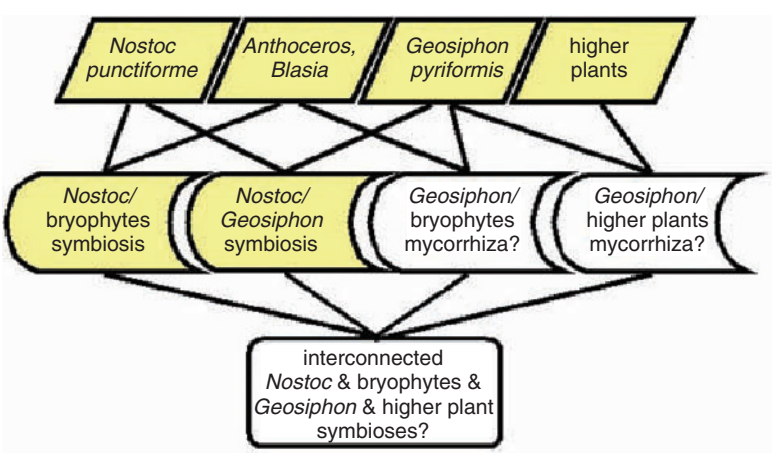

Fig. 16. A possible ecological "symbiosis network" among cyanobacteria, fungi, and plants. Associations which are not highlighted are hypothetical! Further endosymbionts like the BLOs in glomeromycotan fungi may also play an unknown but important role in this network, e.g., for N_2 fixation.

Studies using different lectins revealed that the envelope of the symbiosis-compatible *Nostoc* stage is labeled by a mannose specific lectin (ConA), whereas later stages (heterocysts and hormogonia) showed distinct lectin labeling patterns (Schüßler et al., 1997). Thus the alterations of extracellular glycoconjugates could be involved in partner recognition. Nowadays the symbiosis-compatible *Nostoc* stage is well characterized and a lectin mediated process is indicated by further studies (A. Schüßler and E. Wolf, unpublished observation).

Development of the Symbiosis Each individual *Geosiphon* bladder results from *Nostoc* incorporation by a hypha, as already recognized by Knapp (1933), and each bladder represents a polyenergid cell, coenocytic with the fungal mycelium. After incorporation by the fungus, the *Nostoc* cells first suffer severe stress, as indicated by bleaching of their photosynthetic pigments (Mollenhauer et al., 1996; Fig. 17). They are deformed during the early uptake stages, and some cells may die during this process. The outgrowings of the hyphal tip form an irregularly shaped structure (Fig. 17), which then swells, and after one week the young bladder shows a diameter of up to 100 µm (Fig. 18). Within the first three days, the enclosed *Nostoc* cells recover and then begin to multiply and regenerate heterocysts in about the same frequency as in the free-living filaments (Fig. 19). The endosymbiotic *Nostoc* cells then have an about sixfold larger volume compared with cells outside the bladder (Schüßler et al., 1996) and moreover, under phosphate limitation, divide much faster compared with the free-living ones within the first week (E. Wolf and A. Schüßler, unpublished observation). Individual *Geosiphon* bladders can reach more then 2 mm in length (Figs. 13 and 18) and show a turgor pressure of about 0.6 megapascals (MPa; Schüßler et al., 1995) and live for up to 6 months in laboratory cultures.

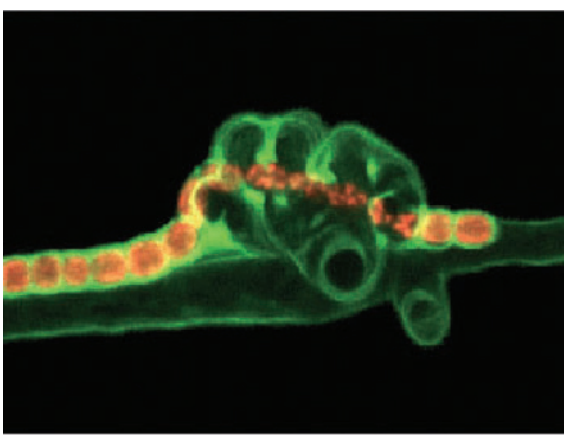

Fig. 17. Confocal laser scanning microscopic projection of a short hypha branching from a main hypha and enclosing a *Nostoc* filament. The extracellular polysaccharides of *Nostoc* and the outer layer of the fungal cell wall are labeled by the fluorescence-coupled lectin ConA (green). The *Nostoc* cells (red, about 4 × 3 µm) that are taken up by the fungal structure show deformations and lower and irregular pigment fluorescence.

Structure and Compartmentation of the Geosiphon Bladder Inside the bladder, the *Nostoc* cells are located within a single, cup-shaped, peripheral compartment, the so-called "symbiosome" (Fig. 20). Lectin labeling experiments combined with electron and fluorescence microscopy showed that the symbiosome space between the *Nostoc* cell-wall and the host symbiosome-membrane contains chitin (Schüßler et al., 1996). This means that the symbiosome-membrane synthesizes chitin and retains this feature from the plasma membrane, from which it was derived by invagination. Interestingly, the symbiotic interface between photobiont and fungus is very similar to that found in AM (Fig. 21). *Geosiphon* bladders are highly vacuolated and contain many lipid droplets in the basal part, which is in contact with the soil substrate. The latter causes a milky white

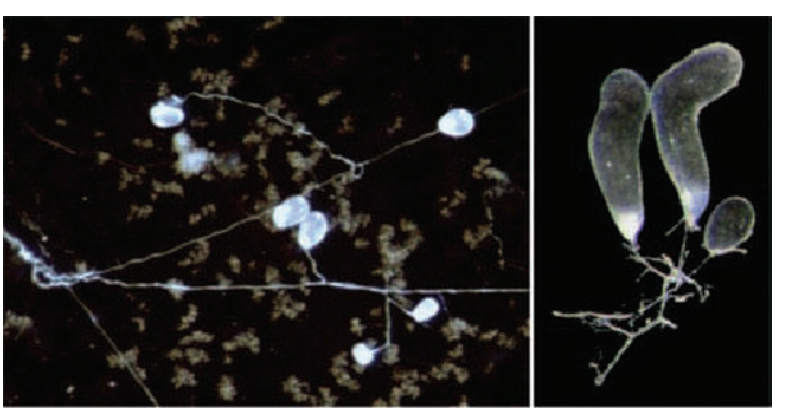

Fig. 18. Young *Geosiphon* bladders, 100–150 µm in size, formed at the fungal mycelium 7–10 days after initial uptake of the cyanobacteria (left). The irregular structures in the background are vegetatively growing *Nostoc* colonies. Two mature bladders of about 1 mm length, together with a young bladder, are shown at the right.

appearance of the bladder base. The dark appearing apical three quarters of the bladder contains the symbiosome and is located above ground. Although the endosymbiotic *Nostoc* cells have a much larger volume compared with free-living ones, they show a normal ultrastructure (Schüßler and Kluge, 2001). Interestingly, an early electron-microscope study of the *Geosiphon* symbiosis led to the "rules of the compartmentation of the eukaryotic cell," also strongly supporting the endosymbiosis theory of the origin of chloroplasts and mitochondria (Schnepf, 1964).

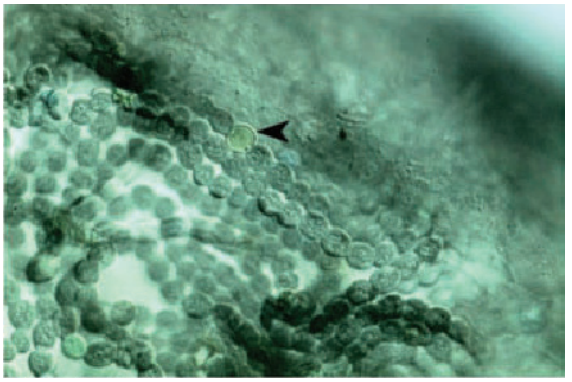

Fig. 19. Endosymbiotic *Nostoc*, about 7 × 6 µm in size, within a *Geosiphon* bladder. One heterocyst is in focus (arrowhead).

Signal Exchange Between Host and Cyanobacterium

Still unknown is what triggers the recognition and the morphological changes that occur during the establishment of the symbiosis. Microscopical studies give no hints for any chemotactic or otherwise directed growth towards the respective symbiosis partner. The growing fungal hyphae seem to contact compatible *Nostoc* stages by chance. However, these observations are mainly based on studies in liquid nutrient solution or on agar plates and might differ in nature. If a suitable stage is contacted by the growing hyphal tip, there have to be highly specific signal perceptions of unknown nature. This is clearly indicated by two facts: 1) the fungus recognizes a *Nostoc* stage (the primordium) only present for some hours in the *Nostoc* life cycle, and 2) the heterocysts are not taken up by the fungus but are cut off when the fungus encloses the vegetative part of the *Nostoc* filament (Fig. 17). The cyanobacteria considerably change their surface carbohydrate composition during the life cycle, and some indications point to a lectin-mediated partner recognition (Schüßler et al., 1997; A. Schüßler and E. Wolf, unpublished observation).

Host-Cyanobiont Interactions Post Infection

Morphological Modifications of the Symbiosis Partners The most obvious morphological

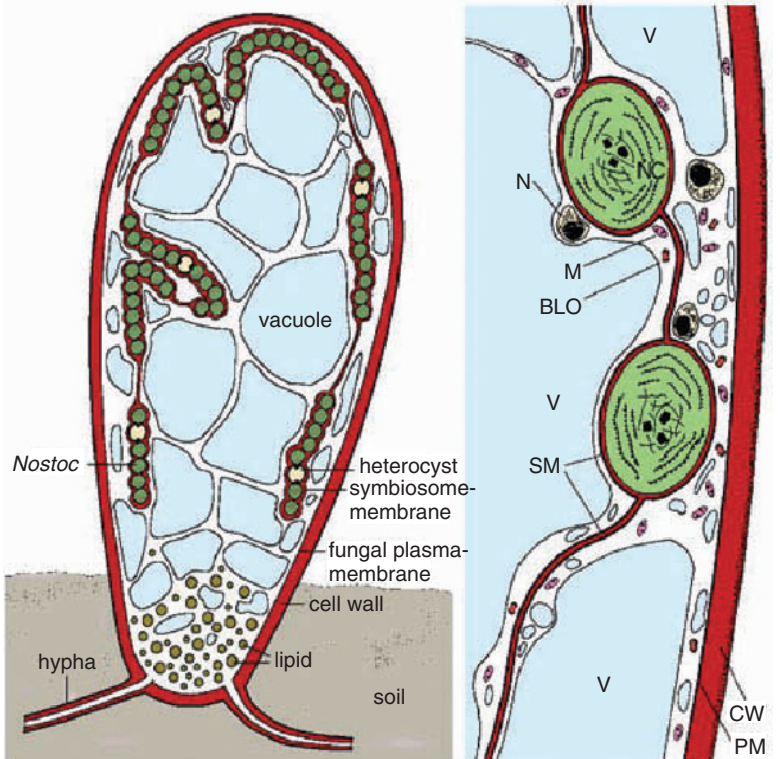

Fig. 20. Schemes of the compartmentation of the *Geosiphon* symbiosis. At the right a magnification of the peripheral part of the bladder is shown. Drawings are based on electron microscope observations. BLO, bacteria-like organism; CW, cell wall; M, mitochondrion; N, nucleus; NC, *Nostoc* cell; PM, plasma membrane; SM, symbiosome membrane; and V, vacuole.

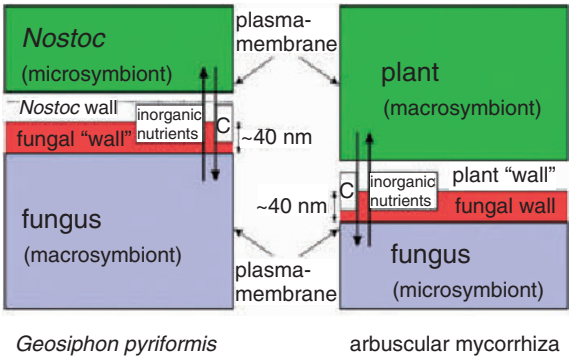

Fig. 21. Structure of the symbiotic interface and bidirectional nutrient flows in the *Geosiphon* symbiosis, in comparison with those in the arbuscular mycorrhiza (AM).

change taking place after partner recognition is the formation of the *Geosiphon* bladder (Figs. 13 and 18). Mature bladders represent big cells, which are coenocytic with the mycelium. They contain large vacuoles in the center and show a clear polarity, with a lipid-storing region in the basal part and the photosynthetically active symbiotic compartment (symbiosome) located in the apical part of the bladder (Fig. 20).

The symbiosome is derived from the invaginated plasma membrane of the fungus and contains the cyanobacteria, which also show an obvious morphological modification, namely an increase in size. Their cells show a six- to eightfold increase in volume compared with free-living vegetative cells. However, the ultrastructure of *Nostoc* in the symbiosis looks relatively normal. One alteration is that the outer membrane is hardly recognizable by electron microscopy. Heterocysts are formed with the same frequency as in free-living colonies, but their cell wall is thinner in the symbiosis, which may indicate a lower O_2 concentration in the surrounding milieu.

N_2 and CO_2 Fixation and Transfer ^{14}C-tracer studies have shown that the *Geosiphon* bladders fix CO_2 both in light and in darkness, whereas the rate of CO_2 fixation in light is much higher (Kluge et al., 1991). In light, largely phosphate esters, polyglucans, free sugars (including trehalose and raffinose), some amino acids and organic acids trap ^{14}C. In darkness, only malic and fumaric acids, together with some amino acids, appear as labeled products. High photosynthetic activity of the endosymbiotic *Nostoc* cells was also shown by photosystem II chlorophyll-fluorescence kinetics (Bilger et al., 1994). The symbiotic *Nostoc* cells achieve much higher steady-state quantum yields and electron transport rates when compared with free-living *Nostoc*.

The capacity for nitrogen fixation is indicated by the occurrence of heterocysts, and considerable nitrogenase activity is associated with the bladders (Kluge et al., 1992). In contrast to symbioses of *Nostoc* with plants (where usually a considerable increase in heterocyst frequency, compared with the free-living cyanobacteria, indicates N_2 fixation as the major role of the cyanobacteria), in *Geosiphon* the relative heterocyst number does not change. Here, the major role of the endosymbiotic *Nostoc* seems to be photosynthesis. However, matter exchange between the partners is still poorly investigated, and it is even possible that the second bacterial endosymbiont (BLO; Figs. 15 and 20), which is typical for many glomeromycotan fungi, contributes to N_2 fixation.

Ecological Importance

Why Is the Symbiosis Mutualistic? The fungal partner of the *Geosiphon* symbiosis belongs to the *Glomeromycota* (AM fungi, Fig. 14) and is, like these, an obligate symbiont. Still unknown is why glomeromycotan fungi are incapable of nonsymbiotic life. Possibly in the future special culture methods will be developed for *in vitro* growth of AM fungi, including *Geosiphon*. Generally in nature glomeromycotan fungi seem not to be capable of saprotrophic life but are dependent on their symbiosis partners for C-delivery. For *Geosiphon* bladders, only molecules with a radius <0.45 nm can pass through the cell wall (Schüßler et al., 1995). Such a pore size is too small for the uptake of sugar molecules from the outside but allows permeation of inorganic ions like phosphate. This might reflect the situation in nature. However, the fine hyphae growing into the substrate may show higher permeability. In any case, by incorporating *Nostoc*, the fungus obtains the needed source of organic compounds.

Nostoc also gains an advantage from the cooperation with the fungal host, which probably improves the supply of the endosymbiont with water, phosphate, and CO_2. Remarkably, all inorganic nutrients, except nitrogen, have to be delivered by the fungus, since the cyanobacteria live intracellularly (Figs. 19–21). Notably, as is usually also the case for the AM, the establishment of the *Geosiphon* symbiosis is strongly promoted by phosphate limitation, which is a severe stress for the photobiont. Preliminary studies moreover show that the intracellular cyanobacteria are protected against heavy metals. Therefore the endosymbionts seem to be protected against abiotic stress factors within the symbiosis.

Evolutionary Implications with Ecological Meaning Symbioses formed by AM fungi are very ancient. It has been proposed that the for-

mation of AM-like symbioses was the initial step allowing plants to colonize land (Pirozynsky and Malloch, 1975). What does this mean? If this hypothesis holds true, the land plants co-evolved with glomeromycotan fungi since their origin. This would have important consequences when interpreting plant ecosystems, since consequently plants probably show nutrient uptake (and other) mechanisms which evolved in dependence with the fungi, and vice versa.

Nowadays, several hints support this ecologically important assumption. AM symbiosis was already formed by the first land plants around 450–500 million years ago (Remy et al., 1994; Redecker et al., 2000). Since AM fungi probably are much older than land plants (Heckman et al., 2001), possibly the glomeromycotan fungi became dependent on the symbiotic carbon supply of photobionts even before land plants evolved (Schüßler, 2002). Therefore, glomeromycotan fungi may have adapted to symbiotic life more then 500 Myr ago, and the *Geosiphon* symbiosis might reflect such an early stage of land-colonizing AM fungal symbioses. Without fossil support this is speculative, but *Geosiphon* clearly shows the ability of glomeromycotan fungi to form symbioses with prokaryotic photoautotrophic organisms. Therefore, cyanobacterial symbioses formed by glomeromycotan fungi could have been an ecologically important step for the colonization of the land habitat. Since AM fungi form symbioses with >80% of the land plants, many ecologically and economically important questions have yet to be answered by future work; some studies may use the *Geosiphon* symbiosis as a model system for the AM (Schüßler, 2002). When performing ecophysiological studies, one should always bear in mind that in nature the mycorrhizas, and not the plant roots themselves, are the chief organs of nutrient uptake.

A Network among Fungi, Cyanobacteria, and Plants? Still unknown is whether *Geosiphon* also forms AM symbioses with plants. Since *Geosiphon* belongs to the monophyletic clade comprising AM fungi, it is tempting to speculate about this. Unpublished results of D. Schwarzott and A. Schüßler show that *Geosiphon* rRNA genes can be PCR amplified from plant roots and *Anthoceros* growing in the natural habitat of *Geosiphon*. However, this is not necessarily evidence for a location within the root and AM formation. The problem is that cleaning the root surface completely from attached fungal hyphae seems impossible, although this is ignored in some published studies. Therefore the sensitive nested PCR approach may be detecting some tiny amounts of externally attached hyphae. Future studies with in situ techniques will have to show whether *Geosiphon* is forming an AM. If this indeed would be the case, one may imagine a complex network of ecological importance (Fig. 16).

Within such a network, symbiotic *Nostoc* could be exchanged between *Geosiphon* and bryophytes, and *Geosiphon* could simultaneously form endosymbiosis with *Nostoc* and AM with plants, thus, for example, delivering N_2 fixed by the cyanobacteria to the plants.

CHAPTER 2.2

Symbiotic Associations Between Ciliates and Prokaryotes

HANS-DIETER GÖRTZ

Introduction

Ciliates are frequently colonized by bacteria. This is partly due to the cytology and biology of these highly evolved heterotrophic protozoa (Hausmann and Bradbury, 1996). As phagotrophic predators on microorganisms, they bear a high risk of microbial, namely bacterial, infections: ingested bacteria may resist digestion, escape from the phagosomes, and persist in the cells as endocytobionts. Traditionally, intracellular bacteria in ciliates have been termed "symbionts" (Preer et al., 1974). Phagocytosis appears to be the usual way infectious bacteria enter their host cells. In addition to intracellular bacteria, ectosymbionts may be intimately associated with ciliates. The most intriguing example is certainly the epixenosomes of *Euplotidium*, which even defend their host against predators (Petroni et al., 2000; see also "Terms in Symbiosis Research").

The bacterial symbionts of ciliates comprise a variety of bacteria in many unrelated genera of different subgroups of proteobacteria. They are alike in that their habitat is the cytoplasm or the nucleus of a ciliate cell. Many of these symbionts appear to be well adapted to their environment; they are no longer free living and have genomes that are reduced in size, indicating a lengthy period of symbiont-host association. Most of the symbionts are not infectious, but a few are *Holospora*: Infectious Bacteria of the Nuclei. These infectious symbionts have developed specific features that guarantee uptake and transport to the intracellular sites where they can multiply. In most cases, it is not clear whether the symbionts provide their hosts with a selective advantage; under laboratory conditions, most of the symbionts have proved to be dispensable. On the other hand, it is significant that the majority of cells of *Paramecium biaurelia* freshly collected from nature contain symbionts (Beale et al., 1969), and work by Landis (Landis, 1981; Landis, 1987) and Kusch (2001) gives evidence that paramecia that bear bacteria of the genus *Caedibacter* (formerly called "kappa particles") have a selective advantage over those that are symbiont-free, see "The Killer Trait in *Paramecium*". Moreover, *Polynucleobacter necessarius* (formerly called "omikron particles") and the closely related omikron-like symbionts occurring in several freshwater *Euplotes* species have been shown to be necessary for survival of their hosts (Heckmann, 1975; Heckmann et al., 1983b; see also "Prokaryotic Symbionts of *Euplotes*"). Since in these cases the hosts depend on their symbionts and those in turn depend upon their hosts, they are no longer free living—the distinction between "symbiont" on the one hand and "organelle" on the other hand becomes blurred.

Ciliates can usually be handled easily, and some of them—particularly species of the *Paramecium aurelia* complex—have been investigated so thoroughly that they can be manipulated in a variety of ways. This has led to a wealth of information about their symbionts that has been reviewed extensively by Preer et al. (1974), Soldo (1974a), Quackenbush (1988), and Pond et al. (1989). It is not possible to list all the types of symbionts of ciliates encountered. Their number is very large, and certainly many more will be added to this list. Few of them, however, have been deposited in stock cultures and have been investigated in such a way that they can easily be identified when found again. An even smaller number have been described with validated binomial names, in keeping with the international rules of nomenclature. Especially these last ones will be discussed in detail in this chapter. A lag phase in the description of new symbionts in ciliates for several years may be partly due to the fact that intracellular bacteria could not be investigated with classical microbiological methods, since they cannot be grown outside their host cells. With the new powerful techniques for detection and phylogenetic classification such as polymerase chain reaction (PCR) and fluorescence in situ-hybridization (FISH) now available, this is changing.

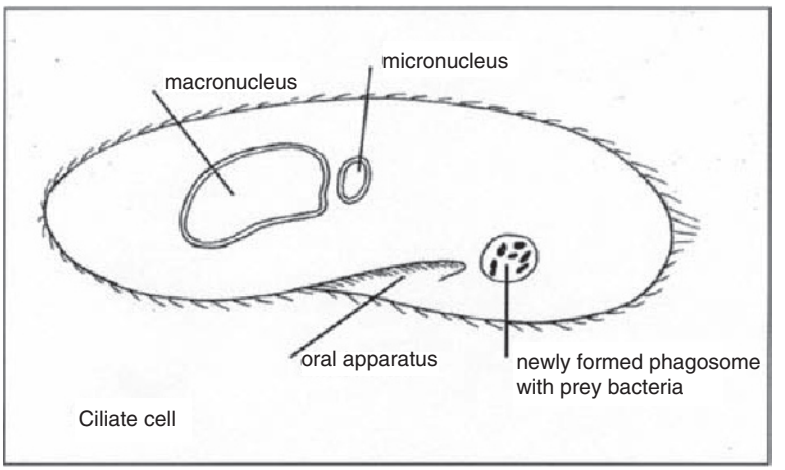

Fig. 1. The ciliate cell. Both macronucleus and micronucleus are encircled by the nuclear envelope with nuclear pores (not shown). Note that the nuclear envelopes have a perinuclear space that may be colonized by certain bacteria. The oral apparatus/cytostome is the only site where phagocytosis takes place.

The Ciliate Cell as a Microcosm

Ciliates—phylum Ciliophora—are large protozoa that offer a variety of suitable habitats within their cells with plenty of space for bacteria (Fig. 1). The ciliate cell is characterized by a highly organized cortex consisting of the plasma membrane, flat vesicles termed "alveoles" underneath the plasma membrane, and a network of microtubules and other cytoskeletal elements. Cilia, the motile organelles of ciliates, are anchored to the cytoskeleton.

Ciliates are heterotrophic. Because of their solid cortex of three membranes and multiple cytoskeletal systems, phagocytosis occurs only at a preformed structure termed the "oral apparatus." This is a complex metaorganelle consisting of a funnel-like pouch with batteries of cilia and a highly ordered cytoskeletal basket at the bottom of which new phagosomes are formed. Newly formed phagosomes are acidified and fuse with primary lysosomes (Fok and Allen, 1988). As known from other professional phagocytes such as macrophages, ingested bacteria are attacked by acidification, oxidative burst, and lysosomal enzymes; see The Nuclei of Ciliates. In spite of these attacks, certain bacteria with appropriate features may survive and even escape from the phagosomes. In the cytoplasm of ciliates, bacteria may prevail in symbiontophorous vesicles or naked (i.e., not encircled by host membranes; Sitte, 1993). Symbionts may also live in the large, somatic macronuclei as well as in the much smaller, generative micronuclei. Of those bacteria that are, however, nuclear-specific, certain species are only found in micronuclei, and others only in macronuclei, of their specific hosts. Bacteria have even been found in the perinuclear space and in the endoplasmic reticulum (Fokin and Karpov, 1995). The ciliate cell thus may be regarded as a microcosm that might contain even different symbionts at any given time.

The Nuclei of Ciliates

Characteristically ciliates have two types of nuclei: small generative micronuclei and large somatic macronuclei (Paulin, 1996). Ciliates multiply by binary division and sexually propagate by conjugation. The latter includes meiosis of the micronucleus, resorption of the old macronucleus, and formation of a new macronucleus from the synkaryon that will also give rise to the new micronucleus. Whereas cytoplasmic symbionts may be simply distributed to daughter cells during binary division, endonuclear symbionts may even make use of the nuclear division machinery. Both micronuclear mitosis and macronuclear division are closed: the nuclear envelopes are maintained, keeping nucleoplasm and cytoplasm separated throughout the cell cycle. Endonuclear symbionts (see "Terms in Symbiosis Research") are therefore caught in the nuclei unless they have developed means of passing through the nuclear envelopes. During conjugation of the host cell, resorption of the old macronucleus may be deleterious to endonuclear symbionts that are not adapted to this process; bacteria are then digested in the process of resorption. New macronuclei developing after conjugation are free of bacteria unless they are infected anew.

In spite of the problems arising for bacteria colonizing nuclei, endonuclear symbionts are frequently found in ciliates because in the nuclei, symbionts should: 1) have access to the most complete supply of metabolites, (2) be more assured of distribution/segregation to the daughter cells at cell division, and (3) be pro-

tected from cellular defense mechanisms. The last reason is more obvious when the fact that symbionts in nuclei are naked—not encircled by host membranes—and less vulnerable to attacks by lytic enzymes, which would be deleterious to nuclear structures such as chromatin, is considered.

The History of Symbiont Research in Ciliates

Prokaryotes living in ciliates were first noticed over a century ago by J. Müller (1856). Rod-shaped structures were observed in the macronuclei and micronuclei of a number of ciliates, and less commonly, in their cytoplasm. In the beginning, it was not clear whether they were parasites or spermatozoa, because the micronucleus was considered to be a testis and the macronucleus an ovary, while chromosome filaments and endonuclear symbionts were mistaken for spermatozoa. This view was corrected by Bütschli (1876), who also wrote the first review on parasites in ciliates (Bütschli, 1889). Accounts of early observations of bacteria in protozoa that followed this initial period were reviewed by Kirby (1941), Wichterman (1953), and Ball (1969).

Interest in prokaryotic symbionts of ciliates arose again in the 1950s when it was discovered that a killer phenotype is frequently associated with them. The possibility that certain ciliate strains kill other strains by liberating a toxic agent into the medium was first expressed by Sonneborn (1938), who noted this phenomen in paramecia during experiments on mating types that involved mixing different strains (see "The Killer Trait in *Paramecium*"). He found that under certain conditions, conjugation could be brought about between killers and sensitive paramecia so that genetic analysis of these traits became technically feasible. Sonneborn (1943) demonstrated that the killer phenotype was an inherited trait transmitted via cytoplasmic particles, which he named "kappa." His findings aroused great interest among geneticists and other biologists because it furnished one of the first clear examples of a cytoplasmic genetic factor. That kappa was an endosymbiont was not known at that time. From data obtained in studies using X-rays, Preer (1948b) determined that kappa was similar in size to bacteria. He subsequently demonstrated the presence of kappa in the cytoplasm of killer paramecia as Feulgen-staining bodies (Preer, 1950). In the following years, cytological, biochemical, and physiological studies by a number of workers established that kappa was actually a Gram-negative bacterium. In 1974, it was given a binomial designation—*Caedobacter taeniospiralis*, which has since been changed to *Caedibacter taeniospiralis* (for a detailed review, see Preer et al., 1974, and Preer and Preer, 1984).

After the initial discovery of the first killer paramecia, other types were found. Siegel (1953) described "mate killers," whose toxins act only after cell-to-cell contact is made during conjugation, and Schneller (1958) described "rapid-lysis" killers, which may injure sensitives in 10 min and kill them in 30 min, a process that is much more rapid than when kappa mediates killing. Over decades, bacterial symbionts had been studied most extensively in the *Paramecium aurelia* species complex (for reviews, see Beale et al., 1969; Preer et al., 1972, 1974; Preer and Preer, 1984; Gibson, 1974; and Soldo, 1974a). They have also been found and studied in other ciliates, particularly in *Paramecium caudatum* (for reviews, see Ossipov, 1981; Görtz, 1983, 2001) and in *Euplotes* species (reviewed by Heckmann, 1983a; see "Prokaryotic Symbionts of *Euplotes*"). Many cases of simultaneous infections of ciliate cells by two or more different bacteria have been observed (Görtz, 1987, 1992a; Görtz unpublished). In each of these killer paramecia, particles were found that later proved to be prokaryotic symbionts. One only needed to wash the paramecia free of bacteria, crush the ciliates, and observe the resulting preparations in a phase contrast microscope to ascertain the presence of the symbionts, see "Identification of Symbionts in *Paramecium*". This procedure also revealed, however, that some strains carry endosymbionts without showing any kind of killing ability. The symbionts of nonkiller paramecia were named "nu" (Sonneborn et al., 1959b).

The presence of endo- and episymbionts of marine and freshwater ciliates living in anaerobic habitats has been generating increasing interest among ecologists and microbiologists. In these habitats, many of the symbionts were identified as methanogenic bacteria (Stumm and Vogels, 1989; Fenchel and Finlay, 1991a; Finlay and Fenchel, 1992; see "Prokaryotic Symbionts of Ciliates from Anaerobic Environments").

We may expect to find many more prokaryotic symbionts of ciliates, once further host species are studied. The description of episymbionts that have a defensive function for their host *Euplotidium* by Rosati, Verni, and colleagues (Rosati, 1999a) is a fantastic example, see "Prokaryotic Ectosymbionts of *Euplotidium*". Only recently these episymbionts have been identified as belonging to the *Verrucomicrobia* (Petroni et al., 2000).

Terms in Symbiosis Research

The following terms are used in this chapter or in the references cited:

Symbiosis—the living together of dissimilarly named organisms. Sometimes the term is used in a restricted sense in the sense of mutualism
Mutualism—associations which involve mutual benefit (symbiosis in its restricted sense)
Parasitism—associations in which there is overt exploitation of one associate
Endosymbiosis—the symbiont lives within its host, intracellular symbiosis
Episymbiosis—the symbiont lives attached to the surface of its host cell
Episymbiont—microorganism living attached to the surface of a host cell
Epibiont—synonymous with episymbiont
Ectosymbiont—synonymous with episymbiont
Xenosome—intracellular symbiont in a broad sense
Endocytobiont—intracellular symbiont in a broad sense of symbiosis
Epixenosome—episymbiont in a broad sense

For definitions of the terms, see Henry (1966), Read (1970), Corliss (1985), Margulis and Fester (1991), Sitte (1993), and Rosati (1999a).

Prokaryotic Symbionts of *Paramecium*

With respect to endosymbionts, *Paramecium* is by far the best-studied ciliate genus. In the *Paramecium aurelia* species complex, consisting of 14 sibling species described by Sonneborn (1975) and named *P. primaurelia* to *P. quadecaurelia*, many different types of endosymbionts have been discovered. They have been thoroughly reviewed by Preer et al. (1974) and descriptions appeared in earlier editions of this book (Preer, 1981; Heckmann and Görtz, 1991). Valuable information on isolation and identification of symbionts is taken from these earlier editions. In the present edition, descriptions of further endosymbionts were added and the information about many symbionts has increased owing to the availability of new techniques. Among the symbionts where a wealth of data has been presented are the *Holospora* bacteria. They differ from most of the *Paramecium* symbionts in being infectious and in their ability to invade nuclei for reproduction. The holosporas are being investigated to elucidate the mechanisms that allow a prokaryote to invade a eukaryote. Being relatively large, the holospora can be seen even at relatively low magnification and are therefore used to monitor their route of infection and the changes they undergo after entering a cell.

Habitat and Biology of the Bacterial Symbionts of *Paramecium*

Paramecia are aerobic ciliates from fresh water and brackish water habitats. Many of the paramecia brought in from nature are found to contain symbionts. Usually, there are hundreds and sometimes even thousands of symbionts per paramecium (see Figs. 2 and 3). Endosymbionts may be found in the micronucleus, macronucleus, perinuclear space and cytoplasm of paramecia. Different types of symbiont invade different parts of the ciliate cell and they are, moreover, often adapted to one *Paramecium* species only. The cell compartment in which a symbiont multiplies and the *Paramecium* species in which multiplication occurs are therefore important taxonomic characters. Though it had been observed that bacterial endosymbionts may prevent secondary infections by another bacterium in laboratory cultures (Ossipov et al., 1975; Görtz, 1983), double and even triple infections are found in cells of natural populations (Görtz, 1992a; Kusch et al., 2000).

Several symbionts have been shown to require the presence of specific *Paramecium* genes for

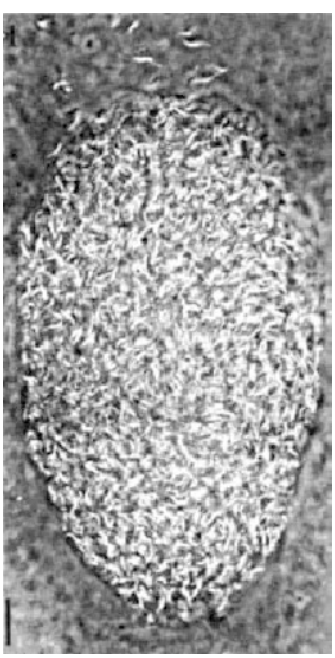

Fig. 2. Vegetative macronucleus of *Paramecium biaurelia* stock 562. The spiral endosymbionts filling the macronucleus are cells of *Holospora caryophila*. A few symbionts are also visible in the cytoplasm. Osmium-lacto-orcein preparation. Whole mount, bright phase contrast. Bar = 10 μm. From Preer (1969).

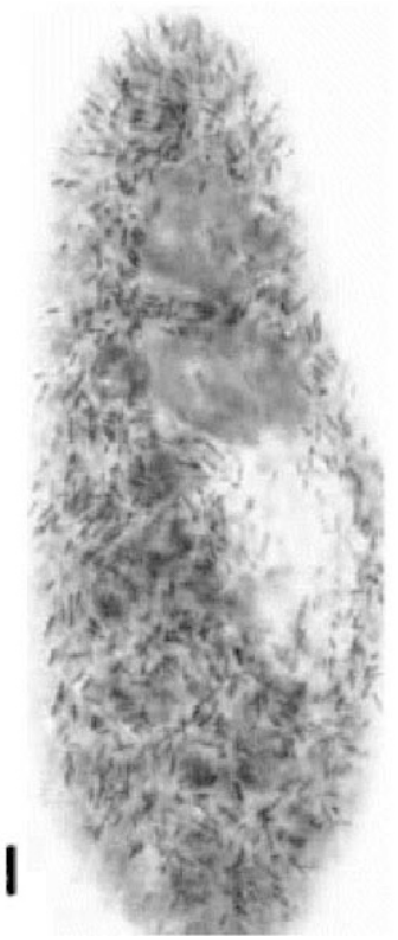

Fig. 3. *Paramecium tetraurelia* stock 239 bearing endosymbiont *Lyticum flagellatum*, seen as dark-staining rods in the cytoplasm. Osmium-lacto-orcein preparation, whole mount, dark phase contrast. Bar = 10 µm. From Preer et al. (1974).

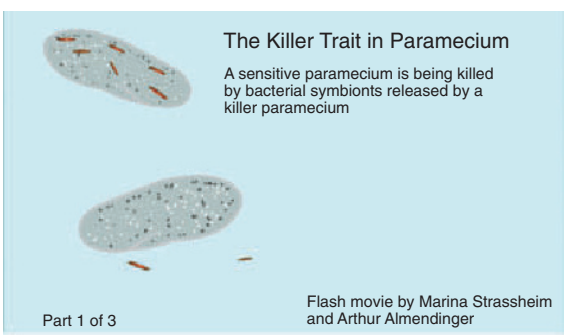
their maintenance (Sonneborn, 1943; Siegel, 1953; Schneller et al., 1959; Gibson and Beale, 1961; Fujishima and Fujita, 1985). lt is not known whether the genes that assure maintenance of the symbionts are active—e.g., providing the symbionts with some essential metabolite—or whether they are merely inactive alleles, the active ones preventing growth of an "invader" (Preer et al., 1974). In this connection, it should be mentioned that the species 3, 7, 9, 10, 11, 12, 13 and 14 have never been found to contain symbionts (Preer and Preer, 1984); however, not all species of the *P. aurelia* complex have been studied with the same thoroughness. lt has been argued that symbionts profit from living inside a paramecium by being better protected from digestion, as compared with free-living species of bacteria, and that symbionts are provided with a convenient and abundant supply of nutrients (Beale et al., 1969). Which metabolites of the host are used, however, is not known.

Although many of the symbionts have a smaller genome size than free-living bacteria (Soldo and Godoy, 1973a) and some of the associations were suggested to be very ancient (Preer, 1977), no indications for a transfer of genes from symbiont to host nucleus have been discovered as has been found in the case of mitochondria (Gellissen and Michaelis, 1987). Schmidt (1984), studying the association of *Caedibacter varicaedens* with *P. biaurelia*, was unable to obtain evidence for a sharing of the translational systems of host and symbiont. His observations indicate that all major proteins found in *Caedibacter* are synthesized in the symbiont itself.

In only a few cases, it has been demonstrated that host cells may profit from bearing symbionts; Soldo (1963) and Soldo and Godoy (1973b) found that it was not necessary to provide a *Paramecium* stock bearing *Lyticum flagellatum* (formerly called "lambda particles") with folic acid, while the same stock freed of this symbiont required the vitamin. Holtzman (1959) observed that *P. pentaurelia* bearing *Pseudocaedibacter falsus* was more resistant to killer paramecia bearing *Lyticum flagellatum* than *P. pentaurelia* strains that were free of symbionts, and Landis (Landis, 1981; Landis, 1987) showed that under natural conditions, paramecia with killer properties have a selective advantage over nonkillers, see "The Killer Trait in *Paramecium*". On the other hand, in the laboratory, the symbionts are all dispensable and many of them are lost when paramecia are cultured for some time. The reason for such loss is in most cases a rapid multiplication of the paramecia, resulting in a dilution of the symbionts and then in their loss. Although there is little information about what occurs in nature, it appears unlikely that reinfection of paramecia that have lost their intracellular bacteria plays a major role for most of the symbionts (Kusch et al., 2001).

Most symbionts of ciliates are not infectious and are propagated in the host population with the divisions of host cells only. An exception to this rule is provided by symbionts of the Holosporaceae. In addition to being propagated with host cell division, they develop forms specialized for infection (infectious forms) that are released and infect new cells upon being taken up with food. Unlike most other endosymbionts, they tend to harm their hosts and can therefore be regarded as parasites, although it cannot be excluded that under certain conditions, the host cells may have advantages from the presence of these symbionts (Görtz, 1983). Interactions between *Holospora* and its host *Paramecium* are described in more detail in the section entitled "Biology of the Holosporaceae."

THE KILLER TRAIT IN *PARAMECIUM* Many of the symbionts of *Paramecium* confer on their hosts the ability to produce toxins capable of killing sensitive *Paramecium* strains of the same species and even of other species, if the toxins are liberated into the medium. The toxin producers are called "killers" and their victims "sensitives." If the toxins act only during the period of cell-to-cell contact at conjugation, the toxin producers are called "mate killers." Different killer stocks of *Paramecium* induce different prelethal symptoms in sensitives mixed with killers. These symptoms include spinning, vacuolization, paralysis, formation of aboral humps, and rapid lysis. The symptoms were taken as crucial characters for identification of a symbiont. The value of such symptoms for identification and determination of the symbionts must, however, be doubted, see "Identification of Symbionts in *Paramecium*". In addition to making their hosts capable of producing toxins, the symbionts also confer upon the hosts specific resistance to the toxins produced. When a symbiont is lost from a killer strain, the paramecia lose both toxin production and toxin resistance (Sonneborn, 1959a).



Video sequence showing killer trait. For the video, see the online version of *The Prokaryotes.*

Killer strains have been reported not only for species of the *P. aurelia* complex but also for *P. caudatum* (Schmidt et al., 1987b; Schmidt et al., 1988), *P. bursaria* (Chen, 1955; Dorner, 1957), and *P. polykaryum* (Takayanagi and Hayashi, 1964). In the latter two species, however, symbionts were not observed, although it is likely that they were present and were responsible for the killing properties of the paramecia.

A feature unique to the killer symbionts of the genus *Caedibacter* is the ability to produce R bodies. These are proteinaceous ribbons, 20–30 μm long, coiled inside the bacterial cell to form a hollow cylindrical structure (Figs. 4–6). This structure has a diameter of about 0.4 μm in all species and is about 0.4 μm long, except in *C. caryophilus* where the R bodies are approximately 0.8 μm in width and length. The R bodies unroll when ingested into a phagosome and also under certain in vitro conditions, e.g., when placed at low pH (Preer et al., 1966).

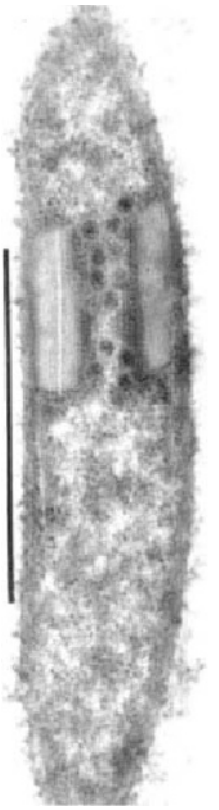


Fig. 4. Electron micrograph of longitudinal section of *Caedibacter varicaedens*, endosymbiont of *Paramecium biaurelia* stock 7 with an R body. Note the numerous dark-staining phages inside the coiled body. Bar = 1 μm. From Preer and Jurand (1968).

It has been suggested that the R bodies play an important role in the killing mediated by *Caedibacter*. Mueller (1963) and Smith-Sonneborn and Van Wagtendonk (1964) demonstrated that only *Caedibacter* particles that contained R bodies were toxic to sensitive paramecia. In addition, R bodies purified from certain strains of *C. varicaedens* have been shown to be toxic to sensitive paramecia (Preer and Preer, 1964; Preer et al., 1972). However, neither the toxin itself nor its mode of action have been identified, nor is it known how paramecia are protected from the toxic action of their own symbionts.

Early observations suggested that the genetic determinants of R bodies are plasmids or bacteriophages that have lost the ability to lyse their host cells—the symbiotic bacteria—upon maturation of the virions (Preer and Preer, 1967; Preer et al., 1974). Dilts (1976) isolated plasmid DNA from *C. taeniospiralis* 51 and suggested

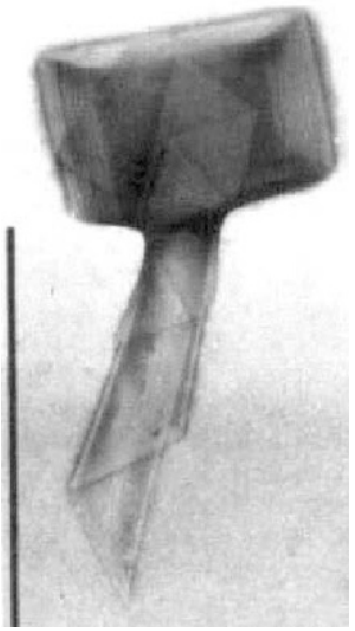

Fig. 5. Electron micrograph of an R body isolated from *Caedibacter taeniospiralis* of *Paramecium tetraurelia* stock 51. The R body begins to unroll from the inside. Negative staining with phosphotungstic acid. Bar = 1 μm. From Preer et al. (1972).

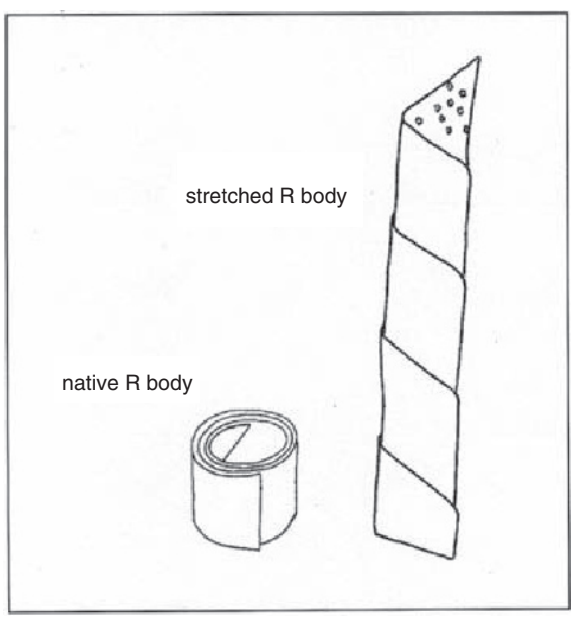

Fig. 6. R bodies of *Caedibacter*. R bodies (refractile bodies) are coiled proteinaceous ribbons. By appropriated triggers, such as acid pH, they are induced to unroll.

that the extrachromosomal DNA might be the determinant of the R bodies. Further investigation revealed that plasmids are present in all strains of *C. taeniospiralis* and that they are highly homologous as determined by restriction mapping (Quackenbush, 1983a). Further evidence that the genetic determinant for R-body synthesis resides on the plasmid was presented by Quackenbush and Burbach (1983b), who cloned portions of a plasmid and obtained expression of the R-body-encoding sequences in *Escherichia coli*. Analysis of various subclones allowed them to determine the approximate location of the R body-encoding sequence. The DNA required for type 51 R body synthesis is about 1.8 kbp in size and has been completely sequenced (see Pond et al., 1989; D. P. Heruth, 1987). However, none of the R body-producing *E. coli* clones was found to be toxic to sensitive paramecia. The DNA sequence required for toxin production has not yet been located. It is believed to reside also on the plasmid (Pond et al., 1989). The R bodies may unroll and destroy phagosomal membranes when ingested, and apparently they play a role in killing mediated by *Caedibacter* (Preer et al., 1974), but their presence is not required for the host cell to resist being killed.

R bodies of some *Caedibacter* species are associated with phage capsids (Fig. 4). The proteins of these R bodies and perhaps also the toxin are encoded on bacteriophage genomes (Quackenbush, 1988; Schmidt et al., 1988; Pond et al., 1989; Fokin and Görtz, 1993). Only *Caedibacter* bearing phages or plasmids may confer the killer trait to their hosts. Heruth et al. (1994) have characterized and sequenced three genes (*rebA*, *rebB* and *rebC*) for synthesis and assembly of R body synthesis in *C. taeniospiralis*. These genes are independent transcriptional units on a plasmid. Two polymerization events were found to be involved in R body assembly: one event requires RebB and RebC; the other requires all three proteins. The RebC protein is apparently involved in posttranslational modifications of RebA and RebB, both of them showing peptide species with different molecular weights. The role of a fourth protein whose gene has not been sequenced remains unknown (Kanabrocki et al., 1986; Heruth et al., 1994).

Dilts and Quackenbush (1986b) have provided evidence that R bodies are required for the killing trait to be expressed but not for resistance of the ciliate host to killing mediated by *C. taeniospiralis*. They described a mutant strain of *C. taeniospiralis* 169 that simultanously lost the ability to produce R bodies and to kill sensitive paramecia, but still rendered its host resistant to killing. Investigations of the R body-encoding plasmid isolated from the mutant revealed that a transposon-like element had been inserted within the R body-encoding region, thereby eliminating R body production. Two separate mutational events occurred in the same cell,

one inactivating the R body-encoding sequence and the other inactivating the toxin-encoding sequence. This shows that R bodies are crucial to expression of the killer trait. Their exact role remains, however, unknown. Evidence indicates that their action probably involves delivery of the toxin to the sensitive paramecium and to its target site by unrolling and penetrating the food vacuole membrane (Dilts, 1986a). Evidence that R bodies are required for killing but not for resistance of the host has also been obtained for *C. caryophilus*. Paramecia bearing mutant *C. caryophilus* with blocked R body synthesis no longer showed a killer trait but were resistant to the toxin (Schmidt et al., 1988).

The R bodies of other species of the genus were shown to be associated with icosahedral viral capsids (Preer and Jurand, 1968; Grimes and Preer, 1971). The capsids were in most cases found to contain DNA (Preer et al., 1971). The relationships between genomes of different phages of kappa and between R body-encoding plasmids and kappaphage genomes have been studied by restriction endonuclease analysis and by DNA-DNA hybridization (Quackenbush, 1978; Quackenbush et al., 1986). These studies demonstrate that the R body-encoding plasmids show little or no homology with kappaphages, and that there is also considerable diversity among the kappaphages.

R bodies have also been reported in the free-living bacteria *Pseudomonas taeniospiralis* (Lalucat et al., 1979) and *P. avenae* (Wells and Horne, 1983). However, with respect to antigenicity, genetic determinants, and other features, these R bodies appear to be unrelated to the R bodies of *Caedibacter* species (Bedingfield et al., 1984; Gibson, 1984; Meenaghan et al., 1984; Kanabrocki et al., 1986; Lalucat et al., 1986). These R bodies have also been reported for *Rhodospirillum centenum*, a nonsulfur photosynthetic bacterium (Favinger et al., 1989). Since R bodies are often present at low frequencies, it appears likely that R body-producing bacteria are more common than previously suspected. With respect to the shape of the ends and the mode of unrolling, the different types of R body vary (for details, see Preer et al., 1974; Quackenbush, 1988, and Pond et al., 1989).

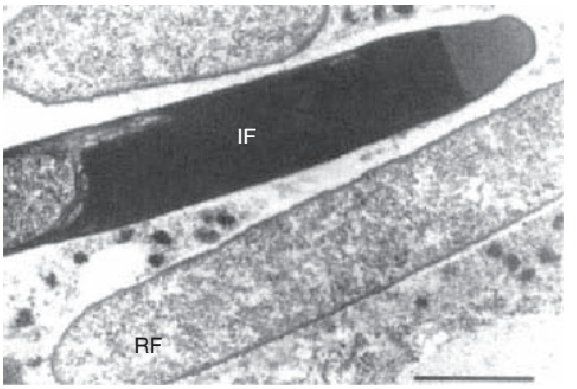

Fig. 7. *Holospora obtusa* in the macronucleus of *Paramecium caudatum*. IF, infectious form; and RF, reproductive form. Bar 1 μm. From Görtz et al. (1988).

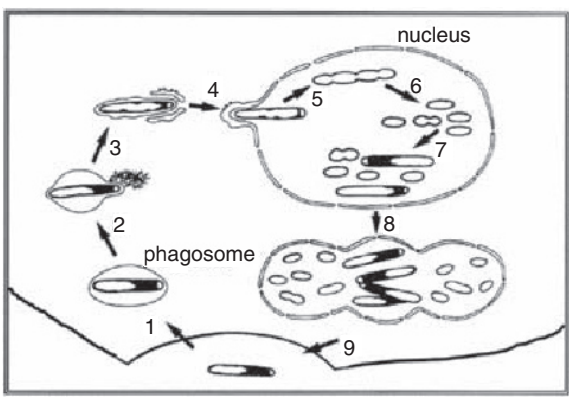

Fig. 8. Infection cycle of *Holospora obtusa*. 1) The infectious form of the bacterium (long rod) is ingested by a *Paramecium caudatum* cell into a phagosome (food vacuole). 2) Microfilaments are nucleated at the phagosomal membrane covering the bacterium protruding from the phagosome. 3) The bacterium is sluiced out of the phagosome. It remains encircled by a host membrane that forms a transport vesicle. Later on, the transport vesicle is surrounded by vesicles of endoplasmic reticulum. These vesicles finally form a secondary transport vesicle. 4) While the inner (phagosome-derived) membrane disintegrates, the membranes originating from endoplasmic reticulum fuse with the membranes of the nucleus, and the bacterium is incorporated into the macronucleus. 5) The nucleus of the bacterium constricts at several sites. 6) The bacterium divides into 4–10 short rods. By this multiple division, the reproductive form is established. 7) The reproductive form multiplies by binary fission. Some of the short rods grow longer and differentiate into infectious forms, see "Development of *Holospora*". 8) At the division of the host cell, mature infectious forms are collected in the connecting piece of the dividing nucleus and 9) are later released from the host cell (Ossipov, 1981; Görtz and Wiemann, 1989; Wiemann and Görtz, 1989).

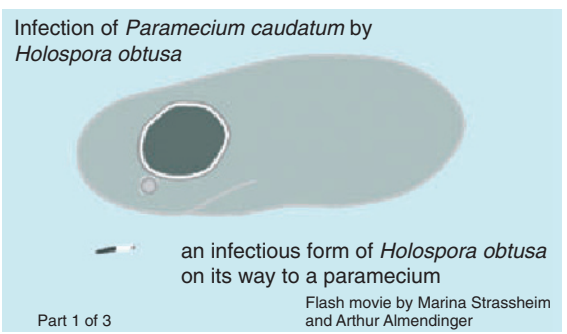
Biology of Holosporaceae All *Holospora* species known up to the present are residents of the micro- or macronuclei of *Paramecium*; see The Ciliate Cell as a Microcosm. The bacteria grow and multiply exclusively in the host nuclei (Figs. 2 and 7) and have evolved mechanisms to invade nuclei as well as to escape from intact nuclei (Hafkine, 1890; Ossipov et al., 1975; Ossipov, 1981; Görtz, 1983; Fokin and Sabaneyeva, 1997; Fig. 8). *Holospora* species are host-specific, infecting only certain species of *Paramecium*, and nucleus-specific, infecting only the micronucleus or the macronucleus. Host cells remain vital with *Holospora* infections and it has been

shown that *Holospora*-bearing paramecia are able to grow, divide and even mate. However, conjugation is unsuccessful, as new macronuclei are apparently not functional (Görtz and Fujishima, 1983), and growth and physiological conditions of infected cells may be affected, depending on culture conditions. In starving *Paramecium* or after inhibition of host protein synthesis, most bacteria differentiate into the infectious form (Fujishima, 1993). Paramecia seem to have mechanisms to cure themselves from endonuclear symbionts. Namely, in "wrong" hosts, infectious forms are digested having been phagocytosed or, if they enter the nucleus, may later be lysed within the nucleus (Skoblo et al., 1990; Ossipov et al., 1993; Fokin and Skovorodkin, 1991; Fokin and Skovorodkin, 1997). This lysis may be due to an unknown mechanism of cellular defense. After lysis of bacteria in the nucleus, host cells remain vital nevertheless.



Video sequence showing infection of *Paramecium* by *Holospora*. For the video, see the online version of *The Prokaryotes.*

Not only the infection cycle but also the development of the Holosporaceae is unique. The bacteria show a developmental cycle with a long infectious form and a short reproductive form (Fig. 9). It is, however, not just the length that characterizes infectious forms, but also their specific organization. Even short forms are infectious (Kawai and Fujishima, 2000). The infectious form is unique among bacteria. It is polarly organized and has a voluminous periplasm (Figs. 7 and 10–12) that contains a number of stage-specific proteins, some of which appear to be released during the infection process (Görtz and Wiemann, 1989a; Dohra et al., 1994; Dohra et al., 1997; Dohra and Fujishima, 1999a; Fujishima et al., 1990a; Wiemann and Görtz, 1991). The cytoplasm is condensed and located toward one end of the symbiont, while a voluminous periplasmic area is located mainly at the other end. The periplasm consists of fine granular, strongly osmiophilic material. Some less osmiophilic material is located at the end, distal from the cytoplasm. Obviously, the infectious form is physiologically inactive. It is a resting stage that may remain vital and infectious outside host cells for days to weeks. Infectious forms were therefore regarded as spores ("holospores;" Hafkine, 1890; Ossipov, 1981). The mode of development and reactivation is, however, different from formation and hatching of endospores (Görtz and Wiemann, 1989a; Fig. 11).

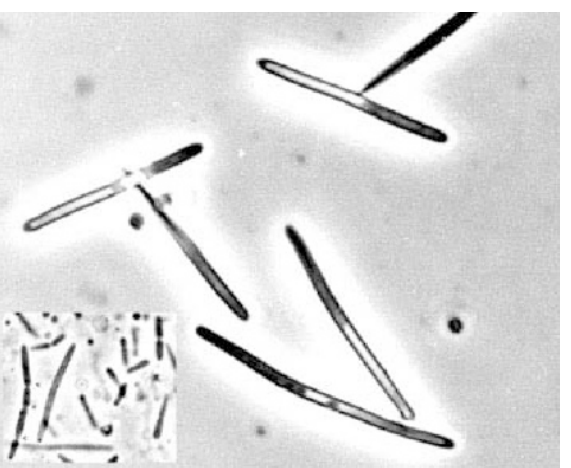


Fig. 9. Phase contrast micrograph of *Holospora obtusa* isolated from *Paramecium caudatum*. Note the peculiar appearance of the infectious forms reflecting their fine structure (Fig. 8). Inset: Developmental stages of *Holospora obtusa*. At the left a bacterium with three constrictions (arrowheads) undergoing multiple division is seen.

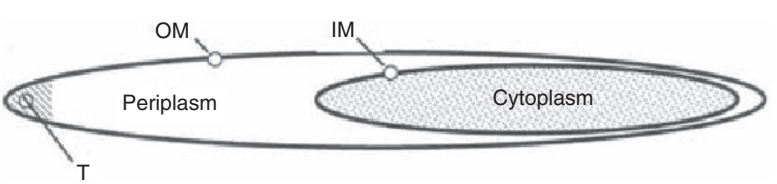

Fig. 10. Diagram of infectious form of *Holospora*. The cytoplasm is condensed and occupies only half the volume of the bacterial cell. Accordingly, the periplasm is extremely voluminous. IM, the inner membrane (cell membrane); OM, the outer membrane; and T, the less electron dense, apically oriented material in the periplasm (special tip).

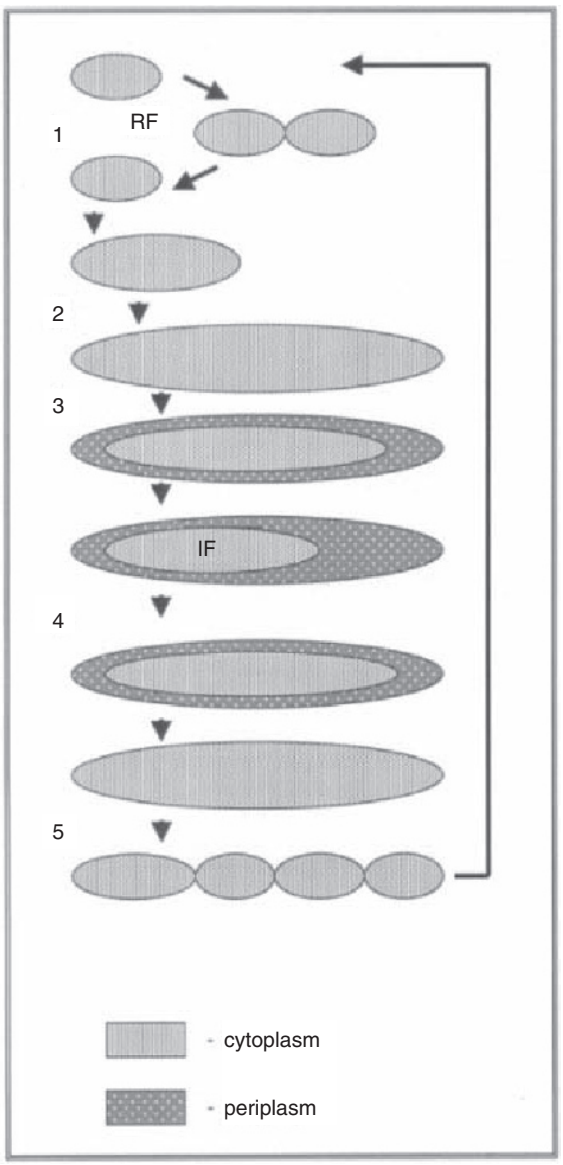

Fig. 11. Developmental cycle of *Holospora*. 1) Reproductive forms (RF) multiply by binary fission. 2) Some reproductive forms grow longer. 3) After having reached their final length, the cytoplasm condenses and proteins are deposited in the periplasm until the periplasm makes up more than half of the total cell volume. At the end of this differentiation, the infectious form (IF) is established. 4) When an infectious form is ingested into a phagosome of a suitable host, it starts to develop into the reproductive form. The cytoplasm expands, while periplasmic proteins are assumed to be secreted. 5) Once the periplasm has almost completely disappeared, the bacterium constricts at several points and undergoes a multiple division. By this division, the reproductive form is established anew.

When an infective form has been taken up by a paramecium and is on its way into the nucleus, the periplasmic material disappears while the cytoplasm expands (Fig. 11). It is assumed that the periplasm of the infectious form contains

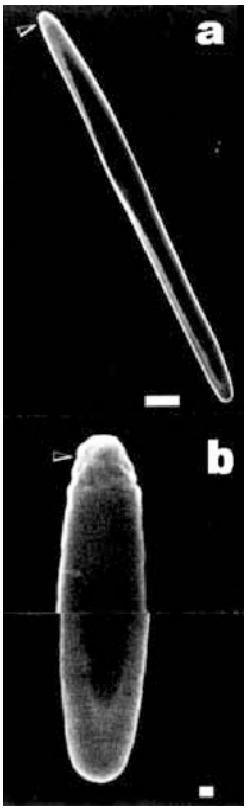

Fig. 12. Scanning electron micrograph (SEM) of the isolated infectious form of *Holospora obtusa*. a) One pole (arrows) of the infectious forms appears rough compared to the other pole. Bar = 1 μm. b) Ends of the bacterium at higher magnification. Bar = 0.1 μm. From Fujishima et al. (1990).

substances that interact with host membranes during the infection process (Görtz et al., 1988; Görtz and Wiemann, 1989a). The further development of the infectious form into the short, reproductive form is completed in the nucleus. Induction of the development of infectious forms appears to be activated by specific triggers of host cells. Acidification of the phagosome and possibly also the actions of oxidative radicals and lysosomal enzymes may be such triggers for the development of infectious forms of *Holospora* and may initiate a recognition mechanism depending upon protein-protein interactions between bacterium and host cell (Wiemann and Görtz, 1991; Fujishima et al., 1997). Apparently, there is a stepwise interaction between invading bacterium and host cell. This is indicated by the observation that the equipment of the invading infectious form with surface proteins changes dramatically (Görtz et al., 1992b).

Certain proteins were immunolocalized in the periplasm of the infectious form (Fig. 13). During the invasion process, some of these proteins were found on the surface of the bacteria after their ingestion into the phagosome, and others

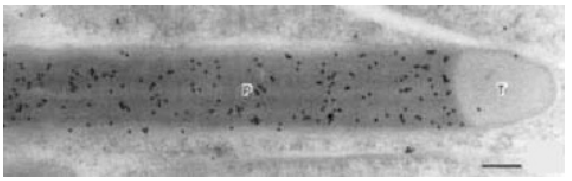

Fig. 13. Immunoelectron micrograph of Holospora obtusa in the macronucleus of *Paramecium caudatum*, treated with a monoclonal antibody specific for a 39-kDa periplasmic protein of the infectious form. Secondary label with gold-anti-mouse IgG. Bar = 0.2 μm. From Dohra et al. (1994).

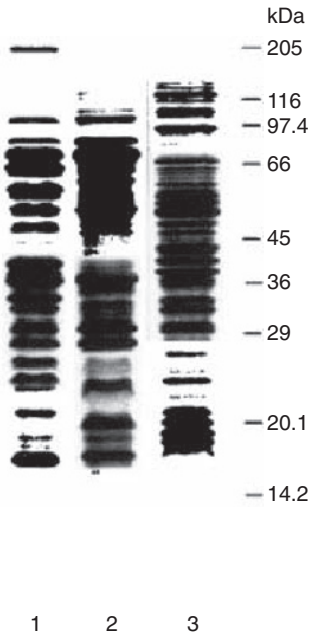

Fig. 14. SDS-polyacrylamide gel electrophoresis of total protein of *Holospora obtusa* and *Escherichia coli*. Lane 1, *H. obtusa*, infectious form (from 2×10^7 cells); lane 2, *H. obtusa*, reproductive form (from 2×10^8 cells); and lane 3, *E. coli* (from 5×10^7 cells). were associated with the phagosomal membrane (Görtz et al., 1990; Fujishima et al., 1990b; Dohra et al., 1994, 1997; Wiemann and Görtz, 1991; H.-D. Görtz, unpublished results). This is what would be expected if such proteins were used for communication with host membranes. Released periplasmic proteins could also protect the bacteria against lysosomal enzymes of the host or inactivate such enzymes. Dohra et al. (1997) have sequenced the gene of a small periplasmic protein of 5.4 kDa. The gene is highly expressed in the intermediate form, a transitional stage in the development from the reproductive into the infectious form of the bacterium. It has been suggested that the protein may function in the recognition process in the early phase of infection. Amino acid sequence similarities with other polypeptides have not been found. Binding experiments of biotinylated macronuclear proteins on blotted *Holospora* proteins had revealed binding to a 50-kDa polypeptide (Ehrsam and Görtz, 1999). The 50-kDa protein was immunolocalized in the periplasm and on the surface of *H. obtusa* on sections for light and electron microscopy and may function in the recognition process during infection. Dohra et al. (1998) have identified a GroEL-like protein in *H. obtusa* that is selectively expressed in the reproductive form.

The infectious form differs from the reproductive form not only in morphology, but also in the protein patterns produced on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE; Figs. 14 and 15). Some proteins specific for the infectious form of *H. obtusa* are located in the periplasm, as shown by means of immune electron microscopy (Fig. 15) using poly- and monoclonal antibodies as probes against these proteins (Wiemann and Görtz, 1991; Dohra et al., 1994).

The fine structure of the reproductive forms of species of *Holospora* is that of Gram-negative bacteria. Freeze-fracture studies of *H. obtusa* revealed that the outer membrane of the reproductive form has a density of intramembrane particles (IMPs) that is similar to that of the inner membrane. In contrast to this, the outer membrane of the infectious form was found to contain only very few IMPs (Görtz et al., 1989b), which corresponds to the observation that the infectious form shows only a limited number of surface proteins (Görtz et al., 1992b). These differences between the two forms correlate with a difference in the behavior of the two forms during the division of the host nuclei. The infectious forms of *H. obtusa* are concentrated in the connecting piece around the separation spindle of the dividing nucleus and are later released from the host cell. The reproductive forms are transported to the poles, and in this way, get into the daughter nuclei (Ossipov et al., 1975; Ossipov, 1981; Görtz and Dieckmann, 1980; Wiemann, 1989a; Wiemann and Görtz, 1989b). Apparently, *H. obtusa* makes use of the division apparatus of the host nucleus.

The physiology of *Holospora* and the triggers needed at different stages of its develoment are still enigmatic. It appears that during development of the infectious into the reproductive form, protein synthesis of the host cell is needed (Dohra and Fujishima, 1999b). It has also been shown that induction of the development of the reproductive form into the infectious form depends upon protein synthesis of the host cell

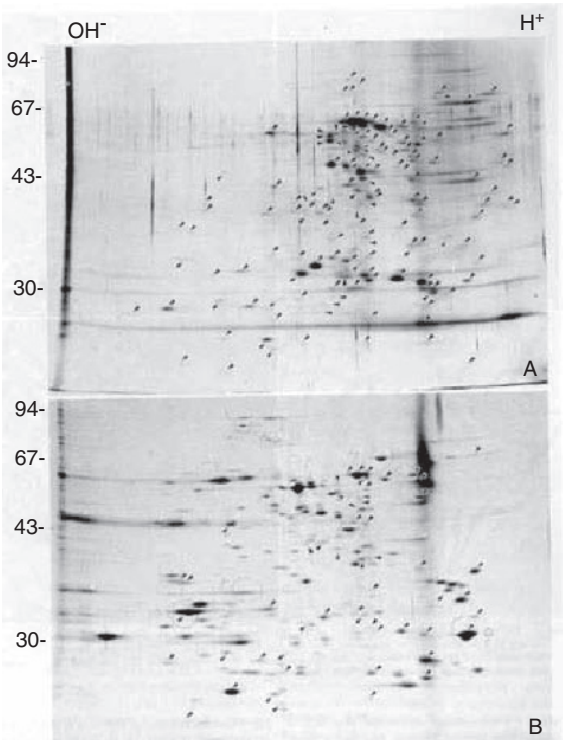

Fig. 15. Two-dimensional sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gels of the reproductive (A) and the infectious (B) forms of *Holospora obtusa*. Spots being unique for either of the forms were labeled with single arrowheads and those common to both of the forms were indicated with white-rimmed arrowheads. From Fujishima et al. (1990).

(Fujishima, 1993). Freiburg (1985) presented evidence that RNA polymerase of infected macronuclei of *Paramecium* had a 5-fold higher activity than that of uninfected nuclei (Freiburg, 1985).

Isolation of Symbiont-Bearing *Paramecium*

Prokaryotic symbionts of *Paramecium* are not free living. They can only be found in their host cells. To investigate the symbionts, paramecia have to be isolated from natural habitats. The techniques used in collecting and cultivating paramecia have been described by Sonneborn (Sonneborn, 1950; Sonneborn, 1970). Paramecia are easily detected in samples of pond or lake water and even in rivers with the help of a dissection microscope. For most species of *Paramecium*, the highest abundance is found in the eulitoral or in the microaerobic areas just above the anaerobic layer of detritus on the water level, where the abundance of bacteria and small eukaryotes is high. In the pelagial—the free water body of a lake—the abundance of paramecia may be low. Few species of *Paramecium* are found in brackish water, and no marine species are known (Wichterman, 1953; Fokin and Chivilev, 1999). *Paramecia* do not form cysts and, unless they have been introduced with the water added, cannot be obtained from infusions of straw or hay. When brought in from nature, the paramecia must be grown slowly at low temperature (about 16°C) without adding any antibiotics, if the purpose is to look for symbionts. Their presence can be monitored as described in the section "Identification of Symbionts in *Paramecium*."

If the paramecia are grown at high fission rates, their symbionts often become diluted and may even be lost. Natural populations of *Paramecium* are infected with symbionts to varying degrees. Most strains carry only one kind of symbiont. A culture containing only one type of symbiont may be obtained, therefore, by isolating a single paramecium and growing it into a clone. If a strain of *Paramecium* does carry more than one type of symbiont, it is often possible to obtain pure cultures by growing the strain at a high fission rate until the symbionts are diluted down to no more than one symbiont per paramecium. Cells isolated at that time and cultured at a low fission rate will grow into populations containing one type of symbiont only. This technique has also been used to separate different types of symbionts (Preer Jr., 1948a).

Culturing Paramecia with Symbionts A method of culturing paramecia involves the use of bacterized cereal leaf medium (Sonneborn, 1970). For a stock solution, 75 g of dried cereal leaves (a mixture of wheat and barley leaves that were harvested before growth of ears) are boiled for 15 min in 1 liter of distilled water. The solution is then filtered, diluted with water (1 : 30), buffered with Na_2HPO_4, and autoclaved. A day before use, the autoclaved medium is inoculated with *Enterobacter aerogenes*, *Klebsiella pneumoniae*, *Micrococcus luteus* or another bacterium suitable as food for *Paramecium*. The medium should have a pH of about 7. The growth rate of *Paramecium* can be regulated by varying the temperature and the amount of bacterized medium that is added to a culture.

Other Culture Methods An even simpler method is to culture paramecia in autoclaved straw or hay infusions. However, this method is less reproducible than the one using cereal leaf medium. For preparing the straw or hay medium, 3–5 g of straw or hay per liter of distilled water is boiled, filtered and buffered with Na_2HPO_4 (pH 6.8–7.0), and then autoclaved. After cooling and a day before use, the medium is inoculated with bacteria.

Unfiltered straw medium, with the straw remaining in the medium, may be used for maintaining stock cultures. In these cultures, paramecia with or without symbionts can be kept for months at low temperatures (6–16°C) without special care. Another, even safer, method for maintaining stocks is to freeze the paramecia and to keep them in liquid nitrogen, from which they may be recovered with their symbionts on thawing (Simon and Schneller, 1973). A great number of *Paramecium* stocks bearing symbionts are maintained in the frozen state at the American Type Culture Collection, Rockville, MD, USA. It appears, however, that some symbionts may be lost after prolonged maintenance in liquid nitrogen.

Some strains of *Paramecium* can also be grown axenically. For sterile growth, the paramecia must first be washed free of bacteria. This is achieved by allowing the paramecia to swim through sterile medium for a time sufficient to permit the bacteria in the food vacuoles to be eliminated (Sonneborn, 1950; Van Wagtendonk and Soldo, 1970). A simple technique modified from Heatherington (1934) is to place several paramecia at one edge of a hole of a depression slide filled with wash fluid, allow them to swim to the other side, and then to transfer them to a new depression. The procedure should be repeated four times before the cells are left in the fifth wash for an hour. They should then be transferred to a new depression and this should be repeated hourly for another 4 hours. A helpful tool for this method and for the growth of small numbers of paramecia is the so-called "three-spot depression slide," also called the "Sonneborn slide." This is a thick slide with three depressions (Fig. 16). For sterile washing, the paramecia must be taken up each time in a new sterile micropipette with as little fluid as possible; slides and wash fluid have to be sterile. The use of antibiotics to obtain bacteria-free cultures is to be avoided because such substances may harm the symbionts.

A method for culturing paramecia without bacteria involves use of the photoautotrophic alga *Chlamydomonas reinhardii* as a food organism (Preer et al., 1974). The medium contains 1 g of yeast autolysate, 0.25 g sodium acetate, 0.625 g of cereal leaves, and 0. 125 g of Na_2HPO_4 in 1 liter of double-distilled water. The medium is dispensed into test tubes, autoclaved and stored. Before it is used, the medium is inoculated with a small number of *Chlamydomonas* and incubated under light for two days. A single bacterium-free paramecium, put into a tube half-filled with this *Chlamydomonas* medium, usually will multiply and ingest most of the algae within 3 to 4 days.

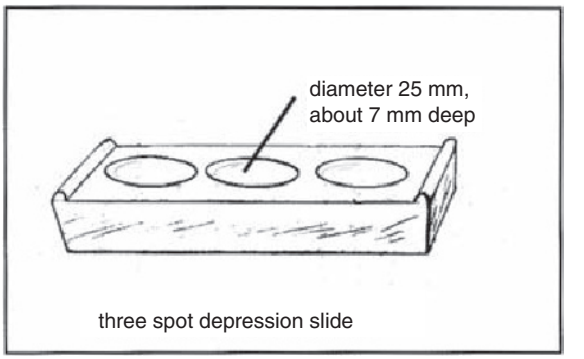

Fig. 16. Three-spot depression slide. Each depression has the volume of about 1.5 ml (Fig. 8). The depression slides may be labeled by pencil on the etched sides. Kept in a moist chamber, the slides may be covered by glass plates supported by the elevated edges of the slides.

Most of the axenic media used for growing paramecia are based on a recipe initially designed by Soldo et al. (1966). Recent modifications by Thiele et al. (1980) and Schönefeld et al. (1986) have proved particularly valuable for large-scale cultures of *P. tetraurelia*. A modification (Soldo, 1987a) that should be capable of supporting the axenic growth of paramecia and many other ciliates of freshwater and marine origin is shown below.

Medium for Axenic Growth of Marine and Freshwater Ciliates (Soldo, 1987a)

Proteose peptone	10.00 g
Trypticase	5.0 g
Yeast nucleic acid	1.0 g
Biopterin	0.5 mg
Folic acid	0.5 mg
Nicotinamide	2.5 mg
D-Pantothenate, Ca	7.5 mg
Pyridoxal hydrochloride	2.5 mg
Riboflavin	2.5 mg
Thiamine hydrochloride	0.01 mg
DL-Thioctic acid	0.01 mg
Phospholipid (oleate-containing)	250 mg
Stigmasterol	2 mg
Distilled water (or seawater)	1 liter

The medium is prepared in distilled water for freshwater ciliates and in seawater (density 1.015–1.026 g/ml) for marine forms. The final pH is 7.2. Stigmasterol is added from a stock solution (0.5 g of stigmasterol dissolved in 100 ml of absolute ethanol, stored at 4°C in a tightly capped plastic bottle) by injection into the culture medium from a syringe.

It is important to transfer paramecia gradually from a bacterized to an axenic medium; the ciliates need to be allowed to adapt slowly. Several procedures have been proposed for this transfer (see, e.g., Van Wagtendonk and Soldo, 1970, and Fok and Allen, 1979). An adapting medium (called "VS medium") based on that of Allen and Nerad (1978) is one containing all the vitamins of the axenic medium given above plus stigmasterol, but not the other components, the pH being adjusted to 7.0. In VS medium, bacteria (e.g., *Klebsiella pneumoniae* previously grown in a tryptone medium) are suspended and adjusted to $OD_{590} = 3.0$ by dilution. The bacteria are then dispensed in 1-ml portions in screw-cap tubes and placed in a deep freeze. The final medium is prepared, about a week's supply at a time, by adding 1 ml of the frozen bacterized VS medium to 9 ml of unbacterized VS medium. This medium is autoclaved and inoculated with paramecia. The protozoa grow in this medium at a rate of 1/2 to 2 fissions per day. Not all stocks of paramecium can be adapted to an axenic medium. Furthermore, some media were found to support growth of paramecia, but the latter were not able to maintain their symbionts under these conditions.

Purificaton of Symbionts from *Paramecium*

The purification of symbionts from paramecia (i.e., separation from host cell material) has been achieved in a number of ways: passage of cell homogenates through ion-exchange cellulose columns (Smith, 1961; Mueller, 1963), through filter paper columns (Preer et al., 1966), and centrifugation (Soldo et al., 1970) have all been used. For many symbionts, Percoll gradient centrifugation proved to be the method of choice (Görtz et al., 1988; Fujishima et al., 1990a). Depending on the type of symbionts, different methods of purification may be neccessary. For example, the R-body-containing *Caedibacter caryophila* can best be isolated with the help of a discontinuous 70% Percoll gradient, whereas isolation of *Caedibacter caryophila* containing no R bodies is better achieved by means of an ECTEOLA (anion exchanger) column (Schmidt et al., 1987c; Schmidt et al., 1988). For the isolation of holosporas, two different approaches have been followed. One method starts with homogenization of the host cells, and the other involves separation of the macronuclei from the cytoplasm and then isolation of the symbionts. The latter method involving prior isolation of nuclei (Freiburg, 1985) proved especially useful for preparing clean reproductive forms of the symbionts because it avoids contamination of the bacteria with food vacuoles. For isolation of nuclei, the paramecia are lysed in a buffer containing 10 mM Tris, pH 7.9, 0.25 M sucrose, 3 mM $CaCl_2$, 8 mM $MgCl_2$ plus 0.1 mM phenylmethylsulfonyl fluoride, 0.1% (w/v) spermidine, and 0.2% Nonidet P40 by gently stirring the cells in an ice-bath and subsequently passing the suspension 5–10 times through a 20-ml pipette. The nuclei are concentrated on a cushion of 1.6 M sucrose by spinning for 10 min at 700 *g*. The purified nuclei are then homogenized in a Mg-free buffer, and the bacteria are pelleted. Two different forms of the bacteria, the infectious and reproductive forms, can be separated by sedimentation. The infectious form sediments at 350 *g* within 10 min, while the reproductive form remains in the supernatant (Görtz et al., 1988).

Protocols for isolating holosporas directly from cell homogenates have been published by Fujishima and Nagahara (1984b), Schmidt et al. (1987a), and Görtz et al. (1988). Infected cells are homogenized in sodium phosphate buffer with a hand homogenizer. The Teflon pestle should fit tightly. The homogenate is then centrifuged at about 3000 *g* for 10 min. The pellet is resuspended in buffer and centrifuged in a preformed continuous gradient of 70% Percoll for 12 min at 40,000 *g*. To maintain the gradient, it is advisable to use a centrifuge with an acceleration rate control. For *H. obtusa*, *H. elegans* and *H. undulata*, the infectious forms then concentrate in a sharp band that is usually uncontaminated with food bacteria and cell debris (microscopical control). The reproductive forms do not form a band in a continuous Percoll gradient. These forms can be obtained with the help of a discontinuous gradient (at 10,000 *g*) where—depending on the species—they form a layer above ca. 60% Percoll. Most of the cell organelles of *P. caudatum* do not enter at the 50% Percoll step.

The isolation procedures described here have been helpful for studying ultrastructural details and protein composition of symbionts, their R bodies, and their DNA. Attempts to culture *Holospora* endosymbionts outside their hosts have been unsuccessful, as has been the case for other symbionts of aerobic ciliates.

Identification of the *Paramecium* Symbionts

Most of the endosymbionts are easy to observe. Paramecia are collected from ponds, lakes or rivers and brought into the laboratory. With the help of a micropipette, a few cells are placed on a microscope slide, covered with a cover glass, and then observed with a light microscope using phase contrast optics. Crushing of the paramecia is sometimes necessary (Preer and Stark, 1953). The classification of the endosymbionts of *Paramecium* is traditionally based on the following characteristics: morphology and killing activity, the species in which they live, DNA base ratios

calculated from the buoyant density (Bd) or from thermal denaturation profiles (T_m), and interstrain DNA/DNA hybridizations. Type strains, which have been deposited at the American Type Culture Collection (ATCC), are listed below by their ATCC numbers. Some type strains have also been deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, St. Petersburg State University, Russia, and can be obtained from that source.

Since endosymbionts do not multiply outside their hosts, characterization based on metabolism and growth, as is customary for bacteria, is not possible. Instead, morphological and biological features and sometimes data on the G+C content of the symbiont's DNA must be used for identification. Nowadays, sequencing of ribosomal genes after PCR amplification and classification by fluorescence in situ hybridization (FISH) using oligonucleotide probes complementary to ribosomal sequences (Fig. 17) have become powerful tools for classification of uncultured intracellular bacteria (Amann et al., 1991; Amann et al., 1995). Nonetheless, detection and sometimes a preliminary identification are still possible with the help of a light microscope equipped with phase contrast, namely, after staining with orcein (Beale and Jurand, 1966; see "Orcein Staining of Intracellular Bacteria").

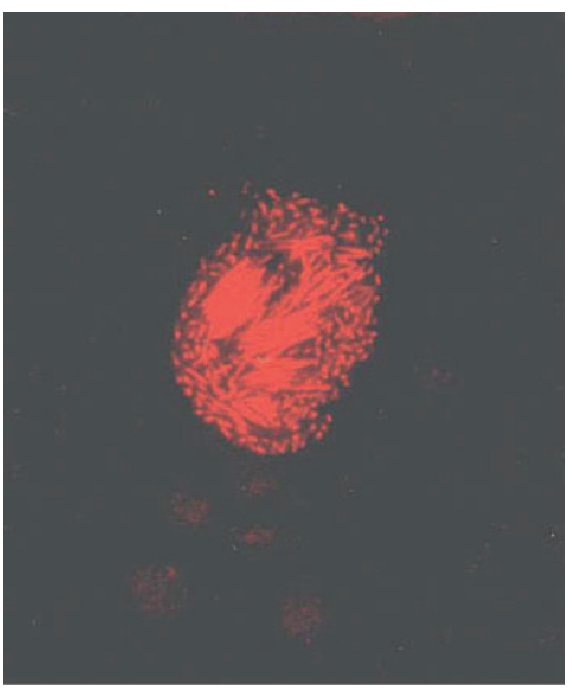

Fig. 17. Fluorescence in situ hybridization (FISH) using an oligonucleotide probe specific for *Holospora obtusa*. Short and long rods of holosporas in the host macronucleus are labeled. Faintly, phagosomes with prey bacteria are visible. From Fokin et al. (1996).

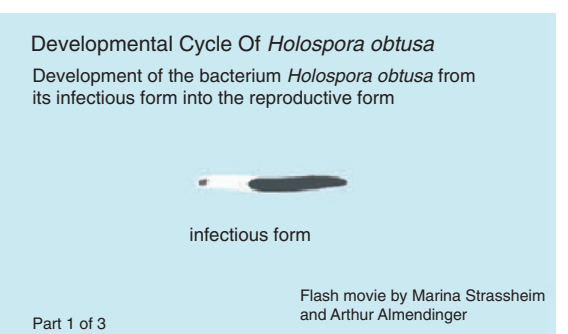
In addition to microscopic observation, killer tests should be performed when a stock is brought in from nature. Standard sensitives (e.g., cells of stock 152 of *P. triaurelia*) may be employed in such tests. Equal volumes of the culture to be tested and a culture of sensitive cells are mixed in a depression slide and observed with appropriate controls for prelethal effects. Mate killing can only be detected by mating sensitive cells with symbiont bearers. Any symbiont-free strain that will mate with an unknown strain is usually adequate. The mode of killing and the features of R bodies (if present), i.e., shape of the ends and the mode of unrolling of the different types of R body (Fig. 6), have been used for classification and determination of killer symbionts (for details, see Preer et al., 1974; Quackenbush, 1988, and Pond et al., 1989). It has now become evident that R bodies and their genetic basis, plasmids or phages, are not adequate for classification of their bacterial hosts (Beier et al., 2001).

In contrast to the killer trait, other biological features may still be of great value for the classification and determination of certain symbiotic bacteria. Such features may be the high infectivity, unique life cycle, and also unique morphology of the infectious forms of the species of the genus *Holospora*; see "Biology of the Holosporaceae". These bacteria are host-specific as well as nucleus-specific, i.e., they infect only one type of nucleus, either the micronuclei or the macronuclei (Ossipov, 1973; Ossipov et al., 1975; Fig. 1; see The Ciliate Cell as a Microcosm). *Holospora* bacteria establish short, reproductive forms that undergo binary fission as well as long, infective forms that leave the paramecium and infect others very efficiently (Ossipov and Podlipaev, 1977; Wiemann and Görtz, 1989b; Wiemann, 1989a; Fujishima et al., 1990b; Figs. 9–11). Namely, the infectious forms have a structure unique among bacteria and their structure may well be used for identification.



Video sequence showing the development of *Holospora*. For the video, see the online version of *The Prokaryotes*.

Orcein Staining of Intracellular Bacteria
A very useful staining technique that allows observations of intracellular bacteria in regular bright field and/or phase contrast is given by Beale and Jurand (1966): Paramecia are placed in a small drop on a slide, and as much of the fluid as possible is withdrawn by a micropipette or filter paper. The paramecia are lightly fixed by exposure to OsO_4 vapor for 6–10 s and immediately stained with a small drop of lacto-aceto-orcein (1 g of orcein dissolved in 25 ml of hot 45% acetic acid, mixed with 25 ml of lactic acid, diluted with water 1 : 1 and then filtered). A coverslip is placed over the drop of stained paramecia and is lightly pressed down, flattening but not disrupting the cells. The preparations can then be observed with a 100X oil immersion objective. To remove lipids that sometimes obscure observation of endosymbionts, the paramecia can be treated with a drop of acetone or a 3 : 1 mixture of ethanol and acetic acid before staining. Orcein-stained preparations can be made permanent by either applying vaseline around the edges of the cover slip or by the following procedure. The slide with the orcein preparation and cover slip is rapidly cooled in liquid nitrogen. The slide is immediately lifted off the cover slip with a razor blade. Cells will remain on the slide. The preparation is dehydrated by dipping it briefly into 50%, 70% and absolute ethanol and adding a small drop of Euparal or other ethanol-soluble resins. The resin layer between slide and cover slip should be extremely thin for optimal optical conditions.

The Taxa of Prokaryotic Symbionts of *Paramecium*

Genus *Caedibacter* (Preer and Preer, 1982)
Cells are straight rods or coccobacilli, 0.4–1.0 μm in diameter and 1.0–4.0 μm in length. Usually less than 10% but sometimes up to 50% of the symbionts contain refractile (R) bodies (Figs. 4–6). Cells containing R bodies are usually longer than those that do not. In addition to R bodies, many spherical phage-like structures or covalently closed circular DNA plasmids are present. The symbionts are Gram-negative and nonmotile. The G+C content of the DNA is 40–44 mol%. Earlier work of this extensively studied genus has been reviewed by Preer et al., 1974; Preer and Preer, 1984, and Pond et al., 1989.

An analysis of the 16S rDNA of *Caedibacter caryophilus*, a killer symbiont dwelling in the macronucleus of *Paramecium caudatum*, revealed an unusual insertion of 194 bp that was not present in mature 16S rRNA (Springer et al., 1993). It was shown that *C. caryophila* contained fragmented 16S rRNA. Insertion of more than 100 bp has been reported for bacterial 23S rDNAs (Roller et al., 1992). Comparable intervening sequences in 16S rRNAs have not been described in free-living or intracellular bacteria. Results obtained by Beier et al. (2001) give evidence that the genus *Caedibacter* is polyphyletic. Apparently, R bodies and their genetic basis, plasmids or phages, are not adequate for classification of their bacterial hosts. The following species have been described:

Caedibacter taeniospiralis *(Preer and Preer, 1982)* Cells are rods, 0.4–0.7 μm in diameter and 1.0–2.5 μm long. The G+C content is 41 mol%. They are found in the cytoplasm of *P. tetraurelia* only. Their R bodies (Fig. 5) unroll from the inside and contain plasmids. Ingestion of R-body-containing symbionts by sensitive paramecia results in the development of clear small blisters on their surface in 2 to 3 h. Between 4 and 5 h, a bulge develops first in the posterior part of the oral side and later moves to the posterior aboral side. The position of the bulge gave rise to the designation "hump killer." Death takes place in 1 to 2 days, the corpses remaining intact for some time. *Caedibacter taeniospiralis* of *P. tetraurelia* stock 51K has been affiliated to γ-subgroup of Proteobacteria according to its ribosomal gene-sequences (Beier et al., 2001). The type strain is found in ATCC strain 30632 (stock 51 of *P. tetraurelia*; see Preer et al., 1974).

Caedibacter varicaedens *(Quackenbush, 1982)* The cells are rods, 0.4–1.9 μm in diameter and 2.0–4.0 μm long. The G+C content of the DNA is 40–41 mol%. They are found in the cytoplasm of *P. biaurelia*. Different strains cause vacuolization, paralysis, or rapid reverse rotation while swimming (spin-killing) of sensitive cells. After 4–6 h of swimming, vigorous rotation to the right becomes nearly uninterrupted, and then becomes slower. R bodies (Fig. 4) unroll from the outside. The outer terminus of the unrolled R body is blunt. The R body is usually associated with bacteriophage capsids. The type strain is found in ATCC 30637 (stock 7 of *P. biaurelia*; see Preer et al., 1974).

Caedibacter pseudomutans *(Quackenbush, 1982)* These are cigar-shaped rods, approximately 0.5 μm in diameter and 1.5 μm long. The G+C content is 44 mol%. They are found in the cytoplasm of *P. tetraurelia* and cause rapid reverse rotations of sensitive paramecia while swimming (spin-killers). The R bodies are of the *C. varicaedens* type. The type strain is found in ATCC strain 30633 (strain 51 ml of *P. tetraurelia*; see Preer et al., 1974).

Caedibacter paraconjugatus *(Quackenbush, 1982)* Cells are small rods and contain phage-like structures. Less than 1% of the symbionts contain R bodies of the *C. varicaedens* type. They are found in the cytoplasm of *P. biaurelia*. Ingestion of symbionts by sensitive strains does not produce any observable toxic effect. Cell-to-cell contact between host and sensitive paramecia is required for toxic effects to be observed in the sensitive paramecia (mate-killers). The type strain is found in ATCC strain 30638 (stock 570 of *P. biaurelia*; see Preer et al., 1974).

Caedibacter caryophilus *(Schmidt et al., 1987b; Euzeby, 1997)* Cells are rods, 0.4–0.7 μm wide and up to 2.5 μm long. Those with R bodies are larger than those without R bodies. The G+C content is 34.6 mol%. They are found in the macronucleus of *P. caudatum*. The R bodies unroll from the inside (with blunt outer terminus and sharp inner terminus) and are associated with phages. Width of R bodies after isolation is 0.8 μm. Sensitive strains are killed by paralysis. Coinfections with *Holospora obtusa*, *H. undulata* and *H. elegans* may occur in natural populations (H.-D. Görtz, unpublished observations). According to its ribosomal gene sequences, *C. caryophilus* has been affiliated to the α-subgroup of Proteobacteria, the closest relative being *Holospora obtusa* (Springer et al., 1993). The type strain is found in ATCC strain 50168 (clone C221 of *P. caudatum*; see Schmidt et al., 1987b).

Genus *Pseudocaedibacter* (Quackenbush, 1982) Cells are rods, 0.25–0.7 μm in diameter and 0.5–4.0 μm long. They do not produce R-body-containing cells. The symbionts are Gram negative and nonmotile. The G+C content of the DNA is 35–39 mol%. The genus includes some species that confer a killer trait on their hosts, some that render them mate killers, and others that do not produce any killing ability. Four species have been described:

Pseudocaedibacter conjugatus *(Quackenbush, 1982)* Formerly called mu particles, these cells are rods, 0.3–0.5 μm in diameter and 1.0–4.0 μm long. The G+C content of the DNA is 35–37 mol%. They are found in the cytoplasm of *P. primaurelia* and *P. octaurelia* where a mate-killer phenotype of the hosts is produced. The type strain is found in ATCC strain 30796 (stock 540 of *P. primaurelia*; see Preer et al., 1974).

Pseudocaedibacter minutus *(Quackenbush, 1982)* Formerly known as "gamma particles," these cells are rods, often double but also single rods 0.25–0.35 μm in diameter and 0.5–1 μm long. The G+C content of the DNA is 38 mol%. They are found in the cytoplasm of *P. octaurelia*. In the host cell, the symbiont is surrounded by an extra set of membranes, apparently continuous with the endoplasmic reticulum of the host. The paramecia which bear these symbionts are very strong killers that cause sensitives to develop vacuoles, swell, finally become spherical and lyse. Death occurs after about 8 h. The type strain is found in ATCC strain 30699 (stock 214 of *P. octaurelia*; see Preer et al., 1974).

Pseudocaedibacter falsus *(Quackenbush, 1982)* Formerly called "nu" and "pi particles," these cells are rods, 0.4-0.7 μm in diameter and 1.0–1.5 μm long. The G+C content of the DNA is 36 mol%. They have no known toxic actions and are found in the cytoplasm of *P. biaurelia*, *P. tetraurelia* and *P. pentaurelia*. The type strain is found in ATCC strain 30640 (stock 1010 of *P. biaurelia*; see Preer et al., 1974).

Pseudocaedibacter glomeratus *(Fokin and Ossipov, 1986)* These are small rods, about 0.3 μm wide and up to 1.2 μm long. They are found in the cytoplasm of *P. pentaurelia* and have no known toxic actions. Symbionts are individually enclosed in vacuoles which are tightly associated with the endoplasmic reticulum. The type strain is strain Bp 171 of *P. pentaurelia* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, St. Petersburg State University, Russia).

Caedobacter chlorellopellens *(Skoblo et al., 1985)* This organism, a symbiont living in the cytoplasm of *P. bursaria* and found to be antagonistic to symbiotic chlorellae, was named "*Caedobacter chlorellopellens*" by Skoblo et al. (1985), who did not know that the genus name *Caedobacter* had been changed to *Caedibacter*. *Caedibacter* was then restricted to symbionts that produce R bodies and confer killer traits upon their host paramecia (Preer and Preer, 1982). The symbiont in *P. bursaria* is egg-shaped, rarely rod-shaped, 0.35 μm wide and up to 1.4 μm long. Since no R bodies were observed and the cells have no known toxic actions on sensitives, placement of the species in the genus *Pseudocaedibacter* seems more plausible. A renomination of the species seems necessary but should be done only after ribosomal sequences have been obtained.

Genus *Lyticum* (Preer and Preer, 1982) Cells are large rods, 0.6–0.8 μm in diameter and 3.0–5.0 μm long. They resemble bacilli in general appearance and bear numerous peritrichous flagella (Figs. 3 and 18) but are not obviously motile. They are enclosed in vacuoles in the cyto-

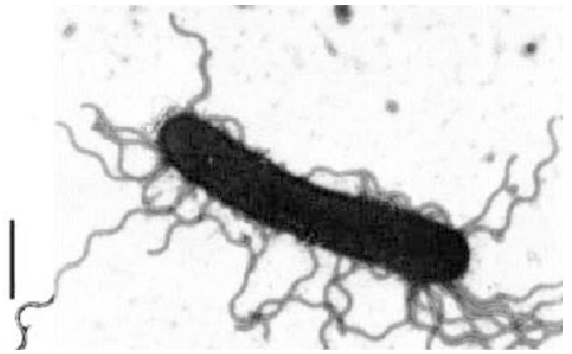


Fig. 18. Electron micrograph of *Lyticum flagellatum* of *Paramecium octaurelia* stock 327. Negative staining with phosphotungstic acid. Bar = 1 μm. From Preer et al. (1974).

plasm of their hosts. They do not contain R bodies. The G+C content is 27 mol% in one type and 45–49 mol% in another type. The symbionts are Gram negative. They produce toxins that kill sensitive paramecia by lysing them within 10–20 min (rapid-lysis killing). Two species have been described:

Lyticum flagellatum *(Preer and Preer, 1982)* Formerly known as "lambda particles," these cells are straight rods, 0.6–0.8 μm in diameter and 2.0–4.0 μm long (Figs. 3 and 18). The G+C content of the DNA is 27 mol% in one strain and 49 mol% in another. They are found in the cytoplasm of *P. tetraurelia* and *P. octaurelia*. The type strain is found in ATTC strain 30700 (stock 299 of *P. octaurelia*; see Preer et al., 1974).

Lyticum sinuosum *(Preer and Preer, 1982)* Formerly, these were called "sigma particles." They are curved or spiral rods, 0.7–0.9 μm in diameter and 2.0–10 μm long, sometimes forming chains of 2–3 cells. The G+C content is 45 mol%. They are found in the cytoplasm of *P. biaurelia*. The type strain is found in ATCC strain 30696 (stock 114 of *P. biaurelia*; see Preer et al., 1974).

Genus *Pseudolyticum* (Boss et al., 1987) These are large symbionts with numerous flagella. No motility has been observed. They may contain refractile bodies consisting of polyhydroxybutyric acid. No killer activity and no infectivity could be detected. Only one species is known:

Pseudolyticum multiflagellatum (Boss et al., 1987) Cells are straight rods, 1.0–2.0 μm in diameter and 3.5–14 μm long. They are found in the cytoplasm of *P. caudatum*. The symbionts are individually enclosed in vacuoles. The membrane of these vacuoles forms numerous projections that are continuous with the endoplasmic reticulum. No toxic actions are known.

Genus *Tectibacter* (Preer and Preer, 1982) The species of this genus are distinguished from other symbionts by a layer of electron-dense material surrounding the outer of the two membranes. The symbionts have sparse peritrichous flagella and show slight motility on occasion. They appear not to be toxic. For a more detailed description, see Preer et al. (1974). Only one species has been described:

Tectibacter vulgaris (Preer and Preer, 1982) Formerly known as delta particles, these cells are straight rods, 0.4–0.7 μm in diameter and 1.0–2.0 μm long. Gram-negative. Hosts: *P. primaurelia*, *P. biaurelia*, *P. tetraurelia*, *P. sexaurelia* and *P. octaurelia*. The type strain is found in ATCC strain 30697 (stock 225 of *P. sexaurelia*; see Preer, 1974).

Genus *Nonospora* (Fokin et al., 1987a) These rod-like symbionts live in the macronucleus. Flagella have not been observed. No toxic actions are known. The symbionts are retained in macronuclear fragments of exconjugants and enter macronuclear anlagen by fusion of old fragments with the anlagen (Fokin et al., 1987a). Only one species has been described:

Nonospora macronucleata (Fokin, Ossipov, Skoblo, Rautian, and Sabaneyeva 1987; Demar-Gervais, 1976). These symbionts are rodlike, 0.2–0.3 μm in diameter and mostly about 1.0 μm long, sometimes forming chains up to 10 μm long. The surface of the symbionts appears irregularly wavy in the electron microscope. They are found in the macronucleus of *P. caudatum*, often clustered in the center of the nucleus.

Genus *Holospora* (Gromov and Ossipov, 1981; Hafkine, 1890) Symbionts of this genus live in the micronucleus or the macronucleus (see The Ciliate Cell as a Microcosm) of *Paramecium* and exist in two forms: a short rod, 1.0–3.0 μm long and 0.5–1.0 μm wide that can replicate; and a long form 5.0–20 μm long and 0.8–1 μm wide that cannot replicate (Figs. 9–11). The long form is released from the host and can infect other paramecia (Fig. 8). The infective form is differentiated into a refractile portion with a less electron dense, pale tip and a posterior part that contains typical bacterial cytoplasm, stains with DNA-specific dyes, and appears dark in phase contrast (Fig. 9). Nine species have been described (see Table 1): *Holospora undulata*, *H. obtusa*, *H. elegans*, *H. acuminata*, *H. caryophila*, *H. recta*, *H. curviuscula*, *H. bacillata*, and *H. curvata*.

The striking similarity of the biology and cytology of the different *Holospora* species led to their classification in one genus, although a com-

parison of the protein patterns of *H. obtusa* and *H. elegans* revealed great differences. Moreover, the hybridization of the total DNAs and a comparison of DNA banding patterns after digestion with restriction enzymes indicate that the two species may not be as closely related as originally assumed (Schmidt et al., 1987a). The differences at the molecular level may suggest that the genus *Holospora* has coevolved with ciliates for a long time.

Holospora were the first intracellular bacteria in *Paramecium* for which the phylogenetic position was determined (Amann et al., 1991). *Holospora obtusa*, *H. elegans* and *H. undulata* belong to the α-group of Proteobacteria. The closest relative among other symbionts in ciliates was found to be *Caedibacter caryophilus*, and the closest relatives among other bacteria found up to now are *Rickettsia* and *Ehrlichia* (Amann et al., 1991; Springer et al., 1993). It is tempting to regard the striking biology (developmental cycle, host specificity for *Paramecium*, etc.) and the unique morphology of the infectious form as homologous features proving the close relationship and monophyletic origin of these bacteria. New observations, however, cast doubt on this possibility (Fokin et al., 1996).

The behavior of the infectious forms of certain *Holospora* species to assemble in the connecting piece of the dividing host nucleus is certainly highly advanced and must be regarded as an apomorphic feature. This behavior ensures that the infectious forms are specifically collected and released by the host cell. *Holospora caryophila*, *H. bacillata* and *H. curvata* do not share this feature with the other holosporas (Fokin et al., 1996; Fokin and Sabaneyeva, 1997), and it is not clear how the bacteria of these species leave their host nuclei. They either are more primitive than the other holosporas, as a quantitative separation of infectious forms and reproductive forms is not observed, or are phylogenetically not closely related. Two species groups may presently be distinguished in the genus *Holospora* (Table 1). It has been hypothesized that the unique behavior of the infectious form to deposit enormous amounts of periplasmic materials polarly could be encoded on a plasmid or phage genome. However, no plasmid or phage genome has been found (M. S. Rautian et al., unpublished results). It is consistent with this observation that the "more advanced" species tested (of which the infectious forms are collected in the separation spindle) were labelled by in situ-hybridization using an oligonucleotide probe designed for *H. obtusa* (Amann et al., 1991; Fokin et al., 1996).

An unnamed symbiont of this *Holospora*-type has repeatedly been observed in *Stentor multiformis* and in *S. polymorphus* (Görtz and Wiemann, 1987); another one has been observed in the peritrich ciliate *Zoothamnium pelagicum* by Laval (1970). Similar morphology and life cycle were also observed in bacterial symbionts in the ciliates *Trithigmostoma cucullulus* (Görtz and Maier, 1991) and *Spirostomum* sp. (H.-D. Görtz, unpublished observation). These observations indicate that symbionts of the genus *Holospora* are not restricted to *Paramecium*. Some strains of *Paramecium* were found to be harmed after infection with holosporas, whereas other strains apparently remained unaffected.

Table 1. Descriptions of *Holospora* spp.

Holospora[a]	Morphology and size of infectious form	Host *Paramecium*	Nucleus	Species group[b]
"*H. acuminata*"	Straight, tapered ends, length 4–6μm	*P. bursaria*	Micronucleus	I
"*H. bacillata*"	Straight, ends rounded, length 5–17μm	*P. woodruffi* *P. calkinsi*	Macronucleus	II
H. caryophila	Spiral, tapered ends, length 5–6μm	*P. biaurelia* *P. novaurelia* *P. caudatum*	Macronucleus	II
"*H. curvata*"	Curved, length 12–20 μm	*P. calkinsi*	Macronucleus	II
"*H. curviuscula*"	Curved, tapered ends, length 6–10 μm	*P. bursaria*	Macronucleus	I
H. elegans	Straight, tapered ends, length 7–18 μm	*P. caudatum*	Micronucleus	I
H. obtusa	Straight, tapered ends, length 7–20 μm	*P. caudatum*	Macronucleus	I
"*H. recta*"	Straight, tapered ends, length 10–15μm	*P. caudatum*	Micronucleus	I
H. undulata	Spiral, tapered ends, length 7–15μm	*P. caudatum*	Micronucleus	I

[a]Names in quotation marks are not validated.

[b]Species of group I are characterized by an escape mechanism of the infectious form from the host nucleus that is regarded as higher evolved. The infectious forms are collected in the connecting piece of the dividing nucleus and later released by the host cell (Fig. 8). Bacteria of species of group I react with a "*Holospora*-specific" oligonucleotide probe in fluorescence in situ hybridization (Fokin et al., 1996). For species of group II, the exact mode by which infectious forms leave their host nuclei is not known. In this group, infectious forms are not collected in the connecting piece of a dividing nucleus (Fokin et al., 1996; Fokin and Sabaneyeva, 1997). *Holospora* species of group II do not react with a "*Holospora*-specific" oligonucleotide probe in fluorescence in situ hybridization.

Holospora undulata *(Hafkine, 1890; Gromov and Ossipov, 1981)* This organism lives in the micronucleus of *P. caudatum*. Two forms are seen: a short, spindle-shaped, reproductive form, about 0.8 μm in diameter and 1.5–2.0 μm long, and a long, spiral-shaped infectious form that has tapered ends and is 7.0–15 μm long. The type strain is found in clone MI-48 of *P. caudatum* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, St. Petersburg State University, Russia).

Holospora obtusa *(Hafkine, 1890; Gromov and Ossipov, 1981)* This organism lives in the macronucleus (Fig. 7). Reproductive forms are short rods, 0.8 μm in diameter and 1.5–2.5 μm long. Infectious forms are long rods with rounded ends, 0.8–1.0 μm in diameter and 7.0–20 μm long. Reflecting the fine structural organization, the infectious form shows a refractile part and a dark part in phase contrast light microsopy (Fig. 9). The type strain is found in clone M-115 of *P. caudatum* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, St. Petersburg State University, Russia).

Holospora elegans *(Hafkine, 1890; Preer and Preer, 1982)* This organism lives in the micronucleus. Reproductive forms are short rods, 0.8 μm in diameter and 1.5–2.0 μm long. Infectious forms are long rods with tapered ends, 0.6–0.8 μm in diameter and 7.0–18 μm long. The type strain is found in ATCC strain 50008 (stock C1O1 of *P. caudatum*; Görtz and Dieckmann, 1980).

Holospora acuminata *(Ossipov, 1980)* This organism lives in the micronucleus of *P. bursaria*. Reproductive forms are fusiform rods, 0.6 μm in diameter and 2.0–2.5 μm long. lnfectious forms are straight fusiform rods with tapered ends, 0.8–1.0 μm in diameter and 4.0–6.0 μm long. The type strain is found in stock AC61-10 of *P. bursaria* (deposited in the culture collection of the Laboratory of Invertebrate Zoology, Biological Research Institute, St. Petersburg State University, Russia).

Holospora caryophila *(Preer and Preer, 1982)* These organisms were formerly known as "alpha particles" (Preer, 1969), live in the macronucleus of *P. biaurelia* (Fig. 2), and may also be found in *P. caudatum* (Görtz, 1987). Reproductive forms are thin, fusiform rods, 0.4 μm in diameter and 1.0–3.0 μm long. Infectious forms are spiral shaped with tapered ends, 0.5 μm in diameter and 5.0–6.0 μm long. The type strain is found in ATCC strain 30694 (stock 562 of *P. tetraurelia*; see Preer et al., 1974).

Holospora recta *(Fokin, 1991)* This organism lives in the micronucleus of *P. caudatum*. Two forms are seen: a short, spindle-shaped, reproductive form, about 0.8 μm in diameter and 1.5–2.0 μm long, and a long, straight infectious form (one end rounded, one end tapered) 10–15 μm long.

Whereas all other *Holospora* spp. listed here definitely appear to be good species, this status has been questioned for *H. recta* by Rautian and Ossipov (M. S. Rautian and D. V. Ossipov, personal communication), who found that a strain of *H. elegans* had a number of individuals with *H. recta*-like features. The question may finally be resolved after molecular data have been obtained from analyses of the different strains.

Holospora curviuscula *(Borchsenius et al., 1983)* Cells live in the macronucleus of *P. bursaria*. They infect only certain strains of three syngens, and in other strains, the development into the infectious form is not completed. Occasionally, infection of both macro- and micronuclei was observed (Skoblo and Lebedeva, 1986). Reproductive forms are fusiform rods, 0.8 μm in diameter and 1.5–2.0 μm long. Infectious forms are slightly curved rods with tapered ends, approximately 0.8 μm in diameter and 6.0–10 μm long.

Holospora bacillata *(Fokin and Sabaneyeva, 1993)* This organism lives in the macronucleus of *Paramecium calkinsi* (Fokin and Sabaneyeva, 1993) and *Paramecium woodruffi* (Fokin et al., 1996; Fokin and Sabaneyeva, 1997). Infectious forms are 5–17.0 μm long, 0.7–0.8 μm wide, straight, rounded at both ends.

Holospora curvata *(Fokin and Sabaneyeva, 1993)* Cells live in the macronucleus of *Paramecium calkinsi* (Fokin and Sabaneyeva, 1993). Infectious forms are 12–20 μm long, 0.7–0.9 μm wide, curved, and rounded at both ends.

Symbionts of *Paramecium* Without Binomial Names Jenkins (1970) described a Gram-negative bacterium living within bulbous distensions of the outer membrane of the nuclear envelopes of both the micro- and macronucleus of a strain of *P. multimicronucleatum*. This symbiont is a very short rod, sometimes appearing nearly coccoid, approximately 0.35 μm in diameter with longer forms reaching 0.7 μm in length. It was named "epsilon."

Another symbiont, reported to occur in the perinuclear space, has been described by Fokin

(1988). It was found inside the nuclear cisternae of the macronuclear envelope of *P. duboscqui*. The symbiont is 0.3 µm in diameter and 0.7–1.4 µm long, looks spindle-shaped and is Gram negative. No killing activity was observed when symbiont bearers were tested against nonsymbiont bearers.

A symbiont studied by Estève (1978) occurs in the macronucleus of *P. caudatum* and confers a killer trait on its host. When it was investigated cytologically, a greatly enlarged macronucleus was observed to contain numerous kappa-like bacteria, some of which contained R bodies. Electron micrographs of this bacterium showed spherical phages inside the R bodies. Schmidt and coauthors assumed that the symbiont is identical with *Caedibacter caryophilus* described by them (Schmidt et al., 1987b).

A so far unnamed symbiont found by Görtz and Freiburg (1984) living in the micronucleus of *P. bursaria* is a small rod, 0.5 µm in diameter and up to 2 µm long. Its ultrastructure suggests that it is a Gram-negative bacterium. No flagella were found and no killing capacity of its host was observed. Another symbiont of the nonkiller type was discovered in the cytoplasm of *P. woodruffi*, a ciliate living in brackish water. The symbiont is a Gram-negative rod (0.2–0.8 µm in diameter and 0.6–2.5 µm long) that lacks flagella and contains hexagonal viroid particles (Fokin et al., 1987b).

In *P. sexaurelia* isolated from an aquarium with tropical fish, a bacterial endosymbiont was observed by Görtz (1981) to invade the macronucleus but not the micronucleus. Once the symbiont has entered the macronucleus, it tends to disappear from the cytoplasm. The bacterium is slightly curved with a diameter of 0.5–0.8 µm and up to 25 µm long. When present in the cytoplasm, the symbiont tends to be closely associated with food vacuoles. Once the symbiont has entered the macronucleus, it multiplies there without causing nuclear hypertrophy. After autogamy, the symbiont is found only in the cytoplasm and not in new macronuclear anlagen. It remains there until a new infection of the macronucleus occurs. The bacterium was observed again in a *P. sexaurelia* isolated by Fokin (Przybosz and Fokin, 1997) from a pond in the Wilhelma (Zoological and Botanical Garden, Stuttgart).

Table 2 summarizes the taxa of prokaryotic symbionts of *Paramecium* and provides a determinative key to their identification.

Table 2. Key to the prokaryotic symbionts of *Paramecium*.

I. Host paramecia are killers or mate killers
  A. Between 2 and 50% of the symbiont population contains R bodies
    1. Host paramecia are killers
      a. Kill by producing aboral humps on sensitive paramecia; R bodies unroll from inside at low pH, reroll at high pH; found in *P. tetraurelia*
      Caedibacter taeniospiralis
      b. Kill in ways other than producing aboral humps
        (1) Found in *P. tetraurelia*; R bodies unroll from the outside irreversibly when exposed to high temperature or certain detergents
        Caedibacter pseudomutans
        (2) Found in *P. biaurelia*; R bodies unroll from outside irreversibly when exposed to high temperature or certain detergents
        Caedibacter varicaedens
        (3) Found in *P. caudatum*, found in the macronucleus only; R bodies unroll from inside
        Caedibacter caryophilus
    2. Host paramecia are mate killers
      Caedibacter paraconjugatus
  B. Symbiont population does not contain R bodies
    1. Host paramecia are killers
      a. Rapid lysis killer; symbionts are large flagellated cells
        (1) Straight rods found in *P. tetraurelia*, *P. octaurelia*
        Lyticum flagellatum
        (2) Sinuous rods found in *P. biaurelia*
        Lyticum sinuosum (Fig. 3)
      b. Kill by vacuolization, symbionts are very small cells, often doublets
        Pseudocaedibacter minutus
    2. Host paramecia are mate-killers
      Pseudocaedibacter conjugatus
II. Host paramecia are nonkillers
  A. Symbionts are present only in the cytoplasm
    1. Symbionts lack flagella
      a. Host: *P. bursaria*; egg-shaped, rarely rod-shaped, up to 1.4 µm long. Antagonistic to symbiotic algae (*Chlorella*) of the host
      Caedobacter chlorellopellens

Table 2. *Continued*

b. Hosts: *P. biaurelia*, *P. tetraurelia*, *P. pentaurelia*; rods, up to 1.2 μm long
Pseudocaedibacter falsus
c. Host: *P. pentaurelia*; rods, up to 1.2 μm long; the symbiont-containing vacuole is surrounded by endoplasmic reticulum
Pseudocaedibacter glomeratus

2. Symbionts with flagella
a. Host: *P. caudatum*; rods; 3.5 to 14 μm long; refractile inclusions (polyhydroxy butyric acid); with numerous flagella, but no motility observed
Pseudolyticum multiflagellatum
b. Host: *P. primaurelia*; rods, up to 2 μm long, Gram negative with a thick surface layer visible in EM; with sparse flagella, occasionally slight motility; coexists with other symbionts such as *Caedibacter* and *Pseudocaedibacter*
Tectibacter vulgaris

B. Symbionts are present almost exclusively in the nuclei
1. Symbionts exclusively in the micronucleus, show two morphologically distinct forms, and are highly infectious
a. Long form of symbiont (infectious form) spiral-shaped, both ends tapered, 7–15 μm long; host: *P. caudatum*
Holospora undulata
b. Long form of symbiont (infectious form) straight rod with tapered ends
(1) Host: *P. caudatum*; long form 7–18 μm long
Holospora elegans
(2) Host: *P. bursaria*; long form 4–6 μm long
Holospora acuminata
c. Long form of symbiont (infectious form) straight rod, one end tapered, one end rounded, host: *P. caudatum*
Holospora recta

2. Symbionts exclusively in the macronucleus
a. Symbionts are highly infectious, two morphologically distinct forms often observable
(1) Long form slightly spiral shaped, with tapered ends, 5–6 μm long; host: *P. biaurelia* (sometimes also observed in *P. caudatum*)
Holospora caryophila (Fig. 2)
(2) Long form straight rod, with rounded ends, 7–20 μm long; host: *P. caudatum*
Holospora obtusa (Fig. 9)
(3) Long form straight rod, with rounded ends, 5–17 μm long; host: *P. calkinsi* or *P. woodruffi*
Holospora bacillata
(4) Long form slightly curved, with tapered ends, 6–10 μm long; host: *P. bursaria*
Holospora curviuscula
(5) Long form curved, both ends rounded, 12–20 μm long, host: *P. calkinsi*
Holospora curvata
b. Symbionts are weakly infectious, only one morphological form observable. Host: *P. caudatum*; rods small, about 1 μm long, sometimes forming "chains" that are up to 10 μm long; mostly aggregated in the center of the macronucleus; may coexist with *H. obtusa* or *H. undulata*
Nonospora macronucleata

Based on the key proposed by Preer (1981) and on information from articles cited in this Chapter.

Prokaryotic Symbionts of *Euplotes*

Endosymbiotic bacteria are also very common in *Euplotes*, a ciliate genus that comprises both freshwater and marine species (Heckmann, 1983a; Petroni et al., 2001). So far, only one of the symbionts has been given a binomial name. The others are still referred to by Greek letters, as was formerly customary for cytoplasmic elements. Several *Euplotes* symbionts remained unnamed or were provisionally given Latin letters as names when they were encountered. However, most of these symbionts are not well characterized.

Habitat of the *Euplotes* Symbionts

All except one of the bacterial symbionts of *Euplotes* are confined to the cytoplasm; see The Ciliate Cell as a Microcosm. They can easily be observed with a phase contrast microscope. Fixation and staining of *Euplotes* with aceto-carmine or lacto-aceto-orcein can be helpful for the observation and identification of these endosymbionts; see Orcein Staining of Intracellular Bacteria. When stained, *Polynucleobacter necessarius* (formerly omikron) and the closely related "omikron-like" bacteria reveal many nucleoids (Heckmann, 1975; Heckmann et al., 1983b; Figs. 19 and 20). It appears that most of the *Euplotes* symbionts cannot grow outside their hosts, although this has been investigated thoroughly only for *P. necessarius*. Like *Caedibacter* and other symbionts of the *P. aurelia* species complex, the *Euplotes* symbionts appear not to be infectious, at least under laboratory conditions, and some are killer symbionts similar to the killer symbionts of *Paramecium*; see The Killer

Trait in *Paramecium*. The symbionts found to date have not been observed to be harmful to their hosts, which, however, in some cases are converted by infection into killers or mate killers. *Polynucleobacter necessarius* and the closely related omikron-like bacteria are essential for their hosts (Heckmann, 1983a).

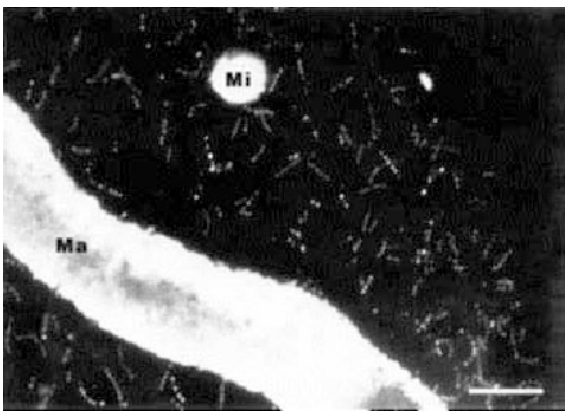

Fig. 19. Fluorescence micrograph of *Polynucleobacter necessarius* in the cytoplasm of a slightly crushed *Euplotes aediculatus* cell after staining with N,N'-diethylpseudoisocyanin chloride. The symbionts are revealed by the DNA-specific yellow fluorescence of their nucleoids. Ma, macronucleus; and Mi, micronucleus. Bar = 1 µm. From Heckmann (1975).

Isolation of the *Euplotes* Symbionts

Euplotes minuta, *E. crassus* and *E. vannus* are marine species. They can be isolated from water samples containing algae or detritus collected at the seashore. All these species can be easily grown in the laboratory in seawater with *Dunaliella salina* as the food organism (for details, see Heckmann, 1963). The other *Euplotes* species listed in Table 3 are freshwater

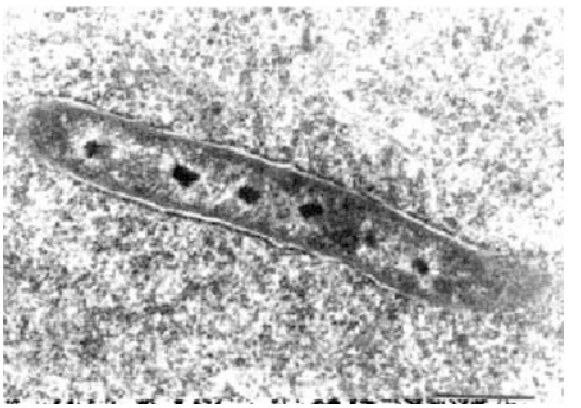

Fig. 20. Electron micrograph of *Polynucleobacter necessarius*. Longitudinal section. The ultrastructure of this symbiont resembles that of Gram-negative bacteria. Bar = 0.5 µm. From Heckmann (1975).

Table 3. Characteristics of the prokaryotic endosymbionts of the genus *Euplotes*.

Symbiont designation	Euplotes species[a]	Site	Killing type	References

Abbreviations: Cy, cytoplasm; Ma, macronucleus; NK, nonkiller; K, killer; MK, mate killer; and ND, not determined.
[a]The typical strain designation is given in parentheses.
[b]Unnamed symbiont that is not omikron-like in *E. aediculatus* stocks 7 and 10.
[c]Unnamed symbiont observed in addition to omikron-like symbionts in stock 11 of *E. octocarinatus*.

organisms that may be collected from ponds. They can be grown in a diluted soil medium (Ruthmann and Heckmann, 1961) or in culture medium for *Euplotes* (CME; Kuhlmann and Heckmann, 1989) and fed with *Chlorogonium elongatum* or *Chilomonas paramecium*. Most *Euplotes* species can also utilize bacteria as food.

Since the symbionts may differ in different strains of a host species, it is advisable to start *Euplotes* cultures from single cells, so that the cultures maintained in the laboratory form clones. In most cases, this will ensure that one is dealing with homogeneous populations of endosymbionts. However, double and triple infections have also been observed.

Polynucleobaeter necessarius is the only endosymbiont of *Euplotes* known so far that has been isolated. In this case, cells of strain 15 of *E. aediculatus* were homogenized mechanically, and the symbionts were then purified by applying the homogenate to an ECTEOLA column, followed by elution with phosphate buffer (Heckmann, 1975; Schmidt, 1982). The procedure basically followed the one developed for the isolation of kappa symbionts from *Paramecium* by Smith-Sonneborn and Van Wagtendonk (1964) and resulted in very clean preparations of symbionts.

Identification of the *Euplotes* Symbionts

The bacterial symbionts of *Euplotes* can be detected by direct observation with a phase contrast microscope, by observation of physiological effects produced on other *Euplotes* cells that lack symbionts, or by a combination of these methods. In the past, identification of symbionts of *Euplotes* has also been done using these methods. Now, at least for *Polynucleobacter necessarius*, formerly omikron particles, identification by FISH using appropriate oligonucleotide probes has become possible.

The Taxa of Prokaryotic Symbionts of *Euplotes*

GENUS *POLYNUCLEOBACTER* (HECKMANN AND SCHMIDT, 1987) These are obligate endosymbiotic bacteria living in the cytoplasm of freshwater ciliates of the genus *Euplotes*. Characterized by multiple nucleoids, these symbionts are essential for their host species and are nonmotile and Gram negative. The type species is *Polynucleobacter necessarius*.

Polynucleobacter was found to belong to the β-subclass of Proteobacteria and shows the closest relationship to *Alcaligenes eutrophus*, *Burholderia solanacearum* and *B. pickettii* (Springer et al., 1996).

Polynucleobacter necessarius *(Heckmann and Schmidt, 1987)* This species was formerly called "omikron." Cells are slightly curved rods, about 0.3 μm in diameter and 2.5–7.5 μm long. If stained with DNA-specific dyes, usually 3–9, but in some cases, up to 12 intensely stained and regularly spaced dots become visible (Fig. 19). They are considered to be nucleoids. When examined with the electron microscope, these nucleoids differ from those of most free-living bacteria by exhibiting an electron-dense central core that resembles the chromatin of eukaryotes (Fig. 20). Whether this core is formed by proteins associated with DNA or some other material is not clear (Heckmann, 1975).

The symbionts are individually contained in vesicles, to which ribosomes are often attached. *Polynucleobacter necessarius* reproduces by transverse binary fission in a typical bacterial manner. However, the fission products have often been found to differ in size. Frequently, a 7 μm long rod containing eight to nine nucleoids was observed to bud off a 2.5 μm piece that contained three nucleoids (Heckmann, 1975).

The G+C content of the DNA of *P. necessarius* is 48 mol% by thermal denaturation. A value that was 2.8 mol% lower was found when the G+C content was calculated from the buoyant density, which was 1.7036 g/cm^3 (Schmidt, 1982). The differences could be caused by rare bases; however, no DNA chemistry has been done for *P. necessarius*. The average DNA content of the symbiont was determined to be 5.8×10^{-3} pg. Taking into account the average number of nucleoids, a DNA content of 0.5×10^9 daltons per nucleoid was calculated. This value is in close agreement with the value of the kinetic complexity of the DNA, which was determined to be 0.57×10^9 daltons when corrected for the G+C content (Schmidt, 1982). Equally small genomes have been reported for *Lyticum flagellatum*, *Pseudocaedibacter conjugatus* and *P. falsus*, endosymbionts of the *P. aurelia* species complex (Soldo and Godoy, 1973a); for xenosomes of *Parauronema acutum* (Figueroa-de Soto and Soldo, 1977); and for chlamydias, rickettsias, and mycoplasmas (Bak et al., 1969). The genomes of these organisms are the smallest known for cells. They code for only about 700–900 proteins.

Heckmann (1975) has shown that it is possible to remove *P. necessarius* from *E. aediculatus* by treating a rapidly growing culture with penicillin (100–500 units/ml) for 5–6 days. Aposymbiotic hosts may undergo one or two fissions but then stop multiplying and die about 15–20 days after the last fission. The same results were obtained with several other antibiotics or with sufficiently high doses of X rays.

Reinfection and rescue of *E. aediculatus* have been achieved either by adding a cell homogenate from symbiont bearers or by injecting symbiont-containing cytoplasm (Heckmann, 1975; Fujishima and Heckmann, 1984a). The type strain is found in ATCC strain 30859 (clone 15 of *E. aediculatus*; see Heckmann and Schmidt, 1987).

THE OMIKRON-LIKE ENDOSYMBIONTS OF *EUPLOTES* These bacteria are very similar in appearance to *P. necessarius*. They were found in six freshwater *Euplotes* species (*E. eurystomus*, *E. plumipes*, *E. octocarinatus*, *E. patella* and *E. woodruffi*) all having a 9 type 1 fronto-ventral cirrus (FVC) pattern (9 FVC double dargyrome; Gates and Curds, 1979) like *E. aediculatus*, the bearer of omikron, and are considered to be closely related. The symbionts may differ from *P. necessarius* in size, shape, and other features, but they always share with *P. necessarius* the characteristic of multiple nucleoids (Heckmann et al., 1983b). Symbionts of this type, but about twice as large as *P. necessarius*, were first noticed by Fauré-Fremiet (1952) in stocks of *E. patella* and *E. eurystomus*. He also observed at that time that small doses of penicillin led to a loss of symbionts and to death of the host ciliates. He therefore suggested that the symbionts might be essential for survival of the ciliate. This was later confirmed when Heckmann et al. (1983b) subjected a large number of stocks of *Euplotes* species with a 9 type 1 cirrus pattern to a penicillin treatment of the kind that had earlier been found to remove *P. necessarius*. They found that all the ciliates stopped dividing and eventually died when their symbionts were removed. Heckmann et al. (1986) suggest that all *Euplotes* species with a 9 type 1 cirrus pattern suffer from a common deficiency that arose in a common ancestor of this group of organisms. This ancestor must have lived in symbiosis with a prokaryote that compensated for the acquired deficiency. *Polynucleobacter necessarius* and the omikron-like symbionts are considered to be progeny of this prokaryote.

SYMBIONTS OF *EUPLOTES* WITHOUT BINOMIAL NAMES As for the symbionts of *Paramecium*, many bacterial symbionts of *Euplotes* have not been given binomial names. For the time being, there is no information about their phylogenetic position. Nevertheless, they are included because they may be identified in further isolations by their host specificities and other distinct biological traits.

THE EPSILON SYMBIONTS OF *EUPLOTES* The epsilon symbionts from killer strains K_1, K_3, and K_7 of *E. minuta*, collected from the Mediterranean Sea at Villefranche-sur-Mer (France), were described by Heckmann et al. (1967). They are small rods, about 0.4 μm in diameter and 0.8–2.5 μm long, when observed in freshly crushed cells with bright phase optics, and appear somewhat darker than free-living bacteria. When the killer strain K_3 was fixed in Schaudinn's fluid, hydrolyzed in 1 N HCl, and stained with basic fuchsin, as described by Dippell and Chao in Sonneborn (1950), several dozen darkly stained bodies were found scattered in the cytoplasm. Their staining properties, size, shape, and cellular distribution resembled that of *Caedibacter* species and other endosymbionts of *Paramecium*. Since epsilon particles were found only in killer strains, it is assumed that they are responsible for the killer phenotype of *E. minuta*.

Siegel and Heckmann (1966) noticed that certain strains of *E. minuta* killed certain other strains of this species when conjugation occurred. It was found that the sensitive cells formed vacuoles, ceased their normal swimming movements, settled to the bottom of the culture vessel, and finally lysed. These changes occurred within 1–4 days after the strains had been mixed. No evidence for killing was observed when cells of the three killer strains were mixed together.

A good example of the difficulties encountered in the identification of endosymbionts is provided by the killer particles of stock VF_{17} of *E. minuta*. Heckmann et al. (1967) had noticed that this strain caused symptoms in sensitives slightly different from those observed in mixtures with the other *E. minuta* killers. Here, vacuole coalescence generally proceeded to the point where only one large vacuole was present in the posterior region of the sensitive, giving the whole affected organism a pear-shaped form. Nevertheless, no morphological differences between these symbionts and epsilon particles could be detected. Later, when stock VF_{17} was employed for cross-breeding experiments in a study of the genetic control of cortical pattern in *E. minuta* (Heckmann and Frankel, 1968), it was found that this stock not only killed sensitive strains via particles liberated into the medium, but also acted as a mate killer. From a pair of conjugants, one generally developed into a healthy looking exconjugant, whereas the other one failed to develop a large macronuclear anlage, became quiescent, and finally died. The surviving exconjugant clones had the same cortical pattern as stock VF_{17} and were all found to act as killers. They were therefore cytoplasmic descendants of the mate-killer parent. That they were true hybrids, i.e., that they had received a gametic nucleus from the sensitive partner, was shown from presence of certain genetic markers followed in these crosses. Whether VF_{17} was host

to a mixed population of symbionts—with one type responsible for the killer trait and the other one for the mate-killer trait, both types being so similar that they could not be distinguished morphologically from each other—or whether a single class of particles present in VF_{17} determined both traits cannot be decided. Both the killer trait and the mate-killer trait were lost concurrently with aging of the stock (Frankel, 1973).

THE ETA SYMBIONT OF *EUPLOTES* The eta symbiont, which was observed only by electron microscopy, is round or oval shaped with an average diameter of 0.9 μm. It is bound by three juxtaposed membranes. The outermost membrane has ribosomes attached to it. The interior of the symbiont is granular with a few scattered fibrous strands (Rosati and Verni, 1977). The symbiont was found in strains of *E. crassus* collected by Luporini (1974) from a site on the coast of Somalia on the Indian Ocean. It was named "eta" by Nobili et al. (1976), who investigated the killer trait conferred on its host by this symbiont. Sensitive testers, when exposed to the culture fluid of killer strains or to a homogenate prepared from cells of these lines, developed a large vacuole in the posterior part of the body within 6–24 hours. Affected cells are gradually transformed into transparent spheres that eventually "explode."

THE B_1 SYMBIONT OF *EUPLOTES* A symbiont very similar in morphology to eta appears to be responsible for the mate-killer properties of strain C_8 of *E. crassus* (Dini and Luporini, 1976); it was named "B_8." When cells of this strain were treated with penicillin, both the mate-killer trait and the symbiont disappeared. Dini and Luporini (1982) provided evidence for the existence of specific host genes required for maintenance of the B_8 particles.

INCONSPICUOUS SYMBIONTS OF *EUPLOTES* The other symbionts of *Euplotes* listed in Table 3 (A, B_3, C, D, and the unnamed ones) have been discovered by chance during electron microscopic investigations of certain strains. No special functions of these symbionts are known, nor have any effects of the symbionts on their hosts been reported. Interestingly, in two cases they have been observed in addition to omikron-like symbionts (Heckmann et al., 1983b; Petroni et al., 2001).

Ectosymbionts of *Euplotidium*

Peculiar ectosymbionts have been observed on the surface of the marine ciliate *Euplotidium itoi* (Fig. 21) and other species of the genus (Verni and Rosati, 1990). Though they have been studied in detail, their phylogenetic position remained obscure over years until their relationship to *Verrucomicrobia* was revealed (Petroni et al., 2000). It is the only ciliate symbiont belonging to *Verrucomicrobia*, while most symbionts of ciliates belong to the Proteobacteria. The authors found two morphologically different forms of the particles. At stage I of the life cycle, the organisms are spherical (1 μm in diameter; Fig. 22) and have a simple bacteria-like organization of their cell. These cells apparently divide by binary fission. Stage I epixenosomes may transform into stage II by gradually acquiring a more complex structure. Fully developed, stage II epixenosomes are larger (2.5 μm long) and egg-shaped (Fig. 23). They contain a sophisticated extrusive structure of a ribbon coiled around a central core surrounded by a basket built of bundles of regularly arranged tubules. The tubules have a number of features in common with eukaryotic microtubules (Rosati et al., 1993a). On top of the extrusive structure in the distal part of the cell body, an electrondense, dome-shaped structure lies underneath the cell membrane (Fig. 23). The dome-shaped structure contains DNA and basic proteins, and its ultrastructure resembles eukaryotic chromatin. The extrusive apparatus may be ejected upon appropriate stimuli (Rosati et al., 1993b).

Habitat and Biology of Epixenosomes of *Euplotidium*

The ciliate hosts of epixensomes, *Euplotidium itoi* and *E. arenarium*, were collected from tide pools along the rocky shore of the Ligurian Sea. As has been shown by Rosati, Verni and collaborators, epixenosomes have defensive function for the host cell (Rosati et al., 1999b). Predators such as the ciliate *Litonotus* easily ingested *Euplotidium* without epixenosomes, whereas they were not able to ingest *Euplotidium* with epixenosomes unless the ejecting capacity of the bacteria was inhibited.

Epixenosomes are arranged in a broad cortical band on the surface of host cells (Fig. 21). Individual bacteria appear fixed in cup-shaped indentations of the ciliate cortex. At these sites, the cortex of host cells is different in symbiont-bearing ciliates compared to symbiont-free cells (Verni and Rosati, 1990; Rosati, 1999a).

Identification of Epixenosomes of *Euplotidium*

While it appears easy to identify epixenosomes of *Euplotidium* as such by their unique site specificity, arrangement on the host cell, and ultrastructure, their phylogenetic position long remained obscure. Earlier attempts of classification of these organisms did not give definite results. Only by using a Eukaryotes forward primer and a backward primer designed for Archaea did amplification of the small ribsomal subunit (SSU) rRNA gene become possible (Petroni et al., 2000). A probe designed for part of the sequence labeled epixenosomes on the host *E. arenarium*.

The Xenosomes of *Parauronema acutum*

The term "xenosome" was coined by Soldo to denote the infectious particles that he found in the cytoplasm of the marine ciliate *Parauronema acutum* (Soldo et al., 1974c). They were later shown to be small bacteria that possess multicopy genomes and resemble *Caedibacter taeniospiralis* (kappa) and other cytoplasmic symbionts of *Paramecium* in many respects; see The Prokaryotic Symbionts of *Paramecium*. Two types of xenosomes were distinguished: killer xenosomes, which inhibit growth when taken up

by susceptible ciliates, especially those of the genus *Uronema* (Soldo and Brickson, 1978), and non-killer xenosomes (Soldo et al., 1987b). The xenosomes have not yet received binomial names.

Habitat of the Xenosomes of *Parauronema acutum*

Parauronema acutum is a small hymenostome marine ciliate that can be maintained axenically. The culture medium is basically that developed for species of the *Paramecium aurelia* complex by Soldo and Van Wagtendonk (1969), distilled water being replaced by seawater (density 1.015–1.026 g/ml) and modified to contain asolectin (500 μg/ml) as the sole source of lipid (Soldo et al., 1974c). The association with xenosomes is stable. Symbiont-bearing strains have now been maintained for more than 15 years.

Xenosomes released from host cells can infect symbiont-free strains of *P. acutum*. A single xenosome is capable of infecting a susceptible cell. However, a threshold of 100–200 xenosomes appears to be required before a single xenosome can infect a potential host (Soldo, 1983a). While phagocytosis is the usual way infectious bacteria enter host ciliates, Soldo and Brickson (1978) found that the symbionts in *Parauronema acutum*, termed "xenosomes" by those authors, penetrate the cell membrane at sites of the cortex other than the oral apparatus.

Soldo and coworkers measured the oxygen consumption of purified xenosome preparations and reported a rate of oxygen uptake of 1.3 nmoles O_2/min/mg of protein, which is higher than the oxygen uptake of *Bdellovibrio* and of the same order of magnitude as that of rickettsiae and *Caedibacter taeniospiralis*. Oxygen uptake is about 20 times lower than that of *E. coli*. The rate of oxygen consumption was found to be stimulated by various fatty acids, by intermediates of the glycolytic pathway, and by intermediates of the citrate cycle with the exception of citrate itself, which had no effect. Cyanide was found to be a potent inhibitor of oxygen consumption of xenosomes (Soldo, 1983a).

Isolation of Xenosomes from *Parauronema acutum*

Xenosomes can be isolated from *Parauronema acutum* by the same procedures as those used for the isolation of *Paramecium* symbionts (Soldo and Godoy, 1974b). It has been shown that killer xenosomes isolated in this way and purified with the help of Percoll gradients retain their ability to infect *P. acutum* and remain capable of killing sensitive *Uronema* strains (Soldo et al., 1986a). Results obtained from experiments in which isolated killer xenosomes lost their capacity to kill after they had been treated with various enzymes or had been coated with antibodies directed against the xenosomes indicate that the toxic principle of the xenosomes is a protein present at or near the surface (Soldo, 1987a).

Identification of Xenosomes from *Parauronema acutum*

These symbionts are rod-shaped, Gram-negative bacteria, 0.3 μm in diameter and 0.8 μm long. The G+C content of the DNA is 33.9 mol%. The symbionts occur in the cytoplasm of the marine ciliate *Parauronema acutum* in numbers ranging from 50 to 300 per cell. Negative staining reveals the presence of flagella, which provide the symbionts with a spinning and darting motility when released from the host (Soldo, 1987a). The xenosomes were found to contain inclusions in the form of helical arrays. These structures (called "H bodies") are about 0.6 μm long and 0.026 μm wide. They occur singly and in multiples and extend almost the entire length of the symbiont. The H bodies were found in over 50% of killer- and non-killer xenosomes (Soldo et al., 1987b).

The genome size of xenosomes was found to be only 515 kbp, which is much smaller than that of free-living bacteria. Analytical measurements and data from sedimentation rate analyses led to the conclusion that the chromosomal DNA exists in the form of nine circularly permuted double-stranded DNA molecules, each about 515 kbp in length (Soldo et al., 1983b). Both the small size and the multicopy nature of the genome are typical of bacterial symbionts rather than for free-living bacteria (Soldo and Godoy, 1973a; Soldo, 1987a).

Killer and non-killer xenosomes both contain plasmids (Soldo et al., 1986b; Soldo, 1987a). The non-killer plasmids consist of two circular DNA duplexes, each 63 kbp in length. The killer plasmid consists of four circular 63-kbp DNA duplexes. When a ciliate, which previously harbored killer xenosomes but had been freed of them, is infected with non-killer xenosomes, it becomes a killer. Soldo et al. (1986b) report that together with this transformation, the restriction pattern of the extrachromosomal DNA is altered. The mechanism by which this transformation takes place is unknown.

Prokaryotic Symbionts of Ciliates from Anaerobic Environments

Ciliates living in an anaerobic habitat, such as the rumen or sewage sludge rich in hydrogen sulfide,

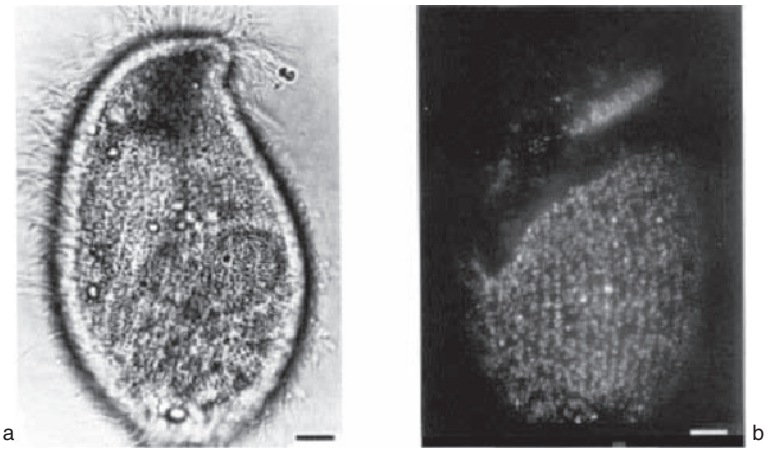

Fig. 24. *Metopus contortus* containing methanogenic endosymbionts: The methanogenic bacteria are located parallel to the kineties (ciliary rows) or the inner side of the cell. Cells are fixed with 1.2% formaldehyde and 0.3% glutaraldehyde. (a) Bright field micrograph. (b) Epifluorescence micrograph. Bars = 10 µm. From Van Bruggen et al. (1986).

show special adaptations. They usually lack mitochondria, bear hydrogenosomes, and are often associated with methanogenic bacteria (Finlay and Fenchel, 1989; Stumm and Vogels, 1989; Fenchel and Finlay, 1991a). It has been shown that anaerobic ciliates generate their energy by converting carbohydrates to lactate, acetate, and butyrate and that they can remove reducing equivalents in the form of H_2 (Müller, 1988). Production of H_2 by proton reduction involves the enzyme hydrogenase. However, this enzyme functions well only if the concentration of H_2 is kept low ($<10^{-5}$ atm). This requirement is apparently achieved by methanogenic bacteria, which consume H_2 and tend to be abundant in these habitats.

Habitat of Prokaryotic Symbionts of Ciliates from Anaerobic Environments

An episymbiotic association with methanogenic bacteria was described for 11 species of rumen ciliates of the family Ophryoscolecidae (Vogels et al., 1980). The attached bacteria were rods 0.9–3.8 µm long and 0.6–0.7 µm wide that occurred as clusters or long chains. The symbionts were identified as methanogens (probably *Methanobrevibacter ruminantium*) on the basis of specific fluorescent coenzymes (F_{350} and F_{420}; Figs. 24 and 25). Experiments with a fistulated sheep revealed a decrease of the association frequency of methanogenic bacteria with rumen ciliates when the hydrogen concentration in the rumen fluid increased and the reverse when hydrogen became scarce (Stumm et al., 1982). This is interpreted in favor of an interspecies transfer of hydrogen. The finding that rumen ciliates have hydrogenosomes, showing strong hydrogenase activity, supports this view (Yarlett et al., 1981). Stumm and Vogels (1989) propose that the attachment of hydrogen-consuming methanogens to rumen ciliates facilitates hydrogen

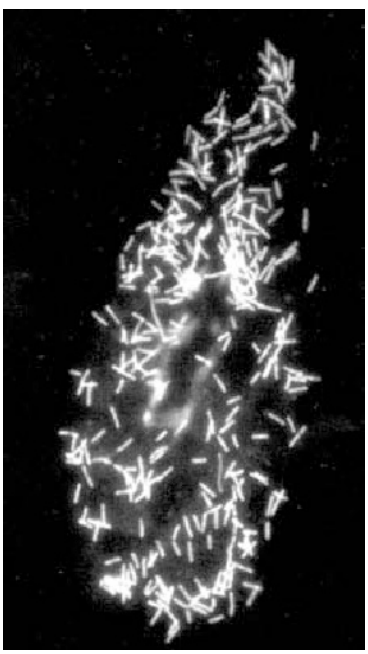

Fig. 25. Autofluorescence of endosymbiotic methanogens in *Metopus palaeformis*. From Finlay and Fenchel (1992).

removal, which is advantageous to both the ciliates and to their episymbionts. Fenchel and Finlay (Fenchel and Finlay, 1990; Fenchel and Finlay, 1991a), however, have argued that the symbiosis is not of great advantage for the ciliates, since the external hydrogen tension is low and diffusion pathways are very short, the problem being greater for the bacteria to get hold of the H_2 that is produced than it is for the ciliate to get rid of it. Fenchel and Finlay (1991) state that the presence of methanogens does not seem to be vital to the ciliates in any case that has been studied.

Episymbiotic bacteria have been known from sand-dwelling ciliates of anaerobic habitats for many years (Sauerbrey, 1928; Kahl, 1933; Kahl,

1935; Fauré-Fremiet, 1950b; Fauré-Fremiet, 1951). They are firmly attached to the cell surface and appear to differ in size, shape, pigmentation, and wall structure from species to species (Fenchel et al., 1977; Fenchel and Finlay, 1991a). Fauré-Fremiet (1950a) carried out a study of the symbionts of two species of the genus *Kentrophoros* (formerly *Centrophorella*). He investigated their symbionts and found them to be attached to the nonciliated dorsal side of these ribbon-shaped ciliates. The oblong symbionts were densely packed and protruded perpendicularly, so that they appeared like bristles of a brush. They were Gram-negative, nonmotile rods, and were observed to divide by longitudinal fission. Besides containing rather large quantities of polysaccharides (indicated by iodine treatment), they contained dark refractive sulfur globules, so that the host appeared black. The dark pigmentation is a strong indication that the symbionts are purple sulfur bacteria (Chromatiaceae). Fauré-Fremiet, who found the symbionts exclusively on the ciliates and neither on accompanying sand grains nor on glass slides that had been in the sand in which these ciliates lived for several days, considered the symbionts as obligately episymbiotic. Electron microscope studies by Raikov (Raikov, 1971; Raikov, 1974) confirmed Fauré-Fremiet's observations and led to the discovery that the episymbiotic bacteria are phagocytized. He studied *Kentrophoros fistulosum* and *K. latum* and found that these ciliates take up the episymbiotic bacteria by pseudopodia-like cytoplasmic protrusions and enclose them in food vacuoles. This may occur at any place on the nonciliated body side of these ciliates, which have no special mouth structures. The unique form of phagocytosis discovered in these species has been named "random phagocytosis." Based on the content of the food vacuole of these ciliates, their epizoic bacteria appear to be their main nutrition source. Fourteen *Kentrophoros* species are now known. They all live in the interstices of sandy marine sediments.

Fenchel et al. (1977) examined marine sediment-dwelling ciliates for cytochrome oxidase activity and for fine-structural details. They found that many of the ciliates of this habitat lacked cytochrome oxidase activity and mitochondria but contained microbodies that were identified as hydrogenosomes (Van Bruggen et al., 1986). In addition, these ciliates harbored a species-specific flora of epi- and endosymbiotic bacteria. Large numbers of symbionts per cell were observed, ranging from about 1000 bacteria per ciliate, corresponding to less than 1% of the host's biomass, to about 100,000 bacteria per ciliate, corresponding to about 20% of the ciliate's biomass. Some of these anaerobic ciliates were found to contain both epi- and endosymbionts, and often more than one type of episymbiont was recognized. Fenchel et al. (1977) hypothesized that the bacteria and the ciliates interact metabolically.

Anaerobic conditions also exist in sediments that are rich in decaying plant material, such as those of freshwater ponds, lakes, ditches and swamps. This habitat, also called "Faulschlamm" in German, was named "Sapropel" by Lauterborn (1901). Endosymbiotic bacteria in sapropelic ciliates were first described by Fauré-Fremiet (1909). Later, Liebmann (Liebmann, 1937; Liebmann, 1938) noted that all the sapropelic ciliates that he investigated contained rod-like bacteria in their cytoplasm. In recent years, this habitat was thoroughly investigated (Stumm and Vogels, 1989; Fenchel and Finlay, 1991a; Hackstein and Stumm, 1994), and it is now, next to the rumen, the best-studied anaerobic habitat. It is inhabited by large numbers of anaerobic protozoa and methanogenic bacteria. A survey of sapropelic ciliates by means of fluorescent microscopy revealed the presence of methanogenic bacteria inside the cells; they were spread throughout the cytoplasm in considerable quantities (Van Bruggen et al., 1983).

Electron microscopic investigations of sapropelic ciliates revealed the absence of mitochondria and the presence of microbodies. Because the bacteria were found to consume hydrogen, it has been hypothesized that the symbiont-associated microbodies are hydrogenosomes (Van Bruggen et al., 1986). In *Metopus striatus*, a Gram-positive rod-shaped bacterium was regularly found to be in close association with a hydrogenosome consisting of a granular matrix surrounded by a membrane (Van Bruggen et al., 1984). The bacterium was isolated and identified as *Methanobacterium formicicum*. A similar or even closer association of hydrogenosomes and methanogenic bacteria is reported for *Metopus contortus* (Van Bruggen et al., 1986; Finlay and Fenchel, 1989; Fig. 26), *Plagiopyla nasuta* (Goosen et al., 1988) and *Plagiopyla frontata* (Embley and Finlay, 1994). A direct proof was provided by Zwart et al. (1988), who demonstrated hydrogenase activity in microbodies of *Plagiopyla nasuta* and *Trimyema compressum*. Whereas methanogens are tightly packed with hydrogenosomes in ciliates such as *M. contortus* and *Plagiopyla frontata* (Fig. 27) and *Trimyema* species (e.g., Finlay and Fenchel, 1989; Fenchel and Finlay, 1991a), the long methanogens found in *Metopus palaeformis* are not closely associated (Finlay and Fenchel, 1991; Fig. 28). Symbionts in this ciliate appear to divide simultaneously and growth rates of ciliates and methanogens are approximatly equivalent (Fenchel and Finlay, 1991b; Finlay and Fenchel, 1992). A comparison of the phylogenetic diversity of

endosymbiotic methanogens and anaerobic ciliates revealed that symbioses have formed repeatedly and independently (Finlay et al., 1993; Embley and Finlay, 1994) with endosymbionts from the genus *Methanobacterium* and from the Methanomicrobiales. The authors found no congruence between the host and endosymbiont trees and thus no evidence of parallel speciation. Congeneric hosts in the genus *Plagiopyla* and *Metopus* contain endosymbionts which are more closely related to free-living methanogens than to each other (Embley and Finlay, 1994).

While many marine anaerobic ciliates have endosymbiotic methanogens, ectosymbiotic bacteria that are often found in addition to the endosymbionts are never methanogens (Fenchel et al., 1977). Fenchel and Finlay (1991) assumed that the ectosymbionts are sulfate-reducing bacteria. Epibiotic bacteria have been reported also on the peritrichous ciliate *Zoothamnium niveum* collected in about 0.5–2.0 m depth on the vertical walls of a tidal channel cut into mangrove peat off the island of Twin Cays (Belize Barrier Reef, Carribean Sea; Bauer-Nebelsick et al., 1996a; Bauer-Nebelsick et al., 1996b). The association appeared to be obligatory (the ciliate being unable to survive without its symbiont), and it was also shown that oxygen and sulfide were

needed simultaneously. The white color of the bacteria is assumed to represent inclusions of elemental sulfur used as storage within the sulfide-oxidizing process. The bacteria were proven to be autotrophic. Epibiotic bacteria have been reported for a number of different species of *Zoothamnium* (cited in Bauer-Nebelsick et al., 1996a) but have not been further investigated.

Isolation of Prokaryotic Symbionts of Ciliates from Anaerobic Environments

For enrichment and culture of sapropelic ciliates, samples from anoxic natural sediments are introduced into mineral media under reducing conditions. Two media which have successfully been used for this purpose are given by Wagener and Pfennig (1987). They also reported the first monoxenic large-scale culture of an anaerobic ciliate. They enriched the ciliate *Trimyema compressum* from anoxic mud samples and then established a pure culture. The ciliate was fed with a bacterial strain isolated from the enrichment culture that proved capable of serving as food. During continued cultivation, *T. compressum* gradually lost its endosymbionts.

An isolation method for methanogenic bacteria from sapropelic ciliates has been described by Van Bruggen et al. (1986): A small number of ciliates is collected with a pipette and is washed free of potential contaminants in an isolation medium under a dissection microscope. The microscope is covered with a plastic hood flushed with nitrogen. The ciliates are then homogenized in an anaerobic glove box. The homogenate with the symbionts is plated on solid isolation medium containing penicillin G or lysozyme, which does not affect methanogenic bacteria. The homogenate is incubated at 22–37°C under an atmosphere of H_2/CO_2 (80/20). In liquid media, growth can be followed by measuring the methane production.

Identification of Prokaryotic Symbionts of Ciliates from Anaerobic Environments

The symbionts of several sapropelic ciliates have been identified as methanogenic bacteria. The endosymbionts of species of the ciliate *Metopus* (Fig. 24) were first recognized to be methanogens by their autofluorescence when irradiated with short-wavelength blue light (Van Bruggen et al., 1983; Van Bruggen et al., 1986). According to Doddema and Vogels (1978), epifluorescence microscopy can detect the presence of the deazaflavin coenzyme F_{420} and the pterin compound F_{342}, both of which are specific for methanogens. The methanogenic character of the endosymbionts has subsequently been proven by studies of the isolated symbionts and measurements of their methane production in situ. The symbionts were finally identified as *Methanobacterium formicicum* (Van Bruggen et al., 1984). The methanogenic symbionts of *Plagiopyla nasuta* were also identified as *M. formicicum* (Goosen et al., 1988). This is a bacterium that often occurs in the sapropel; it is a slender, nonmotile rod, with a diameter of 0.4 μm and a length of 2–7 μm. It was identified by colony form, cell morphology, temperature and pH optimum, substrate specificity, DNA base composition, and type of coenzyme F_{420}. It appears likely that *M. formicicum* is preadapted for endosymbiosis, because symbiont-free lines of the ciliate *Trimyema compressum* could also successfully be infected with this bacterium (Wagener et al., 1990).

Methanoplanus endosymbiosus was isolated from the marine ciliate *Metopus contortus* (Van Bruggen et al., 1986). In liquid media, the isolated bacteria were irregular, nonmotile, nonsporeforming discs with a diameter of 1.6–3.4 μm. In a side view, they appeared as rods that were sometimes branched. The symbionts were osmotically fragile and lysed immediately when suspended in water. Growth and methanogenesis were observed with H_2/CO_2 or formate as substrates, with generation times of 7 or 12 h, respectively. The temperature range from growth was between 16 and 36°C, with an optimum at 32°C. The optimal pH range for growth was 6.8–7.3. Tungsten and NaCl at a concentration of 0.25 M were required for optimal growth. The G+C content of the DNA is 38.7 mol%.

For detecting methanogenic endosymbionts, epifluorescence microscopy proved to be a powerful method. Even when symbionts are inside cells, their blue autofluorescence may be visible. Endosymbionts that fluoresce have been observed in the sapropelic ciliates *Brachonella spiralis*, *Caenomorpha medusula*, *C. universalis*, *Lacrymaria cucumis*, *Metopus es*, *M. laminarius* (Van Bruggen et al., 1983), *Parablepharisma pellitum*, *Metopus palaeformis* and others (Fenchel and Finlay, 1991b). They have not been found in ciliates from aerobic habitats.

CHAPTER 2.3

Bacteriocyte-Associated Endosymbionts of Insects

PAUL BAUMANN, NANCY A. MORAN AND LINDA BAUMANN

Introduction

Intracellular associations between bacteria and insects are widespread in nature (Baumann and Moran, 1997; Buchner, 1965; Dasch et al., 1984; Douglas, 1989; Houk and Griffiths, 1980). Extensive studies of the natural history of such associations have led to the conclusion that they are commonly found in insects that utilize diets containing an excess of one class of compounds but a deficiency of some essential nutrients (Buchner, 1965; Dadd, 1985). It was thought that the function of the endosymbionts was to rectify this imbalance by the synthesis of these essential nutrients for the host. Extensive compilations of the occurrence of endosymbionts in different groups of insects are found in Buchner (1965) and Dasch et al. (1984). Because most of the prokaryotes involved in such associations are not cultivable on common laboratory media, their characterization had to await the development of recombinant DNA methodology. The past 10 years have witnessed the initiation of studies on the intracellular association of prokaryotes with a variety of insect hosts. In this chapter we will provide an overview of the evolution, and where possible, genetics and physiology of such recently studied associations. A summary of some of their features is presented in Table 1, and the phylogeny of the endosymbionts based on 16S rDNA is presented in Fig. 1.

The diversity of symbiotic associations and problems of definitions have been previously discussed and will not be considered here (Smith and Douglas, 1987; Werren and O'Neill, 1997). Some of the phylogenetic studies have included few host taxa and are thus not entirely conclusive; nevertheless, current results suggest that most of the associations considered in this chapter have common features and represent a relatively well-defined type. To aid presentation we will describe these common features, which are established from recent, largely molecular, studies as well as from older investigations based on morphological analyses. References to the earlier studies are found in Buchner (1965), who arrived at similar conclusions. References to recent studies are given as each association is considered.
