CHAPTER 6.2

The Genus *Porphyromonas*

FRANK C. GIBSON AND CAROLINE ATTARDO GENCO

Introduction

Members of the genus *Porphyromonas* are characterized by the production of porphyrin pigments. The genus *Porphyromonas* was recognized as a separate taxon on the basis of ribosomal RNA homology and 16S rRNA data (Olsen et al., 1999). The most extensively characterized species of the genus is *Porphyromonas gingivalis* (a Gram-negative anaerobe), which has been long considered an important pathogen associated with human periodontal disease. Periodontal diseases comprise a group of inflammatory diseases of the gingiva and supporting structures of the periodontium. They (the most common of the destructive oral inflammatory diseases) are characterized by the bacterially initiated conversion of a healthy gingival region to one that is inflamed (gingivitis) and by the destruction of the supporting structures of the teeth (periodontitis). While a large number of different bacterial species exist in the periodontal environment, it is now recognized that the large number of bacteria (bacterial load) per se does not result in the biological progression from health to periodontal disease. Rather the establishment and growth of a very few of the more than 300 proposed different bacterial species resident in the subgingival niche are apparently periodontopathic (Holt et al., 2000), and these include *Fusobacterium nucleatum*, *Bacteroides forsythus*, *Prevotella intermedia*, *Treponema denticola* and *P. gingivalis*. *Porphyromonas gingivalis* is essentially absent during periodontal health, but during disease progression to periodontitis, can reach a very significant percentage of the pathogenic microbiota. Eradication of *P. gingivalis* from the subgingival microbial population correlates with resolution of the disease (Moritz et al., 1998).

Description of the Genus

The twelve species of the genus *Porphyromonas* have been isolated from the oral cavities of humans, dogs, cats, and nonhuman primates. More than likely, members of the genus are also associated with a large number of other warm-blooded animals. These organisms were originally classified in the genus Bacteroides, which is phylogenetically closely related (Fig. 1). Members of the genus are obligatorily anaerobic, nonsporeforming, nonmotile rods (0.5–0.8 by 1.0–3.5 μm; Table 1). They have also been described as cocco-bacilli depending on their stage of growth when they are examined. Characteristic of the genus is the production of large amounts of cell-associated protoheme. The major fermentation end products of growth on complex carbohydrates (except in the case of asaccharolytic *P. gingivalis*) and proteins are n-butyrate, propionate and acetate. These end-products account for much of the malodor associated with oral infections. Small amounts of isovalerate, isobutyrate, succinate and phenylacetate are also produced. While several of the strains (i.e., *P. gingivalis* and *P. macacae*) possess significant proteolytic activity, the other strains are relatively nonproteolytic.

Porphyromonas gingivalis is a nonmotile, asaccharolytic, obligatory anaerobic coccobacillus exhibiting smooth, raised colonies. When grown on a blood agar surface, the colonies are initially white to cream colored. With time (4–8 days), these colonies darken from their edge towards the center to a deep red to black color, which correlates with the concentration of protoheme. The species produce a large number of enzymes, which are active against a broad spectrum of host proteins. *Porphyromonas gingivalis*-derived proteinases can cleave a number of host defense molecules, including proteinase inhibitors, immunoglobulins, iron-containing proteins, bactericidal proteins, extracellular matrix proteins, and proteins intimately involved in phagocytic functions, such as complement fixation (Holt et al., 2000). Recent studies using molecular and immunological approaches have revealed that most of the *P. gingivalis* enzymatic activity is due to the production of cysteine proteinases (see section on Gingipains in this Chapter). Metabolically, the ability of *P. gingivalis* to secrete these cysteine proteinases in a host provides it with

distinct advantages for its survival and growth, including the ability to use host proteins for its growth and metabolism. Since these proteinases cleave both synthetic and host proteins after arginine and lysine residues, their growth is significantly enhanced in the presence of protein hydrolysates (trypticase, proteinase peptone, and yeast extract). *Porphyromonas gingivalis* produces a variety of virulence determinants, which include capsules, fimbriae, lipopolysaccharides, outer membrane proteins, and proteinases. Although these virulence molecules have been extensively described in vitro, their function within the confines of a host remain to be definitively determined.

Significance

Periodontal diseases represent a group of chronic inflammatory diseases of the gingiva and supporting periodontal tissues. Next to dental caries, periodontal disease is one of the most common oral diseases of mankind, and like caries, is initiated by bacterial infection. Although the effect of periodontal health (loss of dentition) on general human health has previously been regarded as a quality of life issue, recent epidemiological data, case studies, and initial scientific observations have begun to challenge this presumption. These studies suggest that periodontal disease may represent a significant risk factor for serious diseases such as cardiovascular and cerebrovascular disease (Beck et al., 1998b; Morrison et al., 1999), as well as potentially being an important cause of pre-term birth in pregnant women (Dasanayake et al., 2001; see section on Systemic Complications of Periodontal Disease in this Chapter). Should future basic research studies confirm these epidemiological associations and indeed demonstrate the causative or exacerbative relationship of periodontal disease and these more severe human diseases, additional studies will be necessary to provide a mechanistic understanding of the processes governing this association. This should ultimately lead to the development of novel prophylactic strategies to prevent the establishment of periodontal disease, such strategies lessening the present dependence on therapeutic strategies to control progression of disease following clinical recognition.

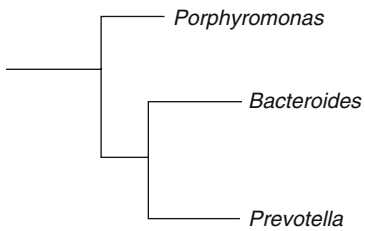

Fig. 1. Phylogenetic relationship of the genus *Porphyromonas* to other members of the family Bacteroideaceae.

Habitats

The oral cavity is a unique anatomical site in the body. It is composed of multiple epithelial and mucosal surfaces, as well as calcified hard tissues. These tissues are constantly bathed by the saliva, a broth of glandular secretions in which variable levels of microorganisms and food particles are suspended (Fig. 2). The gingival sulcus, a 0.5 mm deep crevice (in healthy subjects) between the tooth and the gum, is the portal of entry and

Table 1. The genus *Porphyromonas*.

Classification	Site	Comments
P. asaccharolytica	Periodontal pocket	Type strain for the genus
P. cangingivalis	Subgingival plaque	Periodontal disease in dogs
P. canoris	Subgingival plaque	Periodontal disease in dogs
P. cansulci	Subgingival plaque	Periodontal disease in dogs
P. catoniae	Gingival crevice	Healthy and diseased human gingiva
P. circumdentaria	Gingival margins of mouth	Diseased sites in cats
P. crevioricanis	Gingival crevicular fluids	From beagles
P. endodontalis	Acute periapical	Human abscess
P. gingivalis	Gingival sulcus	Generalized aggressive periodontitis
	Tongue	Periodontal abscesses
	Cheek	Periapical abscesses
	Saliva	
P. gingivicanis	Gingival crevicular fluids	From beagles
P. gulae	Gingival sulcus	From various animal hosts
P. levii	Foot rot lesion	Steer
P. macacae	Periodontal pocket	Nonhuman primate
P. salivosa	Periodontal pocket	Isolated form cat

From Love et al., 1992; Love et al., 1994; M. D. Collins et al., 1994; Hirasawa and Takada, 1994; Paster et al., 1994; Willems and Collins, 1995; Fournier et al., 2001.

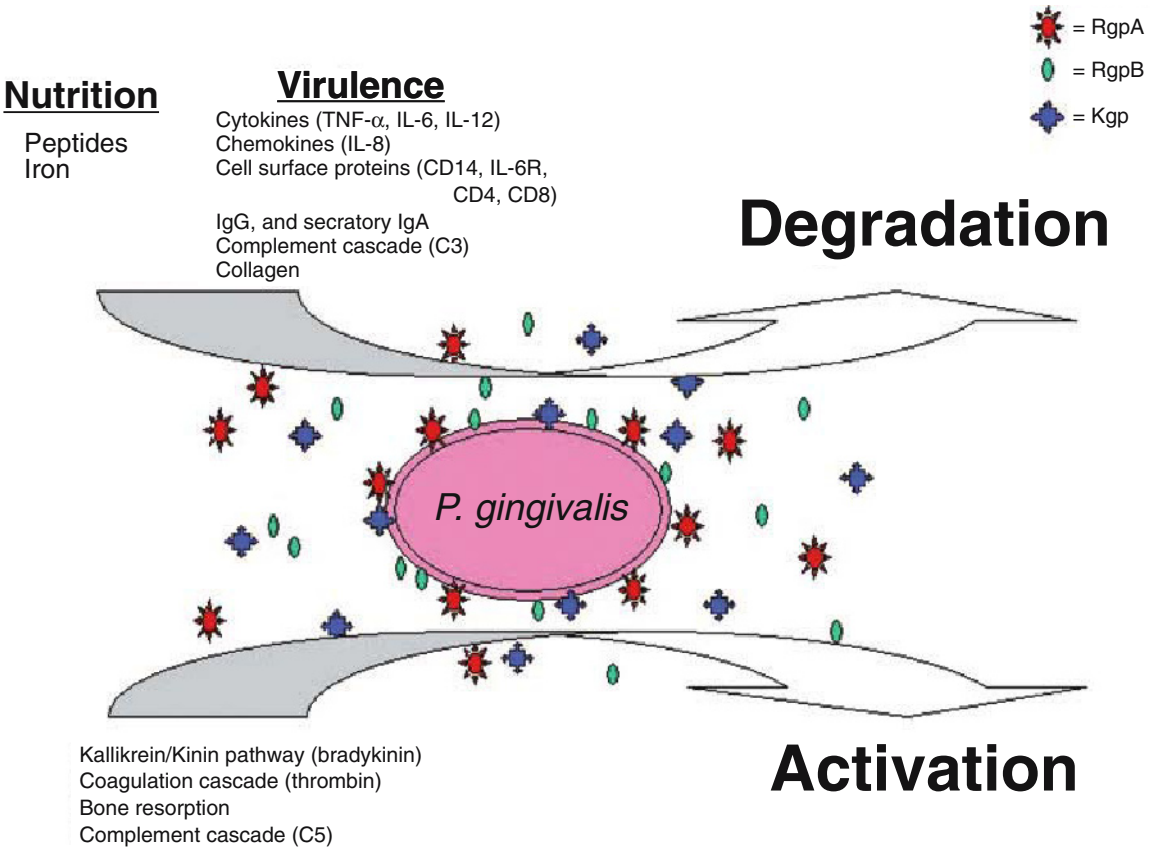

Fig. 2. Differences between a healthy periodontium and a site with generalized aggressive periodontal disease. Healthy site (on left). Site with generalized aggressive periodontal disease (on right). In a healthy site, the subgingival microflora is comprised predominantly of Gram-positive bacteria, although low numbers of Gram-negative bacteria such as *P. gingivalis* may be recovered from periodontally healthy people. There is an intact tooth attachment apparatus with numerous attachment fibrils, few inflammatory cells, and normal levels of alveolar bone. The shift to generalized aggressive periodontal disease results in a change in the composition of the subgingival microflora from predominantly Gram-positive bacteria to predominantly Gram-negative bacteria and the isolation of *P. gingivalis*. There is a subsequent host inflammatory response to the elevated levels of *P. gingivalis* in the gingival sulcus that is characterized by an increase in neutrophils (acute lesion) and mononuclear cells (chronic lesion) at the infected site. Additionally there is loss of the tooth attachment apparatus including loss of attachment fibrils with subsequent erosion of alveolar bone. In severe cases of periodontal destruction, exfoliation of teeth can occur. Emerging data support that *P. gingivalis* invades the tissues subjacent to the gingival sulcus and bacteremia occurs, and this may be related in part to the epidemiological associations of periodontal disease with accelerated cardiovascular disease and preterm-births.

niche for a unique bacterial ecosystem composed of highly adapted microorganisms, most notably *P. gingivalis*. *Porphyromonas gingivalis* appears to colonize solely subgingival sites of the oral cavity but has also been recovered from the tongue, tonsils, saliva, and supragingival dental plaque samples (Socransky and Haffajee, 1992). *Porphyromonas gingivalis* constitutes less than 5% of the cultivable subgingival flora of individuals with gingivitis, but its numbers can increase dramatically in advanced periodontal disease. Since *P. gingivalis* is recovered almost exclusively from disease sites, its primary source of infection remains unknown. Likewise the precise mechanism by which *P. gingivalis* enters the human oral cavity and becomes established within the oral mucosa is not well defined. Evidence indicates that *P. gingivalis* is largely an opportunistic pathogen. Although studies support the transmission of *P. gingivalis* by intimate contact, they do not indicate that transmission results in disease. In addition, data do not exclude the possibility that pathogenic strains have virulence factors that are not present in colonizing healthy individuals. Transient changes in the host immune response and the indigenous microflora may be important cues to *P. gingivalis* to produce a set of factors that are required for pathogenesis (Forng et al., 2000). In addition, the ability of *P. gingivalis* to colonize periodontal sites appears to correlate with the ability of the organism to obtain nutrients for growth and with the anaer-

obic microenvironment within this site (see section on Hemin Acquisition in this Chapter).

Porphyromonas gingivalis encounters a series of obstacles, which are aimed at exclusion of the organism, during colonization of the gingival pocket and include antimicrobial effects of saliva, competition for attachment sites by the antecedent microbiota of the dental plaque, the physical barriers of the gingival environment, as well as the host immune response to this organism. Previous work has demonstrated that *P. gingivalis* can bind to other bacteria as well as saliva-coated hydroxyapatite particles via fimbriae and thus gain a foothold in the oral cavity and the gingival sulcus. Additionally, fimbriae are important in promoting *P. gingivalis* attachment to, and subsequent invasion of, gingival epithelial cells (see section on Fimbriae in this Chapter).

Isolation and Identification

The isolation and identification of the bacterial pathogens associated with periodontal disease have been complicated by the large number of bacterial species (more than 300) present in the oral environment (Holt et al., 2000). Despite this complexity, only a few are clinically associated with this disease, and *P. gingivalis* is the predominate organism associated with generalized aggressive periodontal disease. The genus *Porphyromonas* is a member of the family Bacteroideaceae. Members of this family are obligatory anaerobic, nonmotile, nonsporeforming and Gram negative. The porphyromonads can be distinguished from other members of the family Bacteroideaceae by black-pigmented colonies that develop from cream-colored colonies during growth on blood agar plates, a consequence of storing iron on the surface of these bacteria in the form of protoheme (Shah et al., 1979). Colonies are shiny, convex with smooth edges that appear wet, and slightly mucoid. Proteins constitute the primary source of metabolic energy for members of the genus *Porphyromonas*. *Porphyromonas gingivalis* is an aerotolerant, asaccharolytic member of the genus. Saccharolytic members (including *P. levii* and *P. macacae*) weakly ferment glucose, lactose and/or mannose. The major long chain fatty acid produced by the genus *Porphyromonas* is *iso*-$C_{15:0}$, and the G+C content is 46–54 mol% (Olsen et al., 1999). Isolation of *Porphyromonas* from dental plaque was previously routinely performed on vancomycin-kanamycin blood agar plates. More recently, a selective medium containing colistin, bacitracin and nalidixic acid has been developed for isolation of *P. gingivalis* (Hunt et al., 1986).

Clinical Diagnosis of Periodontal Disease

Following bacterial colonization of the host, the first phase of periodontal disease is characterized by gingivitis (i.e., the conversion of healthy gingival tissue to inflamed tissue). Progression from gingivitis to periodontal disease is determined by several factors including erosion of the supporting attachment apparatus of the teeth and loss of osseous tissue. Assessment of periodontal disease is primarily defined radiographically and by assessment of the degree of tooth attachment loss using a periodontal probe. In severe cases of periodontal disease early loss of dentition can occur. Recently, a reclassification of the various forms of periodontal diseases of humans has been performed on the basis of sets of defined clinical definitions (Armitage, 1999). Previous classification schemes of periodontal disease were inadequate and consisted of classifications such as early onset (juvenile) periodontitis (EOP) including localized juvenile periodontitis (LJP; etiological agent, *Actinobacillus actinomycetemcomitans*) or adult periodontal diseases including rapidly progressive periodontal disease (RPP; etiological agent, *P. gingivalis*); however, it was recognized that the temporal aspects of these conditions were usually not known to the clinician. The new classification scheme consists of the major headings: I. Chronic Periodontitis; II. Aggressive Periodontitis; III. Periodontitis as a Manifestation of Systemic Diseases; IV. Necrotizing Periodontal Disease; and V. Periodontitis Associated with Endodontic Lesions. Thus, previous classification of LJP is now localized aggressive periodontitis, and the classification of RPP is either generalized aggressive periodontitis or chronic periodontitis (Armitage, 1999). This new classification scheme will provide defined criteria on which to base detailed experimental studies into the precise etiology, pathogenesis and treatment regimens for periodontal disease.

Localized and generalized forms of both chronic and aggressive periodontal disease exist. Localized forms typically involve <30% of the sites, while generalized periodontal disease involves 30% of the sites. A severity index based on the observed amount of attachment loss (slight [1–2 mm], moderate [3–4 mm], or severe [5 mm]) can be applied in each case. Periodontal lesions of patients with generalized aggressive periodontal disease present with a predominately neutrophilic cellular infiltrate in the early stages of disease. Interestingly, the cellular composition of a chronic lesion is predominantly monocyte-rich and consists primarily of B cells, plasma cells and T cells. Commonly, a flow-rate

increase is observed in the gingival crevicular fluid (a plasma-derived fluid).

Patients with HIV commonly present with oral infections, and certain lesions such as oral candidiosis or hairy leukoplakia play a part in the diagnosis and staging of HIV infection (Greenspan and Greenspan, 1996). Additionally, severe periodontal infections such as necrotizing ulcerative periodontitis though rare in healthy people are observed in 6–10% of people with significant HIV-related infection. Although the specific immune defect during HIV infection that mediates the acceleration of periodontal disease is not known, it is speculated that the deficiency in T helper cell-mediated immunity plays a significant role in the establishment of necrotizing ulcerative periodontitis (Greenspan and Greenspan, 1996). The specific impact of HIV infection on more aggressive forms of *P. gingivalis*-mediated periodontal disease is yet to be determined.

Because the immune response is important in controlling infectious disease, understanding the impact of immunosuppression on periodontal disease is important. Organ transplant recipients receive chemical immunosuppressive drugs such as cyclosporin or nifedipine to prevent tissue rejection. A common side effect of cyclosporin therapy is gingival enlargement (in up to 30% of patients). However, the effect of cyclosporin-mediated immunosuppression on accelerated periodontal disease is contentious, as both acceleration and protection from periodontal breakdown have been reported (Thomason et al., 1994). Similarly, cancer therapy may exacerbate periodontal infections. High levels of radiation adversely affect the periodontium by involving blood vessels to the periodontium and the periodontal ligament, thus limiting vascular flow and affecting bone repair. Furthermore, irradiated teeth suffer from greater attachment loss than do non-irradiated teeth. Additionally patients with certain types of leukemia that receive chemotherapy and present with neutrophil dysfunction or neutropenia commonly present with a highly attenuated inflammatory response and limited soft tissue healing (Epstein and Stevenson-Moore, 2001).

Treatment of Periodontal Disease

Gingivitis and periodontal disease are the two most common forms of inflammatory diseases of the periodontium. Gingivitis is a reversible disease that commonly can be treated by improving the patient's daily plaque control, as well as regularly scheduled professional cleaning. For patients with periodontal disease, the treatment regimen is significantly different, and commonly the therapy often must be tailored to each individual case on the basis of pattern of attachment loss, local anatomical differences, and type of periodontal disease (Research, Science and Therapy Committee of the American Academy of Periodontology, 2001). Therapy for patients with chronic periodontal disease is aimed at reducing the factors responsible for eliciting the breakdown of the periodontium. This includes scaling (removal of the buildup of dental calculus in the periodontal pocket) and root planing (smoothing of the root surface to promote epithelial reattachment and healing); antimicrobial chemotherapy and surgery to correct the defects and promote tooth attachment and bone regeneration. Scaling and root planing, combined with personal plaque reduction measures, have been shown to be effective for the control of periodontal disease, particularly by shifting the composition of the subgingival microflora from one consisting of Gram-negative anaerobic organisms such as *P. gingivalis* to one more closely associated with periodontal health (Magnusson et al., 1984), reducing clinical measures of inflammation, as well as promoting clinical attachment and decreasing probing depths. However, not all sites infected with *P. gingivalis* respond to scaling and root planing, particularly deep periodontal pockets. In these cases, additional modes of therapy should be used. Other therapies that show promise include the use of growth factors, matrix proteins, and stimulators of bone morphogenesis. The primary goal of all surgical therapy is to significantly decrease the microbial burden and provide an environment to restore periodontal attachment and regeneration of lost tissue. The primary risk factor that complicates the potential benefits of surgical therapy is tobacco use (Haber et al., 1993). Other factors can also complicate the intervention process and include host factors such as diabetes.

Commonly, antimicrobial chemotherapy is incorporated into the clinical treatment regimen of periodontal disease and includes both local and/or systemic therapy. Those antibiotics most commonly used are highly effective against Gram-negative anaerobic organisms (*P. gingivalis*, *B. forsythus* and *P. intermedia*) and include metronidozole and tetracycline. More recently, nonsteroidal, anti-inflammatory drugs such as flurbiprofen, ibuprofen and naproxen have shown benefits in reducing loss of alveolar bone, the osseous tissue supporting the tooth. In addition, subantimicrobial doses of doxycycline regimen have also been shown to be effective in treatment of periodontal disease. In 2000, the United States Food and Drug Administration (FDA) approved the systemic collagenase inhibitor therapy consisting of 20 mg of doxycycline hyclate as an adjunct to scaling and root planing;

however, only limited improvement in periodontal status has been reported (Research, Science and Therapy Committee of the American Academy of Periodontology, 2001). Local delivery of antibiotics has also been shown to be beneficial for periodontal therapy, as the antibiotic is delivered directly to the diseased site at bactericidal levels. The FDA has approved several local delivery systems including ethylene vinyl acetate fiber with tetracycline, a gelatin chip with chlorohexidine, a polymer with minocycline, and a bioabsorbable gel containing doxycycline hyclate (Research, Science and Therapy Committee of the American Academy of Periodontology, 2001).

Porphyromonas gingivalis Virulence Factors

Fimbriae

With only one or two exceptions, all of the *P. gingivalis* strains so far examined contain fimbriae arranged in a peritrichous fashion over the surface of the cell (Handley and Tipler, 1986; Fig. 3). These structures have been isolated, purified and examined both chemically and structurally (Sojar et al., 1991; Yoshimura et al., 1993; Lee et al., 1995). The gene encoding the *P. gingivalis* fimbriae (*fimA*) is resident on the chromosome as a single copy, and all *P. gingivalis* strains so far examined contain the gene (Dickinson et al., 1988; Takahashi et al., 1992; Fujiwara et al., 1993; Sharma et al., 1993; Washington et al., 1993). The *P. gingivalis* fimbriae are not related to fimbriae produced by other black-pigmented Bacteroides species or to most of the other Gram-negative prokaryotes. Different *P. gingivalis* strains produce fimbriae that are heterogeneous with respect to antigenicity, molecular weight of the fimbrillin subunit, N′-terminal sequence of the fimbrillin protein, and DNA sequence (Yoshimura et al., 1984; Yoshimura et al., 1985; Lee et al., 1991; Ogawa et al., 1991; Loos and Dyer, 1992; Fujiwara et al., 1993). Amino acid sequence analysis of the *P. gingivalis* fimbrillins has placed them into four to six major groups (Hamada et al., 1994). Considerable heterogeneity in *fimA* exists amongst *P. gingivalis* strains. Since only one *fimA* gene copy is found on the chromosome, the variation in the fimbrillin gene is most likely due to mutational events and/or genetic exchange between strains and not due to antigenic variation of the fimbriae within the strain. To date, no fimbrillin phase variation has been identified within a *P. gingivalis* strain. Recently a two-component regulatory system has been described in *P. gingivalis*, which appears to be involved in regulation of fimbrillin expression (Hayashi et al., 2000).

Fig. 3. *Porphyromonas gingivalis* virulence factors. This Gram-negative pathogen possesses a broad armamentarium of virulence factors that likely play a significant role in the establishment of periodontal disease. Although not precisely known, it is well established that the development of periodontal disease in response to *P. gingivalis* infection is the result of a complex interplay between the host defenses and the virulence factors expressed by this organism.

There is strong evidence that *P. gingivalis* fimbriae are responsible for binding the bacterium to host tissues. Purified native fimbriae, recombinant fimbriae, synthetic peptides based on the coding region of *fimA*, and anti-fimbriae sera are effective in preventing the attachment of *P. gingivalis* cells to epithelial, fibroblast, and endothelial cell culture systems (Lee et al., 1992; Sharma et al., 1993; Njoroge et al., 1997; Nassar et al., 2002). *Porphyromonas gingivalis fim*A knockout mutants also exhibit a nonadherent and noninvasive phenotype in epithelial, fibroblast, and endothelial cell culture systems (Weinberg et al., 1997). Ogawa et al. (1997) investigated the contribution of various regions of the fimbriae binding to a human gingival fibroblast cell line. Peptides containing amino acids 1–20, 69–80, and 171–181 strongly inhibited binding of purified fimbriae. All of the inhibitory peptides contained the amino acid sequence XLTX. The addition of *P. gingivalis* fimbrillin-specific peptides to the N-terminal domain of fimbrillin to human umbilical vein endothelial cells (HUVEC) also stimulates

interleukin (IL)-8 and monocyte chemoattractant protein (MCP)-1 in these cells (Khlgatian et al., 2002), as well as the cell adhesion molecules intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1 and P- and E-selectins (Khlgatian et al., 2002). It has recently been reported that *P. gingivalis* fimbriae promote adhesion to gingival epithelial cells through interaction with β1 integrins (Yilmaz et al., 2002).

The intact fimbriae, fimbrillin subunits, or synthetic fimbrial peptides of *P. gingivalis* are also capable of eliciting several important host-associated biological responses, which could result in harmful effects in vivo. These include the production of fibroblast-derived thymocyte-activating factor from human gingival fibroblasts (Hirose, 1990), IL-1, neutrophil chemotactic factor KC, and tumor necrosis factor (TNF)-α from mouse peritoneal macrophages (Hanazawa et al., 1991; Hanazawa et al., 1992; Murakami et al., 1993), and IL-6, IL-8 and TNF-α in human peripheral blood monocytes (Ogawa et al., 1991; Hamada et al., 1994). The fimbriae also appear to function as adjuvants (Ogawa et al., 1991; Hamada et al., 1994), as well as being capable of stimulating mitogenic and polyclonal B-cell activation in mouse splenocytes (Ogawa et al., 1991). The fimbriae are also highly immunogenic, eliciting both an antibody and cell mediated response in serum and saliva (Ogawa et al., 1992; Kusumoto et al., 1993; Hamada et al., 1994; Isogai et al., 1994). Animal experiments have also been conducted, which strongly implicate a role for fimbriae in tissue destruction (Evans et al., 1992a; Malek et al., 1994). Immunization of gnotobiotic rats with *P. gingivalis* fimbriae resulted in the protection of the animals from periodontal damage when challenged with live *P. gingivalis* (Evans et al., 1992a). Infection of gnotobiotic rats or mice with a fimA knock-out strain of *P. gingivalis* resulted in a markedly reduced bone loss in comparison to animals infected with the wildtype strain (Malek et al., 1994).

Minor Fimbriae

Electron microscopic examination of a *P. gingivalis* fimA mutant revealed that while the long, thin, classical fimbriae were absent, the surface of these cells was sparsely covered with short fimbriae-like structures, which were unreactive with anti-fimbrial antibody (Hamada et al., 1996). Hamada et al. (1996) isolated and characterized these "minor fimbriae" from the mutant strain, and they were found to have a higher estimated molecular weight than the major fimbrillin, 67 kDa and 41 kDa, respectively. Amino acid compositional analysis of the two fimbriae showed that they contained similar amino acids and were rich in hydrophobic amino acids. The two fimbriae were also antigenically distinct from one another. Antiserum against the 67-kDa fimbriae recognized the short (0.1–0.5 μm) fimbriae found on the mutant but did not react with the long (0.5–1.0 μm) fimbriae in the wildtype strain. While the wildtype fimbriae were involved in adherence to both epithelial cells and fibroblasts, as well as initiating hemagglutination reactions, the minor fimbriae did not possess any hemagglutinating activity. The minor fimbrial protein induces IL-1, IL-6 and TNF expression in macrophages (Hamada et al., 2002). Recent work in a rat animal model also supports a role for the *P. gingivalis* minor fimbriae in bone loss (Umemoto and Hamada, 2003).

Gingipains

The *P. gingivalis* cysteine proteinases (gingipains) have been recognized as major virulence factors of this organism owing to their ability to degrade and inactivate a number of host structural and defense proteins. The *P. gingivalis* gingipains cleave synthetic and natural substrates after arginine and lysine residues and have been designated "gingipain R" and "gingipain K," respectively. The genes encoding the arginine-(*rgpA* and *rgpB*) and the lysine-(*kgp*) specific gingipains have been well characterized (Potempa et al., 1995a; Potempa et al., 1995b). The translated portion of both the *rgpA* and *kgp* genes is composed of four functional regions: the signal peptide, the NH_2-terminal prosequence, the mature proteinase domain, and the COOH-terminal hemagglutinin domain (Okamoto et al., 1996). The COOH-terminal hemagglutinin domain has been demonstrated to bind fibrinogen, fibronectin, hemoglobin, and a number of additional substrates. The *rgpB* gene, which encodes the RgpB protein, is missing the COOH-terminal hemagglutinin domain (Potempa et al., 1995a; Genco et al., 1999; Fig. 4). In some strains of *P. gingivalis*, RgpA, RgpB and Kgp remain attached to the outer membrane, while in others these proteins are found extracellularly. The gingipains are also found associated with outer membrane blebs (Fig. 4). The crystal structure of RgpB has recently been reported (Fig. 5).

RgpA and RgpB are very potent vascular permeability enhancement (VPE) factors of *P. gingivalis*, inducing this activity through plasma prekallikrein activation and subsequent bradykinin release. By itself, Kgp is not able to induce VPE in human plasma, but working in concert with RgpA and RgpB, the pair can induce VPE by cleaving bradykinin directly from high molecular weight kininogen (Fig. 6). Also, RgpA is a

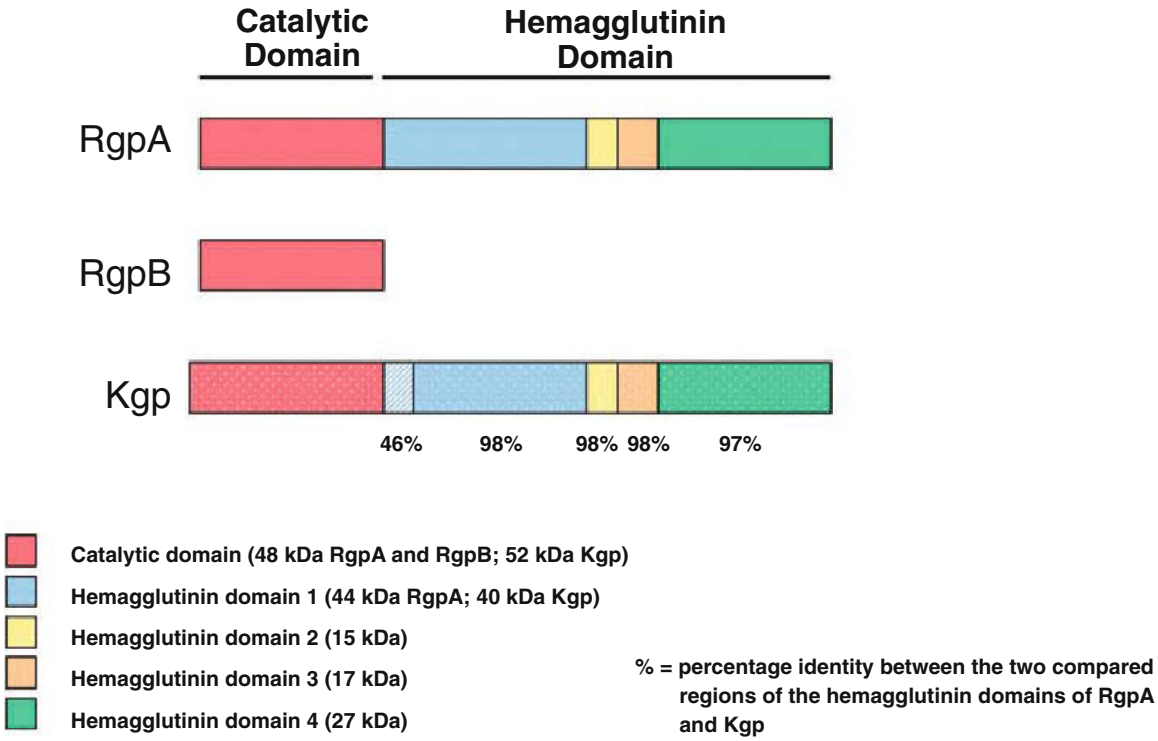

Fig. 4. Structure of the gingipains. The division of gingipains into two groups (arginine-specific [RgpA and RgpB] cysteine-proteinases and lysine-specific [Kgp]) is based on amino acid substrate specificity. RgpA and RgpB are encoded by two different genes, *rgpA* and *rgpB*. Structurally RgpA possesses a catalytic domain (48 kDa) and a hemagglutinin domain comprised of four subdomains (44, 15, 17, and 27 kDa), while RgpB possesses the catalytic domain and a small nonfunctional portion of the hemagglutinin domain. Kgp structurally resembles RgpA, as Kgp possesses both a catalytic (52 kDa) and hemagglutinin domain with four subdomains (40, 15, 17, and 27 kDa). The percentage values define the percent identity of the two compared regions of the hemagglutinin domains of RgpA and Kgp.

very efficient enzyme in terms of the generation of a potent chemotactic factor, C5a, through direct cleavage of C5, which likely contributes to the significant leukocyte infiltration at *P. gingivalis*-induced periodontitis lesions. At the same time, the enzyme degrades C3 and in this way eliminates the creation of C3-derived opsonins, thus rendering *P. gingivalis* resistant to phagocytosis (Cutler et al., 1993). The massive accumulation of neutrophils in the inflamed periodontal tissue importantly contributes to the very high levels of active granular proteinases (elastase, cathepsin G, gelatinase, and collagenase) in gingival crevicular fluid that may be responsible for connective tissue destruction. In such a highly proteolytic environment, subgingival plaque bacteria would clearly thrive owing to the presence of high concentrations of peptides and amino acids (Fig. 6), thus further aggravating tissue destruction. In addition, RgpA and RgpB have been reported to degrade host matrix proteins, which in turn may lead to increased exposure of the cryptic ligands that can result in enhanced fimbria-mediated binding of *P. gingivalis* to periodontal tissues. Recent studies indicating that RgpA can activate factor X suggest that this gingipain could be responsible for the production of thrombin (Imamura et al., 1997).

Among the plasma proteins, fibrinogen seems to be the major target for Kgp. In vitro, this enzyme degrades the fibrinogen A α-chain within minutes, thus rendering it nonclottable. The nonrestricted Kgp activity in periodontal pockets has been postulated to contribute to a bleeding tendency, especially since it also destroys the procoagulant portion of high molecular weight kininogen (Imamura et al., 1995). The ability of the hemagglutinin domains of *P. gingivalis* RgpA and Kgp to hemagglutinate erythrocytes has also been well documented (Potempa et al., 2000). The proteinase-hemagglutinin complexes may thus be important in the uptake of essential growth factors, via hemagglutination, hemolysis of erythrocytes, and subsequent degradation of hemoglobin (Potempa et al., 2000).

Several reports have further defined the role of the *P. gingivalis* gingipains in virulence using various animal models (Genco et al., 1999). Inactivation of *P. gingivalis* cysteine proteinases

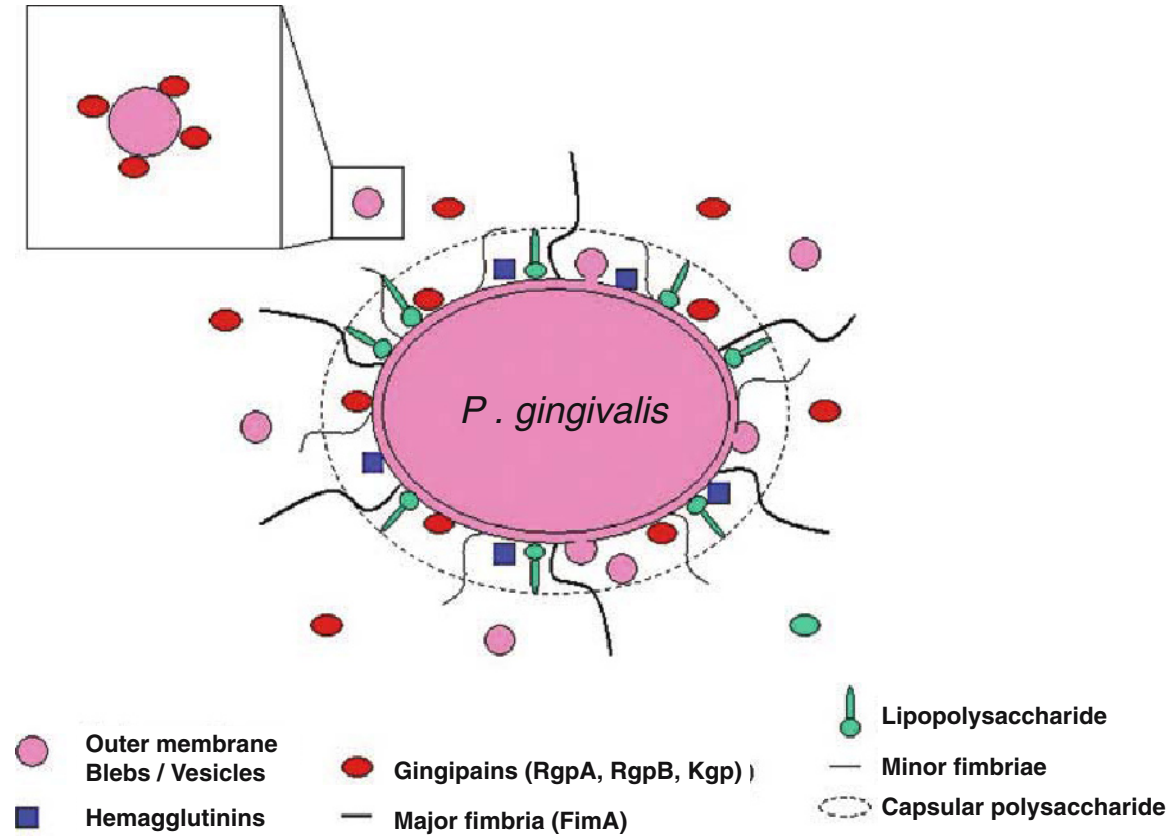

Fig. 5. The X-ray crystallographic structure of RgpB. The catalytic domain of RgpB is subdivided into two subdomains comprised of 4- and 6-strand β-sheets sandwiched between single β-helices. The crystal structures of RgpA and Kgp are currently not known. From Eichinger et al. (1999).

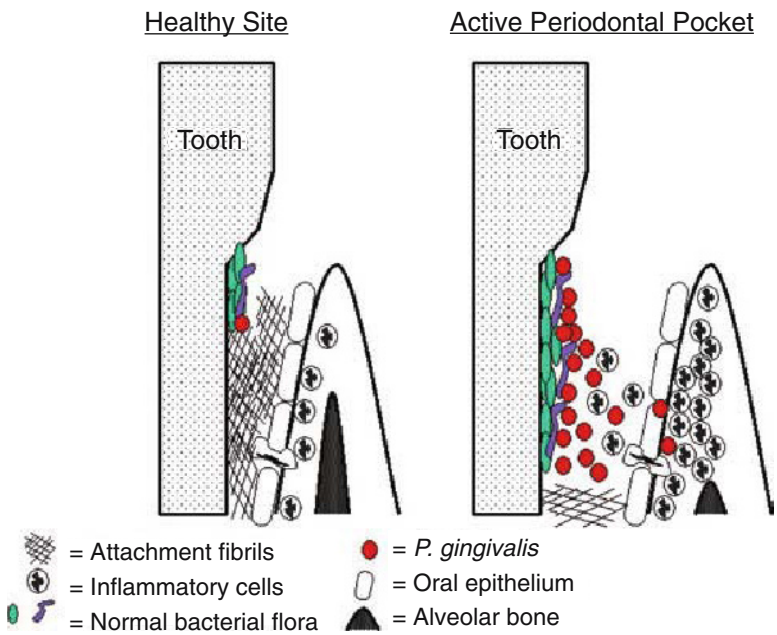

Fig. 6. Known functional roles of the gingipains of *P. gingivalis*. Gingipains are found in either cell bound or secreted forms and have been shown to possess both degradative and immune activating activities, which likely play a significant role in the establishment of periodontal disease.

including the gingipains prior to infection in mice resulted in a decrease in *P. gingivalis* virulence in a mouse chamber model (Genco et al., 1999). *Porphyromonas gingivalis rgpA rgpB* mutants have been shown to exhibit a marked reduction in virulence in a mouse abscess model (Nakayama et al., 1995). The gingipains may contribute to the virulence potential of *P. gingivalis* in a multifactorial manner by influencing adherence to host tissues, degrading host proteins, and disturbing host defenses (Potempa et al., 2000). Further, it is known that RgpA and RgpB may act as processing proteinases responsible for self-maturation, as well as for maturation of Kgp, fimbrillin, and a 75-kDa outer membrane protein. Since fimbrillin, RgpA, RgpB, and Kgp have been documented in the virulence potential of *P. gingivalis*, gingipains may play a central role in the pathogenesis of periodontal disease via the production of pathophysiologically significant bacterial proteins.

Hemagglutinins

Porphyromonas gingivalis produces several distinct hemagglutinins, which are cell surface associated proteins that aid in binding of the bacterium to host cells. Multiple hemagglutinin genes have been identified from *P. gingivalis* (Holt et al., 2000). As discussed above, polypeptides corresponding to the C-terminal domains of the gingipains possess hemagglutnin activity (Potempa et al., 2000). Three additional hemagglutinins have been described. Han et al. (1996) cloned and sequenced the *hagA* gene, which was found to be 7,887 bp in length, encoding a protein of 2,628 amino acids with a molecular mass of 283.3 kDa. Within its open reading frame, four large, contiguous, direct repeats (varying from 1,318 to 1,368 bp) were identified. The repeat unit (HArep), which was assumed to contain the hemagglutinin domain, was also present in other recently reported protease and hemagglutinin genes in *P. gingivalis*. The presence of multiple repeat units may provide a means for *hagA* to undergo rearrangements (duplications or deletions of a repeat unit) and thus antigenic variation. In addition to HagA, HagB and HagC have been characterized and demonstrated to hemagglutinate red blood cells (Lepine et al., 1996b); however, the exact role of these hemagglutinins in pathogenesis has not been defined.

Hemin Acquisition Nutrients are limited in the subgingival crevice and successful colonization by *P. gingivalis* is dependent on the ability of this organism to capture essential nutrients for growth. Perhaps the most obvious of these nutrient requirements is the *P. gingivalis* requirement for hemin (Cutler et al., 1995). Although hemin is a major component of gingival crevice fluid, host iron-chelating proteins such as haptoglobin, albumin, and hemopexin make hemin unavailable for microorganisms (Genco and Dixon, 2001). A *P. gingivalis* outer membrane receptor (HmuR), which is required for both hemoglobin and hemin utilization in *P. gingivalis*, has been described and well characterized (Simpson et al., 2000). Inactivation of *hmuR* resulted in a diminished ability of *P. gingivalis* to bind hemoglobin and to grow with hemoglobin or hemin as sole iron source. Recombinant HmuR has also been demonstrated to bind hemin and hemoglobin (Olczak et al., 2001). Thus, HmuR appears to serve as a major outer membrane hemoglobin receptor in *P. gingivalis*.

The lysine specific cysteine protease (Kgp) has also been demonstrated to specifically bind hemoglobin; however, it is not clear which part of the Kgp complex participates in hemoglobin binding (Sroka et al., 2001). Kgp can also cleave hemoglobin (Nakayama et al., 1995; Abe et al., 1998; DeCarlo et al., 1999; Lewis et al., 1999; Simpson et al., 2000; Sroka et al., 2001). *Porphyromonas gingivalis kgp* mutants grow poorly with hemin or hemoglobin as sole iron sources, further supporting a role for Kgp in hemin and hemoglobin utilization (Genco, 1995a; Simpson et al., 1999). Furthermore, a *P. gingivalis hmuR kgp* mutant displayed a nonpigmented colony phenotype, bound less hemoglobin as compared to the parent strain, and did not grow with hemin or hemoglobin as sole iron source. Although Kgp can be found associated with the *P. gingivalis* outer membrane, it is premature to classify Kgp as a receptor. The amino acid sequence of Kgp has no similarity to TonB-dependent outer membrane proteins. Rather Kgp may function as a soluble hemoglobin binding protein (hemophore), which captures hemoglobin and delivers it to a second outer-membrane-associated receptor, possibly the hemoglobin receptor HmuR. Indeed, we have demonstrated that HmuR interacts with Kgp. This may represent the most efficient system of heme/hemoglobin delivery in *P. gingivalis*. Kgp has been proposed to function as a hemophore that facilitates hemoglobin utilization via HmuR. While HmuR may be capable of permitting growth of *P. gingivalis* with hemoglobin, an interaction with Kgp may increase the overall efficiency of the system.

In addition to the hemoglobin receptor, HmuR, it has been reported that *P. gingivalis* possesses three additional putative TonB-dependent hemin receptors (HemR, Tla and IhtA). It is possible that HemR, Tla and IhtA could function to bind hemin directly; however, conclusive evidence for the role of these proteins

in hemin binding has not been reported. A *P. gingivalis tla* mutant was demonstrated to grow with high levels of hemin; however, growth was decreased with low levels of hemin (Aduse-Opoku et al., 1997). These results indicate that Tla is involved in hemin transport; however, it is not known whether Tla functions in heme capture or in heme binding via a receptor-like mechanism. Definitive roles for HemR and IhtA proteins in hemin transport have not been delineated since Karunakaran et al. (1997) and Dashper et al. (2000) were unable to construct *P. gingivalis* mutants in these proteins.

Lipopolysaccharide (LPS) In comparison to the classical LPS of *Salmonella typhimurium* and *Escherichia coli*, *P. gingivalis* LPS was significantly less endotoxic when assayed by the Limulus amoebocyte lysate assay, Schwartzman reaction, lethality in galactosamine-sensitized mice, and pyrogenicity assay (Nair et al., 1983; Fujiwara et al., 1990; Takada et al., 1990). Endotoxic activity is confined to lipid A, while significant immunobiological activity is contained within the O-antigen (Takada et al., 1990). Studies by Ogawa et al. (1994b) and Tanamoto et al. (1997a) demonstrating that *P. gingivalis* LPS is a poor activator of IL-1 and TNF-α, as compared to enterobacterial LPS, are in contrast to other studies which demonstrated that *P. gingivalis* LPS stimulates equivalent or higher amounts of IL-1/IL-1β (Hanazawa et al., 1985; Koga et al., 1985; Lindemann et al., 1988; Yamazaki et al., 1992; Agarwal et al., 1995) and TNF-α (Lindemann et al., 1988; Agarwal et al., 1995) from human and murine cells. Bramanti et al. (1989) and Sismey-Durrant and Hopps (1991) also reported that *P. gingivalis* LPS was able to stimulate the production of prostaglandin E_2 (PGE_2) from mouse macrophages and rat and human gingival fibroblasts. Similar results reported by Tamura et al. (Tamura et al., 1992; Tamura et al., 1992) have also demonstrated IL-1 and IL-8 stimulation by *P. gingivalis* LPS in human gingival fibroblast cells. While there are reports that *P. gingivalis* LPS is capable of inducing IL-6 in human gingival fibroblasts (Bartold and Haynes, 1991), this induction is thought to be the result of an indirect effect of the LPS stimulating the production of IL-1β (Yamazaki et al., 1992). *Porphyromonas gingivalis* LPS does not stimulate the expression of E-selectin in human umbilical cord endothelial cells, nor does it stimulate neutrophil adhesion to these cells. Employing an in vivo mouse model, Reife et al. (1995) demonstrated that purified *P. gingivalis* LPS mediated a variety of inflammatory responses; however, it did not induce an inflammatory cellular infiltrate, the production of P- or E-selectin, or the production of monocyte chemoattractant protein (MCP)-1 or fibroblast-induced cytokine. The differences in the immunopharmacologic activity of *P. gingivalis* LPS are thought to be due to differences in the chemical structure of *P. gingivalis* LPS and that of the enterobacterial molecule (i.e., specifically, the absence of the 4′-phosphate group and the location and nature of the fatty acids on the *P. gingivalis* lipid A; Takada, 1992; Ogawa, 1994a; Tanamoto et al., 1997b).

Shapira et al. (1994) determined that *P. gingivalis* LPS stimulates cytokine secretion in monocytes by binding to CD14 after the LPS has interacted with soluble serum factors. In contrast to that reported for the enteric LPS, *P. gingivalis* LPS was not able to activate nonmyeloid cells and was, for the most part, significantly less effective than the enteric LPS in activating myeloid cells (Ogawa, 1994a; Darveau et al., 1995; Cunningham et al., 1996; Tanamoto et al., 1997b). It appears that this inability of *P. gingivalis* LPS to stimulate myeloid cells is due to its approximately 100-fold lower ability to bind LPS binding protein (LBP; Cunningham et al., 1996) compared to that observed for the *E. coli* LPS. The mechanism by which soluble CD14 binds to LPS-LBP complex is different in *P. gingivalis* compared to *E. coli* (Shapira et al., 1994). Since *P. gingivalis* LPS-LBP complex is capable of binding to soluble CD14 (Cunningham et al., 1996), some other factor(s) must be responsible for the inability of these complexes to stimulate nonmyeloid cells when they come in contact with LPS from *P. gingivalis*. The low biological activity of *P. gingivalis*, especially its very low endotoxicity, may reflect the organism's ability to colonize and grow in sterile tissue undetected by the host (Darveau et al., 1995).

Capsule

Many bacteria produce capsular polysaccharides, and the importance of capsular polysaccharides in infectious diseases has been studied in detail (Lindberg, 1999). Epidemiological and case report data indicate that, of the infections caused by anaerobic bacteria, the majority of these isolates are encapsulated (Kasper et al., 1977; Onderdonk et al., 1977; Brook and Walker, 1983; Brook, 1994; Califano et al., 1999) and include *Bacteroides* sp., *Prevotella* sp., *Fusobacterium* sp. and *Porphyromonas* sp. (Brook, 1994). The sugar composition of *P. gingivalis* capsular polysaccharide has been shown to consist of glucose, glucosamine, galactosamine and galactosaminuronic acid residues, while the LPS saccharide chains are comprised primarily of rhamnose, glucose and galactose (Schifferle et al., 1989). Bramanti et al. (1989) reported that

the polysaccharide component of *P. gingivalis* LPS was rhamnose, glucose, galactose, mannose, glucosamine and galactosamine. More recent chemical analysis of *P. gingivalis* surface polysaccharides by Farquharson et al. (2000) reported the saccharide structure of *P. gingivalis* capsular polysaccharide consisted of mannuronic acid, glucuronic acid, galactose, and 2-acetamido-2-deoxy-D-glucose. To date, six capsular serotypes of *P. gingivalis* have been described (Laine et al., 1996); however, a significant number of nontypeable *P. gingivalis* capsule serotypes appear to exist (Laine et al., 1997). Epidemiological studies are beginning to define the distribution of these serotypes associated with human periodontal disease (Laine et al., 1997; Califano et al., 1999).

Porphyromonas gingivalis capsular polysaccharide appears to promote phagocytosis of this organism by polymorphonuclear neutrophils (PMNs), as a polysaccharide mutant was more resistant to opsonophagocytic uptake by PMNs (Genco et al., 1995b). Van Winkelhoff et al. (1993) reported that encapsulated *P. gingivalis* causes serious forms of infection using a murine model. Laine and van Winkelhoff (1998) confirmed this observation and demonstrated that mice challenged with encapsulated *P. gingivalis* developed more severe infections than mice challenged with unencapsulated strains. Lithium diiodosalicylate extracts of *P. gingivalis* possess vaccine potential; however, this extract is complex and likely contains several antigens including capsular polysaccharide (Chen et al., 1990). A conjugate vaccine consisting of *P. gingivalis* capsular polysaccharide and *P. gingivalis* fimbriae was shown to prevent *P. gingivalis* infection using a murine subcutaneous challenge model (Choi et al., 1998). Additionally emerging animal model data support that purified *P. gingivalis* CPS (capsular polysaccharide) may represent a novel vaccine candidate as mice immunized with *P. gingivalis* CPS developed elevated serum levels of IgM and IgG that reacted with *P. gingivalis* whole organisms, and these animals were protected from *P. gingivalis*-elicited oral bone loss (Gonzalez, 2003).

Genetic Variability and Genomics

Porphyromonas gingivalis can modulate gene expression through genomic rearrangement and transposition, a factor that could contribute to this organism's ability to evade host detection and become established in the oral cavity. As discussed above, the structures of the *rgpA* and *rgpB* genes are very similar except that the *rgpB* gene does not possess most of the hemagglutinin domain present in the C-terminal region of the *rgpA* gene. It has been postulated that the two *rgp* genes were generated through the duplication of an ancestor *rgp* gene, insertion of the hemagglutinin domain region into one copy of the two resulting *rgp* genes (or deletion of the region from one *rgp*) and homologous recombination between the proteinase domain regions of the two *rgp* genes. It is appealing to speculate that this type of rearrangement may be responsible for the genetic diversity of this family of genes. Interestingly, the presence of nonreciprocal recombination in *P. gingivalis* was experimentally proven using suicide/integration plasmid systems.

Comparison of the nucleotide sequences of *rgpA* and *kgp* indicates that a majority of the C-terminal sequences of these genes are identical. It has been suggested that recombinational rearrangement (such as transposition or gene conversion) may have occurred in this nucleotide region between *kgp* and *rgpA*. Gene conversion type recombination has been observed in *P. gingivalis* (Nakayama et al., 1995; Okamoto et al., 1996), and thus it is reasonable to postulate that recombination between *P. gingivalis rgpA* and *kgp* could occur by such a mechanism. There are numerous examples in which gene conversion results in antigenic variation of surface proteins in a variety of bacterial pathogens (Seifert and So, 1988). The ability to undergo antigenic variation protects pathogens from immunological challenge by their hosts.

In addition to gene conversion, transposition may be a mechanism for recombinational rearrangements in *P. gingivalis* (Barkocy-Gallagher et al., 1996; Simpson et al., 1999). It is well established that genes proximal to an insertion element can be transposed or deleted (Ajioka, 1989; Galas, 1989). Interestingly, the *P. gingivalis* endogenous insertion sequence (IS) element IS*1126* was found 3′ to the *kgp* gene, and it was suggested that this IS element could serve as one end of a composite transposon (Barkocy-Gallagher et al., 1996). Recombination within the locus encoding Kgp could thus have occurred via a transposition event. In support of this contention, Simpson et al. (1999) found that IS*1126* is capable of transposition in *P. gingivalis*. Analysis of a *P. gingivalis* strain in which IS*1126* was mobilized indicated that IS*1126* had inserted directly upstream of the *kgp* gene. The demonstration of the mobilization of the second endogenous *P. gingivalis* insertion element, PGIS*2*, in the *P. gingivalis* chromosome has also been reported (Wang et al., 1997). Thus, the ability of IS elements to be mobilized within *P. gingivalis*, together with the finding that these elements are commonly found flanking the *kgp* locus, indicates that the variability in this locus may be due to genomic rearrangements facilitated by trans-

positional events. Further support of an active recombination system in *P. gingivalis* comes from the isolation of the *P. gingivalis recA* homolog (Fletcher et al., 1997).

The *P. gingivalis* genome has been completely sequenced and has revealed the presence of numerous IS elements and transposons in this organism (The Institute for Genomic Research website). Recently a DNA array based on the complete genome sequence has been generated and is available to examine gene expression. It is anticipated that with the complete sequence in hand, additional bacterial virulence factors will be defined and the regulation of these factors in response to specific environmental cues will be examined.

Regulation

During the transition from health to disease, a number of environmental changes are apparent in the oral ecological niche occupied by *P. gingivalis*. The gingival sulcus and periodontal pockets do not represent favorable environments for oral microbial flora to proliferate and colonize, and only a limited number of highly evolved species can colonize this area (Socransky and Haffajee, 1992). This is assumed to result from the pH, temperature, and oxygen availability, which limit the growth of a number of bacterial species. In addition, these environmental changes serve as important cues for this organism to regulate gene expression. The mean temperature of the gingival sulcus is 35°C, with a consistent range of 30–38°C (Socransky and Haffajee, 1991). The mean temperature is slightly higher (36.8°C) in inflamed periodontal pockets (Kung et al., 1990; Fedi and Killoy, 1992). Like other pathogenic microorganisms, *P. gingivalis* mounts a heat shock response when exposed to elevated temperature (an important homeostatic mechanism; Lu and McBride, 1994; Vayssier et al., 1994). GroEL (HSP60 family) and DnaK (HSP70 family) homologs have been described in *P. gingivalis* (Lu and McBride, 1994; Vayssier et al., 1994). In addition to reporting the response to temperature changes, Vayssier et al. (1994) have also reported that an increase in oxygen tension and acidic pH induce GroEL. Amano et al. (1994) have reported on a heat shock inducible 55-kDa protein, which may be related to HSP60. Further studies are needed to clarify the exact types and numbers of heat-shock proteins synthesized by *P. gingivalis* in response to an upward shift in temperature and to determine the function of these proteins and their involvement in pathogenicity.

Increased expression of *P. gingivalis* fimbrillin and superoxide dismutase (SOD) in response to a shift in growth temperature from 37 to 39°C has been reported (Amano et al., 1994). In contrast, in a separate study, *P. gingivalis* was observed to exhibit an increase in *fimA* promoter activity when the growth temperature was downshifted from 37 to 34°C (Xie et al., 1997). Although the precise biological function of temperature-regulated fimbrillin expression and SOD activity is not clear, it was suggested that downregulation of fimbrillin expression may help *P. gingivalis* evade the host immune system and that elevated SOD activity may enable *P. gingivalis* to survive in environments containing high levels of neutrophil-generated superoxide (Amano et al., 1994).

The pH range within gingival pockets is reported to be 7.0–8.5 (Cimasoni, 1983). The pH in the periodontal pocket increases accordingly as the periodontal pockets deepen and the host inflammatory response is induced (Bickel and Cimasoni, 1985). The optimal pH for growth of *P. gingivalis* is within the range 7.5–8.0 (Marsh et al., 1994); however, *P. gingivalis* has often been recovered from disease sites with elevated pH. The ability of *P. gingivalis* to grow at elevated pH may confer a great advantage to this bacterium over other species and may explain its association with disease. One factor contributing to the growth stability of *P. gingivalis* in this pH range may be the expression of the *sod* gene. Lynch and Kuramitsu (1999) have reported that in addition to oxidative stress and temperature, *sod* expression is also influenced by pH. Compared with acidic conditions (pH 6.0), *sod* expression increases significantly at neutral (pH 7.0) or slightly alkaline (pH 8.0) conditions (Lynch and Kuramitsu, 1999). Trypsin-like and chymotrypsin-like activity have also been observed to increase as pH increases, until maximal activity is reached at pH 8.0, suggesting that during initial stages of infection, *P. gingivalis* responds to the environmental pH changes by producing enzymes with maximal host tissue damage potential (McDermid et al., 1988). It has now become evident that the majority of trypsin-like activity produced by *P. gingivalis* is due to the production of the arginine- and lysine-specific cysteine proteinases (see section on Gingipains in this Chapter). It has been demonstrated that the optimal activity of these enzymes is achieved at a pH of 8.0. The increased activity of the *P. gingivalis* gingipains may serve to inactivate the host immune system components such as complement and immunoglobulins.

The hemin concentration in the periodontal pocket can vary significantly depending on the degree of inflammation and bleeding at this site. The regulation of *P. gingivalis* gene products involved in hemin-binding and transport is controlled by the level of hemin and iron (Carman

et al., 1990; Grenier, 1991; Smalley et al., 1991; Cutler et al., 1995). Transcription of the *hmuR* and *kgp* genes is negatively regulated by iron, and the *hmuR* and *kgp* promoters contain binding sequences for ferric uptake regulator protein (Fur; Forng et al., 2000; C. A. Genco, unpublished data). In several Gram-negative pathogens, Fur functions as a general global regulator and controls the expression of not only genes required for iron transport but also genes required for virulence. The recent report of a *P. gingivalis fur* homolog (C.A. Genco, unpublished data), together with the identification of several iron regulated receptors, suggests that the global negative regulator Fur may be operative in *P. gingivalis*.

In addition, both the induction and repression of expression of specific virulence factors in response to hemin have been reported (Cutler et al., 1995). Limitation of hemin during *P. gingivalis* growth affects hemolytic, trypsin-like protease and hemagglutination activities of *P. gingivalis* whole cell and extracellular vesicles. The expression of *P. gingivalis* proteinases can vary in response to hemin, as well as to specific growth phase (Carman et al., 1990). Trypsin-like protease activity was higher in hemin-excess *P. gingivalis* cultures, while collagenolytic activity was higher in hemin-restricted *P. gingivalis* cultures (Carman et al., 1990). An increase in extracellular vesicle production by hemin-limited *P. gingivalis* cultures has also been reported (McKee et al., 1986), and vesicles isolated from hemin-limited *P. gingivalis* cultures have also been shown to possess higher trypsin-like protease and hemagglutination activities (Smalley et al., 1991). Although hemin-restricted cultures have a lower overall level of trypsin-like activity and a reduction in total culture biomass, the activity present in extracellular vesicles from hemin-restricted cultures is greater than that of hemin-excess cultures (Smalley et al., 1991). Recent studies have demonstrated that expression of the *P. gingivalis* hemagglutinin genes *hagB*, *hagC*, and *hagD* is regulated by hemin (Lepine and Progulske-Fox, 1996a; Han et al., 1998). Modifications of the antigenicity of *P. gingivalis* LPS have also been reported in response to hemin limitation (Cutler et al., 1996). Hemin limitation and growth in the presence of 1% serum or saliva have also been reported to reduce transcription of the *fimA* gene.

Growth of *P. gingivalis* under hemin-restricted conditions results in increased virulence as assessed in a mouse model (Bramanti and Holt, 1993), and this increase may be explained by the increased expression of *P. gingivalis* outer membrane components and their associated enzymatic activities, which directly contribute to the overall pathogenic potential when this organism enters a hemin-limited environment. *Porphyromonas gingivalis* may adapt to changes in this environment by turning off the expression of some virulence factors and turning on the expression of others. The balance of virulence factor expression may be controlled through a number of yet to be identified regulatory proteins acting together or alone.

Recent studies have also begun to define the role of density-dependent gene regulation in *P. gingivalis*. This organism is frequently found within a mixed-species biofilm that exists in the gingival crevice. Additionally *P. gingivalis* can invade, replicate and persist in high density within gingival epithelial cells. In many Gram-negative and Gram-positive bacteria, the density dependent regulation of gene expression is controlled through quorum sensing. Quorum sensing involves the synthesis and detection of extracellular signaling molecules termed "autoinducers." In *Vibrio harveyi*, the *luxS* gene is required for type 2 autoinducer production. Recently a functional *luxS*-dependent signaling pathway was identified in *P. gingivalis*. The regulation of this system was demonstrated to be in response to cell density and osmolarity. In addition, differential display PCR showed that the inactivation of the *P. gingivalis luxS* resulted in the upregulation of HemR and RgpA (Choi et al., 2001).

During the early onset of periodontal disease, polymorphonuclear leukocyte infiltration within the subepithelial connective tissue and the loss of epithelial cell attachment to the tooth enamel are observed. Subsequently, T-cells and macrophages are recruited into the area underlying the pocket epithelial cells. This array of antagonistic cells is accompanied by the release of biologically active cytokines such as IL-1, IL-6, and TNF-α (Cutler et al., 1995; Darveau et al., 1998). To date little is known about the expression of specific bacterial components in response to the host inflammatory response; however, the induction of a host inflammatory response in response to bacterial infection clearly changes the local environment in which *P. gingivalis* resides. Although there is no hard evidence yet that the host response influences gene expression in *P. gingivalis*, this concept warrants further investigation. With the development of new methodologies, bacterial genes that are regulated by the host response should be easily identified.

Innate Host Immune Response

The innate immune response during an acute infection can be broadly broken down in to four stages: 1) recognition and processing of the

foreign particle, 2) antigen presentation, 3) immune cell recruitment with cell activation, and 4) directed killing of the foreign material with subsequent resolution of the inflammatory response. In the case of chronic diseases such as periodontal disease, it is not understood why the host is unable to fully resolve the infection. Mounting evidence supports that both host immunological defects and bacterial virulence strategies play important roles in the chronic nature of periodontal disease. As the topic of innate immunity has been studied in detail for over 100 years, in this section, we will concentrate primarily on the innate host response to *P. gingivalis*.

During periodontal health, the tissues adjacent to and underneath the gingival epithelium commonly possess a modest accumulation of neutrophils that are believed to be important in clearing any transient bacteria that gain access to these tissues. However, in patients in the acute or active stage of periodontal disease, the periodontium presents with a neutrophilic cellular infiltrate that switches to a predominating monocytic cellular infiltrate in chronic lesions. Understanding the complex cellular interactions that occur during periodontal disease is critical to defining a mechanistic approach to determine what bacterial factors might be responsible for this response. Gingival crevicular fluid obtained from periodontal disease sites has high levels of IL-1β, IL-8, and IL-10 and the chemokine RANTES (regulated upon activation, normal T cell expressed and secreted; Gamonal et al., 2000), IL-6, transforming growth factor, PGE_2, IL-2, TNF-α, and interferon (IFN)-γ (Salvi et al., 1998). The mechanisms by which *P. gingivalis* stimulates cytokine and chemokine production are not well known, but recent in vitro studies have been performed with *P. gingivalis* as well as with purified antigens from this organism. Numerous studies have been performed using various experimental criteria, and as a result it has become obvious that the host cell type, the number of bacteria, and the amount of antigen being tested are critical to the reported observations.

Innate Response of Relevant Host Cells In Vitro

ORAL EPITHELIAL CELLS. Oral epithelium, and more specifically gingival epithelium, represents one of the initial host barriers to *P. gingivalis* when this organism is present in the gingival sulcus. Several studies have begun to characterize the host response of oral epithelial cells to *P. gingivalis*. Challenge of oral epithelial cells with *P. gingivalis* elicits a TNF-α and IL-1β response. Additional studies have demonstrated that these cells also express cell adhesion molecules on their surface in response to *P. gingivalis* infection and include ICAM-1 and VCAM-1 (Wang et al., 1999). Interestingly, work by Darveau et al. (1998) has demonstrated that gingival epithelial cells challenged with *P. gingivalis* LPS fail to produce IL-8; furthermore, *P. gingivalis* LPS stimulation functions as a potent inhibitor of subsequent *E. coli* LPS stimulation of IL-8. This mechanism has been coined "localized chemokine paralysis." This mechanism, along with the ability of *P. gingivalis* gingipains to digest cytokines and chemokines (see section on Gingipains in this Chapter), is an attractive mechanism by which *P. gingivalis* may be able to circumvent the host response.

POLYMORPHONUCLEAR NEUTROPHILS. Anatomically, healthy people possess a layer of neutrophils that reside immediately below the epithelium of the gingival sulcus. It has been suggested that these cells perform immune surveillance and quickly clear any low level contamination of the subepithelial tissues. During the switch from periodontal health to periodontal disease, these infected sites typically present with an influx of PMNs. Recent studies have begun to focus on the response of PMNs to *P. gingivalis* infection, as well as investigating the potential of *P. gingivalis* to modulate the response of these cells during the infectious process. In vitro, PMNs challenged with live *P. gingivalis* produce the proinflammatory cytokines TNF-α, IL-1β and IL-6. Interestingly these cells also express IL-10 (a cytokine commonly associated with regulation of the host immune response). More recent studies have concentrated on the host responses to *P. gingivalis* fimbriae, LPS and gingipains. PMNs produce IL-8 and MCP-1 in response to live *P. gingivalis* infection. Interestingly, *P. gingivalis* viability is not necessary for stimulating chemokine production from PMNs as viable and heat-killed *P. gingivalis* elicits similar levels of these chemokines. Recent studies have focused on the PMN response to defined *P. gingivalis* antigens including LPS, fimbriae and gingipains. *Porphyromonas gingivalis* LPS upregulates complement receptor 3 on the PMN surface, as well as stimulates IL-1β, TNF-α and IL-8. Purified fimbrillin monomer (43-kDa protein), as well as a 24-mer-peptide sequence from the fimbrillin protein, possesses potent IL-8 stimulating activities. The effect of gingipains on PMN function is not known directly; however, recent studies using defined gingipain mutants of *P. gingivalis* show that gingipains downregulate the transcription of genes responsible for chemokine production (Nassar et al., 2002).

MONOCYTES. Monocytes represent the primary cell population present in chronic

periodontal lesions. Despite this observation, relatively few studies have focused on the interaction of monocytes and *P. gingivalis*; however, it is well known that monocytes commonly serve as primary antigen presenting cells. Of the studies that have been performed, the majority of work has focused on the inflammatory response of monocytes to *P. gingivalis* or defined antigens of this organism such as LPS. Studies have focused on the use of both human monocytic cells, as well as cells of murine origin, and despite some differences, the trend is that *P. gingivalis* stimulation of monocytes leads to the expression of TNF-α, IL-1β, MCP-1, IL-6, IL-8, nitric oxide, as well as PGE_2; however, *P. gingivalis* strain-dependent activation of monocytes has been reported. The relationship between tobacco use and periodontal disease is well documented. It has been reported that nicotine affects the host by upregulating inflammatory mediator expression of monocytes in response to *P. gingivalis* LPS. The result of this upregulation is elevated IL-1β production, a molecule whose activity is associated with bone remodeling and is commonly detected in crevicular fluids of patients with periodontal disease.

It is now well established that Gram-negative enteric LPS signals host cell activation through the Toll-like receptor (TLR)-4. TLRs are a family of pattern recognition receptors that function as cognate receptors, and currently there are 10 identified TLRs. Recent data suggested that *P. gingivalis* LPS stimulates human monocytes to produce cytokines; this process involves CD14 and TLR-2, and the p38 mitogen-activated protein (MAP) kinase activation is involved in this pathway. As discussed above, *P. gingivalis* LPS is not a potent endotoxin, and this is likely due to the unique fatty acid composition of the lipid A of *P. gingivalis*.

A limited number of studies have been performed to assess the effect of other defined antigens of *P. gingivalis* with monocytes. It has been suggested that fimbriae can stimulate monocyte differentiation, TNF-α and the chemokine KC (keratinocyte-derived cytokine) production. After the initial interaction of *P. gingivalis* fimbriae with macrophages, neutrophil chemotactic factor and protein kinase C are rapidly induced (Hanazawa et al., 1992; Murakami et al., 1994). Associated with this interaction is the formation of a 68-kDa phosphorylated protein within the confines of the macrophage, the induction being mediated by prior induction of protein kinase C. Fimbriae have also been suggested to inhibit caspase-3, an important molecule in cell apoptosis. In these studies, it was demonstrated that fimbria-specific antibody was able to neutralize this activity. As decreased apoptosis appears to be linked to chronic infections, these results suggest that *P. gingivalis* prevents monocyte cell apoptosis and thus facilitates the chronic nature of this disease.

DENDRITIC CELLS. A relatively new area is the role that dendritic cells may play in *P. gingivalis*-mediated periodontal disease. Recent studies by Cutler et al. (1999) suggest that dendritic cells and T-cells aggregate at sites of periodontal damage. Using in vitro techniques, it has been shown that these dendritic cells produce a variety of molecules in response to *P. gingivalis* LPS including accessory molecules involved in antigen presentation, the inflammatory mediators IL-1β and PGE_2, as well as the immunoregulatory cytokines IL-10 and IL-12. It is suggested that the high levels of IL-10 detected in dendritic cell supernatant fluids may downregulate the local immune response in a way that facilitates the chronic nature of *P. gingivalis*-mediated periodontal disease.

T CELL RESPONSES. The primary response of T cells is to coordinate the host effector response that includes mobilization of both innate and adaptive arms of a host response to rid the host of the infectious agent. Using specialized receptors, T cells recognize foreign antigens presented to these cells by antigen-presenting cells such as monocytes, and subsequently these cells undergo clonal expansion and secrete a plethora of cytokines that are responsible for dictating the host response. Little is known about the T cell-specific responses that occur during *P. gingivalis*-mediated periodontal disease. The numbers of T cells present in periodontal lesions extracted from patients with adult periodontal disease are elevated as compared to those of normal subjects (Gemmell and Seymour, 1998); however, the cytokine responses to *P. gingivalis* are not very different. The use of T cell clones established from periodontal disease patients has demonstrated that these cells produce chemokines (MCP-1, MIP-1α and RANTES) and cytokines (IFN-γ, IL-4 and IL-10) in response to *P. gingivalis* challenge, supporting the importance of IFN-γ and a Th1-like response in the progression of periodontal disease (Gemmell et al., 1999). CD_4^+ T cell specific responses are critical to the progression of oral bone loss in response to *P. gingivalis* oral challenge, and mice deficient in IFN-γ and IL-6 are also resistant to *P. gingivalis*-mediated oral bone loss (Baker et al., 1999; Baker et al., 2001). Recently, attempts have been made to better understand the predominating T cell response of patients with periodontal disease due to *P. gingivalis*, in an attempt to define whether Th1 or Th2 responses predominate. On the basis of antibody data, it appears that a *P. gingivalis*-specific Th1 response predominates in humans during periodontal disease as compared with

normal control subjects. What is not known, however, is why this mechanism is not protective. It is intriguing to speculate that by modifying the host T cell-mediated immune response, human periodontal disease can be limited. Future studies will better define the role of T cell-mediated host responses to *P. gingivalis*-elicited periodontal disease.

VASCULAR ENDOTHELIUM. The emergence of epidemiological data suggesting a connection between *P. gingivalis*-mediated periodontal disease and systemic diseases such as cardiovascular and cerebrovascular disease (see section on Systemic Complications of Periodontal Disease in this Chapter) has prompted investigators to study the interaction of *P. gingivalis* with vascular endothelium. Seminal studies by Deshpande et al. (1998a) demonstrated that *P. gingivalis* is able to actively invade endothelium, and these studies have been confirmed by Dorn et al. (1999). HUVECs or human aortic endothelial cells (HAECs) challenged with heat-killed *P. gingivalis* produce IL-8, while challenge of these cells with live *P. gingivalis* fails to produce this response. Although these cells do not secrete IL-8, live *P. gingivalis* challenge does stimulate IL-8 gene transcription. The precise mechanism by which *P. gingivalis* "uncouples" IL-8 production is unknown; however, through use of genetically defined *P. gingivalis* strains, it appears that gingipains are important in modifying this response at the transcriptional level, as well as by degrading secreted IL-8 (Nassar et al., 2002). *Porphyromonas gingivalis* LPS and fimbria are able to stimulate chemoattractants such as IL-8 and MCP-1 from endothelial cells challenged with *P. gingivalis*. Additionally, emerging data demonstrate that endothelial cells infected with *P. gingivalis* produce an array of cell adhesion molecules. The importance of cell adhesion molecules is the localization of immune cells present in the circulation to a site of infection. HUVECs infected with *P. gingivalis* produce P- and E-selectins, as well as ICAM-1 and VCAM-1, as compared with resting endothelial cells (Khlgatian et al., 2002). In the event that a clear experimental connection between periodontal disease and cardiovascular disease is established, it will be important to understand the cellular response of vascular cells to *P. gingivalis* in more detail.

COMPLEX CELL CULTURE SYSTEMS. Recently it has become clear that the result of using single cells to determine the host response to *P. gingivalis* challenge may be misleading and that the use of complex cell culture systems infected with more than one *P. gingivalis* cell could be revealing. Infection of oral epithelial cells with *P. gingivalis* results in inhibition of trans-epithelial migration of PMNs. *Porphyromonas gingivalis* infection of endothelial cells also appears to downregulate the cells in such a manner as to make them unresponsive to *E. coli* LPS challenge. This localized chemokine paralysis appears to play an important role in the host response to *P. gingivalis* infection by limiting inflammatory cell migration and in part explains why *P. gingivalis* is not efficiently cleared during infection. *Porphyromonas gingivalis* or *P. gingivalis* fimbriae leads to a synergistic chemokine response in endothelial/PMN or endothelial/macrophage cultures that is not observed when either cell type is infected in monoculture. The elevated IL-8 and MCP-1 responses may likely govern the activation and migration of PMNs and monocytes to this site; however, precise assays to define this aspect of inflammation are still needed.

COMPLEMENT. As an important molecule of the innate immune response, complement has opsonic properties, functions as a chemoattractant for localizing inflammatory cells at the site of infection, and mediates killing activity. Control of complement activity is therefore an important part of the regulatory mechanism of the host innate response. Complement deposition occurs by two distinct pathways, either in the presence of specific antibody (classical pathway) or in direct response to microbial products (alternate or properdin pathway). The classical pathway of complement activation is important in the clearance of *P. gingivalis*; however, as is discussed in the section dealing with adaptive host immunity (see the section Adaptive Immune Response in this Chapter), patients with *P. gingivalis*-mediated periodontal disease produce antibodies with weak complement activating properties.

PATTERN RECOGNITION MOLECULES AND TOLL-LIKE RECEPTORS. One important area that is emerging in innate immunity is the role of pattern recognition molecules in modulating the response of a cell to a specific microbial structure. Currently the mechanism by which *P. gingivalis* activates cells is under intensive study to determine which pattern recognition receptors are engaged, what signal transduction events are activated following receptor-ligand binding, and what subsets of genes are activated as a result of this binding. Much of the early work in this area focused on the ligand-ligand interactions of *E. coli* LPS, as this form of endotoxin is highly associated with endotoxic shock and vascular collapse. A synthesis of this data indicates that enteric LPS interacts with TLR-4 via a CD14-dependent process (Heumann and Roger, 2002), and NFκB is translocated prior to initiation of gene transcription, which results in a TNF-α-mediated proinflammatory response that dominates the host

endotoxic response; however, the data for *P. gingivalis* infection and the interaction of specific virulence factors with pattern recognition molecules are not as clear. It is well accepted that *P. gingivalis* LPS binds to CD1; however, the specific binding site that is engaged by *P. gingivalis* LPS is different than the site used by *E. coli* LPS. Toll-like receptor (TLR 2 rather than TLR-4) is engaged by *P. gingivalis* LPS on vascular endothelium; however, it appears that TLR-4 is engaged by *P. gingivalis* LPS on monocytes. Recent data support involvement of both TLR-2 and TLR-4 in the context of live *P. gingivalis* infection, as macrophages from C3H/HeJ mice (which have a point-mutated TLR-4 rendering it nonfunctional; Poltorak et al., 1998) respond to *P. gingivalis* challenge albeit to a lesser extent than do wildtype murine macrophages (C. A. Genco, unpublished data). Because pattern recognition affects the host response as well as the complexity of the interaction of *P. gingivalis* with cells of various lineages, additional work in this area is required and should increase understanding of *P. gingivalis* surface structures important in stimulating a host response and lead to new treatments (based on circumventing these processes) for *P. gingivalis*-mediated periodontal disease.

Adaptive Immune Response

The production of specific antibody to a bacterial pathogen is a common host response that in most cases is highly efficient in promoting clearance of the invading organism. These antibodies assist in clearance primarily by 1) opsonizing the organism, thus allowing neutrophil Fc receptor-mediated recognition and killing, and 2) facilitating complement deposition. Individuals colonized with *P. gingivalis* possess elevated levels of serum antibody specific for this organism and its individual components (Kinane et al., 2000). Currently there is no antibody response that can be used clinically to demonstrate the presence of periodontal disease or for differential diagnosis. Initial studies by Moulton et al. (1981) demonstrated that the serum of patients with adult periodontal disease contain elevated levels of *P. gingivalis*-specific IgG, IgM and IgA. Following this report, a majority of the subsequent studies from the United States or other countries support that levels of *P. gingivalis*-specific IgG are elevated in the serum of patients with generalized aggressive periodontal disease; however, this is controversial, as other reports suggest no differences or highly variable results between patients and controls. Yet despite this potent antibody response, the host is unable to adequately control *P. gingivalis*-mediated periodontal disease. The reasons for this lack of control are not known; however, several important possibly concurrent processes involving host factors (such as antibody avidity, antibody subtype, and host Fc receptor profiles) and bacterial factors (such as degradation of antibody by gingipains and the *P. gingivalis* serotype present in the oral cavity) could provide an explanation.

On the basis of several studies, it appears that the high levels of IgG produced in response to *P. gingivalis* infection are primarily of low avidity. The reason for the low avidity of these antibodies is not known. However, IgG antibodies of low avidity do not bind efficiently to the bacterium and would not be expected to efficiently opsonize *P. gingivalis*. Assessments of the IgG subclass during generalized aggressive periodontal disease indicate that a range of isotypes is produced by patients with *P. gingivalis* periodontitis (Kinane et al., 2000). Studies by Whitney et al. (1992) reported high levels of IgG with reactivities increasing in the order $IgG_2 > IgG_3 > IgG_1 > IgG_4$ in patients with generalized aggressive periodontitis; however, most of the IgG_2 appears to be directed toward the LPS and capsular polysaccharide of *P. gingivalis* (Ogawa et al., 1990; Califano et al., 1999). Interestingly, the preponderance of IgG_2 produced in response to *P. gingivalis* challenge may, in fact, facilitate the chronic nature of generalized aggressive periodontal disease as IgG_2 possesses weak complement fixation activity and is a poor opsonin as compared with the other IgG isotypes.

More recent studies have begun to assess the levels of IgG produced to defined *P. gingivalis* antigens during periodontal disease. Patients with generalized aggressive periodontal disease possess high levels of IgG (predominantly IgG_2) directed to a gingipain complex consisting of RgpA-Kgp. Additional studies indicate that patients produce high levels of IgG to the individual gingipains RgpA, RgpB and Kgp as compared with control subjects, and the RgpA- and RgpB-specific (but not Kgp-specific) IgG can facilitate opsonophagocytosis of *P. gingivalis* by naïve human neutrophils. The IgG isotype response in the serum of periodontitis patients to *P. gingivalis* fimbriae is predominately IgG_3, while other antigens appear to elicit IgG_1-specific and IgG_4-specific responses.

In addition, it has been demonstrated that gingipains, specifically RgpA, possess the ability to degrade IgG (Holt et al., 2000). This strategy would certainly create an environment "locally cleared" of antibody by both *P. gingivalis* secreted and membrane-bound gingipains. These degraded antibodies by not recognizing *P. gingivalis*, mediating opsonophagocytosis, or mediating complement fixation would create a local

environment favorable to *P. gingivalis* survival within the host.

Systemic Complications of Periodontal Disease

Diabetes Diabetes affects more than 13 million people in the United States and approximately 600,000 new cases are diagnosed each year. Diabetes has been identified as a significant risk factor for periodontal disease and can aggravate the severity of periodontal infections (Matthews, 2002; Teng et al., 2002). It has been shown that even in children, insulin-dependent diabetes is associated with an increase in periodontal disease. Factors that increase the severity of inflammatory diseases, such as impaired neutrophil function, excessive inflammatory response, collagen turnover defects, impaired wound healing, and periodontal flora changes, have been associated with diabetes pathogenesis. Patients with insulin-dependent diabetes express high levels of proinflammatory mediators compared with matched non-diabetic, normal individuals. Both PGE_2 and IL-1β have been found in significantly higher levels in the gingival crevicular fluid of diabetic patients as compared with non-diabetic control subjects when matched for periodontal disease severity. Similar results have been observed for TNF-α expression. Recent studies also indicate that periodontal disease can adversely impact glycemic control in diabetes. Periodontal treatment that decreases the bacterial challenge and the resulting inflammatory periodontal destruction can improve glycemia in some diabetic patients. Overall, the evidence supports the view that the relationship between diabetes and periodontal disease is bidirectional (Soskolne and Klinger, 2001). Although information about the molecular pathogenesis of periodontal infections in diabetes is just becoming available, the molecular and cellular aspects of host-parasite interactions are poorly understood and warrant definitive investigation.

Cardiovascular Disease Several reports have described an association between periodontal disease and coronary artery disease. These include case control studies, which demonstrated significant associations after correction for cholesterol, smoking, hypertension, social class, and body mass index (Beck and Offenbacher, 1998a; Beck et al., 1998b; Beck et al., 2001). The biological consequences of oral infection with *P. gingivalis* and the risk for acute myocardial infarction and other vascular phenomena are supported by the following: 1) *P. gingivalis* can induce aggregation of platelets (Pham et al., 2002) and trigger cytokines, which play a role in atheroma formation through bacterial products such as LPS and fimbriae. 2) *P. gingivalis* can cause local inflammation (which leads to ulceration of the gingivae) and local vascular changes (which increase the incidence and the severity of transient bacteremias when the gingivae are traumatized). Procedures such as dental extraction, periodontal surgery, tooth scaling, and even tooth brushing can lead to the presence of oral bacteria in circulating blood. 3) Injured or activated endothelial cells, resulting from *P. gingivalis*-induced alterations in the endothelial cell, may show a variety of atherogenic properties including increased procoagulant activity, secretion of vasoactive and inflammatory mediators, and expression of adhesion molecules. 4) *P. gingivalis* may be released into the bloodstream, which could have direct or indirect effects. Direct effects would include the aggregation of platelets triggered by *P. gingivalis* surface antigens, gingipains, and fimbriae, leading to thrombus formation. Indirect effects may be mediated via LPS and other bacterial components that could trigger cytokine production by macrophages in situ in atheromatous plaque. This could lead to accumulation of lipid and foam cell formation and trigger endothelial cells to form IL-1β, which increases thrombus adherence. The consequences of these direct and indirect effects may include bacterial induced thrombi, which attach to atheromatous plaques in the heart vessel wall, leading to ischemic heart disease and the risk for myocardial infarction. Chronic and multiple transient bacteremias could also trigger macrophages and endothelial cells to blood vessels and increase formation of atheromatous plaques to which thrombi could then attach, precipitating acute myocardial infarction.

The gingival sulcus is believed to be the most likely area of entry of oral bacteria into the bloodstream and the integrity of the basement membrane of the oral mucosa and particularly the gingival sulcus is paramount in the protection of patients at risk for cardiovascular disease. The ability of *P. gingivalis* to invade and replicate within endothelial cells (Deshpande et al., 1998b) suggests that this organism possesses mechanisms for survival within vascular endothelial cells. Injured or activated endothelial cells (during infection) may show various atherogenic properties including increased procoagulant activity, secretion of vasoactive and inflammatory mediators, and expression of adhesion molecules. E-selectin, ICAM-1, and VCAM-1 have been detected in atherosclerotic areas of human arteries, and inflammatory cells are abundant at these sites. Invasion of vascular and heart endothelial cells by *P. gingivalis* after entry into the bloodstream may contribute to the pathology of cardiovascular disease.

PRE-TERM BIRTH Recent epidemiological studies have implicated periodontal disease as a risk factor for pre-term birth (Offenbacher et al., 1998). Human studies in patients with periodontal disease and animal studies have suggested that infection with *P. gingivalis* may be an important component in the underlying association in linking periodontal disease to pre-term birth. Several plausible hypotheses support a link between maternal periodontal disease and pre-term birth. In particular, maternal periodontal infection may influence pre-term delivery through mechanisms involving inflammatory mediators. Using a subcutaneous chamber mouse model, it was demonstrated that *P. gingivalis* infection was associated with hepatic and uterine translocation, and this dissemination correlated with fetuses that exhibited growth restriction (Collins et al., 1994). Likewise, *P. gingivalis* challenge was demonstrated to induce maternal elevated proinflammatory cytokine responses (TNF) and decreased anti-inflammatory cytokine response (IL-10). These systemic changes have been associated with fetal growth restriction. Translocation of *P. gingivalis* or specific bacterial components into the placenta may induce placental immune responses that impair placental function, thereby mediating fetal growth restriction. Clearly additional studies in well-defined animal models will further define the mechanisms associated with *P. gingivalis*-induced inflammatory responses in the context of pre-term birth.

Animal Models

A variety of animal models (such as rodents, dogs, sheep and nonhuman primates) have proven useful for expanding our understanding of *P. gingivalis*-elicited periodontal disease. No single animal model effectively mimics all aspects of periodontal disease. Thus a variety of models are needed to provide a complete picture of the pathogenesis of *P. gingivalis*-elicited periodontal disease. A recent review article discusses many of the studies performed in animals to address various aspects of *P. gingivalis* infection and host response, as well as discusses the benefits and limitations of each of these animal model systems (Genco et al., 1998).

Initial studies to address the association of dental plaque and periodontal disease pathogenesis were performed in dogs (Genco et al., 1998). These studies demonstrated a link between the presence of plaque and subsequent development of periodontal disease. Unfortunately, *P. gingivalis* does not appear to play a role in the development of periodontitis in dogs. A seminal study by Holt et al. (1988) demonstrated that the primate *Macaca fascicularis* orally challenged with *P. gingivalis* developed periodontitis, thus establishing a direct link between *P. gingivalis* infection and the development of periodontal disease. Rodents, owing to their small size and cost, have proven very useful in defining various aspects of periodontitis. A murine abscess model has been used by many investigators to study *P. gingivalis* disease pathogenesis. In this model, localized subcutaneous injection of *P. gingivalis* leads to an initial focal lesion with the development of secondary spreading lesions. This abscess model has also demonstrated that attenuation of *P. gingivalis* virulence directly impacts disease progression, as gingipain double knockout mutant ($RgpA^-$ and $RgpB^-$) exhibited less abscess formation than did wildtype *P. gingivalis* (Nakayama et al., 1995). A murine subcutaneous chamber model has proven particularly useful for studying the temporal interaction between *P. gingivalis* and the host immune system, with particular emphasis in studying PMN/*P. gingivalis* interactions (Genco et al., 1998). Additionally both mice and rats have proven effective for studying the impact of *P. gingivalis* oral challenge and subsequent development of oral bone loss (Baker et al., 1994; Malek et al., 1994; Gibson and Genco, 2001).

In addition to animal studies of *P. gingivalis* infection's effect on induction of disease, other studies have looked at mechanisms for preventing *P. gingivalis*-mediated periodontal disease. Although conflicting reports exist, it is established that patients with generalized aggressive periodontitis develop specific antibody to *P. gingivalis*; however, this antibody does not appear to provide protection. By contrast, several studies have demonstrated that immunization of rodents and primates with either *P. gingivalis* whole organism preparations or specific antigens purified from this organism protects against periodontitis (Evans et al., 1992b; Moritz et al., 1998; Gibson and Genco, 2001; Rajapakse et al., 2002). Additionally, strategies specifically designed to assess control of the innate immune response as a way to block *P. gingivalis* from causing periodontal disease are yielding interesting data. Recently, the importance of the proinflammatory cytokines TNF-α and IL-1β in the bone loss process has been demonstrated by the observation that nonhuman primates given TNF-α and IL-1β receptor agonists are protected from accelerated inflammatory cell response to *P. gingivalis* oral challenge using a ligature based model. Novel vaccine candidates for use in the prevention of periodontal disease will undoubtedly be found.

Emerging epidemiological data support that periodontal disease represents an important risk factor for cardiovascular disease and pre-term

child delivery (Beck et al., 2001; Dasanayake et al., 2001; Genco et al., 2002). Moreover, periodontal disease is also more prevalent in diabetics (Zachariasen, 1991). Owing to the clinical connection between systemic disease and periodontal disease, animal models to study the impact of *P. gingivalis* infection on cardiovascular disease, diabetes, and pre-term birth will continue to be useful (Genco et al., 1998).

Conclusions and Future Directions

It is apparent that we have entered an exciting era of research as it relates to the interactions of *P. gingivalis* and the host. The complete repertoire of genes in *P. gingivalis* is available as a result of the DNA sequencing of the genome of this organism. Knowledge of the entire genomic sequence will allow us to identify additional virulence genes and to determine the components of the system(s) that regulate them. As seen with other microorganisms, the mechanisms of *P. gingivalis* virulence gene regulation in response to environmental cues may be extremely complex. Understanding the mechanism of virulence gene regulation in response to the local environment of the host will provide crucial information in the development of effective treatments targeted at eradication of these periodontal disease pathogens. The recent studies, which document that periodontal infection may represent a risk factor for other systemic conditions (Beck and Offenbacher, 1998a; Offenbacher et al., 1998), further support efforts into understanding the unique interactions between *P. gingivalis* and the response to environmental cues of the host. A number of different animal models have been used to evaluate the complex interactions between *P. gingivalis* and the host and have been an important research tool to study the pathogenesis of *P. gingivalis*-mediated periodontal diseases. Numerous investigations have elucidated important aspects of the complex interactions of *P. gingivalis* with the intact host through the use of various animal models. These animal models have enabled investigators to more clearly define the role of specific *P. gingivalis* factors in virulence and periodontal disease pathogenesis. Likewise, we have learned a great deal about the role of the host response in disease pathology; however, it is clear that there is much more to be gained from further studies in animal models. A concentrated effort is required to more completely characterize the pathogenesis of periodontal breakdown in rodent and primate models, since these models seem to hold the greatest promise in pathogenesis studies. Without baseline information, development and testing of potential therapies designed to disrupt the pathogenesis of disease will be significantly delayed. A concerted effort is also required to evaluate the role of periodontal infections on systemic diseases, including coronary artery disease, diabetes, adverse pregnancy outcomes, and other infections, such as endocarditis, respiratory infections, and HIV infection in relevant animal models.

CHAPTER 6.3

An Introduction to the Family Flavobacteriaceae

JEAN-FRANÇOIS BERNARDET AND YASUYOSHI NAKAGAWA

Introduction

An overview of the family Flavobacteriaceae (Reichenbach, 1992, emend. Bernardet et al., 1996, Bernardet et al., 2002) is appropriate because its genera have widely diverse ecological niches and physiological characteristics. Even within some genera, individual species may show contrasting characteristics. Indeed, although some genera were grouped long ago on the basis of common habitats and phenotypic traits (Reichenbach, 1989; The Order Cytophagales in second edition), others were subsequently attributed on the basis of molecular studies. However, the characteristics shared by most genera are presented in this introductory chapter so as to avoid repetition in subsequent chapters on member genera. The term "flavobacteria," although devoid of nomenclatural status, will be used in this chapter for convenience to represent all members of the family.

In previous editions of *Bergey's Manual of Systematic Bacteriology* and of *The Prokaryotes*, the organisms now included in the family Flavobacteriaceae were distributed among different and unrelated chapters, i.e., in *Bergey's Manual* in the chapters "Genus *Flavobacterium*" (Holmes et al., 1984a) and "Order I. *Cytophagales*" (Reichenbach, 1989), and in the second edition of *The Prokaryotes* in the chapters The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella* and The Order Cytophagales; (see the sections Phylogeny and Taxonomy in this Chapter). Conversely, these chapters also dealt with other organisms that were subsequently not included in the family (Bernardet et al., 1996). In spite of the considerable taxonomic modifications that occurred since their publication, these chapters (see also Reichenbach and Dworkin, 1981a; Reichenbach and Dworkin, 1981b) contain a huge amount of useful information that is still mostly valid; they deserve to be consulted by those interested in these organisms.

The very first suggestion of a family Flavobacteriaceae was in a PhD thesis study (Jooste, 1985). The family was then mentioned by Reichenbach (1989) in the first edition of *Bergey's Manual of Systematic Bacteriology*, although not formally described (Holmes, 1997). The family was validated (Reichenbach, 1992), its description published (Bernardet et al., 1996) and subsequently emended following the description of new genera (Bernardet et al., 2002). The family Flavobacteriaceae belongs to the phylum *Cytophaga-Flavobacterium-Bacteroides* (CFB; see the chapter on The Order Cytophagales in second edition), together with several other families and many isolated taxa (Bernardet et al., 2002; see the sections Phylogeny and Taxonomy in this Chapter). With the exception of the family Bacteroidaceae, this phylum falls within the competence of the Subcommittee on the Taxonomy of *Flavobacterium* and *Cytophaga*-like Bacteria of the International Committee on Systematics of Prokaryotes website. This subcommittee has issued minimal standards for the description of new taxa in the family (Bernardet et al., 2002).

The genus *Flavobacterium* (Bergey et al., 1923, emend. Bernardet et al., 1996) is the type genus of the family Flavobacteriaceae that currently also includes *Aequorivita* (Bowman and Nichols, 2002), *Arenibacter* (Ivanova et al., 2001; Nedashkovskaya et al., 2003c), *Bergeyella* (Vandamme et al., 1994a), *Capnocytophaga* (Leadbetter et al., 1979), *Cellulophaga* (Johansen et al., 1999), *Chryseobacterium* (Vandamme et al., 1994a), *Coenonia* (Vandamme et al., 1999), *Croceibacter* (Cho and Giovannoni, 2003), *Empedobacter* (Vandamme et al., 1994a), "*Fucobacter*" (Sakai et al., 2002), *Gelidibacter* (Bowman et al., 1997), *Mesonia* (Nedashkovskaya et al., 2003a), *Muricauda* (Bruns et al., 2001), *Myroides* (Vancanneyt et al., 1996), *Ornithobacterium* (Vandamme et al., 1994b), *Polaribacter* (Gosink et al., 1998), *Psychroflexus* (Bowman et al., 1998), *Psychroserpens* (Bowman et al., 1997), *Riemerella* (Segers et al., 1993), *Salegentibacter* (McCammon and Bowman, 2000), *Tenacibaculum* (Suzuki et al., 2001), *Ulvibacter* (Nedashkovskaya et al., 2003b),

Vitellibacter (Nedashkovskaya et al., 2003d), *Weeksella* (Holmes et al., 1986a) and *Zobellia* (Barbeyron et al., 2001). The family also comprises two generically misclassified organisms, [*Cytophaga*] *latercula* (Lewin, 1969) and [*Cytophaga*] *marinoflava* (Colwell et al., 1966).

In this edition, those genera that contain many species are treated in individual chapters, while those that share some particular physiological or ecological characteristics and those that are clinically significant in humans or animals are grouped together in particular chapters. The chapters are as follows: "The Genus *Flavobacterium*," by J.-F. Bernardet and J. Bowman; "The Genus *Chryseobacterium*," by J.-F. Bernardet, C. Hugo and B. Bruun; "Marine Members of the Family Flavobacteriaceae" (i.e., the genera *Aequorivita*, *Arenibacter*, *Cellulophaga*, *Croceibacter*, "*Fucobacter*," *Gelidibacter*, *Mesonia*, *Muricauda*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Salegentibacter*, *Tenacibaculum*, *Ulvibacter*, *Vitellibacter* and *Zobellia*, as well as [*Cytophaga*] *latercula* and [*Cytophaga*] *marinoflava*), by J. Bowman; "Capnophilic Bird Pathogens in the Family Flavobacteriaceae: *Riemerella*, *Ornithobacterium*, and *Coenonia*," by P. Vandamme, M. Hafez, and K.-H. Hinz; "The Genus *Capnocytophaga*," by E. Leadbetter; "The Genera *Myroides* and *Empedobacter*," by C. Hugo and B. Bruun; and "The Genera *Bergeyella* and *Weeksella*," by C. Hugo and B. Bruun.

Phylogeny

The current view of phylogenetic relationships between the family Flavobacteriaceae and other taxa in the *Cytophaga-Flavobacterium-Bacteroides* (CFB) phylum, and among taxa in the family, mostly results from extensive 16S rRNA/rDNA sequence analyses and DNA-rRNA hybridization experiments performed over nearly twenty years (e.g., Gherna and Woese, 1992; Nakagawa and Yamasato, 1993; Bernardet et al., 1996; Bowman et al., 1998; Suzuki et al., 2001; Nakagawa et al., 2002). Although considerable progress was made since then, the very first phylogenetic tree of this phylum, based on 16S rRNA oligonucleotide catalogs, already clearly distinguished a *Bacteroides* branch from another branch grouping organisms now attributed to the genera *Cellulophaga*, *Empedobacter*, *Flavobacterium* and *Sphingobacterium* (Paster et al., 1985). Procedures to determine the almost complete 16S rRNA sequence, as well as efficient methods of alignment, treeing algorithms, and statistical analyses, are now readily available, which has made it possible to resolve phylogenetic relationships much more accurately and reliably (Bernardet et al., 2002). However, since differences in 16S rRNA sequences of up to 5% have been found among strains of some species included in the family (Clayton et al., 1995; Triyanto and Wakabayashi, 1999), the sequences of additional strains should be obtained and compared. Several publications, including some dealing with members of the family, showed that the use of 16S rRNA sequence analysis to infer phylogenetic relationships should be restricted to the generic and suprageneric levels and that the resolution of the technique is not adapted to the delineation of new species (see Bernardet et al. [2002] and references therein).

Yamamoto and Harayama (1996) have shown that a phylogenetic analysis based on the DNA gyrase B subunit gene (*gyrB*) may have a greater degree of resolution than that based on the 16S rRNA sequence, because protein-encoding genes evolve faster than rRNA genes. When this technique was applied to many representatives of the CFB phylum, the resulting phylogenetic tree was almost equivalent to that resulting from 16S rRNA sequence analysis (Suzuki et al., 2001).

Phylogenetic relationships among prokaryotes were also deduced from signatures in different protein sequences. These signatures support a linear rather than tree-like relationship between the main eubacterial phyla, "suggesting that the major evolutionary changes within *Bacteria* have taken place in a directional manner" (Gupta, 2000). In this study, members of the CFB phylum were shown to belong to a "*Chlamydia-Cytophaga*-green sulfur bacteria group" that constitutes an intermediate evolutionary step between *Spirochetes* and ε- and δ-proteobacteria, a result in accordance with previous 16S rRNA data (Olsen et al., 1994). Hence, although their degree of resolution is different, the various molecules used for phylogenetic analyses do yield concordant data.

The position of the family Flavobacteriaceae in the CFB phylum is shown in Fig. 1. The phylogenetic relationships of the taxa classified in the family are shown in Fig. 2. Invalid taxa belonging to the family for which 16S rRNA sequence is available have been included in Fig. 2 for information; their names are given in quotation marks.

Taxonomy

Taxonomy of the family Flavobacteriaceae was reviewed in detail when minimal standards for

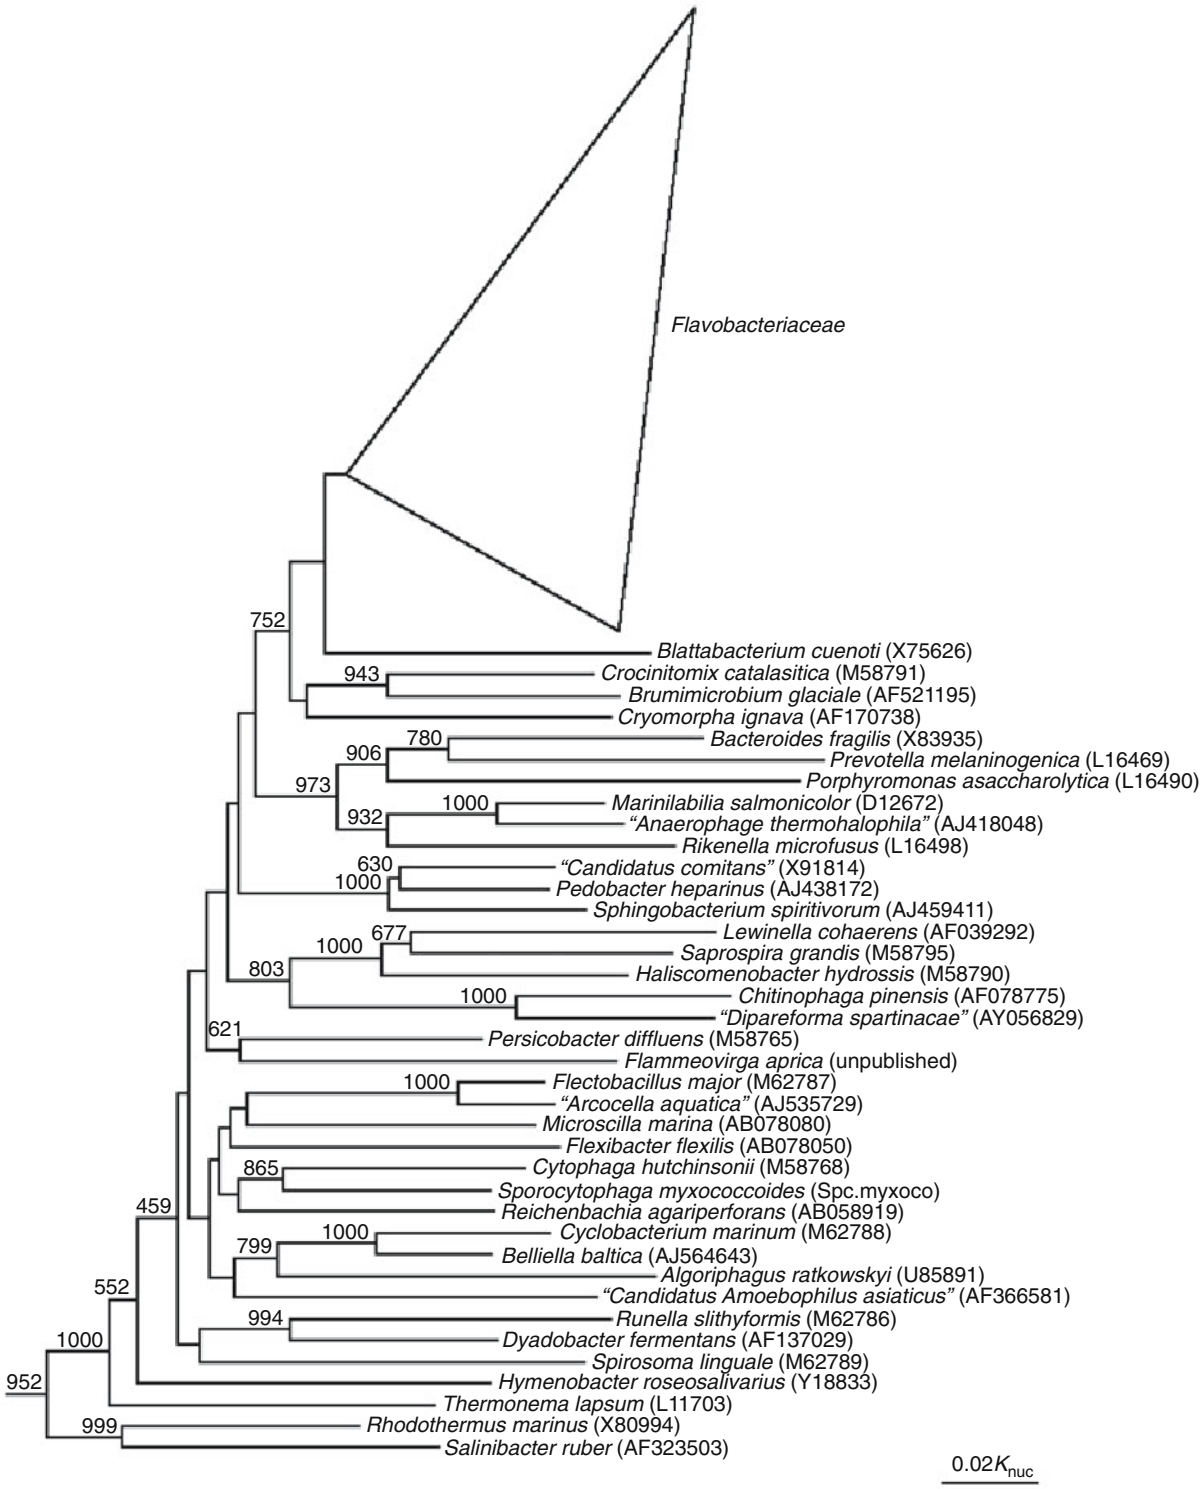

Fig. 1. Phylogenetic position of the family Flavobacteriaceae in the *Cytophaga-Flavobacterium-Bacteroides* phylum based on 16S rRNA sequence comparisons using the neighbor-joining method (Saitou and Nei, 1987). Sequences are taken from the DNA Data Bank of Japan (DDBJ) and GenBank nucleotide databases, apart from the sequence of *Sporocytophaga myxococcoides*, which comes from the Ribosomal Database Project (Maidak et al., 1999). All validly described genera in the phylum are represented by the sequence of the type strain of their type species. Accession numbers for the sequences are given in parentheses. Scale bar, 0.02 K_{nuc} (Kimura, 1980). The numbers on the branches represent the confidence limits estimated by a bootstrap analysis (Felsenstein, 1985) of 1000 replicates; confidence limits less than 50% are not shown. Sequences were aligned using the Clustal W ver. 1.8 software package (Thompson et al., 1994). The alignments were modified manually against the 16S rRNA secondary structure of *Escherichia coli* (Gutell et al., 1985). Positions at which the secondary structures varied in the strains (positions 66–104, 143–220, 447–487, 841–845, 991–1045, 1134–1140, and 1446–1456) and all sites which were not determined in any sequence were excluded from the analysis. *Agrobacterium tumefaciens*, *Bacillus subtilis*, and *Escherichia coli* were used as outgroups.

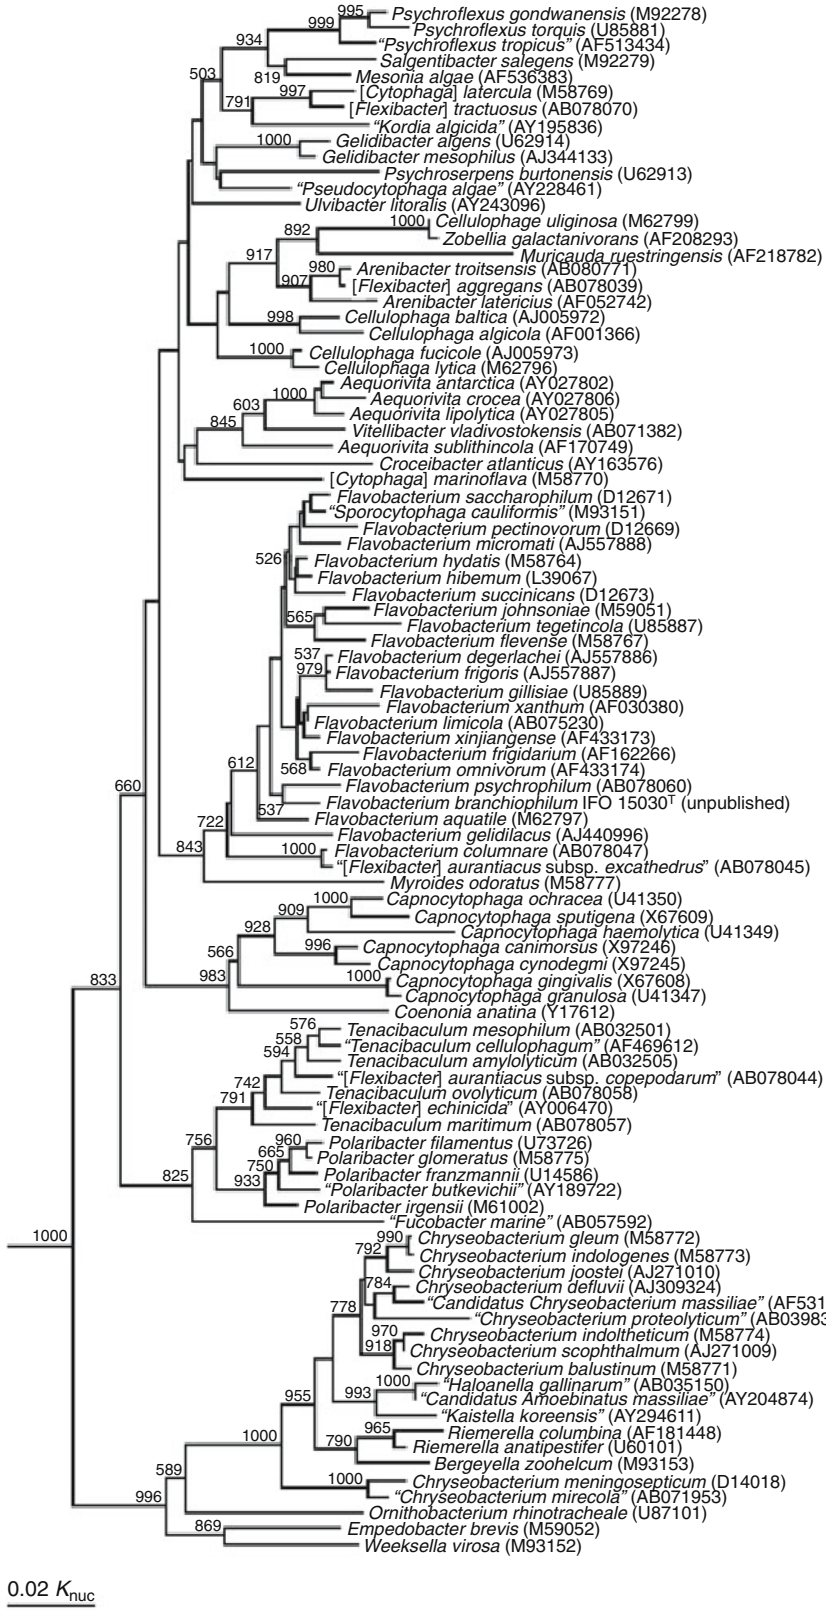

Fig. 2. Phylogenetic relationships among representatives of the family Flavobacteriaceae based on comparisons of 16S rRNA sequences. All species of Flavobacteriaceae are included except *Myroides odoratimimus*, for which no data are available. Invalid taxa for which 16S rRNA sequence is available have also been included for information; their names are in quotation marks. Other details are given in the legend to Fig. 1.

the description of new taxa in the family were proposed (Bernardet et al., 2002). At that time, the *Cytophaga-Flavobacterium-Bacteroides* (CFB) phylum comprised the families Bacteroidaceae, Cytophagaceae, Flavobacteriaceae, Sphingobacteriaceae and Spirosomaceae, as well as a number of taxa unattributed to any family. A new family Cryomorphaceae was described since then for various polar organisms (Bowman et al., 2003). The taxonomic status of these families is rather different: while the families Bacteroidaceae (Paster et al., 1994), Cryomorphaceae (Bowman et al., 2003), Flavobacteriaceae (Bernardet et al., 1996) and Sphingobacteriaceae (Steyn et al., 1998) were defined on firm phenotypic and genomic grounds, taxa included in the families Cytophagaceae (Reichenbach, 1989; The Order Cytophagales in second edition) and Spirosomaceae (Raj and Maloy, 1990) were actually shown to be only distantly related (see Bernardet et al. [2002] and references therein), making their thorough emendation necessary. Indeed, these two families were deleted from the CFB phylum (renamed "Bacteroidetes") in the "Taxonomic Outlines of the Prokaryotic Genera" for the second edition of *Bergey's Manual of Systematic Bacteriology*, while several new families were proposed. For instance, a family Blattabacteriaceae was also created to accommodate the closest relatives of flavobacteria, the endosymbionts of insects (see the section Habitat in this Chapter).

The definition of higher taxa in the CFB phylum is even more confusing. Taxa currently belonging to the family Flavobacteriaceae were included in the order Cytophagales when it was described (Leadbetter, 1974), as was the family itself when it was created (Reichenbach, 1989). However, the delineation of the order and its connections with the CFB phylum was far from clear as shown by the variable taxa attributed to the order in the successive editions of *Bergey's Manual* and *The Prokaryotes* (Leadbetter, 1974; Reichenbach and Dworkin, 1981b; Reichenbach, 1989; see The Order Cytophagales in second edition). Moreover, the genus *Flavobacterium* was dealt with in separate chapters (Holmes et al., 1984a; see The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella* in the second edition) and its relationships with members of the Cytophagales were questioned (Reichenbach, 1989). Phylogenetic studies considerably improved the situation at the genus and family levels, but the structure and limits of the order remained unclear (Nakagawa and Yamasato, 1993; Nakagawa and Yamasato, 1996; Bernardet et al., 1996; Bernardet et al., 2002). The order Cytophagales was maintained (although its composition was not specified) as the type order of a new class Flavobacteria in the "bacterial megaclassification" proposed by Cavalier-Smith (2002), whereas the order disappeared from the above-mentioned "Taxonomic Outlines of the Prokaryotic Genera" in which three new orders (i.e., Bacteroidales, Flavobacteriales and Sphingobacteriales) were proposed, each being the sole order of three corresponding new classes (i.e., Bacteroidetes, Flavobacteria and Sphingobacteria). Interestingly, the families included in the class Flavobacteria (proposed in these two studies) are quite different: for instance, the family Bacteroidaceae may be included in the class (Cavalier-Smith, 2002) or not. These differing views demonstrate that much additional data are still necessary to homogenize the delineation and naming of higher taxa, and that investigators experienced in the taxonomy of this group should be consulted. Taxa even higher than classes were also proposed: the three classes defined for the *Bergey's Manual* comprise the phylum "*Bacteroides*", while the megaclassification includes the classes Flavobacteria and Chlorobea in a division *Sphingobacteria* (Cavalier-Smith, 2002). Although the relationships of the CFB phylum with the genus *Chlorobium* and other green sulfur bacteria were indeed demonstrated by 16S rRNA (e.g., Olsen et al., 1994; Paster et al., 1994) and protein (Gupta, 2000) data, the definition of the division based on the presence of sphingolipids is questionable, since only a few taxa included in the division contain sphingolipids in their cytoplasmic membrane (e.g., *Bacteroides*, *Prevotella*, *Porphyromonas*, *Sphingobacterium* and *Flectobacillus*) and since sphingolipids also exist in bacterial taxa that do not belong to the division and even in fungi (Olsen and Jantzen, 2001).

Table 1 (updated from Bernardet et al., 2002) lists currently recognized genera in the family Flavobacteriaceae as well as their type species, the different species, and their type strain, the source and G+C content of the type strains, the most relevant references (which are not necessarily the original descriptions), the list of collections in which the type strains were first deposited, and the names previously attributed to some species. Invalid taxa and the two generically misclassified species [*Cytophaga*] *latercula* and [*Cytophaga*] *marinoflava* are included for information. The current taxonomic status and standing in nomenclature of flavobacteria may be found at the List of Bacterial Names with Standing in Nomenclature (Euzéby, 1997). Taxonomy of each genus in the family

Table 1. Currently recognized genera and species classified in the family Flavobacteriaceae.[a]

Genera and species[b]	Type strain	G + C (mol%)	Source	Reference(s)
Genus *Aequorivita*				Bowman and Nichols, 2002
Aequorivita antarctica[T]	ACAM 640	39	Under-ice sea water, Prydz Bay, Antarctica	Bowman and Nichols, 2002
Aequorivita crocea	ACAM 642	34	Sea water, Mertz Polynya, Antarctica	Bowman and Nichols, 2002
Aequorivita lipolytica	ACAM 641	36	Sea water, Mertz Polynya, Antarctica	Bowman and Nichols, 2002
Aequorivita sublithincola	ACAM 643	37	Sublithic cyanobacterial community, Vestfold Hills, Antarctica	Bowman and Nichols, 2002
Genus *Arenibacter*				Ivanova et al., 2001
Arenibacter latericius[T]	KMM 426	38	Marine sediment, Indian Ocean, 1988	Ivanova et al., 2001
Arenibacter troitsensis	KMM 3674	40	Marine sediment, Sea of Japan, 2000	Nedashkovskaya et al., 2003c
Genus *Bergeyella*				Vandamme et al., 1994a
Bergeyella zoohelcum[T,c]	NCTC 11660	35	Human sputum, United States	Holmes et al., 1986b
Genus *Capnocytophaga*				Leadbetter et al., 1979; Holt and Kinder, 1989
Capnocytophaga canimorsus	ATCC 35979	37	Human blood after dog bite, United States	Brenner et al., 1989; Vandamme et al., 1996
Capnocytophaga cynodegmi	ATCC 49044	36	Dog mouth, United States, 1979	Brenner et al., 1989; Vandamme et al., 1996
Capnocytophaga gingivalis[AL]	ATCC 33624	40	Periodontitis in human, United States, 1978	Leadbetter et al., 1979; Vandamme et al., 1996
Capnocytophaga granulosa	JCM 8566	42	Human dental plaque, Japan	Yamamoto et al., 1994; Vandamme et al., 1996
Capnocytophaga haemolytica	JCM 8565	44	Human dental plaque, Japan	Yamamoto et al., 1994; Vandamme et al., 1996
Capnocytophaga ochracea[T,AL]	ATCC 27872	39	Human oral cavity	Leadbetter et al., 1979; Vandamme et al., 1996
Capnocytophaga sputigena[AL]	ATCC 33612	38	Periodontitis in human, United States, 1978	Leadbetter et al., 1979; Vandamme et al., 1996
Genus *Cellulophaga*				Johansen et al., 1999
Cellulophaga algicola	ACAM 630	37	Surface of marine alga, Antarctica	Bowman, 2000
Cellulophaga baltica	LMG 18535	33	Surface of marine alga, Svaneke, Denmark	Johansen et al., 1999
Cellulophaga fuciola	LMG 18536	32	Surface of marine alga, Hirsholm, Denmark	Johansen et al., 1999
Cellulophaga lytica[T,AL,d]	ATCC 23178	33	Beach mud, Limon, Costa Rica	Lewin, 1969; Reichenbach, 1989; Johansen et al., 1999
Cellulophaga uliginosa[e]	ATCC 14397	42	Marine sediment	ZoBell and Upham, 1944; Reichenbach, 1989; Bowman, 2000
Genus *Chryseobacterium*				Holmes et al., 1984a; Vandamme et al., 1944a
Chryseobacterium balustinum[AL,f]	NCTC 11212	33	Blood of freshwater fish, France, 1959	Holmes et al., 1984a
Chryseobacterium defluvii	DSM 14219	?	Activated fludge, Germany	Kämpfer et al., 2003
Chryseobacterium gleum[T,AL,g]	ATCC 35910	37	Human vaginal swab, United Kingdom, 1979	Holmes et al., 1984b
Chryseobacterium indologenes[AL,h]	NCTC 10796	38	Human trachea at autopsy, 1958	Yabuuchi et al., 1983
Chryseobacterium indoltheticum[AL,i]	ATCC 27950	34	Marine mud	Campbell and Williams, 1951
Chryseobacterium joostei	LMG 18212	37	Raw cow milk, South Africa, 1981	Hugo et al., 2003
Chryseobacterium meningosepticum[AL,j]	ATCC 13253	37	Human cerebrospinal fluid, USA, 1949	King, 1959; Holmes et al., 1984a
"Chryseobacterium proteolyticum"	NIBHT 17664	37	Soil, rice field, Tsukuba, Japan	Yamaguchi and Yokoe, 2000
Chryseobacterium scophthalmum[k]	CCM 4109	34	Gills of marine fish, United Kingdom, 1987	Mudarris et al., 1994

Genus *Coenonia*				Vandamme et al., 1999
Coenonia anatina[T]	LMG 14382	35	Peking duck, Germany, 1991	Vandamme et al., 1999
Genus *Croceibacter*				Cho and Giovannoni, 2003a
Croceibacter atlanticus[T]	HTCC 2559	35	Seawater, Sargasso Sea, Atlantic Ocean, 2001	Cho and Giovannoni, 2003a
Genus *Empedobacter*				Vandamme et al., 1994a
Empedobacter brevis[T,AL,l]	NCTC 11099	33	Human bronchial secretion, Switzerland, 1976	Holmes et al., 1978; Holmes et al., 1984a
Genus *Flavobacterium*				Bernardet et al., 1996
Flavobacterium aquatile[T,AL,m]	ATCC 11947	33	Deep well, United Kingdom	Holmes et al., 1984a; Bernardet et al., 1996
Flavobacterium branchiophilum[n]	ATCC 35035	34	Gills of salmon, Japan, 1977	Wakabayashi et al., 1989; Bernardet et al., 1996
Flavobacterium columnare[o]	NCIMB 2248	32	Kidney of salmon, United States, 1955	Bernardet and Grimont, 1989b; Bernardet et al., 1996

is detailed in individual chapters as presented in the Introduction.

Habitat

The wide range of different habitats among (and sometimes within) the genera is one of the most intriguing characteristics of the family Flavobacteriaceae. Although the authors of the corresponding chapters in the previous editions of *Bergey's Manual of Systematic Bacteriology* and of *The Prokaryotes* (Holmes et al., 1984a; Reichenbach, 1989; see The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella*; The Order Cytophagales in this Volume) were actually referring to wider groups of organisms (see the Introduction), the habitats they listed are still valid for the current members of the family, as shown by a recent review (Jooste and Hugo, 1999). Taking into account the taxa described since then, the various habitats of flavobacteria may be as follows: soil; freshwater environments; marine environments; food and dairy products and their processing environments; specimens from humans; hospital equipment and devices; diseased dogs and cats; diseased amphibians and reptiles; diseased freshwater and marine fish; diseased mollusks, crustaceans, and sea urchins; diseased birds; eggs and digestive tract of insects; vacuoles or cytoplasm of amoebae; and diseased plants (see Table 1). All of these habitats are dealt with in detail in the chapters listed in the Introduction.

Another, very particular, habitat of flavobacteria was revealed by 16S rRNA analysis: some bacterial intracellular symbionts of insects are the closest relatives of bacteria in the family Flavobacteriaceae (Bernardet et al., 2002). First discovered in various cockroaches and termites, these uncultivable organisms were classified in the genus *Blattabacterium* (Dasch et al., 1984; Bandi et al., 1994). Related bacteria were subsequently detected in other roach species (Clark and Kambhampati, 2003) as well as in ladybird beetles; in the latter case, these intracellular bacteria were shown to kill male embryos they enter and to be maternally inherited (Hurst et al., 1997; Hurst et al., 1999). Other vertically transmitted bacteria in mites, ticks and wasps were attributed to the CFB group, although a close relationship with the flavobacteria was not demonstrated. These organisms also appear to be responsible for various reproductive anomalies in their hosts, such as parthenogenesis or feminization of haploid genetic males (Weeks et al., 2001; Zchori-Fein et al., 2001).

New insights on the distribution of flavobacteria in various environments have resulted from recent studies investigating the phylogenetic composition of bacterial communities. Some of the techniques used (such as phenotypic tests, fatty acid analysis, or sequencing of the 16S rRNA) required that bacteria be isolated first (Bowman et al., 1997; Jaspers et al., 2001; Nakagawa et al., 2001; Johansen and Binnerup, 2002; Van Trappen et al., 2002). Other studies used culture-independent identification methods such as fluorescent in situ hybridization (FISH) with rRNA-targeted oligonucleotide probes, denaturing-gradient gel electrophoresis (DGGE), or sequencing of cloned 16S rRNA genes fragments (Manz et al., 1996; Hugenholtz et al., 1998; O'Sullivan et al., 2002). Most of these surveys considered the whole CFB group, whose members were shown to be much more abundant in most environments than previously estimated from cultured isolates (Eilers et al., 2000; Jaspers et al., 2001). Important populations of CFB were found in freshwater environments (Manz et al., 1999; Brümmer et al., 2000; Jaspers et al., 2001; Kirchman, 2002), marine environments (Cottrell and Kirchman, 2000; Eilers et al., 2000; Kirchman, 2002) especially in polar regions (Bowman et al., 1997; Ravenschlag et al., 2001), soils (Borneman et al., 1996; Johansen and Binnerup, 2002), and even special industrial environments (Whiteley and Bailey, 2000). Although important variations in the structure of bacterial communities may occur over time, the CFB usually constitute one of the major groups of heterotrophic bacteria (Kirchman, 2002). They frequently participate in biofilms (Burchard and Sorongon, 1998; Manz et al., 1999; Brümmer et al., 2000; O'Sullivan et al., 2002) and seem to play an important role in biogeochemical cycles, using their diverse enzymes to degrade a variety of complex organic substrates (Reichenbach, 1989; Kirchman, 2002; Johansen and Binnerup, 2002; see The Order Cytophagales in second edition; see also the section Identification in this Chapter). Other surveys of bacterial communities identified more specifically members of the family Flavobacteriaceae in various environments. Many organisms, sharing a high 16S rRNA sequence homology with described taxa in the family or representing new taxa, were found among the particle-attached bacteria in a river estuary (Crump et al., 1999), in various mangrove samples from the subtropical zone of Japan (Nakagawa et al., 2001), in bacterioplankton assemblages from the Arctic Ocean (Bano and Hollibaugh, 2002), in a glacier in China (Zhu et al., 2003), and in several Antarctic lakes (Van Trappen et al., 2002). Indeed, surveys performed in these freshwater or marine, tropical or polar environments have resulted in the description of many new taxa in the family. They are dealt with in chapters on their respective genera.

Identification

The following description of the family Flavobacteriaceae is from Bernardet et al. (2002):

Emended description of the family Flavobacteriaceae Reichenbach 1992: Cells are short to moderately long rods with parallel or slightly irregular sides and rounded or slightly tapered ends. They are usually 0.3 to 0.6 μm wide and 1 to 10 μm long though members of some species may form filamentous flexible cells (e.g., *Flavobacterium* and *Tenacibaculum*) or coiled and helical cells (*Polaribacter*, *Psychroflexus*, and *Psychroserpens* strains) under certain growth conditions; ring-shaped cells are not formed. Cells in old cultures may form spherical or coccoid bodies (e.g., *Flavobacterium*, *Gelidibacter*, *Psychroserpens*, and *Tenacibaculum*). Gram negative. Nonsporeforming. Gas vesicles are produced in members of some *Polaribacter* species. Flagella are usually absent; the only *Polaribacter irgensii* strain available is flagellated, but motility has not been observed in wet mounts. Nonmotile (*Bergeyella*, *Chryseobacterium*, *Coenonia*, *Empedobacter*, *Myroides*, *Ornithobacterium*, *Polaribacter*, *Psychroserpens*, *Riemerella*, *Salegentibacter* and *Weeksella* strains, and *Psychroflexus gondwanensis* strains) or motile by gliding (*Capnocytophaga*, *Cellulophaga*, *Gelidibacter*, *Flavobacterium*, *Tenacibaculum* and *Zobellia* strains, and *Psychroflexus torquis* strains).

Growth is aerobic (*Bergeyella*, *Cellulophaga*, *Chryseobacterium*, *Empedobacter*, *Flavobacterium*, *Gelidibacter*, *Myroides*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Salegentibacter*, *Tenacibaculum*, *Weeksella*, and *Zobellia* strains) or microaerobic to anaerobic (*Capnocytophaga*, *Coenonia*, *Ornithobacterium*, and *Riemerella* strains). The optimum temperature is usually in the range from 25 to 35°C, but members of some species or genera are psychrophilic or psychrotrophic (*Flavobacterium psychrophilum* and the Antarctic *Flavobacterium* species, as well as *Gelidibacter*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, and *Salegentibacter* strains). Members of some taxa are halophilic to varying degrees (*Cellulophaga*, *Gelidibacter*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Salegentibacter*, *Tenacibaculum* and *Zobellia* strains).

Colonies are nonpigmented (*Bergeyella*, *Coenonia*, *Ornithobacterium*, and *Weeksella* strains) or pigmented by carotenoid or flexirubin pigments or both (*Capnocytophaga*, *Cellulophaga*, *Chryseobacterium*, *Empedobacter*, *Flavobacterium*, *Gelidibacter*, *Myroides*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Riemerella*, *Salegentibacter*, *Tenacibaculum* and *Zobellia* strains).

Menaquinone 6 is either the only respiratory quinone or the major respiratory quinone. Chemoorganotrophic. Intracellular granules of poly-β-hydroxybutyrate are absent. Sphingophospholipids are absent. Homospermidine is the major polyamine though agmatine, cadaverine, and putrescine are frequently present as minor components. Crystalline cellulose (i.e., filter paper) is not decomposed. The DNA base composition ranges from 27 to 44 GC mol%.

Mostly saprophytic in terrestrial and aquatic habitats. Several members of the family are commonly isolated from diseased humans or animals, some species are considered true pathogens. The type genus is *Flavobacterium* Bergey, Harrison, Breed, Hammer, and Huntoon 1923, as emended in 1996 (Bernardet et al., 1996).

Other taxa included in the family Flavobacteriaceae are the genera *Bergeyella*, *Capnocytophaga*, *Cellulophaga*, *Chryseobacterium*, *Coenonia*, *Empedobacter*, *Gelidibacter*, *Myroides*, *Ornithobacterium*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Riemerella*, *Salegentibacter*, *Tenacibaculum*, *Weeksella* and *Zobellia*. Several species unaffiliated to any genus also belong to the family. Several intracellular symbionts of insects and intracellular parasites of amoebae are closely related to the family.

Since this emended description was published, several new species in the genera *Cellulophaga* (Bowman, 2000), *Chryseobacterium* (Hugo et al., 2003; Kämpfer et al., 2003), *Flavobacterium* (McCammon and Bowman, 2000; Humphry et al., 2001; Tamaki et al., 2003; Van Trappen et al., 2003a; Van Trappen et al., 2003b; Zhu et al., 2003), and *Gelidibacter* (Macián et al., 2002), as well as the new genera *Aequorivita* (Bowman and Nichols, 2002), *Arenibacter* (Ivanova et al., 2001; Nedashkovskaya et al., 2003c), *Croceibacter* (Cho and Giovannoni, 2003), *Mesonia* (Nedashkovskaya et al., 2003a), *Muricauda* (Bruns et al., 2001), *Ulvibacter* (Nedashkovskaya, 2003b) and *Vitellibacter* (Nedashkovskaya et al., 2003d), have been validly published or validated after publication (Cho and Giovannoni, 2003). Although not validly published, "*Chryseobacterium proteolyticum*" (Yamaguchi and Yokoe, 2000) and "*Fucobacter marina*" (Sakai et al., 2002) also belong to the family. New taxa, however, do not make another emendation of the family necessary, since their characteristics are in accordance with the current description. The only exception is *Muricauda ruestringensis*, which is facultatively anaerobic and may exhibit long cellular appendages (Bruns et al., 2001).

Table 2 lists the differentiating characteristics of taxa classified in the family, updated from Bernardet et al. (2002). Those taxa that have not been validly published, as well as the two generically misclassified species [*Cytophaga*] *latercula* and [*Cytophaga*] *marinoflava*, are included for information. Additional phenotypic characteristics that differentiate 1) the *Capnocytophaga* species, *Coenonia anatina*, *Ornithobacterium rhinotracheale* and *Riemerella anatipestifer* are described in Vandamme et al. (Vandamme et al., 1994b; Vandamme et al., 1999); 2) the genera *Aequorivita*, *Arenibacter*, *Cellulophaga*, *Croceibacter*, "*Fucobacter*," *Gelidibacter*, *Mesonia*, *Muricauda*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Salegentibacter*, *Tenacibaculum*, *Ulvibacter*, *Vitellibacter*, and *Zobellia*, as well as [*Cytophaga*] *latercula* and [*Cytophaga*] *marinoflava*, are described in Bowman et al. (Bowman et al., 1997; Bowman et al., 1998), Gosink et al. (1998), Johansen et al. (1999), McCammon and Bowman (2000), Barbeyron et al. (2001), Bruns et al. (2001), Ivanova et al. (2001), Suzuki et al. (2001), Bowman and Nichols (2002), Macián et al. (2002), Sakai et al.

Table 2. *Footnote Continued*

Symbols: +, positive reaction; –, negative reaction; (+), weak positive reaction; v, varies within and/or between species; *v*, varies between references; and *, data in these two boxes were erroneously inverted in Bernardet et al. (2002).
Abbreviations: FL, free-living; P, parasitic; S, saprophytic; fe, freshwater environment; me, marine environment; te, terrestrial environment; ND, not determined or determined for some species only; F, flexirubin type pigment; and C, carotenoid type pigment.

[a] The number of species is given in parentheses below the name of the genus.
[b] Type of pigment in *Capnocytophaga gingivalis*. Not determined in the six other *Capnocytophaga* species.
[c] *Chryseobacterium meningosepticum* strains either are not pigmented or produce a weak yellow pigment (e.g., the type strain; Bruun and Ursing, 1987). Members of all other *Chryseobacterium* species produce a bright yellow to orange pigment.
[d] Type of pigment in *Polaribacter glomeratus*. Not determined in the three other *Polaribacter* species.
[e] Number of species positive for this characteristic among the 22 valid *Flavobacterium* species. Only specified when 12 or more species are positive.
[f] Most strains are positive for this characteristic.
[g] Most strains are negative for this characteristic.
[h] Strain dependent for *Chryseobacterium indologenes*. Positive for other *Chryseobacterium* species except *C. scophthalmum*, "*C. proteolyticum*," and *C. defluvii*.
[i] Negative for *Psychroflexus torquis* (J. P. Bowman, personal communication); not determined for *Psychroflexus gondwanensis*.
[j] Not determined for "*Chryseobacterium proteolyticum*"; positive for all other *Chryseobacterium* species.
[k] Positive for all *Chryseobacterium* species, except *Chryseobacterium scophthalmum*.
[l] Positive for all *Capnocytophaga* species, except *Capnocytophaga canimorsus*.
[m] Negative for *Tenacibaculum maritimum* (Burchard, 1999). Not determined in the three other *Tenacibaculum* species.
[n] A greyish-white to beige pigment is produced by *Riemerella columbina* strains on Columbia blood agar (Vancanneyt et al., 1999).

Bowman (personal communication), and Nedashkovskaya (personal communication).

(2002), Cho and Giovannoni (2003a), and Nedashkovskaya et al. (Nedashkovskaya et al., 2003a; Nedashkovskaya et al., 2003b; Nedashkovskaya et al., 2003c; Nedashkovskaya et al., 2003d); and 3) the genera *Bergeyella*, *Chryseobacterium*, *Empedobacter*, *Flavobacterium*, *Myroides* and *Weeksella* are described in Bernardet et al. (1996). Differentiating characteristics for species in each genus are presented in the chapters listed in the Introduction.

In the minimal standards proposed for describing new taxa of the family Flavobacteriaceae (Bernardet et al., 2002), particular methods to determine phenotypic properties were suggested and should preferably be used. Some of these properties are of particular importance to differentiate among members of the family Flavobacteriaceae and the family from related taxa in the *Cytophaga-Flavobacterium-Bacteroides* group. Since the conditions in which the tests are performed are critical, some procedures (updated from Bernardet et al., 2002) are recommended below.

Chemotaxonomically Significant Components

All current members of the family Flavobacteriaceae exhibit menaquinone 6 as their only or major respiratory quinone (Bernardet et al., 1996), whereas menaquinone 7 is present in members of all related families and taxa that have been tested (Hanzawa et al., 1995). As stated in the description of the family, homospermidine is the major polyamine of its members, though agmatine, cadaverine, and putrescine are frequently present as minor components (Hamana and Nakagawa, 2001a; Hamana and Nakagawa, 2001b). Unlike members of the family Sphingobacteriaceae (Steyn et al., 1998), flavobacteria do not contain sphingophospholipids (Bernardet et al., 1996). Fatty acid composition provides high quality taxonomic information, mainly at the generic and specific levels (Vandamme et al., 1996). The predominant fatty acids found in members of the family Flavobacteriaceae are usually characteristic of genera, though some fatty acid profiles help to differentiate species (Vandamme et al., 1994b; Vandamme et al., 1996; Bernardet et al., 1996; Vancanneyt et al., 1996; Bowman et al., 1997; Bowman et al., 1998; Gosink et al., 1998; Barbeyron et al., 2001), provided standardized culture conditions are used. Species of the genera *Capnocytophaga* (Vandamme et al., 1996), *Myroides* (Vancanneyt et al., 1996) and *Riemerella* (Vancanneyt et al., 1999) can be readily differentiated by their protein profiles. This is particularly important for the genera *Myroides* and *Riemerella* for which few differential characteristics are available. However, for some other genera, such as *Flavobacterium*, some species can be identified by their very typical protein profiles, whereas others exhibit intraspecific heterogeneity (Bernardet et al., 1996). Again, to compare protein profiles accurately, highly standardized procedures must be used to obtain, scan, and numerically analyze sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) electrophoregrams.

Production of Enzymes

Although members of the family differ widely in their enzymatic abilities, many of them can degrade different kinds of organic macromolecules (Reichenbach, 1989; The Order Cytophagales in second edition). Interestingly, the recent description of several new taxa in the family actually resulted from enzymatic screenings performed on environmental isolates aimed at discovering potentially useful exoenzymes (Yamaguchi and Yokoe, 2000; Barbeyron et al., 2001; Humphry et al., 2001; Sakai et al., 2002). The array of enzymes produced by flavobacteria understandably depends on the major biopolymers available in their habitats (Kirchman, 2002). For instance, those living in soil and freshwater frequently synthesize cellulose-, pectin-, xylan-, and chitin-degrading enzymes that decompose dead plants, fungi, and insects (Reichenbach, 1989; Haack and Breznak, 1993; Cottrell and Kirchman, 2000; Johansen and Binnerup, 2002), while the marine flavobacteria usually produce enzymes that degrade agars, laminarin, xylan, fucoidan, and carrageenans from micro- or macroalgae (Johansen et al., 1999; Barbeyron et al., 2001; Humphry et al., 2001; Sakai et al., 2002). Proteolytic enzymes are also synthesized by flavobacteria in various environments. They probably play an important role in the virulence of some of the pathogenic members of the family. For instance, the fish-pathogenic *Flavobacterium* species produce extracellular proteases that degrade collagen, elastin, fibrinogen, and keratin (Otis, 1984; Holt, 1988). Combined with enzymes that degrade the complex polysaccharides of connective tissue, such as hyaluronic acid and chondroitin sulfate (Otis, 1984; Teska, 1993), they are responsible for the extensive necrotic lesions that occur in infected fish.

Among the complex organic substrates that some flavobacteria are able to degrade, cellulose has a particular taxonomic significance. Members of some taxa degrade soluble cellulose

derivatives such as carboxymethylcellulose or hydroxyethylcellulose, but since enzymes other than cellulases may degrade these compounds, this does not demonstrate that these taxa are cellulolytic. The decomposition of crystalline cellulose (i.e., filter paper) requires the production of a specific cellulase, and hence only strains able to degrade filter paper should be regarded as cellulose degraders (Reichenbach, 1989). The inability to degrade crystalline cellulose has been confirmed in members of most taxa included in the family Flavobacteriaceae (Bernardet, 1989a; Reichenbach, 1989; The Order Cytophagales in second edition; J.-F. Bernardet, unpublished observation), including members of the recently described genera *Aequorivita*, *Arenibacter*, *Cellulophaga*, *Croceibacter*, *Gelidibacter*, *Mesonia*, *Muricauda*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Salegentibacter*, *Ulvibacter*, *Vitellibacter* and *Zobellia*, as well as members of recently described *Flavobacterium* species (Gosink et al., 1998; Barbeyron et al., 2001; Bruns et al., 2001; Ivanova et al., 2001; Bernardet et al., 2002; Bowman and Nichols, 2002; Cho and Giovannoni, 2003; Nedashkovskaya et al., 2003a; Nedashkovskaya et al., 2003b; Nedashkovskaya et al., 2003c; Nedashkovskaya et al., 2003d). This characteristic distinguishes members of the family Flavobacteriaceae from those of the genus *Cytophaga*, now restricted to cellulolytic organisms (Nakagawa and Yamasato, 1996). Hence, it is essential 1) that strains be tested for their ability to degrade filter paper both on a nutrient-containing agar (presence of a cellulase) and on a mineral agar (ability to use cellulose as the only carbon source; The Order Cytophagales in second edition) and 2) that the cellulose derivatives that are used be specified.

Pigments

Members of most genera classified in the family Flavobacteriaceae produce light to bright yellow or orange pigments though nonpigmented taxa (*Bergeyella zoohelcum*, *Coenonia anatina*, *Ornithobacterium rhinotracheale* and *Weeksella virosa*) and strains (e.g., some *Chryseobacterium meningosepticum* strains are nonpigmented while others, including the type strain, exhibit a weak yellow pigmentation; Bruun and Ursing, 1987) do occur. These pigments may belong to the carotenoid or to the flexirubin types depending on the genus. However, the genus *Flavobacterium* includes carotenoid-producing and flexirubin-producing species, as well as species producing both types of pigment (Reichenbach, 1989; Bernardet et al., 1996). The localization of the two types of pigment is different (i.e., carotenoids in the cytoplasm and flexirubins in the outer membrane), and several different compounds of each type may be synthesized by one single strain (The Order Cytophagales in second edition). Carotenoid pigments are usually produced by members of marine species while flexirubin pigments are more frequently associated with clinical, freshwater or soil organisms (Reichenbach, 1989). Pigments are usually nondiffusible, but the beige pigment produced by members of *Riemerella* species is diffusible on some solid media (e.g., trypticase soy agar; J.-F. Bernardet, unpublished results).

Although chromatography and spectrophotometry are the most accurate techniques for determining the type of pigment produced by bacteria (Weeks, 1981), a simple test may be performed when these methods are unavailable: colonies having a flexirubin type of pigment exhibit an immediate color shift from yellow or orange to red, purple or brown when flooded with 20% KOH and revert to their initial color when flooded by an acidic solution once the excess of KOH has been removed (Reichenbach, 1989). Since the color shift may pass unnoticed when the KOH solution is poured directly over a thin colony on an agar plate, it is strongly recommended that the test be performed on a small mass of bacterial cells collected with a loop and deposited on a glass slide placed on a white background (Bernardet et al., 2002). Another similar mass of bacteria on which no KOH is poured may be used as a control. The color change induced by KOH is not absolutely specific for the flexirubin type of pigment (Fautz and Reichenbach, 1980), but it is still helpful when combined with the results of other tests.

Gliding Motility

The taxonomic significance of this property was once considered so high that headings of a chapter in *The Prokaryotes* (Reichenbach and Dworkin, 1981a) and of a section in *Bergey's Manual* (Larkin, 1989) were based on it. However, the fact that this type of bacterial motility is not restricted to the CFB phylum (Burchard, 1981; Reichenbach, 1989), and that gliding motility in some members of the phylum was not evident, verified Reichenbach's prediction: "Most probably, gliding motility will lose its determining character in this taxonomic group, and eventually there may be order(s), families, and perhaps even genera that comprise motile and nonmotile species" (The Order Cytophagales in second edition). Hence, although not a sound criterion to define the family Flavobacteriaceae, gliding motility is still an important characteristic

for differentiating between genera classified in the family and between species of some genera. However, precautions need to be taken, as its unequivocal recognition is not always easy. Gliding motility is highly dependent on growth conditions such as the temperature (McGrath et al., 1990) and the concentration of nutrients in the growth medium; the latter should preferably be low (Reichenbach and Dworkin, 1981a). Conversely, strains of *Gelidibacter mesophilus* appear to exhibit gliding motility only when specific carbohydrates are added to the medium (Macián et al., 2002). When gliding is strongly suspected but not readily observed by microscopic examination of a drop of liquid culture with a conventionally used coverslip, it should be tested using the hanging drop technique: the coverslip on which the drop has been deposited should be turned upside down and placed on tiny stands on a glass slide; bacteria are then observed through the coverslip. Gliding must be checked on the edge of the hanging drop and at the bottom surface of the coverslip, as this phenomenon is exclusively exhibited by bacteria in contact with a solid and wet surface, such as glass, plastic or agar. Unlike flagellar motility, gliding motility cannot occur when bacterial cells are suspended in a liquid. The movements involved in gliding motility were described previously (Henrichsen, 1972; Reichenbach and Dworkin, 1981a; Reichenbach, 1989). When gliding, bacterial cells may also bend, change direction suddenly, or rotate around one end that remains attached to the surface while the rest of the cell points away from the surface (Reichenbach, 1989). When gliding motility is very slow and hardly noticeable, it may be detected by comparing the position of bacteria in the same area at several minute intervals. Gliding can usually be suspected from the more or less rhizoidal aspect of the edge of the colonies (provided the agar is not too dry), but it cannot usually be detected in bacteria collected on agar and suspended in saline. Direct microscopic examination of the edge of a young colony, either on an open agar plate at the highest magnification possible without using immersion oil or using oil-immersion microscopy after covering the colony with a glass coverslip, may reveal either gliding itself or the slime tracks left on agar by gliding bacteria (Burchard, 1981; Bowman, 2000; The Order Cytophagales in this Volume). Chamber culture may also be used (Reichenbach and Dworkin, 1981a). The use of phase contrast microscopy is always preferable to visualize gliding motility (Bowman, 2000). Interestingly, gliding motility may be related to another characteristic exhibited by some flavobacteria, i.e., adherence of colonies to the agar and of bacterial growth on the glass flask walls in liquid culture (McGrath et al., 1990; Burchard and Sorongon, 1998; Bernardet et al., 2002). Adherence presumably facilitates the participation of flavobacteria to biofilms (see the section Habitat in this Chapter). Combined with gliding motility, this property could also be responsible for the invasion of host tissue by the fish-pathogenic *Flavobacterium* and *Tenacibaculum* species. However, only few investigations have been conducted on the adherence of flavobacteria (Burchard and Sorongon, 1998; Burchard, 1999; Decostere et al., 1999a; Decostere et al., 1999b). Both adherence and gliding motility are likely related to the production of slime by many flavobacteria (Reichenbach, 1989; The Order Cytophagales in this Volume). For instance, slime may be revealed using the Congo red test in *Flavobacterium columnare* and *Tenacibaculum maritimum*, two gliding species whose colonies adhere strongly to the agar; also, slime production increases the viscosity of liquid cultures of *T. maritimum* (see Bernardet et al. [2002] and references therein).

Salinity Requirement

The salinity requirement of members of a potentially new taxon is an important property to be investigated since several genera included in the family Flavobacteriaceae are composed of strains retrieved from seawater or ice, marine sediments, beach mud, marine animals, marine algae, hypersaline lakes, or lakes with salinity similar to that of seawater (Bowman et al., 1997; Bowman et al., 1998; Gosink et al., 1998; Barbeyron et al., 2001; Bruns et al., 2001; Humphry et al., 2001; Ivanova et al., 2001; Bowman and Nichols, 2002; Macián et al., 2002; Sakai et al., 2002; Cho and Giovannoni, 2003; Nedashkovskaya et al., 2003a; Nedashkovskaya et al., 2003b; Nedashkovskaya et al., 2003c; Nedashkovskaya et al., 2003d; see Table 1). Some bacterial strains isolated from high-salinity environments require artificial or natural seawater, either pure or diluted, for growth, whereas other isolates are able to grow on standard media which contain adequate NaCl concentration or after the addition of NaCl. For instance, the two *Chryseobacterium* species isolated from marine environments (i.e., *C. indoltheticum* and *C. scophthalmum*) grow on trypticase-soy agar (0.5 % NaCl) even better than on Bacto marine agar 2216 (1.95 % NaCl among other salts); interestingly, the six other *Chryseobacterium* species are also able to grow on both trypticase-soy agar and marine agar although they occur in non-marine environments (J.-F. Bernardet, unpublished results).

Capnophilic Metabolism

Members of most genera assigned to the family Flavobacteriaceae are composed of aerobic organisms which grow in ambient air. However, *Capnocytophaga*, *Coenonia*, *Ornithobacterium* and *Riemerella* strains require various concentrations of carbon dioxide. Culture conditions are given in detail in the corresponding chapters. After several subcultivations, some strains may be adapted to grow under aerobic conditions, although growth is always significantly better under microaerophilic conditions (Segers et al., 1993; Vandamme et al., 1994b; Vandamme et al., 1996; Vandamme et al., 1999; Vancanneyt et al., 1999). Growth should be tested under both conditions; it is usually very poor or absent under strict anaerobic conditions. Members of the genus *Muricauda* are facultative anaerobes (Bruns et al., 2001), and some *Flavobacterium* species may also grow under anaerobic conditions when certain growth factors are provided (Bernardet et al., 1996).

Genetics

Genetics of members of the family Flavobacteriaceae has been poorly investigated and few data are available. Gliding motility is the only mechanism whose genetics was extensively studied recently: mutagenesis was used to identify at least six different genes required for the gliding of *Flavobacterium johnsoniae* (Hunnicutt et al., 2002). However, mechanisms responsible for gliding motility are complex and probably differ among the organisms that exhibit this kind of motility (McBride, 2001). The same group also developed techniques for the genetic manipulation of various flavobacteria, such as a system of gene transfer, a selectable marker, a suicide vector, and a transposon (McBride and Baker, 1996; McBride and Kempf, 1996). Chromosomal DNA of flavobacteria was only studied for its taxonomic and phylogenetic applications, such as the determination of DNA/DNA homology and the G+C content of the DNA and the comparison of 16S rRNA or *gyrB* genes sequences (Bernardet et al., 2002; see the section Phylogeny in this Chapter). Several molecular techniques (e.g., rRNA gene restriction patterns [ribotyping], randomly amplified polymorphic DNA [RAPD], restriction fragment length polymorphism [RFLP], pulsed field gel electrophoresis [PFGE], etc.) were used to type collections of flavobacterial strains for epidemiological studies. Plasmid DNA was investigated for the same purpose and plasmid profiles of collections of strains have been compared. Among the 128 bacteria listed in the National Center for Biotechnology Information (NCBI) website whose whole genomes have been sequenced, *Bacteroides thetaiotaomicron* was the only member of the CFB phylum; the genomes of three more members of the phylum (i.e., *Cytophaga hutchinsonii*, *Porphyromonas gingivalis* and *Prevotella intermedia*) were being sequenced, but no member of the family Flavobacteriaceae was listed.

Pathogenicity

Members of certain species in the family Flavobacteriaceae are etiologic agents of diseases in humans, birds, fishes, and other animals (see the section Habitat in this Chapter), but the relationship to the host may differ (The Order Cytophagales in this Volume; Jooste and Hugo, 1999). Most of them are opportunistic, invading hosts already immunocompromised individually or as a result of poor farming conditions or environmental disorders. Hence, these organisms may also be isolated from environmental samples; this is the case for the potentially pathogenic members of the genera *Flavobacterium* and *Chryseobacterium* and for members of the genera *Myroides*, *Empedobacter*, *Bergeyella* and *Weeksella*. Some truly parasitic pathogens exist in the family, however, and are exclusively retrieved from diseased hosts; this is the case for the bird pathogens, i.e., members of the genera *Riemerella*, *Ornithobacterium* and *Coenonia*. Although *Capnocytophaga* species belong to the normal bacterial flora of humans, they too may become pathogenic. Human infections caused by flavobacteria are uncommon but may be serious owing to the fact that patients are immunocompromised; moreover, strains are frequently highly resistant to many antimicrobial agents. Pathogenicity is dealt with in detail in the chapters listed in the Introduction.

Applications

Understandably, practical aspects and applications of members of the family Flavobacteriaceae are related to their habitats and to their relationship to the host (see the section Habitat in this Chapter). Positive aspects include synthesis of a number of enzymes potentially useful in industry or medicine; turnover of organic matter in soil, water, and sewage plants; decomposition

of pesticides and insecticides; destruction of toxic proliferative algae; and symbiosis with various insects. Negative effects include spoilage and defects of food (meat, fish, and dairy products); infections in humans and animals; and destruction of valuable algae and vegetables (Holmes et al., 1984a; Reichenbach, 1989; The Genera Flavobacterium, Sphingobacterium and Weeksella in this Volume; The Order Cytophagales in this Volume). Practical aspects and applications are dealt with in the chapters listed in the Introduction.

CHAPTER 6.4

The Genus *Flavobacterium*

JEAN-FRANÇOIS BERNARDET AND JOHN P. BOWMAN

Introduction

The genus *Flavobacterium* Bergey, Harrison, Breed, Hammer, and Huntoon 1923, emend. Bernardet, Segers, Vancanneyt, Berthe, Kersters, and Vandamme 1996 (Bergey et al., 1923; Bernardet et al., 1996) is probably one of the best examples of the revolution brought to the classification of a bacterial taxon by the use of the phylogenetic techniques based on the comparison of 16S rRNA sequences. Of the seven species considered in the previous edition of *Bergey's Manual of Systematic Bacteriology* (Holmes et al., 1984), only the type species *F. aquatile* was finally retained while several other taxa, previously misclassified in other genera, were added to form an extensively emended genus *Flavobacterium* (Bernardet et al., 1996). Since then, the genus has considerably expanded owing to the description of many new species mostly originating from polar habitats. The organisms currently included in the genus *Flavobacterium* were distributed among different chapters in previous editions of *Bergey's Manual* and of *The Prokaryotes*. In *Bergey's Manual*, *Flavobacterium aquatile* was dealt with in the chapter "Genus *Flavobacterium*" (Holmes et al., 1984), while several other *Flavobacterium* species were considered (under other generic epithets) in the chapter "Order I. *Cytophagales*" (Reichenbach, 1989) in the second edition of *The Prokaryotes*. The latter species were also included in the chapter The Order Cytophagales in the second edition, while *F. aquatile* was excluded from the chapter The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* also from this Volume and not considered anywhere else! These chapters contain a wealth of information and are still well worth consulting.

The history and structure of the family Flavobacteriaceae, of which the genus *Flavobacterium* is the type genus, are presented in the chapter "An Introduction to the Family Flavobacteriaceae" in this Volume. The taxonomic and nomenclatural issues concerning the genus *Flavobacterium* are dealt with by the subcommittee on the taxonomy of *Flavobacterium* and *Cytophaga*-like bacteria of the International Committee on Systematics of Prokaryotes. This subcommittee has issued minimal standards for the description of new taxa in the genus *Flavobacterium* and other genera in the family Flavobacteriaceae (Bernardet et al., 2002).

Few species in the genus *Flavobacterium* have been extensively studied and most of them are represented by one strain (i.e., the type species *F. antarcticum* as well as *F. aquatile*, *F. flevense*, *F. frigidarium*, *F. gillisiae*, *F. granuli*, *F. hydatis*, *F. omnivorum*, *F. pectinovorum*, *F. saccharophilum*, *F. xanthum* and *F. xinjiangense*) or a limited number of strains in culture collections. Exceptions are the fish-pathogenic species, of which many strains are usually available; owing to their economic significance worldwide, they have been the subject of numerous studies (see the sections "Habitat and Ecology" and "Pathogenicity and Epidemiology" in this Chapter) and will provide many examples in this chapter.

Phylogeny

Sequences of 16S rRNA and DNA gyrase large subunit (*gyrB*) genes (Weisburg et al., 1985; Woese et al., 1990; Nakagawa and Yamasato, 1993; Suzuki et al., 2001) locate the genus *Flavobacterium* within the phylum "Bacteroidetes," clustering appropriately in a central position in the family Flavobacteriaceae (Bernardet et al., 1996) where it represents the type genus. Within the family Flavobacteriaceae, the genus *Flavobacterium* branches between two primary lineages, one consisting of mostly marine genera and the other of non-marine genera (see the chapters An Introduction to the Family Flavobacteriaceae in this Volume and The Marine Clade of the Family Flavobacteriaceae: The Genera *Aequorivita*, *Arenibacter*, *Cellulophaga*, *Croceibacter*, *Formosa*, *Gelidibacter*, *Gillisia*, *Maribacter*, *Mesonia*, *Muricauda*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Robiginitalea*, *Salegentibacter*, *Tenacibaculum*, *Ulvibacter*, *Vitellibacter* and *Zobellia* in this Volume). This

intermediate position corresponds well with the ecophysiology of the genus, which is relatively diverse (including species from freshwater and from marine ecosystems; see the section Habitat and Ecology in this Chapter). The deepest known branching members of the genus (*F. gelidilacus*, *F. columnare* and *F. aquatile*) are from freshwater ecosystems, suggesting that more halotolerant and marine-derived members of the genus (such as *F. flevense*, *F. gillisiae*, *F. frigidarium*, etc.) may have been distributed into and adapted to seawater/estuarine type environments in the past. Since practically no member of the genus is known to require Na^+ ions for growth, the adaptation to marine environments appears so far to be incomplete (see the section Physiology in this Chapter). Figure 1 presents the phylogenetic tree of the genus *Flavobacterium* based on 16S rRNA gene sequences.

Sequencing of the 16S rRNA gene has over time helped clarify the taxonomy of the genus *Flavobacterium* and is the means to definitively assign new strains within the genus. Phylogenetic data however indicate that several nomenclatural anomalies remain unresolved. Though many *Flavobacterium* species originally included in the older descriptions of the genus (Holmes et al., 1984) have been reclassified (Bernardet et al., 1996; see the section Taxonomy), the taxonomy of several validly described *Flavobacterium* species (J. P. Euzéby, List of Bacterial Names with Standing in Nomenclature) is yet to be officially corrected. For example, the species [*F.*] *devorans* and [*F.*] *yabuuchiae* are believed to be synonyms of *Sphingomonas paucimobilis* (Yabuuchi et al., 1979; Bauwens and De Ley, 1981) and *Sphingobacterium spiritovorum* (Takeuchi and Yokota, 1992), respectively. The species [*F.*] *mizutaii* and [*F.*] *ferrugineum* are clearly generically misclassified and are most closely related to the genera *Sphingobacterium* and *Chitinophaga*, respectively (Gherna and Woese, 1992; Nakagawa and Yamasato, 1993). No phylogenetic data are available for several species including [*F.*] *acidificum*, [*F.*] *acidurans*, [*F.*] *oceanosedimentum*, [*F.*] *resinovorum* or [*F.*] *thermophilum*. On the basis of DNA base composition data, all of these rather obscure species are misclassified and constitute species in completely separate bacterial phyla. For example, Holmes et al. (1984) considered [*F.*] *acidificum* to be a strain of "*Erwinia herbicola* subsp. *Ananas*" (now *Pantoea ananatis*), a member of the Gammaproteobacteria, while others such as [*F.*] *oceanosedimentum* are Gram-positives belonging to the *Bacillus* branch of the Firmicutes.

There are also discrepancies even with better-studied species. For example, sequences provided for the type strain of *F. psychrophilum* are quite different (Fig. 1). Substantial heterogeneity amongst strains classified as *F. columnare* and *F. johnsoniae* is also notable. However, in the case of *F. columnare*, this apparent heterogeneity is caused by a misidentification of the strain ATCC 43622, which more likely belongs to *F. johnsoniae*. The bona fide *F. columnare* strains are indeed grouped within a single cluster in the phylogenetic tree; the division of this cluster in three subclusters was already reported by Triyanto and Wakabayashi (1999), who based their description of three *F. columnare* genomovars on differences in 16S rRNA sequences, restriction fragment length polymorphism (RFLP), and DNA-DNA hybridization. A misidentification is not the explanation for the distance between the *F. johnsoniae* strain DSM 425 and the *F. johnsoniae* type strain, however, since their whole-cell protein and fatty acid profiles are closely related (J.-F. Bernardet, unpublished data). Some of these limitations have already been reported as early as 1984 by Reichenbach (1989) and this genetic diversity may also suggest the potential presence of additional *Flavobacterium* species amongst culture collection strains.

Taxonomy

The long and complex history of the genus *Flavobacterium* up to its emendation in 1996 has been presented in several publications (Holmes et al., 1984; Holmes et al., 1992; Bernardet et al., 1996; the chapter on The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in this Volume) and will not be repeated here. As a result of an extensive polyphasic study (Bernardet et al., 1996), the genus *Flavobacterium* was shown to comprise the ten following valid species: *F. aquatile* (Holmes et al., 1984), *F. branchiophilum* (Wakabayashi et al., 1989), *F. columnare* (Bernardet and Grimont, 1989), *F. flevense* (Van der Meulen et al., 1974), *F. hydatis* (basonym, [*Cytophaga*] *aquatilis*; Strohl and Tait, 1978), *F. johnsoniae* (Reichenbach, 1989), *F. pectinovorum* (Reichenbach, 1989), *F. psychrophilum* (Bernardet and Grimont, 1989), *F. saccharophilum* (Agbo and Moss, 1979), and *F. succinicans* (Anderson and Ordal, 1961). (The references given here are the most relevant, although not necessarily the original descriptions.) This study also demonstrated that the invalid taxa "[*Cytophaga*] allerginae" (see the section Pathogenicity and Epidemiology in this Chapter), "[*Cytophaga*] *xantha*," "[*Flexibacter*] *aurantiacus* subsp. *excathedrus*," "[*Promyxobacterium*] *flavum*," and "[*Sporocytophaga*] *cauliformis*" belong to the genus (Bernardet et

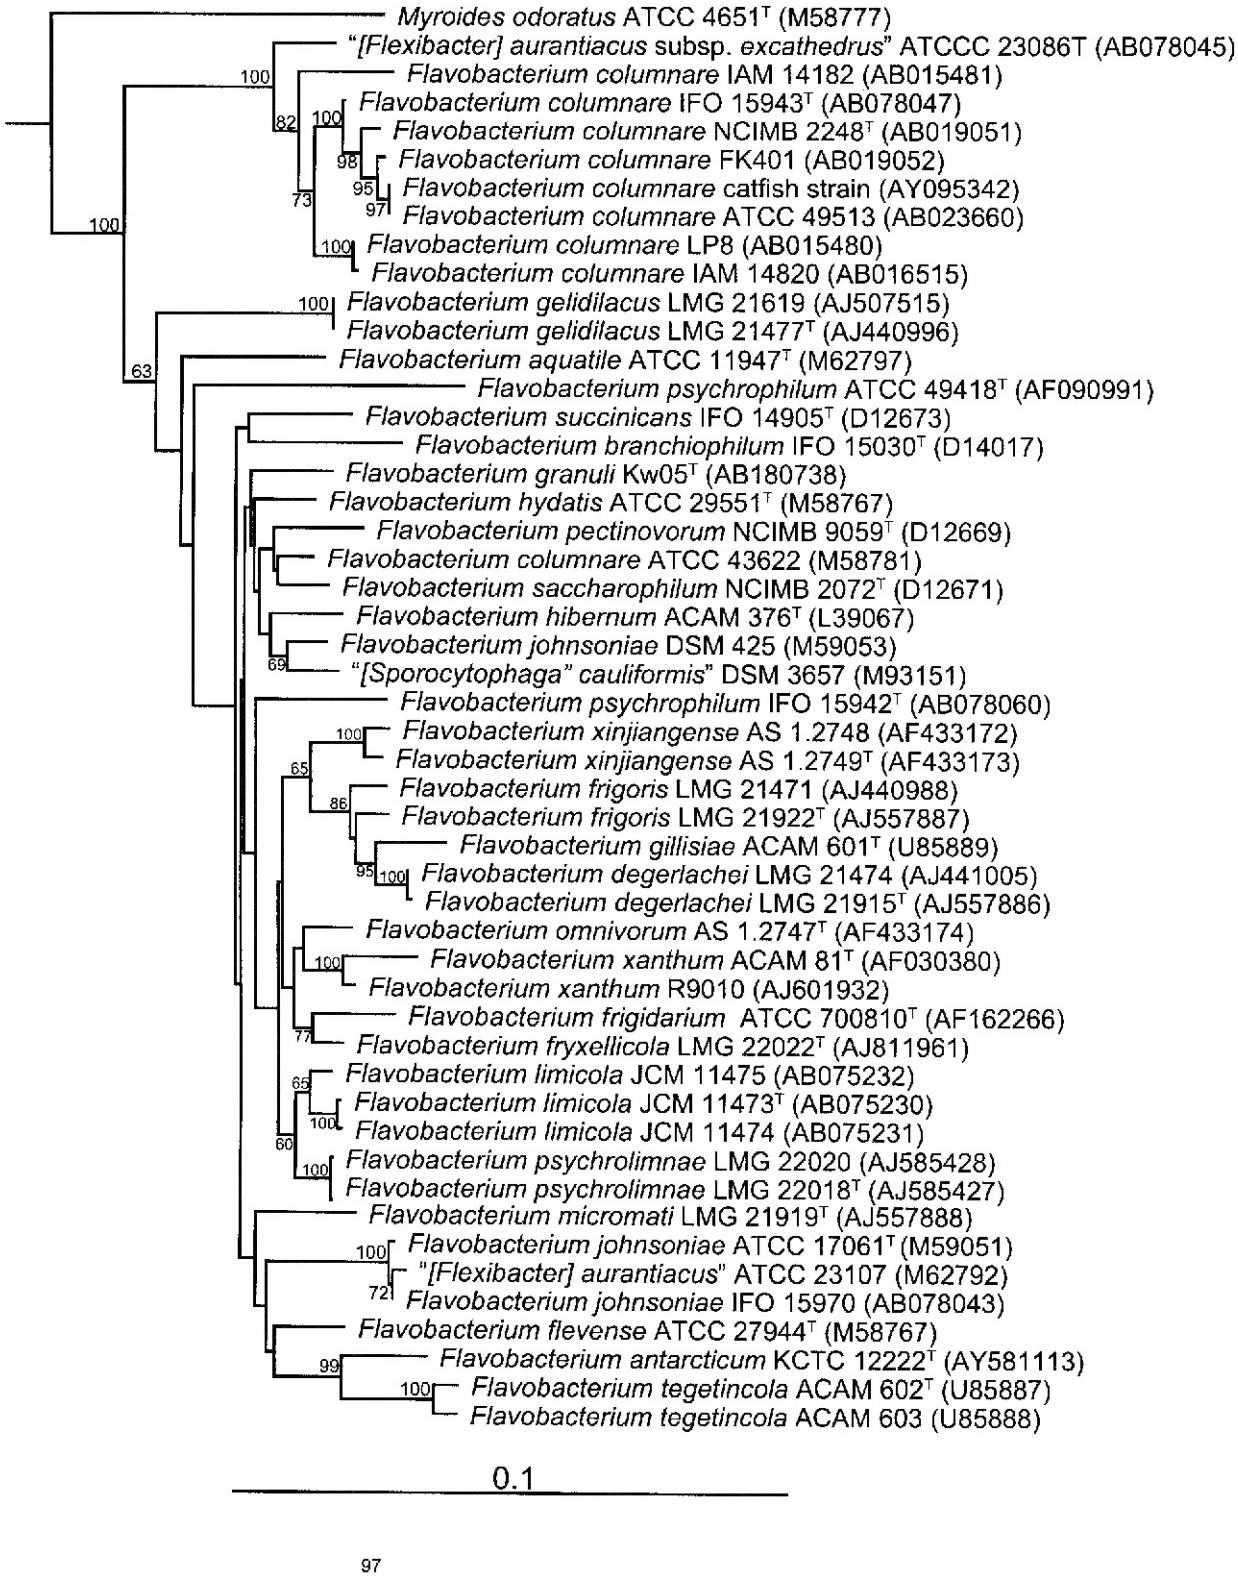

Fig. 1. A maximum likelihood distance phylogenetic tree created by the neighbor-joining procedure (Saitou and Nei, 1987) based on near complete 16S rRNA gene sequences of the genus *Flavobacterium*. The outgroup for the tree was *Myroides odoratus*. The bar indicates maximum likelihood distance.

al., 1996). Except the latter, these invalid and poorly studied taxa are each represented by a single strain. Since then, "[*Cytophaga*] *xantha*" has been validly published under the name *Flavobacterium xanthum* as a result of an extensive study of Antarctic organisms (McCammon and Bowman, 2000). The scant information available on the four remaining invalid taxa may be found in Reichenbach (1989). The determination of the 16S rRNA sequence of "[*Sporocytophaga*] *cauliformis*" and "[*Flexibacter*] *aurantiacus* subsp. *excathedrus*" has confirmed their attribution to the genus *Flavobacterium* (Fig. 1).

Since the emendation of the genus *Flavobacterium*, members of the family Flavobacteriaceae have been shown to represent an important bacterial group in Antarctic environments (Bowman et al., 1997; Van Trappen et al., 2002; see the section Habitat and Ecology in this Chapter); however, the presence of gliding "cytophagas" (which would likely be classified as *Flavobacterium* nowadays) in polar lakes had been noticed long ago (Christensen, 1974). Subsequently, extensive studies of bacterial strains retrieved from various regions of Antarctica have resulted in the description of several new *Flavobacterium* species: *F. antarcticum* (Yi et al., 2005) and *F. fryxellicola* and *F. psychrolimnae* (Van Trappen et al., 2005), *F. hibernum* (McCammon et al., 1998), *F. gillisiae* and *F. tegetincola* (McCammon and Bowman, 2000), *F. frigidarium* (Humphry et al., 2001), *F. gelidilacus* (Van Trappen et al., 2003a), and *F. degerlachei*, *F. frigoris* and *F. micromati* (Van Trappen et al., 2003a). Not from Antarctica but still from cold environments came *F. limicola* (Tamaki et al., 2003), *F. omnivorum* and *F. xinjiangense* (Zhu et al., 2003). Hence, taking into consideration the previously described *F. psychrophilum*, sixteen among the twenty-six current valid *Flavobacterium* species are distinctly psychrophilic or psychrotolerant. While *F. flevense* was the only halophilic species of the ten known in 1996, nine of those published since then may be considered halophilic or halotolerant (see the sections Habitat and Ecology, Identification, and Physiology in this Chapter). Features of the valid *Flavobacterium* species and invalid taxa are listed in Table 1.

Many other organisms, validly published or not, were included in the genus *Flavobacterium* since it was created in 1923 (Bergey et al., 1923). Most of them were subsequently attributed to other or new genera (e.g., the genera *Cellulophaga*, *Chryseobacterium*, *Empedobacter*, *Myroides*, *Pedobacter*, *Psychroflexus*, *Salegentibacter*, *Sphingobacterium* and *Zobellia*; see the corresponding chapters The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in the second edition; The Genus *Chryseobacterium* in this Volume; The Marine Clade of the Family Flavobacteriaceae: The Genera *Aequorivita*, *Arenibacter*, *Cellulophaga*, *Croceibacter*, *Formosa*, *Gelidibacter*, *Gillisia*, *Maribacter*, *Mesonia*, *Muricauda*, *Polaribacter*, *Psychroflexus*, *Psychroserpens*, *Robiginitalea*, *Salegentibacter*, *Tenacibaculum*, *Ulvibacter*, *Vitellibacter* and *Zobellia*; An Introduction to the Family Flavobacteriaceae; The Genera *Bergeyella* and *Weeksella*; and The Genera *Myroides* and *Empedobacter* all in this Volume) while others (for which no 16S rRNA sequences are available) still appear in the lists of *Flavobacterium* species pending further investigation. Complete lists of organisms currently belonging to the genus *Flavobacterium* or that were attributed to it for some time may be found in the chapter "Taxonomic Outlines of the Prokaryotes" of the second edition of Bergey's Manual (Garrity and Holt, 2001) and in the *List of Bacterial Names with Standing in Nomenclature* (Euzéby, 1997; List of Bacterial Names with Standing in Nomenclature). These lists also provide the current taxonomic status and standing in nomenclature of the taxa that were subsequently excluded from the genus *Flavobacterium*.

Habitat and Ecology

Habitats known to harbor *Flavobacterium* strains are listed in Table 2.

Members of the genus *Flavobacterium* are widely distributed in nature, occurring mostly in aquatic ecosystems ranging in salinity from freshwater to seawater. *Flavobacterium* species have never been isolated from hypersaline waters: the extremely halotolerant Antarctic species formally referred to as "[*F.*] *salegens*" and "[*F.*] *gondwanense*" are now *Salegentibacter* and *Psychroflexus*, respectively (Bowman et al., 1998; McCammon and Bowman, 2000), genera which are core members of the marine clade of the family Flavobacteriaceae. By comparison, *Flavobacterium* species have a distinct predilection to low salinity, cool to cold environments and are commonly isolated from polar lakes (Van Trappen et al., 2002) and from streams, rivers, lakes and muddy soils in other cold environments. Unidentified members of the genus were also reported from marine algae (Maeda et al., 1998; Adachi et al., 2002) and mangrove environments (Nakagawa et al., 2001), although none of them actually required seawater for growth. Most *Flavobacterium* species are psychrotolerant (rather than psychrophilic, as defined by Morita 1975) and grow well at 4°C and optimally at 20–30°C. Currently, *Flavobacterium* species have been successfully isolated from temperate to polar low salinity ecosystems which on a biogeographical level correlates well with their

cold-oriented ecophysiology. Various *Flavobacterium* spp. thus have biotechnological potential and ecological interest owing to their ability to produce cold-active enzymes. Some of these enzymes may even be implicated in pathogenicity such as in coldwater disease in fish caused by *F. psychrophilum*.

As a matter of fact, several freshwater species are (or potentially are) the etiological agents of fish diseases (see the section Pathogenicity and Epidemiology in this Chapter), including *F. columnare*, *F. branchiophilum*, *F. hydatis*, *F. johnsoniae*, *F. psychrophilum* and *F. succinicans*. Strains of these species have been isolated from external lesions and internal organs of salmon and other fish, but in some cases also from the surrounding water. The growth requirements of species such as *F. branchiophilum* and *F. psychrophilum* are rather fastidious (see the section Isolation and Cultivation in this Chapter), suggesting their primary habitat could be limited to the fish tissue environment where they exist as a parasite or saprophyte depending on the immunological state of the fish and the virulence of individual strains. Recent data suggest pathogens such as *F. psychrophilum* can survive for long periods in water, with survival enhanced by sediment-derived nutrients; a salinity of 6 however drastically reduces the number of culturable *F. psychrophilum* cells (Madetoja et al., 2003). Other species such as *F. succinicans* and *F. hydatis* are less exacting and thus may be simple

Table 1. Currently recognized species classified in the genus *Flavobacterium*.[a]

Species[b]	Type strain	G+C (mol%)	Source	Reference(s)	Number of strains
Flavobacterium antarcticum	JCM 12383	38	Soil, King George Island, Antarctica	Yi et al., 2005	1
Flavobacterium aquatile [T, AL, c]	ATCC 11947	33	Deep well, United Kingdom	Holmes et al., 1984; Bernardet et al., 1996	1
Flavobacterium branchiophilum [d]	ATCC 35035	34	Gills of salmon, Japan, 1977	Wakabayashi et al., 1989; Bernardet et al., 1996	16, 2, 30
Flavobacterium columnare [e]	NCIMB 2248	32	Kidney of salmon, United States, 1955	Bernardet and Grimont, 1989c; Bernardet et al., 1996	7, 5, 20
Flavobacterium degerlachei	LMG 21915	34	Microbial mats, Lake Ace, Vestfold Hills, Antarctica	Van Trappen et al., 2003b	14, 5, 14
Flavobacterium flevense [AL, f]	ATCC 27944	35	Freshwater lake, The Netherlands	Van der Meulen et al., 1974; Bernardet et al., 1996	1
Flavobacterium frigidarium [g]	ATCC 700810	35	Marine sediment, Adelaide Island, Antarctica	Humphry et al., 2001	1
Flavobacterium frigoris	LMG 21922	34	Microbial mats, Watts Lake, Vestfold Hills, Antarctica	Van Trappen et al., 2003b	19, 5, 19
Flavobacterium fryxellicola	LMG22022	35	Microbial mats, Lake Fryxell, Dry Valley, Antarctica	Van Trappen et al., 2005	3, 3, 3
Flavobacterium gelidilacus	LMG 21477	30	Microbial mats, freshwater and saline lakes, Antarctica	Van Trappen et al., 2003a	22, 5, 22
Flavobacterium gillisiae	ACAM 601	32	Sea ice, Prydz Bay, Antarctica	McCammon and Bowman, 2000	1
Flavobacterium granuli	IAM15099	36	Wastewater treatment plant, beer brewery, South Korea	Askan et al., 2005	1
Flavobacterium hibernum [h]	ACAM 376	34	Freshwater lake, Antarctica	McCammon et al., 1998	2, 2, 2
Flavobacterium hydatis [AL, j]	ATCC 29551	34	Gills of salmon, United States, 1974	Strohl and Tait, 1978; Bernardet et al., 1996	5, 1, 5
Flavobacterium johnsoniae [AL, j]	ATCC 17061	35	Soil or mud, United Kingdom	Reichenbach, 1989; Bernardet et al., 1996	5, 11, 30
Flavobacterium limicola	JCM 11473	34	River sediment, Ibaraki Prefecture, Japan	Tamaki et al., 2003	3, 3, 3
Flavobacterium micromati	LMG 21919	33	Microbial mats, Grace Lake, Vestfold Hills, Antarctica	Van Trappen et al., 2003b	3, 3, 3
Flavobacterium omnivorum	AS 1.2747	35	Frozen soil, China No. 1 glacier, Xinjiang, China, 1999	Zhu et al., 2003	1
Flavobacterium pectinovorum [k]	NCIMB 9059	35	Soil, United Kingdom	Reichenbach, 1989; Bernardet et al., 1996	8, 1, 8
Flavobacterium psychrolimnae	LMG22018	35	Microbial mats, Lake Fryxell, Dry Valleys, Antarctica	Van Trappen et al., 2005	4, 4, 4

Table 1. *Continued*

Species[b]	Type strain	G+C (mol%)	Source	Reference(s)	Number of strains
Flavobacterium psychrophilum [l]	NCIMB 1947	33	Kidney of salmon, United States, 1955	Bernardet and Grimont, 1989c; Bernardet et al., 1996	7, 6, 200
Flavobacterium saccharophilum [m]	NCIMB 2072	36	River Wey, United Kingdom, 1976	Agbo and Moss, 1979; Reichenbach, 1989; Bernardet et al., 1996	4, 1, 4
Flavobacterium succinicans [n]	DSM 4002	37	Fin of salmon, United States, 1954	Anderson and Ordal, 1961; Reichenbach, 1989; Bernardet et al., 1996	3, 3, 3
Flavobacterium tegetincola	ACAM 602	34	Cyanobacterial mat, marine salinity lake, Antarctica	McCammon and Bowman, 2000	2, 1, 2
Flavobacterium xinjiangense	AS 1.2749	34	Frozen soil, China No. 1 glacier, Xinjiang, China, 1999	Zhu et al., 2003	1
Flavobacterium xanthum [o]	IAM 12026	36	Soil, Showa station, Antarctica, 1967	Inoue and Komagata, 1976; Reichenbach, 1989; McCammon and Bowman, 2000	1
"[*Cytophaga*] *allerginae*"	ATCC 35408	34	Water in air-cooling unit, Florida	Liebert et al., 1984; Reichenbach, 1989; Bernardet et al., 1996	1
"[*Flexibacter*] *aurantiacus* subsp. *excathedrus*"	ATCC 23086	33	Pool in cathedral, Cartago, Costa Rica	Lewin, 1969; Reichenbach, 1989; Bernardet et al., 1996	1
"[*Promyxobacterium*] *flavum*"	DSM 3577	35	Rhizosphere of tomato plant, Russia	Reichenbach, 1989; Bernardet et al., 1996	1
"[*Sporocytophaga*] *cauliformis*"	NCIMB 9488	36	Water, Lake Constance, Germany	Gräf, 1962 Reichenbach, 1989; Bernardet et al., 1996	2, 2, 2

Abbreviations: [T], type species; [AL], the species is cited on the Approved Lists of Bacterial Names (Skerman et al., 1980; Moore et al., 1985); ACAM, Australian Collection of Antarctic Microorganisms, University of Tasmania, Hobart, Tasmania, Australia; AS, culture collection of the Institute of Microbiology, Academia Sinica, Beijing, China; ATCC, American Type Culture Collection, Manassas, VA, United States; DSM, Deutsche Sammlung von Mikroorganismen, Braunschweig, Germany; IAM, culture collection of the institute of Applied Microbiology, University of Tokyo, Japan; JCM, Japanese Collection of Microorganisms, Tokyo, Japan; LMG, BCCM/LMG bacteria collection, Laboratorium voor Microbiologie, University of Gent, Gent, Belgium; NCIMB, National Collection of Industrial and Marine Bacteria, Aberdeen, Scotland.

[a] Names in quotation marks have not been validly published. Brackets indicate generically misclassified bacteria. Accession number is that in the recognized culture collection in which the type strain was first deposited. The origin and G + C content are those of the type strain. When more than one strain are known, three numbers are given, i.e., the number of strains on which the original description was based, the number of strains currently available in the largest culture collections (ATCC, CIP [Collection de I'Institut Pasteur, Paris, France], DSM, LMG, and NCIMB), and the approximate number of strains which have been included in further studies and which are or may still be maintained in specialized culture collections, respectively.

[b] Previous names and corrected epithets of species (taken from Euzéby [1997]; List of Bacterial Names with Standing in Nomenclature) are as stated in footnotes c to o.

[c] "[*Bacillus*] *aquatillis*" Frankland and Frandlnad 1889, "*Bacterium aquatillis*" Chester 1897, "[*Flavobacterium*] *aquatilis*" Bergey et al. 1923, "[*Chromobacterium*] *aquatilis*" Topley and Wilson 1929, and "[*Empedobacter*] *aquatile*" Brisou et al. 1960.

[d] *Flavobacterium branchiophila* Wakabayashi et al. 1989.

[e] "[*Bacillus*] *columnaris*" Davis 1922, "[*Chondrococcus*] *columnaris*" Ordal and Rucker 1944, [*Cytophaga*] *columnaris* Garnjobst 1945, Reichenbach 1989, and [*Flexibacter*] *columnaris* Leadbetter 1974, Bernardet and Grimont 1989c.

[f] [*Cytophaga*] *flevensis* van der Meulen et al. 1974, Reichenbach 1989.

[g] "*Flavobacterium xylanivorum*," name as deposited in the 16S rRNA sequence databases and in the ATCC.

[h] "*Flavobacterium ameridies*," name as deposited in the 16S rRNA sequence databases.

[i] [*Cytophaga*] *aquatilis* Strohl and Tait 1978.

[j] [*Cytophaga*] *johnsonae* Stanier 1947, Reichenbach 1989, and "[*Cytophaga*] *johnsonii*" Stanier 1957.

[k] "*Flavobacterium pectinovorum*" Dorey 1959, "[*Empedobacter*] *pectinovorum*" Kaiser 1961, and [*Cytophaga*] *pectinovora* Reichenbach 1989.

[l] [*Cytophaga*] *psychrophila* Borg 1960, Reichenbach 1989, and [*Flexibacter*] *psychrophilus* Bernardet and Grimont 1989c.

[m] [*Cytophaga*] *saccharophila* Agbo and Moss 1979.

[n] [*Cytophaga*] *succinicans* Anderson and Ordal 1961, Reichenbach 1989, and "[*Flexibacter*] *succinicans*" Leadbetter 1974.

[o] "[*Cytophaga*] *xantha*" Inoue and Komagata 1976.

Table 2. Habitats which are known to harbor described *Flavobacterium* species.

Species	Known habitat(s)
	Freshwater fish
F. branchiophilum	Diseased gills of various fish species; United States, Canada, Hungary, Japan, and Korea
F. columnare	External lesions and internal organs of many fish species; worldwide
F. hydatis	Diseased gills of salmon; United States
F. psychrophilum	External lesions and internal organs of (mostly) salmonid fish; United States, Canada, Chile, Europe, Japan, Korea, Tasmania
F. succinicans	External lesions of salmon and aquarium water (containing salmon); United States
	Temperate freshwater and soil
F. aquatile	Well water; United Kingdom
F. flevense	Freshwater and muddy soils, e.g., from Ijsselmeer, the Netherlands
F. granuli	Wastewater treatment plant, beer brewery; South Korea
F. johnsoniae	Soil (as for *F. pectinovorum*), compost, freshwater and freshwater sediment, also external lesions of various fish species; worldwide
F. limicola	Freshwater river sediment, e.g., from Japan
F. pectinovorum	Temperate, moist, organic-rich soils, e.g., from the United Kingdom
F. saccharophilum	Freshwater sediment; United Kingdom
"[*Cytophaga*] *allerginae"*	Water in an air-cooling unit; United States
"[*Flexibacter*] *aurantiaus* subsp. *Excathedrus"*	Freshwater pool; Costa Rica
"[*Promyxobacterium*] *flavum"*	Rhizosphere of tomato plant; Russia
"[*Sporocytophaga*] *cauliformis"*	Freshwater lake (Lake Constance)
	Cold environments
F. antarcticum	Organic-rich soil (penguin habitat); Antarctica
F. degerlachei	Microbial mats, freshwater lakes; Antarctica
F. frigidarium	Marine sediment, sea-ice; Antarctica
F. frigoris	Microbial mats, freshwater lakes; Antarctica
F. fryxellicola	Microbial mats, fresh/brackish water lakes; Antarctica
F. gelidilacus	Microbial mats, freshwater and saline lakes; Antarctica
F. gillisiae	Rich basal algal assemblages of sea-ice; Antarctica
F. hibernum	Freshwater lakes fed by glacial run-off; Antarctica
F. micromati	Microbial mats, freshwater lakes; Antarctica
F. omnivorum	Frozen soil, glacier; China
F. tegetincola	Microbial mats, freshwater to marine salinity lakes; Antarctica
F. xanthum	Muddy soil, pond mud, algal mats, freshwater lakes in Antarctica; freshwater eutrophic lakes in Germany
F. xinjiangense	Frozen soil, glacier; China

freshwater commensals but may possess opportunistic pathogenic responses. Strains of *F. columnare* also can kill cysts of the protistan pathogen *Giardia lamblia* in the presence of elevated Ca^{2+} ions (Rodgers et al., 2003), suggesting that the biological interactions of pathogenic and other *Flavobacterium* species could be quite diverse (see the section Applications in this Chapter).

Other *Flavobacterium* species appear to be harmless, chemoheterotrophic species that play a role in mineralizing various types of organic matter (carbohydrates, amino acids, proteins, and polysaccharides) in aquatic ecosystems (see the sections Identification and Physiology in this Chapter), although many early reports of bacteria, fungi, dead insects, and nematods being degraded by so-called "*Flavobacterium*" in soil are questionable. A member of the genus *Flavobacterium* was recently retrieved from paper mill slime, but its role in the process was not determined (Oppong et al., 2003). The 16S rRNA gene sequence was the only clue to the attribution to the genus *Flavobacterium* of several bacterial strains retrieved from the guts of mosquitoes (Campbell et al., 2004). Some species appear to be cosmopolitan (e.g., *F. johnsoniae* and *F. xanthum*), isolated from different habitats across several continents; however, the knowledge of the distribution of most *Flavobacterium* species is severely limited and data for most species are based only on one survey. In addition, specific ecological knowledge for most species is absent, including their specific functional roles and interactions with microorganisms and metazoa. The fish pathogens are exceptions, though even for these the data are still relatively limited.

Temperate freshwater and freshwater sediments (groundwater, lakes, rivers and ponds) are known to be habitats for the species *F. johnsoniae*, *F. saccharophilum*, *F. flevense*, *F. limicola*

and *F. xanthum* (Tamaki et al., 2003), while microbial mats and water of Antarctic oligotrophic lakes harbor *F. tegetincola*, *F. xanthum*, *F. hibernum*, *F. xinjiangense*, *F. gelidilacus*, *F. degerlachei*, *F. micromati*, *F. frigoris*, *F. fryxellicola* and *F. psychrolimnae* (Jaspers et al., 2001; Van Trappen et al., 2002; Van Trappen et al., 2003a; Van Trappen et al., 2003b; Pearce, 2003; Van Trappen et al., 2005; Table 2). The latter set of species tends to be more cold-adapted than the temperate species with growth temperature limits only slightly over 25°C. Soil is also a habitat for *Flavobacterium* species including *F. pectinovorum*, *F. johnsoniae* and *F. antarcticum* (Yi et al., 2005). The soils in which they have been found were moist and organic rich; arid desert or infertile soils were not known to harbor *Flavobacterium* species until a *Flavobacterium* sp. was recently isolated from samples of arid soil (Bodour et al., 2003). Two species, *F. omnivorum* and *F. xinjiangense*, were isolated from entrained frozen soil recovered from a glacier in western China (Xinjiang Province; Zhu et al., 2003). The soil was frozen into the glacier long in the past with the freeze-resistant species probably surviving there ever since. Most bacteria found in glacial deposits are usually hardy soil-type bacteria that are probably distributed into glacial environments either by wind-dispersion or by being trapped during one of the past ice ages. The species *F. gillisiae* and *F. frigidarium* were isolated from polar sea-ice, Antarctic marine salinity lakes, and marine sediment (e.g., Bowman et al., 1997; McCammon and Bowman, 2000; Humphry et al., 2001; Brinkmeyer et al., 2003) and could have a wider distribution in cold ecosystems. Culture-independent studies using polymerase chain reaction (PCR)-amplification and sequencing of cloned 16S rRNA genes so far indicate *Flavobacterium* species are more or less limited to the environments already indicated above (see the section Identification in this Chapter). Using phenotypic characteristics and 16S rRNA gene sequences, Zdanowski et al. (2004) identified several *Flavobacterium* sp., *Chryseobacterium* sp. and *Gelidibacter* sp. strains among the extremely diverse bacterial community in penguin guano in Antarctica. Indeed, the new species *F. antarcticum* was isolated from a soil sample collected from a penguin habitat (Yi et al., 2005).

Such artificial, moist environments as air-cooling units are also colonized by members of the genus *Flavobacterium*; for instance, a *Flavobacterium* sp. strain was involved in several human cases of respiratory disease which occurred during the eighties in a United States textile facility (Flaherty et al., 1984; Liebert et al., 1984; see the section Pathogenicity and Epidemiology in this Chapter). Another, very unusual environment for *Flavobacterium* strains was discovered when amoebae were shown to harbor intracellular members of the genus (Müller et al., 1999; Horn et al., 2001; see the section Pathogenicity and Epidemiology in this Chapter). One of the most recently described *Flavobacterium* species, *F. granuli*, was isolated from anaerobic granules in the wastewater treatment plant of a beer brewing factory in South Korea (Aslam et al., 2005). These granules, composed of microorganisms, inorganic nuclei and extracellular polymers, result from the flocculation of sludge in the reactor.

The ecology and habitats of bacterial genera belonging to the family Flavobacteriaceae were reviewed by Jooste and Hugo (1999). They were also extensively described for some of the bacterial species now encompassed in the genus *Flavobacterium* by Reichenbach (1989) and in the chapter The Order Cytophagales in the second edition. Many early publications reported the degradation of food products by poorly identified "*Flavobacterium*" strains; however, these food-related members of the family Flavobacteriaceae have subsequently been moved to the genera *Bergeyella*, *Chryseobacterium*, *Empedobacter*, *Myroides* and *Weeksella* (Engelbrecht et al., 1996; Jooste and Hugo, 1999; see the three corresponding chapters in this Volume—The Genera *Bergeyella* and *Weeksella*, The Genera *Myroides* and *Empedobacter* and The Genus *Chryseobacterium*). *Flavobacterium* spp. were isolated or identified from their 16S rRNA gene sequence from poultry and the air of poultry processing establishments (Georgnaras et al., 1996; Ellerbroek, 1997), dairy products (Cousin, 1982), and traditional alcoholic beverages in Nigeria (Sanni et al., 1999) and Mexico (Escalante et al., 2004), but the identification procedure was insufficient to determine whether these isolates were true *Flavobacterium* strains or belonged to other genera in the family Flavobacteriaceae. Bacterial strains, identified as members of the genus *Flavobacterium* based on phenotypical characteristics, were isolated from the surface and muscle of fresh or ice-stored sardines, but they were not considered to play an important role in the spoilage of the fish (Gennari and Cozzolino, 1989; Elotmani et al., 2004). This was also the opinion of González et al. (2000) about the *F. aquatile* strain they isolated from muscle samples of ice-stored rainbow trout. The isolation of *Flavobacterium* strains from fish products is not surprising since they have long been known to belong to the normal bacterial flora of freshwater fish and fish eggs. From their phenotypic traits, the *Cytophaga*-like strains reported from the surface of salmonid eggs (Bell et al., 1971; Barker et al., 1989) and gills (Trust, 1975; Nieto et al., 1984) could actually well have been *Flavobacterium* isolates. Unidentified *Flavobacterium* strains were also reported from

egg, skin, gill, and intestine samples (Trust, 1975; Barker et al., 1989; Nedoluha and Westhoff, 1997; Al-Harbi and Uddin, 2003; Míguez and Combarro, 2003; Mahmoud et al., 2004), as well as from the rearing pond water and sediment (Nedoluha and Westhoff, 1997; Al-Harbi and Uddin, 2003) of various fish species, but not from the fish diet (Nedoluha and Westhoff, 1997). Members of the *Flavobacterium-Cytophaga* group represented 9% of all bacteria identified by fluorescent in situ hybridization (FISH) in the tank water of an eel intensive culture system, and even higher numbers of the same organisms occurred in the eel slime (Moreno et al., 1999).

Isolation and Cultivation

Being classic aerobic chemoheterotrophs, members of *Flavobacterium* species can be readily cultivated on several commercially available organic media. The presence of NaCl and the concentration of organic extracts strongly affect growth. This is the major reason growth of freshwater species, including the fish pathogens, is so poor on media such as marine and nutrient agars that contain substantial amounts of NaCl. The procedures available for the enrichment, isolation, and cultivation of some of the bacterial species now encompassed in the genus *Flavobacterium* were extensively described by Reichenbach (Reichenbach, 1989; Reichenbach, 1992); the corresponding information for the *Flavobacterium* species published since then was included in their individual descriptions. The cultivation of bacterial genera belonging to the family Flavobacteriaceae was reviewed by Jooste and Hugo (1999). Media and optimal incubation temperatures for known *Flavobacterium* spp. are indicated in Table 3. Although they do allow limited bacterial growth, some incubation tem-

Table 3. Media and incubation temperature for routine cultivation of *Flavobacterium* species.

Species	Anacker and Ordal's agar	Nutrient agar	Trypticase soy agar	Marine 2216 agar	Incubation temperature (°C)
Na^+-sensitive fish pathogens[a]					
F. branchiophilum	+[b]	–	–	–	20–25

F. xanthum	+	+	+	+	15–20

Abbreviations: +, good growth; w, weak or reduced growth; –, no or scant growth; and NT, not tested.

[a]Fish-pathogenic species will also grow well on Modified Shieh's medium (Song et al., 1988a).

[c]*Flavobacterum psychrophilum* strains grow better on Anacker and Ordal's agar containing an enriched amount of tryptone (e.g., 5 g·liter^{-1}) or on Modified Shieh's agar.

[d]For the routine cultivation of *F. xinjiangense*, PYG agar or broth can also be used (Zhu et al., 2003).

peratures and media in this table are not recommended for routine cultivation of some species.

All species can be grown conveniently on agar media although *F. columnare* strains tend to adhere strongly to the agar surface (see the section Identification in this Chapter). Many species can grow on rich media such as nutrient broth and agar and trypticase soy broth and agar (TSA); most of them can also be readily grown on media containing a lower concentration of nutrients such as R2A and other media typically used for growing freshwater bacterial chemoheterotrophic species. *Flavobacterium omnivorum* and *F. xinjiangense* grow well on rich glucose-containing media such as peptone-yeast extract-glucose (PYG; Zhu et al., 2003); this is presumably also true for other *Flavobacterium* species, although glucose does not improve the growth of *F. columnare* (Song et al., 1988b). Modified Shiehs (Song et al., 1988b) or Anacker and Ordal's media (Anacker and Ordal, 1955), with incubation at 20°C, can be used for general cultivation, as almost all *Flavobacterium* species should grow well under these conditions. Nutrient, trypticase soy, Marine 2216, and R2A broth and agar media are commercially available. The formulae for some of the other media mentioned are detailed at the end of this section.

Flavobacterium are best isolated directly from source material (water, mud, soil, fish tissue, etc.) onto agar media. Selective culturing techniques generally have not been developed for the majority of *Flavobacterium* species, except for the fish pathogens (see below). The distinctive yellow pigmentation and shiny, slightly mucoid appearance of the colonies of most *Flavobacterium* species provide a direct means for selection of putative *Flavobacterium* strains. Further identification relies then on phenotypic characteristics and 16S rRNA gene sequencing (see the section Identification in this Chapter).

The isolation procedure used can take advantage of the fact that most *Flavobacterium* species are adapted to cool to cold ecosystems: incubation temperature thus can be set to 4–20°C. Indeed, the isolation of *Flavobacterium* species from permanently cold ecosystems such as sea-ice, glacial seawater, and polar lake samples can be enhanced by a pre-enrichment step at a low temperature, typically 2–4°C for 1–2 days in a suitable medium. This boosts the populations of heterotrophic psychrophilic species, which respond rapidly to high levels of organic nutrients. The pre-enrichment culture is then spread-plated onto the corresponding agar medium. This process was used for the isolation of *F. gillisiae* and *F. tegetincola* from Antarctic ice and water samples using Marine 2216 agar (McCammon and Bowman, 2000), for the isolation of *F. xinjiangense* and *F. omnivorum* from glacial entrained soil using PYG medium (Zhu et al., 2003), and for the isolation of several species from Antarctic lake algal mat material using TSA and R2A (Van Trappen et al., 2002).

Some *Flavobacterium* species can be isolated on media containing a specific substrate, such as chitin or pectin (Reichenbach, 1989). *Flavobacterium frigidarium* can be enriched from marine sediments in a liquid xylan-containing mineral salts medium; after several weeks enrichment at 4°C, the species can be isolated and purified using the same medium solidified with agar (Humphry et al., 2001).

Understandably, the fish-pathogenic *Flavobacterium* species (see the sections Habitat and Ecology and Pathogenicity and Epidemiology in this Chapter) have received considerable attention to develop appropriate isolation media (Holt et al., 1993; Turnbull, 1993; Wakabayashi, 1993; Austin and Austin, 1999). After the Anacker and Ordal's medium (frequently called "cytophaga medium" in the fish pathology literature) was first proposed for the cultivation of *F. columnare* (Anacker and Ordal, 1955), several other media were evaluated for improved bacterial growth, including the Shieh's medium, both in its original formula (Shieh, 1980) and in a modified, more simple formula (Song et al., 1988b), and the tryptone-yeast extract-salts medium (TYES; Holt, 1988; Holt et al., 1993). *Flavobacterium columnare* is usually isolated from superficial lesions in diseased fish (see the section Pathogenicity and Epidemiology in this Chapter) in which many other bacteria also proliferate (Hawke and Thune, 1992; Tiirola et al., 2002). To prevent the overgrowth of the pathogen by saprophytic bacteria and their antagonistic effect (Chowdhury and Wakabayashi, 1989; Tiirola et al., 2002), selective media were devised on the basis of the resistance of *F. columnare* to neomycin, polymyxin B and tobramycin (Fijan, 1969; Bullock et al., 1986; Griffin, 1992; Hawke and Thune, 1992; Decostere et al., 1997) and on its ability to degrade gelatin (Bullock et al., 1986; Griffin, 1992). One such formula (Selective Flexibacter Medium; Bullock et al., 1986) is given below. Serial dilution of infected samples has also been advocated to favor the isolation of fish-pathogenic *Flavobacterium* species (Tiirola et al., 2002). No growth of *F. columnare* was reported on TSA, nutrient agar or Marine 2216 media. All *F. columnare* strains are able to grow at 18, 25 and 30°C; some of them may also grow at 15 or 37°C, depending on the temperature of the environment they were isolated from (Decostere et al., 1998; Triyanto and Wakabayashi, 1999).

Many formulae have also been proposed for the growth of *F. psychrophilum* (Holt et al., 1993; Madetoja and Wiklund, 2002; Nematollahi et al., 2003b; Cepeda et al., 2004). Anacker and Ordal's

medium has been widely used. To improve the growth of *F. psychrophilum*, several modifications of the original formula have been proposed, such as increasing the tryptone content to 2 g·liter^{-1} (Wakabayashi and Egusa, 1974) or 5 g·liter^{-1} (Bernardet and Kerouault, 1989; Crump et al., 2001) or adding 10% fetal bovine serum (Obach and Baudin-Laurencin, 1991; Brown et al., 1997) or 3% fish blood (Crump et al., 2001). Daskalov et al. (1999) also reported improved growth, gliding motility, and pigmentation of *F. psychrophilum* when grown in Anacker and Ordal's agar and broth supplemented with skimmed milk and 0.5 g·liter^{-1} each of D(+) galactose, D(+) glusose, and L-rhamnose. The Shieh's medium (Shieh, 1980; Holt et al., 1993), the tryptone-yeast extract-salts medium (TYES; Holt et al., 1993; Crump et al., 2001), and the nutrient agar and broth (Secades et al., 2001; Secades et al., 2003) also give good growth. Although the growth of *F. psychrophilum* on TSA was sometimes reported, most authors agree that no or only negligible growth occurs on this medium. The isolation of *F. psychrophilum* from blisters or internal organs usually results in the growth of pure cultures; but a tobramycin-containing medium has been proposed to prevent the overgrowth of *F. psychrophilum* by other bacteria when external lesions are sampled (Kumagai et al., 2004). This organism is not particularly fastidious, although its growth is inevitably slower than that of other fish-pathogenic *Flavobacterium* species owing to its lower range of temperature tolerance. *Flavobacterium psychrophilum* grows at temperatures between 4 and 23°C; most strains do not grow or grow very weakly at 25°C (Bernardet and Kerouault, 1989; Holt et al., 1989; Brown et al., 1997; Uddin and Wakabayashi, 1997), although growth at 25°C was reported for some strains (Ostland et al., 1997; Madetoja et al., 2001). Optimum growth occurs at 15 (Holt et al., 1989) to 20°C (Uddin and Wakabayashi, 1997). One of the main reasons for trying to improve the yield of *F. psychrophilum* in culture was to obtain large masses of bacteria that could be used for preparing a vaccine against the severe salmonid diseases it is responsible for worldwide (see the section Pathogenicity and Epidemiology in this Chapter). Recently, Crump et al. (2001) achieved large-scale production of *F. psychrophilum* in a 35-liter fermenter containing 28 liters of TYES broth supplemented with 1% maltose and 0.02% sodium acetate with stirring and aeration. Supplementation of TYES with 0.5 g·l^{-1} glucose also enhanced the growth of *F. psychrophilum*, resulting in improved recovery of the bacterium from stored cultures and infected fish and in increased production of biomass in liquid culture (Cepeda et al., 2004). Standard procedures for such investigations of *F. psychrophilum* as experimental infection, antimicrobial susceptibility testing, and virulence studies require the use of accurate numbers of viable bacteria. Improvements in the growth media and careful handling of the bacteria in isotonic suspension media resulted in predictable production of viable *F. psychrophilum* cells and allowed an absorbance/colony-forming-units relation curve to be established (Michel et al., 1999). However, as stated by Faruk (2000): "It should be noted that the growth of each *F. psychrophilum* isolate differed considerably. Ideally, a growth curve should have been prepared for each isolate to examine individual life cycles of the isolates." *F. psychrophilum* may enter a "viable but non-cultivable" state (Michel et al., 1999; Madetoja and Wiklund, 2002; Vatsos et al., 2002).

Strains of *F. johnsoniae* (originally isolated from soil samples on chitin-containing media; Stanier, 1947; Reichenbach, 1989) and *F. hydatis* grow well on media with rather low-nutrient content such as Anacker and Ordal's and modified Shieh's, as well as on more nutrient-rich nutrient media and TSA, on which they produce flat, translucent, spreading, pale yellow colonies with filamentous to rhizoid margins or raised to convex, round to undulate, opaque, bright yellow colonies with entire to irregular margins, respectively (Strohl and Tait, 1978; Reichenbach, 1989; J.-F. Bernardet, unpublished data). Hence, these media are currently used for the isolation of *F. johnsoniae* strains from fish (Carson et al., 1993), as well as for the growth of the numerous *F. johnsoniae*-like and *F. hydatis*-like strains also isolated from fish (J.-F. Bernardet, unpublished data; see the section Pathogenicity and Epidemiology in this Chapter). However, as for *F. columnare*, these organisms occur in external lesions and their recovery may be hampered by the presence of numerous saprophytic bacteria. Given the very limited impact of these organisms in fish pathology, no selective medium was devised. Incubation temperatures of 20–30°C are convenient for routine cultivation.

Flavobacterium branchiophilum is the most fastidious of all fish-pathogenic *Flavobacterium* species (Heo et al., 1990; Turnbull, 1993; Ko and Heo, 1997; see the section Pathogenicity and Epidemiology in this Chapter). Growth on Anacker and Ordal's agar is slow, with colonies appearing only after 2–5 days of incubation at 18°C. Colonies are light yellow, translucent, non-spreading, circular with regular edges; the latter characteristic is due the absence of gliding motility in *F. branchiophilum* (Wakabayashi et al., 1989; Ostland et al., 1994). Growth periods of up to seven days were used for some studies, and the enrichment of the medium with serum, gelatin or starch was suggested (Ko and Heo, 1997). For

primary isolation from gill samples, Ostland et al. (1994) plated serial 10-fold dilutions of gill tissue on Anacker and Ordal's agar and incubated the plates at 12 or 18°C for 6–12 days. The growth of several *F. branchiophilum* strains was compared on different media: no growth occurred on TSA, nutrient agar, and Mueller Hinton; only limited growth occurred on Anacker and Ordal's agar enriched to 5 g·liter^{-1} of tryptone; growth was distinctly better on original Anacker and Ordal's agar, modified Shieh's agar, *Microcyclus-Spirosoma* agar (medium no. 81 of the National Collections of Industrial, Food and Marine Bacteria [NCIMB] catalogue of strains), and Medium for Freshwater Flexibacteria (NCIMB medium no. 218; Lewin, 1969); and the best growth was achieved on casitone yeast extract agar (NCIMB medium no. 101; J.-F. Bernardet, unpublished data). Different temperatures were also compared, and the 20–25°C range was found convenient (J.-F. Bernardet, unpublished data).

The four invalid taxa which belong to the genus *Flavobacterium*, i.e., "[*Cytophaga*] *allerginae*," "[*Flexibacter*] *aurantiacus* subsp. *excathedrus*," "[*Promyxobacterium*] *flavum*" and "[*Sporocytophaga*] *cauliformis*," all grow well on nutrient, Anacker and Ordal's, and modified Shieh's media at 25°C; growth on TSA was not tested (Reichenbach, 1989; J.-F. Bernardet, unpublished data).

Anacker and Ordal's Medium (Anacker and Ordal, 1955)

Tryptone (or pancreatic digest of casein)	0.5 g
Yeast extract	0.5 g
Beef extract	0.2 g
Sodium acetate	0.2 g
Agar (optional)	10 g
Distilled water	1000 ml

Adjust pH to 7.2–7.4 and autoclave 15–20 min at 121°C.

The original recipe, used to grow *F. columnare* in agar deeps, included 0.4% agar only; in their 1959 publication, the same authors raised the agar concentration to 0.9% for streaking material from lesions of fish (Anacker and Ordal, 1959). However, an agar concentration of 1–1.5% is recommended for more comfortable streaking (Wakabayashi and Egusa, 1974; Bernardet, 1989a; Michel et al., 1999). A selective medium for the isolation of *F. columnare* was obtained by adding neomycin (5 μg·ml^{-1}) and polymyxin B (200 IU·ml^{-1}) to this medium (Hawke and Thune, 1992), while tobramycin (5 μg·ml^{-1}) was added to modified Anacker and Ordal's medium for the selective isolation of *F. psychrophilum* (Kumagai et al., 2004). The brand of beef extract used was shown to influence the growth of *F. psychrophilum* (Lorenzen, 1993).

Modified Shieh's Medium (Song et al., 1988b)

Yeast extract	0.5 g
Peptone	5 g
Sodium acetate	10 mg
$BaCl_2 \cdot H_2O$	10 mg
K_2HPO_4	0.1 g
KH_2PO_4	50 mg
$MgSO_4 \cdot 7H_2O$	0.3 g
$CaCl_2 \cdot 2H_2O$	6.7 mg
$FeSO_4 \cdot 7H_2O$	1.0 mg
$NaHCO_3$	50 mg
Distilled water	1000 ml
Agar (optional)	15 g

Autoclave 15–20 min at 121°C.

The original Shieh's recipe (Shieh, 1980) was modified by omitting the glucose, pyruvate and citrate following the demonstration that these components did not improve the growth of *F. columnare*. Decostere et al. (1997) devised a selective medium for the isolation of *F. columnare* by adding 1 μg·ml^{-1} of tobramycin to this medium.

Peptone-Yeast Extract-Glucose (PYG; Zhu et al., 2003)

Polypeptone	5 g
Tryptone	5 g
Yeast extract	10 g
Salt solution	40 ml
Agar (optional)	15–20 g
Distilled water	910 ml
Salt Solution	
$CaCl_2$	0.2 g
$MgSO_4 \cdot 7H_2O$	0.4 g
K_2HPO_4	1.0 g
KH_2PO_4	1.0 g
$NaHCO_3$	10 g
NaCl	2.0 g
Distilled water	1000 ml

Adjust pH to 7.2 and autoclave 15–20 min at 121°C. Add 50 ml of 20% (w/v) D-glucose filter-sterilized stock solution to each 1 liter of medium following autoclaving.

Selective Flexibacter Medium (Bullock et al., 1986)

Tryptone	2.0 g
Yeast extract	0.5 g
Gelatin	3.0 g
Agar	15 g
Distilled water	1000 ml

Autoclave 15–20 min at 121°C; when cooled to 45°C, add filter-sterilized neomycin sulfate (0.004 g).

Tryptone Yeast Extract Salts (TYES; Holt, 1988)

Tryptone	4.0 g
Yeast extract	0.4 g
$MgSO_4 \cdot 7H_2O$	0.5 g
$CaCl_2 \cdot 2H_2O$	0.5 g
Distilled water	1000 ml

Adjust pH to 7.2 and autoclave 15–20 min at 121°C.

Identification

Characteristics which differentiate members of the genus *Flavobacterium* from members of other genera in the family Flavobacteriaceae are listed in Table 2 of the chapter An Introduction to the Family Flavobacteriaceae in this Volume; those characteristics that differ among species in the genus *Flavobacterium* are listed in Table 4 below; see also the section Physiology.

The following description of the genus *Flavobacterium* is cited from Bernardet et al., 1996:

Emended description of the genus *Flavobacterium* Bergey, Harrison, Breed, Hammer, and Huntoon 1923. Cells are rods with parallel or slightly irregular sides and rounded or slightly tapered ends and usually are 2 to 5 μm long and 0.3 to 0.5 μm wide. Under certain growth conditions, some species may also produce shorter (1-μm) or longer (10- to 40-μm) filamentous cells. The longer rods are flexible. Motile by gliding (this characteristic has not been observed in *Flavobacterium branchiophilum*). Flagella are absent. Gram negative. Resting stages are not known. Intracellular granules of poly-β-hydroxybutyrate are absent. Colonies are circular, convex or low convex, and shiny with entire or wavy edges (sometimes sunken into the agar) on solid media containing high levels of nutrients. On solid media containing low levels of nutrients most species also produce flat or very thin, spreading, sometimes very adherent swarms with uneven, rhizoid, or filamentous margins. Colonies are typically yellow (they vary from cream to bright orange) because of nondiffusible carotenoid or flexirubin types of pigments or both, but nonpigmented strains do occur. Most species do not grow on seawater-containing media; an exception to this is *Flavobacterium flevense*. Most species are able to grow on nutrient agar and on Trypticase soy agar. Chemoorganotrophic. Aerobic with a respiratory type of metabolism. When certain growth factors are provided, *Flavobacterium hydatis* and *Flavobacterium succinicans* also grow anaerobically (Anderson and Ordal, 1961; Chase, 1965; Reichenbach, 1989; Strohl and Tait, 1978). Peptones are used as nitrogen sources, and NH_3 is released from peptones; growth occurs on peptone alone. Acid is produced from carbohydrates by all species except *Flavobacterium columnare* and *F. psychrophilum*. All species except *Flavobacterium pectinovorum* decompose gelatin and casein, and several species also hydrolyze various polysaccharides, including starch, chitin, pectin, and carboxymethyl cellulose. *Flavobacterium pectinovorum* and *Flavobacterium saccharophilum* are also agarolytic. Cellulose is never decomposed. Tributyrin and Tween compounds are decomposed. Indole is not produced. Catalase is produced. Cytochrome oxidase is produced by all species except *Flavobacterium saccharophilum*.

Menaquinone 6 is the only respiratory quinone. The predominant fatty acids are 15:0, 15:0 iso, 15:1 iso G, 15:0 iso 3OH, summed feature 4 (15:0 iso 2OH, 16:1 ω7c, or 16:1 ω7t or any combination of these fatty acids), 16:0 iso 3OH, 17:1 iso ω9c, and 17:0 iso 3OH. Sphingophospholipids are absent. Homospermidine is the major polyamine in all 10 *Flavobacterium* species; all species except *Flavobacterium branchiophilum* and *Flavobacterium saccharophilum* also contain putrescine as a minor component (Hamana and Matsuzaki, 1990; Hamana and Matsuzaki, 1991; Hamana et al., 1995). Spermidine and spermine are also minor components in *Flavobacterium branchiophilum*, while *Flavobacterium johnsoniae* is the only member of the genus that contains minor amounts of agmatine and 2-hydroxyputrescine (Hamana et al., 1995). The optimum temperature range for most species is 20 to 30°C; the optimum temperature range for *F. psychrophilum* is 15 to 18°C.

These organisms are widely distributed in soil and freshwater habitats, where they decompose organic matter. Several species are pathogenic for freshwater fish (*Flavobacterium branchiophilum*, *Flavobacterium columnare*, *F. psychrophilum*) or occasionally are isolated from diseased freshwater fish (*Flavobacterium hydatis*, *Flavobacterium johnsoniae*, *Flavobacterium succinicans*). The G+C contents of the DNAs are 32 to 37 mol%. The type species is *Flavobacterium aquatile* (Frankland and Frankland, 1889) Bergey, Harrison, Breed, Hammer, and Huntoon 1923.

The publication of sixteen additional *Flavobacterium* species since 1996 did not challenge the core of this emended description. However, additional comments are necessary on some of the characteristics included; these comments are cited below in the order of the above comments.

In some *Flavobacterium* species, spherical degenerative forms usually considered nonviable, often referred to as "spheroplasts," appear in aging liquid cultures (Reichenbach, 1989); they were long mistaken for microcysts (Ordal and Rucker, 1944; Pacha and Ordal, 1970; Bullock et al., 1971; Farkas, 1985; Fig. 2). They have been noticed in *F. columnare* (Garnjobst, 1945; Song et al., 1988a, 1988b; Tiirola et al., 2002; J.-F. Bernardet, unpublished data), *F. succinicans* (Anderson and Ordal, 1961), *F. psychrophilum* (J.-F. Bernardet, unpublished data), *F. johnsoniae* (Stanier, 1947; Liao and Wells, 1986) and *F. branchiophilum* (Ostland et al., 1994).

Few electron microscopy studies have been performed on members of the genus *Flavobacterium*. Reichenbach (1989) reviewed the early

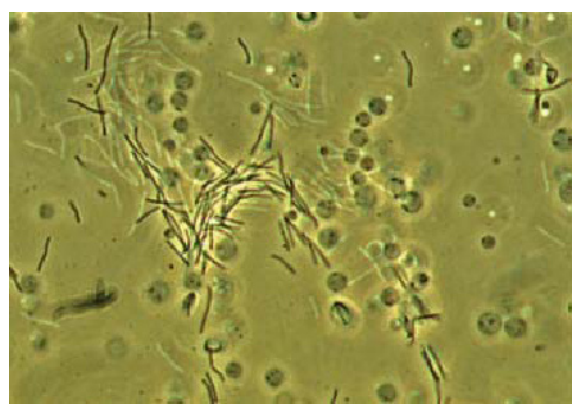

Fig. 2. Spheroplasts of *F. columnare*. Spherical degenerative forms called "spheroplasts" appeared as soon as 24 h in this shaken Anacker and Ordal's broth culture incubated at room temperature (phase-contrast microscopy, ×1000).

studies, and some of the recently described species, namely *F. branchiophilum* (Wakabayashi et al., 1989; Ostland et al., 1994; Ko and Heo, 1997), *F. frigidarium* (Humphry et al., 2001), *F. limicola* (Tamaki et al., 2003) and *F. xinjiangense* and *F. omnivorum* (Zhu et al., 2003), were also investigated using transmission electron microscopy. These studies revealed a structure of the cell wall typical of Gram-negative bacteria. *Flavobacterium branchiophilum* and *F. frigidarium* exhibit fimbria-like structures (Heo et al., 1990; Humphry et al., 2001). Nonflagellar appendages were also found in *F. aquatile*; nonfunctional pseudoflagellar structures were noticed in the same species, but this was not confirmed by further investigations (see Holmes et al. [1984] and references therein). A capsule was evidenced in *F. columnare* and *F. frigidarium* using electron microscopy and biochemical studies (Decostere et al., 1999; Humphry et al., 2001; MacLean et al., 2003); conventional microscopy also showed *F. hibernum* cells have a thick capsule when grown at 4°C (McCammon et al., 1998). Most of the newly described *Flavobacterium* species do not exhibit gliding motility; in *F. gelidilacus*, gliding motility is a strain-dependent characteristic (Van Trappen et al., 2003a). In this species and in *F. hibernum*, gliding only occurs on nutrient-poor media (McCammon et al., 1998; Van Trappen et al., 2003), which is consistent with previous reports on other *Flavobacterium* species (Reichenbach, 1989; Bernardet et al., 1996; Bernardet et al., 2002). *F. psychrophilum* is considered a poor glider, although gliding motility was indeed observed on some strains (Schmidtke and Carson, 1995; Lumsden et al., 1996; Ostland et al., 1997; Lee and Heo, 1998; Madetoja et al., 2001); however, *F. psychrophilum* usually exhibits only a slow and weak gliding motility compared to other gliding *Flavobacterium* species (Bernardet and Kerouault, 1989; Cipriano et al., 1995; Iida and Mizokami, 1996). *Flavobacterium pectinovorum* was the only species able to grow on marine media among the ten *Flavobacterium* species known in 1996. Except *F. antarcticum*, the *Flavobacterium* species which were isolated from soil or freshwater, i.e. *F. hibernum*, *F. limicola*, *F. omnivorum*, *F. xinjiangense*, *F. granuli*, *F. fryxellicola* and *F. psychrolimnae*, cannot grow on marine media. All other newly described *Flavobacterium* species (i.e., *F. degerlachei*, *F. frigidarium*, *F. frigoris*, *F. gelidilacus*, *F. gillisiae*, *F. micromati*, *F. tegetincola* and *F. xanthum*) were retrieved from marine or saline environments and are consequently able to grow on marine media (McCammon et al., 1998; McCammon and Bowman, 2000; Humphry et al., 2001; Tamaki et al., 2003; Van Trappen et al., 2003a; Van Trappen et al., 2003b; Zhu et al., 2003; Aslam et al., 2005). However, since most of them do not require NaCl for growth, they were described as merely halotolerant, not halophilic organisms. The range of NaCl concentrations they tolerate varies widely among species; in the case of *F. frigidarium*, it also varies with the composition of the growth medium used (Humphry et al., 2001). NaCl inhibits the growth of *F. limicola*, although it may tolerate up to 1.5% NaCl (Tamaki et al., 2003). Although different terms are sometimes used (e.g., chemoheterotroph [McCammon and Bowman, 2000; Tamaki et al., 2003] and heteroorganotrophic [Zhu et al., 2003]), all *Flavobacterium* species described since 1996 are chemoorganotrophic and strictly aerobic. *Flavobacterium branchiophilum* was confirmed as an obligate aerobe (Ostland et al., 1994) rather than a facultative anaerobe as previously reported (Ferguson et al., 1991). No growth factors are necessary; however, growth may be stimulated by various mineral or biological compounds, e.g., vitamins for *F. gillisiae* (McCammon and Bowman, 2000), yeast extract for *F. limicola* (Tamaki et al., 2003), and fetal bovine serum and trace mineral elements for *F. psychrophilum* (Michel et al., 1999).

In the emended description of the genus *Flavobacterium* (Bernardet et al., 1996), indole production was negative and catalase production positive for all ten species; this is still the case for the sixteen *Flavobacterium* species described since then. However, the production of catalase is weak in some *Flavobacterium* species (e.g., *F. psychrophilum*; Bernardet and Kerouault, 1989); in such cases, the production of oxygen bubbles by bacteria flooded with oxygen peroxide should be tested on fresh colonies and checked under a stereomicroscope (×20). Characteristics that are variable between *Flavobacterium* species (i.e., degradation of various polysaccharides, casein and gelatin, production of acid from carbohydrates, and production of cytochrome oxidase) are listed in Table 4. Surprisingly, even though several among the newly described *Flavobacterium* species originate from marine environments, the only new agarolytic species is *F. limicola*, isolated from freshwater (Tamaki et al., 2003). Tween 80 was decomposed by all ten *Flavobacterium* species in 1996. Although this characteristic was not tested for all newly described species, *F. limicola*, *F. omnivorum* and *F. xinjiangense* do not decompose this compound (Tamaki et al., 2003; Zhu et al., 2003), contrary to *F. antarcticum* (Yi et al., 2005). The decomposition of tributyrin, a trait for which all ten *Flavobacterium* species gave a positive reaction, was not tested in the sixteen new species. *Flavobacterium limicola*, *F. johnsoniae* and *F. granuli* were also shown to be the only urea-hydrolyzing *Flavobacterium* species among those tested (Reichenbach, 1989; Carson et al., 1993; Tamaki et al., 2003; Aslam et al., 2005). The overall fatty

acid profiles of the *Flavobacterium* species described since 1996 resemble those of the ten previously known species, with only slight discrepancies in the major and minor constituents (McCammon et al., 1998; McCammon and Bowman, 2000; Humphry et al., 2001; Tamaki et al., 2003; Van Trappen et al., 2003a; Van Trappen et al., 2003b; Zhu et al., 2003). Only *F. hibernum* and *F. xanthum* have been tested for their polyamine composition; homospermidine is still the only or major polyamine in these two species (Hamana and Nakagawa, 2001). The low optimum temperature range for *F. psychrophilum*, which was an exception in the 1996 genus description, is now shared by all new species; this is not surprising since they were all retrieved from cold environments. (*Flavobacterium granuli*, isolated from a wastewater treatment plant, is an exception; it grows at 37°C and maybe more (Aslam et al., 2005). Their optimum temperature varies from 11°C for *F. omnivorum* and *F. xinjiangense* (Zhu et al., 2003) to 26°C for *F. hibernum* (McCammon et al., 1998) and is around 15–20°C for all other species. The lowest temperature for growth is 0°C for *F. gillisiae*, *F. tegetincola*, and *F. limicola* (McCammon and Bowman, 2000; Tamaki et al., 2003), lower than 0°C for *F. frigidarium* and *F. xanthum* (McCammon and Bowman, 2000; Humphry et al., 2001), and as low as –7°C for *F. hibernum* (McCammon et al., 1998). All *F. columnare* strains tested are able to grow at 18 and 30°C, but only some of them grow at 15 or 37°C (Triyanto and Wakabayashi, 1999); strains of *F. psychrophilum* usually grow at 4–23°C (Holt et al., 1989; see the sections Isolation and Cultivation and Pathogenicity and Epidemiology in this Chapter). Cold and polar (as well as marine or saline) environments must be added to the temperate soil and freshwater habitats listed in the 1996 description, but no other fish-pathogenic *Flavobacterium* species was described. Since the G+C content of *F. gelidilacus* is around 30 mol% (Van Trappen et al., 2003b), the range of G+C content for species in the genus *Flavobacterium* is now 30–37 mol%. Although slightly lower (29 mol% for some *F. branchiophilum* strains; Wakabayashi et al., 1989) and higher (38 mol% for *F. succinicans*; Anderson and Ordal, 1961) values were reported, they have subsequently been re-evaluated (Reichenbach, 1989; Bernardet et al., 1996).

In the minimal standards proposed for describing new genera and species in the family Flavobacteriaceae (Bernardet et al., 2002), particular methods were suggested to determine some of these phenotypic properties since the conditions in which the tests are performed are critical. These procedures (updated from Bernardet et al., 2002) are listed below in the order shown in Table 4.

Colony Morphology and Gliding Motility

Provided identical growth conditions are used, colony morphology may help in differentiating between *Flavobacterium* species (Reichenbach, 1989; J.-F. Bernardet, unpublished results). Characteristics such as iridescent waves (Fig. 3A) and spreading (Figs. 3B and 3C) to rhizoidal

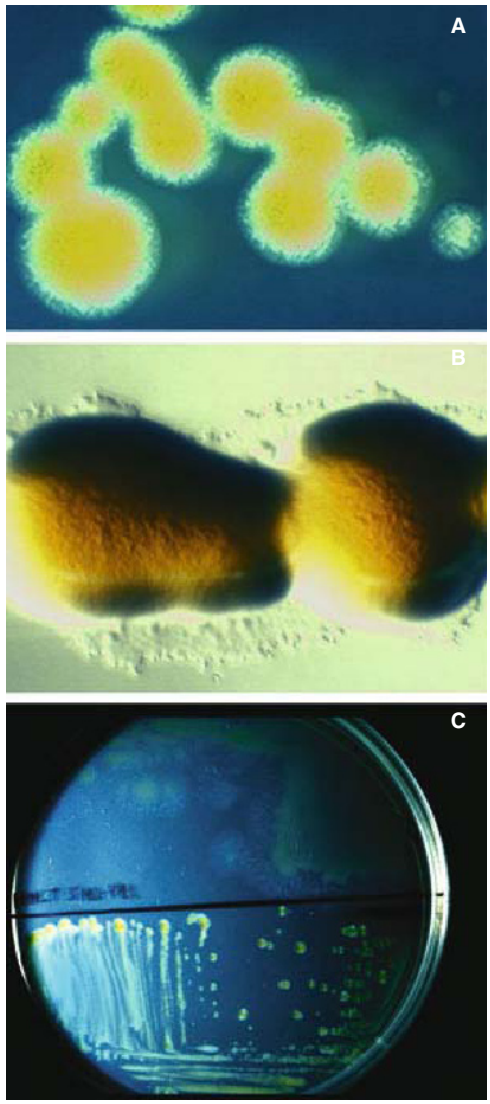

Fig. 3. Colonies of *F. psychrophilum*. Typical yellow, circular, convex, nonadherent colonies of *F. psychrophilum* after a five-day incubation on Anacker and Ordal's agar (containing 0.5% tryptone instead of 0.05%) at 18°C; under the stereomicroscope and oblique transillumination, shiny, iridescent, kaleidoscopic waves are clearly visible (A; size of the colonies is ~1–3 mm). Colonies of another strain, observed under the same conditions, exhibit zones of thin bacterial growth spreading from otherwise entire edges (B; size of the colonies ~0.5–1.5 mm). On the same Anacker and Ordal's agar plate (5 days, 18°C), two *F. psychrophilum* strains exhibit very different colony types: at the bottom of the photograph, the type strain NCIMB 1947^T produced typical circular colonies, whereas at the top another strain produced flat spreading colonies (C).

edges (Figs. 4A to 4F) are best revealed under stereomicroscopic examination (×20) through oblique transmitted light (Anderson and Ordal, 1961; Bernardet, 1989b; Bernardet and Kerouault, 1989). Different strains of *F. columnare*, *F. psychrophilum*, *F. pectinovorum* and *F. succinicans* may produce different colony types, i.e., compact with regular margins or spreading with uneven to rhizoid margins (Fig. 3C); some strains may even exhibit different colony types on the same agar plate (Anderson and Ordal, 1961; Bernardet, 1989a; Bernardet, 1989b; Bernardet and Kerouault, 1989; Schmidtke and Carson, 1995; Lee and Heo, 1998).

Anacker and Ordal's medium (see the section Isolation and Cultivation in this Chapter) is recommended to observe the typical spreading or swarming colonies exhibited by most gliding *Flavobacterium* species (Holmes et al., 1984; Bernardet, 1989a; Bernardet, 1989b; Bernardet and Kerouault, 1989; see the section Isolation and Cultivation in this Chapter). Under direct microscopic examination, their rhizoid or filamentous margin is composed of numerous bacterial cells, alone or in small groups, slowly gliding on the wet surface of the agar and progressing towards the periphery (Fig. 4F). Gliding may be readily observed; in other cases, the slime tracks left on agar by gliding cells are clearly visible (Burchard, 1981; Reichenbach, 1992; J.-F. Bernardet, unpublished data; Fig. 4G). The cells are able to glide either as single cells or as groups of cells. In this sense, their behavior is strikingly similar to the "A" (adventurous) and "S" (social) motility of *Myxoccoccus xanthus*, referred to in the chapter on The Myxobacteria in this Volume.

Information on gliding motility, methods available to observe it in liquid and solid cultures, and the relationship among gliding, production of slime, and adherence are given in Bernardet et al. (2002) and in the chapter An Introduction to the Family Flavobacteriaceae in this Volume.

Adherence of colonies to the agar is also a useful feature; it can be determined by trying to collect colonies on agar plates with a loop. Colonies of *F. pectinovorum* merely exhibit a sticky or mucoid consistency, while separating colonies from agar can be nearly impossible in some *Flavobacterium columnare* strains (Garnjobst, 1945); adherence of this pathogen to fish tissue is considered an important virulence factor (see the section Pathogenicity and Epidemiology in this Chapter). However, adherence may be lost after several subcultures: the National Collections of Industrial, Food, and Marine Bacteria (NCIMB, Aberdeen, Scotland) replaced its culture of the *F. columnare* type strain (NCMB 1038^T) by an adherent subculture (NCIMB 2248^T) after the original one lost its typical adherence. Adherence is also exhibited by *F. columnare* cells in still or slowly agitated liquid cultures: yellow filamentous clumps or tufts of bacterial cells adhere at the surface of the glass flask, forming a thick ring at the upper level of the liquid medium (Fig. 5). When the liquid culture is agitated using a magnet, the latter may be completely covered by these adherent clumps (Garnjobst, 1945; Shamsudin and Plumb, 1996; Newton et al., 1997; Decostere et al., 1998; J.-F. Bernardet, unpublished results).

Such clumps (as well as the warty center of some colonies and the "columns" of bacterial cells that appear on infected tissue; see the section Pathogenicity and Epidemiology in this Chapter) were already noticed in early studies and mistaken for fruiting bodies. This confusion, together with that of the spheroplasts for microcysts, led early authors to assign *F. columnare* to the myxobacteria, and hence the long used epithet "[*Chondrococcus*] *columnaris*" (Ordal and Rucker, 1944; Pacha and Ordal, 1970; Bullock et al., 1971). Conversely, Garnjobst correctly identified the spheroplasts and, since she did not observe fruiting bodies, she ascribed this organism to the genus *Cytophaga*, which was indeed much closer to the currently accepted taxonomic affiliation (Garnjobst, 1945).

Adsorption of Congo Red

Congo red adsorption is tested by directly flooding some colonies on the agar with a few drops of a 0.01% aqueous solution of the dye; after about two min, the dye is gently rinsed with water and the color of these colonies compared to that of control colonies not covered with the dye (Fig. 6). In the case of *Flavobacterium columnare*, the Congo red-staining material has been shown to be an extracellular galactosamine glycan in the slime (Johnson and Chilton, 1966).

Congo red may also be included in the agar; *F. columnare* colonies growing on this medium are red (P. Koski, personal communication). However, when *F. psychrophilum* was tested on a Congo red-containing agar, bacterial growth was strongly inhibited by the dye (Crump et al., 2001). Among the tested *Flavobacterium* species described since 1996, only colonies of *F. limicola* and *F. frigidarium* were shown to adsorb Congo red (Humphry et al., 2001; Tamaki et al., 2003). For the latter species, this trait was actually not definitely demonstrated since the authors carefully stated that "There seemed to be absorption of Congo red by colonies . . ."; in the same study, Congo red was also used to reveal the xylanase activity of the isolate (Humphry et al., 2001).

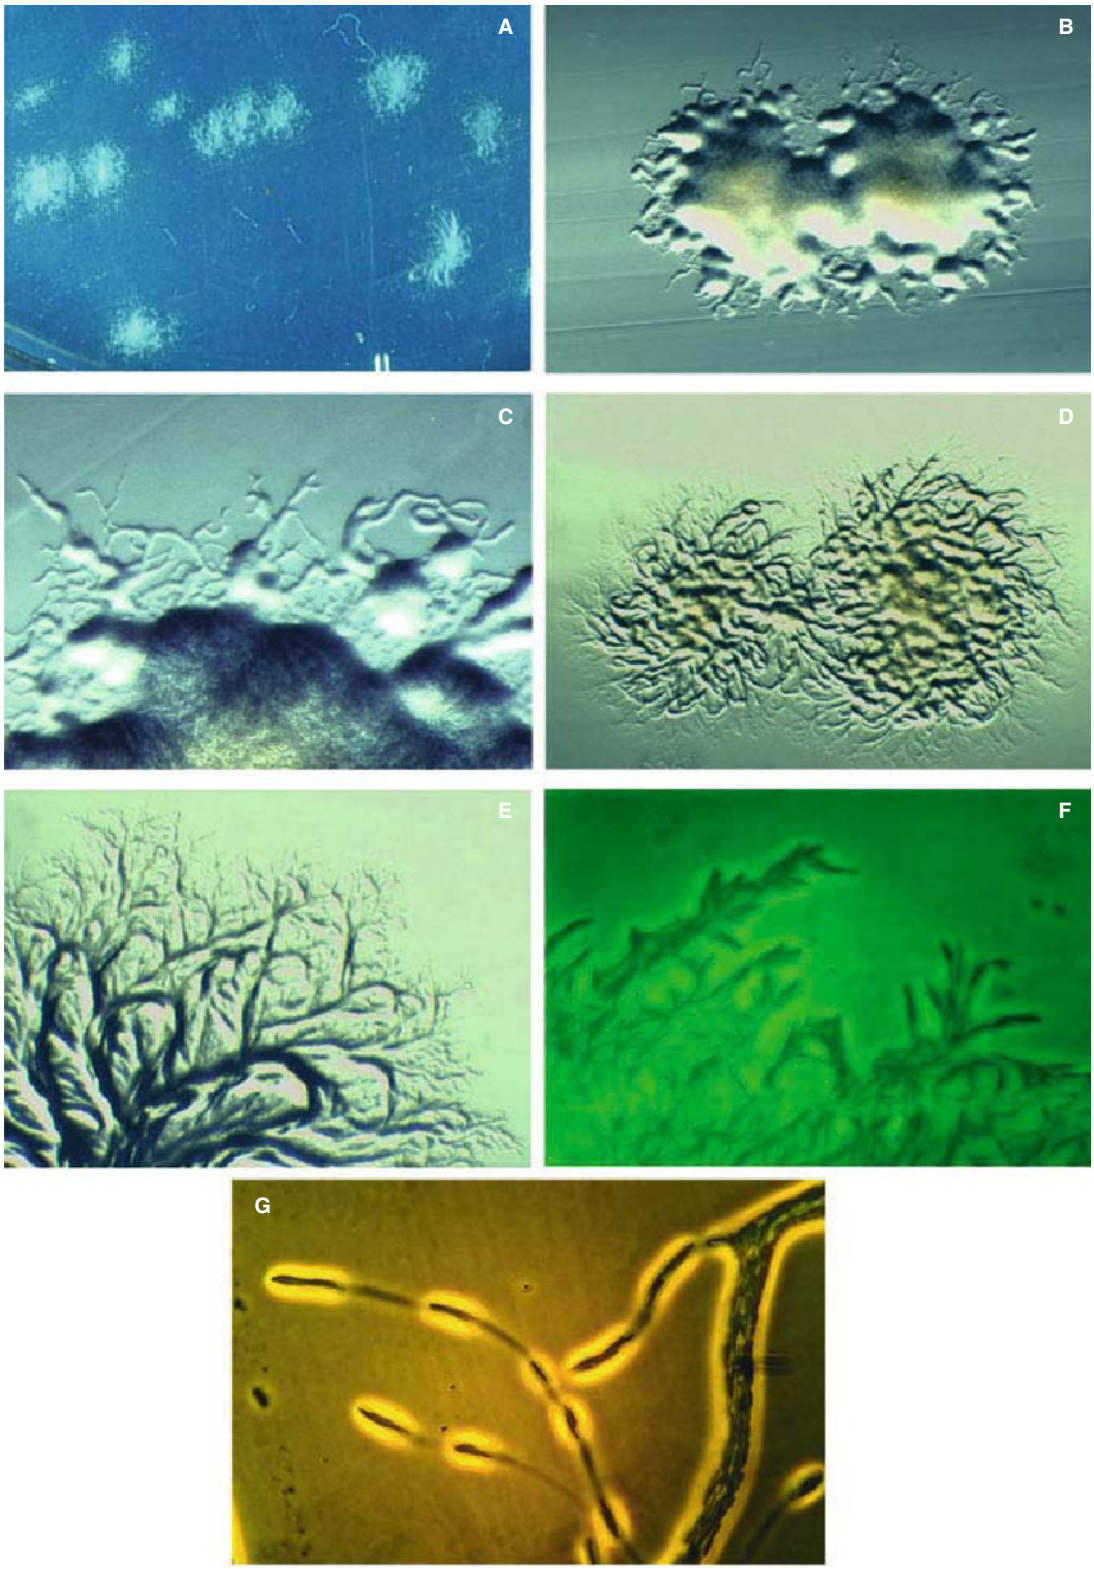

Fig. 4. Colonies of *F. columnare*. Grown on Anacker and Ordal's agar at 22°C for three days, a *F. columnare* strain produced typical pale yellow, flat, dry, rhizoid and adherent colonies (A; field of the view: approx. 5 × 3 cm). The rhizoid aspect of the edges is better seen under the stereomicroscope and oblique transmitted illumination: B and C, moderately rhizoid colonies, and D and E, very rhizoid colonies (size of the colonies: approx. 5 mm). Phase-contrast microscopy reveals groups of parallel bacterial cells spreading from the edge of a colony of the *F. columnare* type strain, NCIMB 2248^{T} (F; field of the view: approx. 0.2 × 0.14 mm). When growth and optical conditions are favorable, the observation of the edge of a *F. columnare* colony on Anacker and Ordal's agar under phase-contrast microscopy (×40) may reveal the slime tracks left by groups of bacterial cells gliding at the surface of the agar (G).

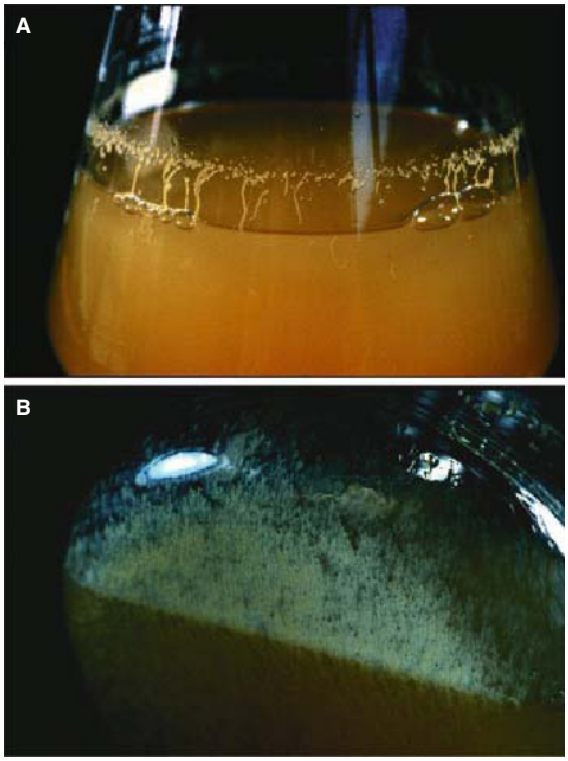

Fig. 5. Adherence of *F. columnare*. A *F. columnare* strain was cultivated for three days at 25°C in 1 liter of Anacker and Ordal's broth (enriched to 0.5% tryptone instead of 0.05%) with gentle orbital shaking. Numerous filamentous clumps of bacteria adhered to the glass, forming a ring at the top edge of the broth surface (A) and carpeting the walls of the flask (B shows the bottom of the tilted flask).

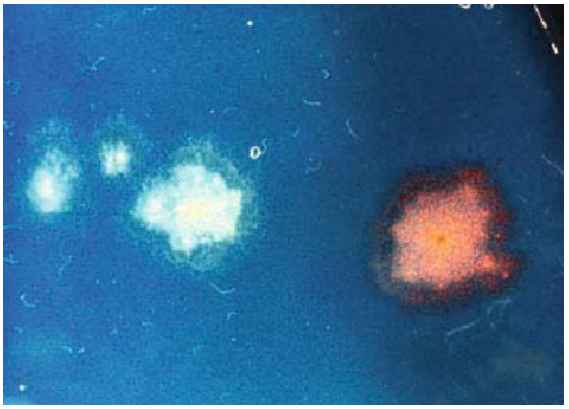

Fig. 6. Congo red test. The color of rhizoid *F. columnare* colonies was checked after flooding the colony on the right hand side with an aqueous 0.01% Congo red solution and gentle rinsing using distilled water: the colony has adsorbed the red dye, demonstrating the presence of a galactosamine glycan component in the bacterial slime (field of the view: approx. 5 × 3 cm).

Determination of Pigment

Information on the different types of pigment produced by members of the family Flavobacteriaceae and on methods to identify these pigments is given in Bernardet et al. (2002). Briefly, an easy although not absolutely specific method to demonstrate the production of flexirubin type pigments is to flood a mass of bacterial cells collected on agar with 20% KOH and to compare the resulting color with that of a control mass that has not been flooded with KOH. When the yellow color of the strain is caused by flexirubin type of pigments, the mass immediately turns dark red, purple or brown (Reichenbach, 1989; Fig. 7). When the yellow color is presumably caused by carotenoid type of pigments, no color change develops.

Several other KOH techniques were proposed. For example, KOH may be directly poured over colonies on an agar plate (e.g., Crump et al., 2001). However, the resulting color-shift may pass unnoticed on a thin layer of bacteria (Cipriano et al., 1996); this was probably why *F. psychrophilum* was first considered devoid of flexirubin type pigments by some authors (e.g., Holt, 1988). Alternatively, a loopful of bacterial cells may be streaked onto filter paper soaked in 1N NaOH (Brown et al., 1997). A "string test" was also proposed (Cipriano et al., 1996). Finally, the KOH test may be performed after methanol/chloroform extraction of the pigments from the pellet of a liquid culture (Maeda et al., 1998). The genus *Flavobacterium* includes carotenoid-producing and flexirubin-producing species, as well as species that produce both types of pigments (Reichenbach, 1989; Bernardet et al., 1996). The more frequent association of carotenoid pigments with marine species and flexirubin pigments with freshwater or soil organisms (Reichenbach, 1989) is not especially clear for members of the genus *Flavobacterium*: the yellow color of *F. frigidarium* and *F. gillisiae*, the only species originating from marine environments, is indeed caused by carotenoid pigments, but several other *Flavobacterium* species produce this type of pigment even though they occur in nonmarine environments (Table 4).

Degradation of Cellulose and Cellulose Derivatives

Some species in the family Flavobacteriaceae degrade soluble cellulose derivatives such as carboxymethylcellulose or hydroxyethylcellulose but, since enzymes other than cellulases can degrade these compounds, this does not demonstrate that these species are cellulolytic. The decomposition of crystalline cellulose (i.e., filter paper) requires the production of a specific cel-

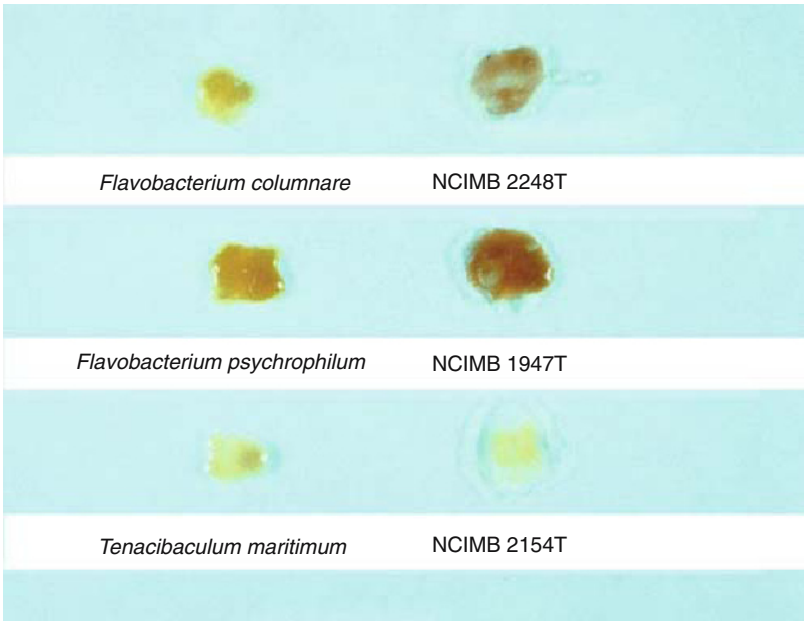

Fig. 7. KOH test for the detection of flexirubin type pigments. After two masses of bacterial cells of *Flavobacterium columnare*, *F. psychrophilum* and *Tenacibaculum maritimum* were deposited on a glass slide, those on the right hand side were flooded with a drop of 20% KOH. The immediate color shift from yellow to brownish pink of the two *Flavobacterium* strains revealed the presence of flexirubin type pigments, whereas the unchanged cream color of the *Tenacibaculum* strain suggested that it is rather due to carotenoid type pigments.

lulase, and hence only strains able to degrade filter paper should be regarded as cellulose degraders (Reichenbach, 1989). The ten *Flavobacterium* species known in 1996 were considered unable to degrade crystalline cellulose and this inability has subsequently been confirmed in members of the recently described *Flavobacterium* species (J. P. Bowman, unpublished results). Hence, this characteristic distinguishes members of the genus *Flavobacterium* from those of the genus *Cytophaga*, now restricted to cellulolytic organisms (Nakagawa and Yamasato, 1996). Two recent publications may challenge this clear-cut distinction. The degradation of cellulosic plant fibers by a number of soil organisms was investigated, and nine cellulolytic isolates were assigned to *F. johnsoniae* (Lednicka et al., 2002). However, these strains were exclusively identified through fatty acid analysis, a technique that is considered to provide taxonomic information mainly at the generic level in the family Flavobacteriaceae (Bernardet et al., 2002). A cellulose-degrading bacterial strain isolated from freshwater proved capable of killing the cyst form of the protozoan parasite *Giardia lamblia*; the determination of the sequence of its 16S rRNA showed a close relationship with those of several *F. columnare* strains, and the isolate shares a number of phenotypic traits with this species (Rodgers et al., 2003). Although some other traits as well as the G+C content were at variance with *F. columnare*, and although a high 16S rRNA homology does not guarantee conspecificity (Bernardet et al., 2002), it is still likely this isolate indeed belongs to the genus *Flavobacterium* or at least to the family Flavobacteriaceae.

Several *Flavobacterium* species are able to degrade various cellulose derivatives, carboxymethylcellulose (CMC) being the most frequently tested (Table 4), for instance, on a 0.5% CMC overlay agar (McCammon et al., 1998). Alternatively, 3% of high viscosity CMC sodium salt may be added to any liquid medium with a rather low nutrient content (e.g., Anacker and Ordal's medium; see the section Isolation and Cultivation in this Chapter); the medium is homogenized by vigorous shaking, distributed in deep glass tubes, and autoclaved. After the gelified medium was inoculated and incubated for several days, its consistency is compared to that of a control, uninoculated, tube. Depending on the ability of the strain to degrade CMC, the medium may be partially or totally liquefied (Bernardet, 1989a; Van Trappen et al., 2003a; Van Trappen et al., 2003b; Fig. 8).

Degradation of Other Biomacromolecules

The degradation of biomacromolecules other than those mentioned above, particularly polysaccharides and proteins, by bacterial species now included in the genus *Flavobacterium* was extensively reviewed by Reichenbach (1989). The degradation of various macromolecules has also been reported in recently described *Flavobacterium* species (Table 4). Most *Flavobacterium* species are able to degrade a variety of polysaccharidic components of algae, plants, fungi, or insects such as agar (Fig. 9), alginate, chitin, laminarin, pectin, xylan, etc. (Stanier, 1947; Van der Meulen et al., 1974; Liao and Wells, 1986; Reichenbach, 1989; Humphry et al., 2001).

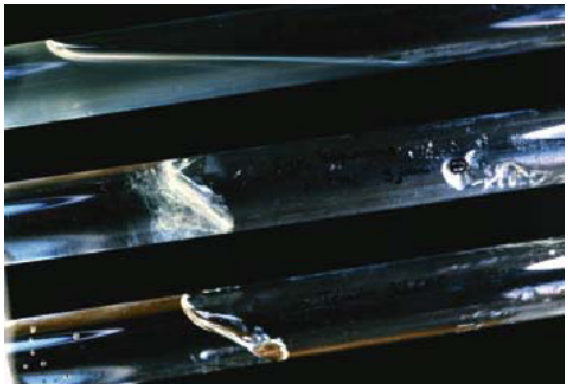

Fig. 8. Hydrolysis of carboxymethylcellulose. Each tube contained 10 ml of Anacker and Ordal's broth gelified with 3% high-viscosity CMC. The tube at the bottom of the figure was an uninoculated control, whereas the two other tubes were inoculated and incubated at 22°C for three days. The tubes were then tilted to reveal the consistency of the medium. Inoculated with *Pedobacter heparinus*, which did not hydrolyze CMC, the medium in the middle tube had the same consistency as that in the control tube. Conversely, the *F. johnsoniae* strain inoculated in the upper tube completely hydrolyzed CMC, turning the medium to liquid.

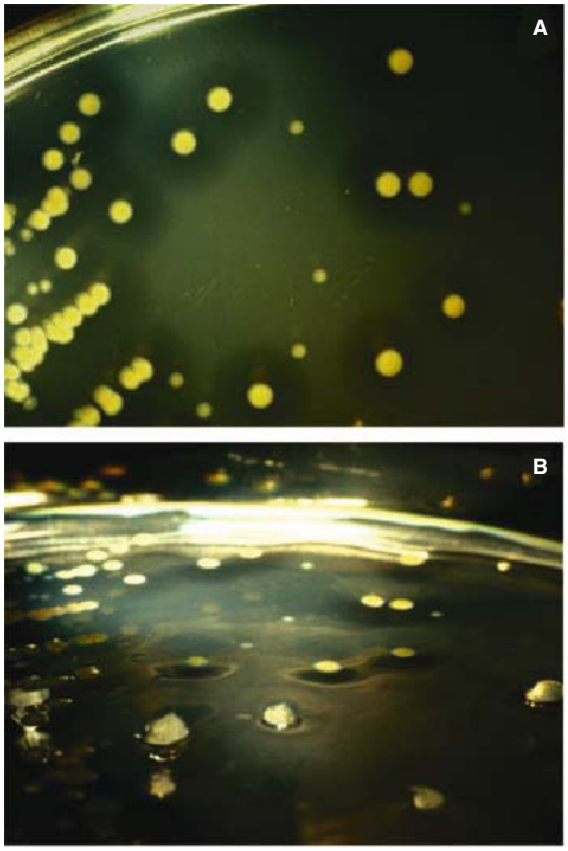

Fig. 9. Hydrolysis of agar. After a four-day incubation at 22°C on Anacker and Ordal's medium with 1.2% (w/v) agar, *F. flevense* has hydrolyzed the surrounding agar: colonies are situated in the center of shallow craters (Fig. 9B), under and around which the agar is softened and more transparent; hence the clear halos surrounding colonies (Fig. 9A).

Interestingly, the fish pathogens *F. columnare* and *F. psychrophilum* have long been considered unable to degrade any polysaccharide (Bernardet and Grimont, 1989). However, it was later discovered that they are actually able to degrade some particular complex acidic polysaccharides of connective tissue such as chondroitin sulfate and hyaluronic acid (Otis, 1984; Griffin, 1991; Teska, 1993; Stringer-Roth et al., 2002). Degradation of chondroitin sulfate was even included in an identification scheme for *F. columnare* (Griffin, 1992). Hence, these polysaccharide-degrading enzymes likely participate in the severe skin and muscular necrotic lesions that frequently occur in infected fish (see the section Pathogenicity and Epidemiology in this Chapter) in combination with the various extracellular proteases also produced by *F. columnare* and *F. psychrophilum*. These proteases, considered important virulence factors, are able to degrade components of muscle, cartilage, and connective tissue such as elastin, type IV collagen, fibrinogen, gelatin, laminin, fibronectin, actin and myosin (Otis, 1984; Holt, 1988; Bertolini and Rohovec, 1992; Bertolini et al., 1994; Nomura and Ohara, 1994; Newton et al., 1997; Ostland et al., 2000; Secades et al., 2001; Secades et al., 2003). The two metalloproteases purified from *F. psychrophilum*, produced under different physiological conditions, exhibit a broad range of hydrolytic activity and are adapted to low temperatures, being optimally produced at 12°C (Secades et al., 2001; Secades et al., 2003). Ostland et al. (2000) demonstrated that in vitro casein-, gelatin- and collagen-degrading activities of *F. psychrophilum* strains were associated with their ability to produce muscle necrosis when injected in rainbow trout. Interestingly, the optimum temperature for protease production was consistently 4–9°C below the optimum temperature for growth for all strains tested (Uddin and Wakabayashi, 1997). The low temperature of protease production may be related to the range of temperature at which outbreaks of the diseases caused by *F. psychrophilum* in salmonid fish occur (see the section Pathogenicity and Epidemiology in this Chapter). In *F. branchiophilum*, the extracellular products contain a protease, a phosphatase, and a phosphoamidase but no hemolysin or endotoxin; when juvenile rainbow trout were immersed in the extracellular products, gill lesions similar to those which occur during the natural infection were observed (Ototake and Wakabayashi, 1985; see the section Pathogenicity and Epidemiology in this Chapter). As in many microorganisms adapted to cold

environments, the production of the extracellular protease found in *F. limicola* is enhanced at low temperatures (Tamaki et al., 2003).

Production of Cytochrome Oxidase

Although the different techniques available to detect the production of cytochrome oxidase have not been compared on all *Flavobacterium* species, it has been demonstrated that the presence of cytochrome oxidase was more readily evidenced in *F. columnare* and *F. psychrophilum* using discs impregnated with dimethyl-*p*-phenylene diamine oxalate than using liquid tetramethyl-*p*-phenylene diamine dihydrochloride reagents (Koski et al., 1993; J.-F. Bernardet, unpublished results). This characteristic should be tested on fresh colonies since it becomes difficult to detect after more than 3–4 days cultivation, especially on species that yield a weak positive reaction such as *F. psychrophilum* (Bernardet and Kerouault, 1989).

Commercial Identification Galleries

In addition to (or instead of) the standard biochemical tests, commercially available kits, strips, and galleries have been extensively used over the last decade to help identify *Flavobacterium* strains. However, since most of these systems are aimed at the identification of human pathogens, the temperature and time of incubation must be adapted to test bacteria that do not grow at 37°C. API galleries (bioMérieux) have frequently been used. While API 20E galleries are not well adapted to most *Flavobacterium* strains (J.-F. Bernardet, unpublished results), API 20NE, API ZYM, API ID 32E, API 32GN and API 50CH have yielded interesting results when used at temperatures that were close to the optimum of the *Flavobacterium* species tested. As for API ZYM galleries, the time of incubation usually varied from the 4 h recommended by the manufacturer (Van Trappen et al., 2003a; Van Trappen et al., 2003b; Aslam et al., 2005) to overnight (Bernardet, 1989b; Bernardet and Grimont, 1989; Bernardet and Kerouault, 1989; Madetoja et al., 2001), although incubation time up to two or three days was sometimes used (Ostland et al., 1994; Humphry et al., 2001). API ZYM galleries were used to differentiate the most common fish pathogenic bacteria, including *F. columnare* (Sakai et al., 1993). API galleries in which bacterial growth is necessary were also incubated for two to three days (McCammon et al., 1998; Humphry et al., 2001; Van Trappen et al., 2003a; Van Trappen et al., 2003b) and up to ten days for API 50CH galleries (Bernardet, 1989b; Bernardet and Grimont, 1989; Bernardet and Kerouault, 1989). Except *F. columnare* (Bernardet, 1989b) and *F. psychrophilum* (Bernardet and Kerouault, 1989), all *Flavobacterium* species tested in API 50CH galleries were able to utilize a variety of substrates. Preliminary studies also demonstrated that *F. johnsoniae*-like fish isolates utilize a number of substrates in Biotype 100 galleries (bioMérieux; J.-F. Bernardet and C. Bizet, unpublished data). Various substrates were also utilized by *F. hibernum* (after incubation times of 4 and 24 h) and *F. limicola* in GN MicroPlates (Biolog; McCammon et al., 1998; Tamaki et al., 2003).

Besides the above-mentioned identification methods, other usually more sophisticated techniques are available to help identify *Flavobacterium* strains and species. The application of most of these techniques to the differentiation of members of the family Flavobacteriaceae was already considered by Bernardet et al. (2002) and in the chapter An Introduction to the Family Flavobacteriaceae in this Volume; some additional information primarily on the genus *Flavobacterium* is provided below.

Composition of the Cell Wall and Membrane

Reichenbach (1989) reviewed data available on the structure and composition of the cell wall and membrane in several bacterial species now attributed to the genus *Flavobacterium*. Since then, fish-pathogenic species were investigated in this regard, mostly to characterize antigens that could be targets for potential vaccines and diagnostic tests (see the section Pathogenicity and Epidemiology in this Chapter). Low- and high-molecular-mass lipopolysaccharides were identified in *F. psychrophilum*, the latter containing the O-antigen (Crump et al., 2001; MacLean et al., 2001); a very unusual sugar in the O-chain may constitute a specific diagnostic target (Crump et al., 2001). Also in *F. psychrophilum*, the outer membrane protein was tested as a possible vaccine (Rahman et al., 2002), a major glycoprotein antigen was purified and characterized (Merle et al., 2003) and a surface antigenic protein was isolated and partially characterized (Massias et al., 2004). Outer membrane proteins and the lipopolysaccharide of *F. columnare* were also studied (Shamsudin, 1994); the structure of the lipopolysaccharide O-antigen was only recently characterized and shown to differ from that of *F. psychrophilum* (MacLean et al., 2003). The structure of the glycopeptides resulting, together with the lipopolysaccharide (LPS) and the capsular polysaccharide from the phenol-water extraction of *F. columnare* cells, was determined; its role in pathogenesis and its antigenic

properties are not known yet (Vinogradov et al., 2003).

As do other members of the family Flavobacteriaceae, *Flavobacterium* species contain menaquinone 6 as their only respiratory quinone and do not contain sphingophospholipids (Bernardet et al., 1996).

The kind of chemotaxonomic information resulting from the analysis of whole-cell fatty acid methyl esters (FAMEs) is discussed in the chapter An Introduction to the Family Flavobacteriaceae in this Volume. Recently, fatty acid analysis has been used extensively for rapidly clustering large numbers of polar bacterial isolates; representative strains in each cluster were then submitted to phylogenetic analysis (see Van Trappen et al. [2002] and references therein). Those isolates that were subsequently shown to belong to the genus *Flavobacterium* mostly contained branched fatty acids (saturated, unsaturated, or saturated and hydroxylated; Van Trappen et al., 2002). These fatty acids, which contribute to the membrane fluidity at low temperature, were abundant in all psychrophilic *Flavobacterium* species (Zhu et al., 2003) and no evidence of polyunsaturated fatty acids was found (Humphry et al., 2001). The overall fatty acid compositions of newly described *Flavobacterium* species were similar to that cited in the genus description (see above), except for some discrepancies in relative proportions (e.g., Van Trappen et al., 2003, 2005; Aslam et al., 2005; Yi et al., 2005) and failure to detect 15:1 *iso* G. Among those fatty acids already listed in the genus description, 15:0, 15:0 *iso*, 15:0 *iso* 3OH, 16:0 *iso* 3OH, 17:1 *iso* 30H and particularly 16:1 ω7c were the most abundant components in most new species (McCammon et al., 1998; McCammon and Bowman, 2000; Humphry et al., 2001; Tamaki et al., 2003; Van Trappen et al., 2003a, Van Trappen et al., 2003b, 2005; Zhu et al., 2003; Aslam et al., 2005; Yi et al., 2005). Additional components which may account for a significant fraction of the total fatty acid composition of the recently described *Flavobacterium* species were 15:0 *anteiso*, 15:1, 15:1 *iso*, 15:1 ω6c, 15:1 *iso* ω10c, 16:0 *iso*, 16:1 *iso*, 17:1 ω6c, and summed feature 3. The decisive influence of growth temperature and medium on the relative amounts of the various fatty acids, although already recognized (McGrath et al., 1990), was again noticed in *F. limicola* (Tamaki et al., 2003). Therefore, although there are no species-specific fatty acid profiles in the genus *Flavobacterium*, it is still possible to define a rather typical profile for the genus itself. Given the necessary technical skill and equipment, the determination of the fatty acid profile helps assignment of new isolates to the genus.

Whole-Cell Protein Analysis

Again, provided the skill and equipment for highly standardized sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE), numerical analysis of the resulting electrophoregram, and database comparison are available, the determination of whole-cell protein profiles may also help assign new isolates to published *Flavobacterium* species or delineate new species (Bernardet et al., 1996; Bernardet et al., 2002). A good correlation between high DNA homology and high similarity of whole-cell protein patterns was noticed among several members of the family Flavobacteriaceae (Vandamme et al., 1996; Bernardet et al., 2002; the chapter An Introduction to the Family Flavobacteriaceae in this Volume). Some *Flavobacterium* spp. (*F. columnare* and *F. psychrophilum*) could indeed be readily identified by their typical protein profile, but others (*F. branchiophilum*, *F. johnsoniae* and *F. succinicans*) because of intraspecific heterogeneity could not (Bertolini and Rohovec, 1992; Bernardet et al., 1996; Cipriano et al., 1996). For yet other species, no conclusion could be drawn owing to the limited number of strains tested/available. In *F. columnare* and *F. psychrophilum*, whole-cell protein patterns remained consistent regardless of the growth medium used (Cipriano and Teska, 1994). Unfortunately, none of the sixteen recently described *Flavobacterium* species was investigated for their protein profiles.

Multilocus Enzyme Electrophoresis

Multilocus Enzyme Electrophoresis (MEE) was used as an attempt to classify 106 strains of yellow, Gram-negative, nonflagellated organisms isolated from fish or freshwater environments; one of the four groups delineated by this technique was entirely composed of *F. columnare* strains (Starliper et al., 1988).

DNA-DNA Hybridization

DNA-DNA similarity, as determined using quantitative DNA-DNA hybridization, is still the acknowledged standard for species delineation, together with ΔT_m when available (Wayne et al., 1987; Stackebrandt et al., 2002). The different techniques available and a review of their application to members of the family Flavobacteriaceae were discussed extensively by Bernardet et al. (2002), and only additional information especially focused on the genus *Flavobacterium* will be given here. DNA-DNA hybridization

experiments performed on members of the species classified in the genus have revealed that the 70% cut-off value proposed by Wayne et al. (1987) does apply to *Flavobacterium* species. Strains belonging to the same species share DNA relatedness well above 70% (i.e., 75–100%), whereas DNA relatedness is distinctly below this value (i.e., 4–50%) when strains belonging to different *Flavobacterium* species are hybridized (Bernardet and Grimont, 1989; McCammon et al., 1998; McCammon and Bowman, 2000; Humphry et al., 2001; Tamaki et al., 2003; Van Trappen et al., 2003a; Van Trappen et al., 2003b; Zhu et al., 2003; Van Trappen et al., 2005). The range of DNA relatedness between different strains of the same species may be rather wide (from approximately 75% to close to 100%); this is the case for *F. columnare* (Bernardet and Grimont, 1989), *F. branchiophilum* (Wakabayashi et al., 1989), *F. limicola* (Tamaki et al., 2003) and *F. fryxellicola* (Van Trappen et al., 2005). In the particular case of *F. branchiophilum* and *F. johnsoniae*, DNA relatedness values among some strains were as low as 67% (Wakabayashi et al., 1989) and 60% (Bernardet et al., 1996), respectively; however, ΔT_m values well below 5°C have shown that such strains nevertheless belong to the same species (Bernardet et al., 1996). Three distinct hybridization groups were delineated within a collection of *F. columnare* strains; each was characterized by a particular 16S rDNA restriction pattern and a particular nucleotide signature in its 16S rRNA sequence (Triyanto and Wakabayashi, 1999). However, since no phenotypic characteristics were available to differentiate them, these groups could only be considered genospecies or genomovars. Intraspecific DNA relatedness cannot be assessed in *Flavobacterium* species for which only one bona fide strain is available, namely *F. antarcticum*, *F. aquatile*, *F. flevense*, *F. frigidarium*, *F. gillisiae*, *F. granuli*, *F. hydatis*, *F. omnivorum*, *F. pectinovorum*, *F. saccharophilum*, *F. xanthum* and *F. xinjiangense*.

Sequence Analysis of Small Subunit rRNA and *gyrB* genes

Sequences of the 16S rRNA gene of all valid *Flavobacterium* species are now available; their comparison, combined with earlier data resulting from DNA-rRNA hybridization experiments (Bauwens and De Ley, 1981; Bernardet et al., 1996), provides a distinct view of the phylogenetic relationships within the genus *Flavobacterium* (Fig. 1) and between the genus and other members of the family Flavobacteriaceae (see Figs. 1 and 2 of the chapter An Introduction to the Family Flavobacteriaceae in this Volume). Although 16S rRNA delivers valuable information to delineate taxa at the genus and family level, it should not be used as the only genomic method to delineate bacterial species, with the exception of noncultivable organisms. As shown by several studies, some of them dealing with members of the very family Flavobacteriaceae, the arbitrary cut-off value of 97% 16S rRNA sequence homology is frequently not correlated with DNA-DNA homology (see Bernardet et al. [2002] and references therein). For instance, values of 16S rRNA sequence similarity of 97.2–98.7% were recently found between several *Flavobacterium* species (Van Trappen et al., 2003b, 2005). The sequence of *gyrB* genes, encoding the subunit B protein of DNA gyrase, may also be used for phylogenetic studies. Until now, only the *gyrB* sequences of *F. aquatile*, *F. johnsoniae*, *F. psychrophilum* and "[*Sporocytophaga*] *cauliformis*" are available (Izumi and Wakabayashi, 2000; Suzuki et al., 2001); hence, an evaluation of the respective phylogenetic interest of *gyrB* and 16S rRNA is not possible yet. In the genus *Tenacibaculum*, another member of the family Flavobacteriaceae, interspecific DNA relatedness values have been shown to be more distinctly correlated to the sequence similarity of *gyrB* than to that of 16S rRNA (Suzuki et al., 2001).

A combination of two or more of the above techniques will provide a polyphasic approach to the identification of new *Flavobacterium* isolates (Vandamme et al., 1996). Indeed, it is this kind of approach that has allowed the successful identification and description of all recently published *Flavobacterium* species. Below, we list some other possible techniques for detecting *Flavobacterium* strains in the environment and in clinical samples without requiring previous culture, as well as the methods currently available to type collections of *Flavobacterium* strains.

Molecular Detection and Identification

Several culture-independent molecular methods have been used extensively over the last decade to investigate the phylogenetic composition of bacterial communities in various environments (see the section Habitat and Ecology in this Chapter and the chapter An Introduction to the Family Flavobacteriaceae in this Volume). However, although part of the panel of species used to design the rRNA-targeted oligonucleotide probes for fluorescent in situ hybridization (FISH) was *Flavobacterium* species, no probe specifically targeting members of the genus

Flavobacterium is available yet. Published probes had a broad specificity, usually including the whole *Cytophaga-Flavobacterium-Bacteroides* (CFB) group or parts of it (Manz et al., 1996; Maeda et al., 1998; Weller et al., 2000; Adachi et al., 2002; O'Sullivan et al., 2002). Hence, it is not possible to determine the proportion of *Flavobacterium* species among other members of the CFB group in the environments investigated. Other surveys of bacterial communities used the sequencing of cloned 16S rRNA gene fragments; this technique allowed the detection of several organisms distinctly belonging to the genus *Flavobacterium* in the Columbia and Delaware estuaries (Crump et al., 1999; Kirchman et al., 2003). Denaturing gradient gel electrophoresis (DGGE) of 16S rDNA fragments has also become a popular method to assess the diversity of bacterial flora. It was recently found, however, that *Flavobacterium* strains were the only members of the aquatic bacterioplankton studied that possessed multiple melting domains in their 16S rDNA; these domains were responsible for fuzzy bands on the gel and consequently for poor resolution of DGGE at the species level when commonly applied universal primers were used (Kisand and Wikner, 2003). This problem could lead to misinterpretation of DGGE data and thereby to incorrect estimates of the number of *Flavobacterium* species in natural bacterial communities.

A variety of PCR tests were published for the economically significant fish-pathogenic *Flavobacterium* species, i.e., *F. branchiophilum*, *F. columnare* and *F. psychrophilum* (see the section Pathogenicity and Epidemiology in this Chapter). Classical PCR assays using either 16S rRNA- or *gyrB*-targeted primers (Toyama et al., 1994; Toyama et al., 1996; Urdaci et al., 1998; Izumi and Wakabayashi, 2000) were devised, and procedures for nested PCR (Baliarda et al., 2002; Taylor and Winton, 2002), multiplex PCR (del Cerro et al., 2002), and TaqMan PCR (del Cerro et al., 2002) were also published. These PCR tests were used either to confirm the identification of cultured isolates or to specifically detect the pathogens in the tissue of diseased or apparently healthy fish (Wiklund et al., 2000; Baliarda et al., 2002), in ovarian fluid and eggs (Izumi and Wakabayashi, 1997; Kumagai and Takahashi, 1997; Baliarda et al., 2002), and in water samples (Wiklund et al., 2000; Madetoja and Wiklund, 2002). *F. psychrophilum* was also detected in water samples (Vatsos et al., 2002) and fish organs (Liu et al., 2001) by in situ hybridization using fluorescein-labeled PCR primers. Attempts were made to identify fish-pathogenic *Flavobacterium* species from samples of skin lesion by direct broad-range PCR amplification using universal primers followed by sequencing of the partial 16S rDNA PCR products; sequences similar to those of *F. columnare*, *F. psychrophilum* and *F. hibernum* were found (Tiirola et al., 2002). Presumptive identification at the generic and specific level of different fish pathogens including *F. columnare* and *F. psychrophilum* was also obtained directly from fish tissue using terminal restriction fragment length polymorphism (T-RFLP) analysis of 16S rRNA genes (Nilsson and Strom, 2002).

Typing of Collections of *Flavobacterium* Strains

MOLECULAR TYPING. Several different molecular methods have been used to type collections of *Flavobacterium* strains. Understandably, because of the economic significance of the fish pathogenic species, and because collections of strains of widely different geographic origins and host species were available, typing methods have preferentially been tested on these species. Depending on the primers used, random amplified polymorphic DNA (RAPD) was shown to provide both a typing of *F. psychrophilum* and *F. columnare* strains and a clear differentiation between all *Flavobacterium* species tested (Chakroun et al., 1997); from a practical point of view, this technique was able to distinguish *F. psychrophilum* from other fish-pathogenic *Flavobacterium* species which may occur in the same environment (Crump et al., 2001). Ribotyping (or rRNA gene restriction pattern analysis) was also performed on *F. psychrophilum* strains using several different restriction endonucleases. All four strains tested by Ciprian et al. (1996) exhibited the same ribotype; however, different ribotypes were found when larger collections of strains were studied. Similar to what was obtained using RAPD, some of the ribotypes identified among 85 *F. psychrophilum* strains were distinctly correlated with the fish species from which the strains were isolated, whereas no correlation with the geographic origin was found (Chakroun et al., 1998). One ribotype was highly dominant among 299 Danish strains, and a relationship was found among this ribotype, serotype, and virulence (Madsen and Dalsgaard, 2000). Madetoja et al. (2001) also noted this relationship, but again no correlation with the geographic origin was found; interestingly, this study showed that different clones of *F. psychrophilum* could be isolated during the same outbreak. Three different restriction fragment length polymorphism (RFLP) patterns of PCR-amplified 16S rDNA were found in a collection of *F. columnare* strains, each corresponding to one of the three DNA-DNA hybridization groups identified in this species (Triyanto and

Wakabayashi, 1999; see above). In *F. psychrophilum*, RFLP of the amplified *gyrB* gene yielded different results depending on the kind of primers (i.e., universal versus *F. psychrophilum*-specific) used to amplify the gene; a certain correlation between RFLP patterns and the species of fish host was noticed (Izumi et al., 2003b). Five different plasmid profiles were found when a collection of mostly Danish *F. psychrophilum* isolates was investigated; a ~3.2-kb plasmid was present in most strains (Lorenzen et al., 1997). Chakroun et al. (1998) found that most of the 85 *F. psychrophilum* strains they tested harbored at least one plasmid and that eleven different plasmid profiles occurred; even strains belonging to the same ribotype could exhibit different plasmid profiles, and the approximate size of the plasmids varied from 2.1 to 20 kb. Thirty-seven strains originating from widely different geographic areas (i.e., the United States, Chile, Japan, and several European countries), most of them retrieved from rainbow trout, shared the same 3.5-kb plasmid (Chakroun et al., 1998). A 3.3-kb plasmid was found in 284 among 299 Danish *F. psychrophilum* strains studied, but no clear correlation was noted between the presence of this plasmid and the virulence of strains (Madsen and Dalsgaard, 2000). Among the four different plasmids found in a collection of *F. psychrophilum* isolates from various fish species and geographic areas, the 3.4 kb plasmid occurred mostly in rainbow trout isolates while two other plasmids seemed restricted to Japanese isolates; no plasmid was associated with antibiotic resistance (Izumi and Aranishi, 2004a). Given the rough method used in these studies to evaluate the plasmid size, it is most likely that the 3.2-, 3.3-, 3.4- and 3.5-kb plasmids they reported are actually identical. This plasmid, called "pCP1," was sequenced and used to develop cloning vectors for *F. johnsoniae* (McBride and Kempf, 1996; see the section Genetics in this Chapter).

Hence, the above-mentioned fingerprinting techniques may be powerful molecular tools for the epidemiological tracing of the infections caused by *Flavobacterium* species in fish, provided a sufficient number of strains representing a variety in origins is tested.

Recently, repetitive extragenic palindromic DNA-PCR (rep-PCR) fingerprinting was used to investigate the genomic diversity of clusters previously delineated by fatty acid analysis among a collection of polar isolates (Van Trappen et al., 2003, 2005). The results confirmed that strains sharing the same rep-PCR profile are closely related. Among the six new *Flavobacterium* species described by these authors, *F. degerlachei*, *F. micromati*, *F. fryxellicola* and *F. psychrolimnae* were each comprised of strains that exhibited the same rep-PCR profile, whereas *F. frigoris* and *F. gelidilacus* included strains representing two or three different rep-PCR profiles, respectively (Van Trappen et al., 2003a, Van Trappen et al., 2003b, 2005). Hence, this technique may either differentiate *Flavobacterium* species from each other or be used for intraspecific typing.

SEROLOGICAL TYPING. Fish-pathogenic *Flavobacterium* species have been extensively investigated for possible serotyping with applications to epidemiological studies and diagnostic tests in view; however, only a few studies included strains originating from various fish species and geographic areas. Early studies were reviewed by Reichenbach (1989). Many serotyping schemes were published, but it is only recently that investigators began identifying and characterizing bacterial antigens presumably responsible for the different serotypes (see the section Composition of the Cell Wall and Membrane in this Chapter). As for *F. psychrophilum*, three to seven serotypes were recognized by different authors depending on the origin and number of strains studied and on the technique used (i.e., rabbit or trout mono- or polyclonal antibodies; microtiter or slide agglutination with or without reciprocal absorption of antisera; double immunodiffusion; or enzyme linked immunosorbent assay [ELISA]; Holt, 1988; Wakabayashi et al., 1994; Lorenzen and Olesen, 1997; Izumi and Wakabayashi, 1999; Dalsgaard and Madsen, 2000; Madetoja et al., 2001; Mata et al., 2002). Recently, a new serotype was described and the different serotyping systems were compared and harmonized (Izumi et al., 2003a). No association was found between the serotypes of *F. psychrophilum* strains, their geographical origin, and the host fish species of origin (Faruk, 2000). Serological studies on *F. columnare* are scarce and early (Pacha and Ordal, 1970; Bullock, 1972; Sanders et al., 1976); again, serological relationships did not reveal a pattern based on fish host, tissue, or geographic origin (Shamsudin, 1994). Only limited numbers of *F. branchiophilum* strains have been studied; although common antigens were shared by Japanese, Canadian, and Hungarian strains, antigenic diversity was also found, even among isolates originating from the same region (Huh and Wakabayashi, 1989; Ostland et al., 1994; Ko and Heo, 1997).

BACTERIOCIN TYPING. Bacteriocins produced by some *F. columnare* strains are lethal to other strains of the same species; nine *F. columnare* types were defined according to their susceptibility to seven different bacteriocins, and a partial correlation was noted between these types and serotypes (Anacker and Ordal, 1959). Chase (1965) observed growth medium-dependent differences in the production of

these "columnaricins"; the highest production occurred during the late exponential growth phase (Needleman and Pacha, 1974).

MISCELLANEOUS. Early studies, reviewed by Reichenbach (1989), have reported the presence of phages in *F. columnare* and *F. johnsoniae*, but no practical utilization (e.g., for the typing of strains or as a control method during outbreaks of fish disease) was suggested. Recently, a *Flavobacterium* sp. was identified as a phage host in Arctic sea ice, but its highest 16S rRNA sequence homology (with *F. hibernum*) was only 94% (Borriss et al., 2003).

The only *Flavobacterium* species for which a particular odor, called "sickening," "distinct, fruity," or "pronounced and somewhat characteristic," was noted is *F. columnare* (Garnjobst, 1945; McCarthy, 1975; Shamsudin and Plumb, 1996).

The susceptibility to a range of antibiotics has been tested in only some members of the genus *Flavobacterium*. On the whole, and contrary to other members of the family Flavobacteriaceae such as the genus *Chryseobacterium* (see the corresponding chapter The Genus *Chryseobacterium* in this Volume), *Flavobacterium* strains are not considered to be highly resistant to antimicrobial drugs. Obviously, the fish pathogens have been particularly studied in this regard to determine which drugs might be used to treat infections. The drug susceptibility of *F. columnare* and *F. psychrophilum* were determined (Fijan and Voorhees, 1969; Amin et al., 1988; Hawke and Thune, 1992; Soltani et al., 1995; Shamsudin and Plumb, 1996) and their intrinsic resistance to certain antibiotics was used to propose selective media (Fijan, 1969; Decostere et al., 1997; Kumagai et al., 2004; see the section Isolation and Cultivation in this Chapter). A particular medium was proposed to test the antibiotic susceptibility of *F. columnare* (Hawke and Thune, 1992). Antimicrobial resistance patterns of bacterial strains and minimum inhibitory concentrations of commonly used antibiotics were determined for *F. columnare*, *F. johnsoniae* and *F. psychrophilum* to validate their clinical efficacy when fish were administered bath or oral treatment (Bernardet, 1989b; Bernardet and Grimont, 1989; Bernardet and Kerouault, 1989; Soltani et al., 1995; Lorenzen et al., 1997; Rangdale et al., 1997; Bruun et al., 2000, 2003; Izumi and Aranishi, 2004). Media were compared and standards were recommended to assess the minimal inhibitory concentration of chloramphenicol and florfenicol in various bacterial fish pathogens, including *F. psychrophilum* (Michel et al., 2003). In *F. psychrophilum* as in other Gram-negative bacteria, the co-occurrence of resistance to quinolones and specific mutations of the A subunit of DNA gyrase (GyrA) demonstrated that GyrA is an important target for quinolones (Izumi and Aranishi, 2004b). An extreme susceptibility to penicillin G was noted in *F. branchiophilum* (Ostland et al., 1994). Antibiotics for treatment of fish were selected from among those antibiotics that are toxic to fish-pathogenic *Flavobacterium* species but are not toxic to fish or banned from use on fish farms. Further information on the practical use of antibiotics in the treatment of fish is given in the section Pathogenicity and Epidemiology. Among the recently described *Flavobacterium* species, only *F. frigidarium* (Humphry et al., 2001) and *F. granuli* (Aslam et al., 2005) were tested for their antimicrobial resistance pattern, which proved similar to those of *F. columnare* and *F. psychrophilum*; *F. frigidarium* was found to be highly resistant to kanamycin (Humphry et al., 2001). The carbapenem-hydrolyzing β-lactamase from the *F. johnsoniae* type strain has recently been purified and characterized; the analysis of its sequence revealed that it is closely related to the β-lactamase produced by other members of the family Flavobacteriaceae such as *Chryseobacterium meningosepticum* and *C. indologenes* (Naas et al., 2003; see the chapter The Genus *Chryseobacterium* in this Volume).

Preservation

Flavobacterium species can be preserved for multiple-year periods by simple cryopreservation at –70°C or less, using 10–30% (v/v) glycerol as a cryoprotectant within a routine growth medium such as Anacker and Ordal's broth (see media formulae in the section Isolation and Cultivation). This procedure has been proposed for *F. branchiophilum* (Wakabayashi et al., 1989), *F. columnare* (Shamsudin and Plumb, 1996), *F. psychrophilum* (Madsen and Dalsgaard, 1998), and *F. antarcticum* (Yi et al., 2005) and used successfully by J.-F. Bernardet (unpublished data) for all *Flavobacterium* species using the CAS broth (i.e., 1% casitone [Difco], 0.1% $MgSO_4 \cdot 7H_2O$, pH 6.8 unadjusted) recommended by Reichenbach (1989) to which 10% sterile glycerol was added. Commercial cryopreservative media are also convenient (Cepeda et al., 2004). Storage in liquid nitrogen may also be used, the CAS medium being supplemented with 5% dimethylsulfoxide (DMSO; Reichenbach, 1989).

A study by Desolme and Bernardet (1996) indicated that lyophilization (freeze-drying) of *F. columnare* and *F. psychrophilum* (and thus of most other generally more robust *Flavobacterium* species) was effective using a suspension medium consisting of 2/3 Difco Bacto Brucella broth and 1/3 filtered and heat-inactivated (1 h at 56°C) horse serum. Lyophilization was also

used to preserve *F. branchiophilum* (Ostland et al., 1994). The frozen cells can be revived using Anacker and Ordal's agar. Better results for some of the more sensitive fish pathogenic strains, such as *F. psychrophilum*, can be obtained by reviving on Anacker and Ordal's medium enriched to 0.5% tryptone and supplemented with 5% defibrinated horse serum (Difco) and a trace element solution as described by Michel et al. (1999).

Most of the cold-adapted species can also be stored as live cultures on agar slants at low temperature. The best temperature is 2°C, which reduces the incidence of fungal contamination. However this procedure needs to be verified on a case-by-case basis, as some species may show poor survival in this manner of storage after more than 3 months. Many of the cold-adapted Antarctic species such as *F. tegetincola* can survive at least 18 months this way. Most fish-pathogenic *Flavobacterium* strains will survive for several months or even years when heavily inoculated in deep tubes containing Anacker and Ordal's medium gelified with 0.4% (w/v) agar maintained at 4°C (Anacker and Ordal, 1955; J.-F. Bernardet, unpublished data).

The influence of the preservation procedure on the virulence stability of a *F. psychrophilum* strain was evaluated using experimental infection of rainbow trout fingerlings and determination of the lethal dose 50%. Cultures were revived after 1, 8 and 23 months of storage by lyophilization, freezing at –80°C, and maintenance at 4°C in Anacker and Ordal's agar deeps: whatever the preservation procedure, virulence was maintained after 1 and 8 months of storage; after 23 months, the bacteria kept in agar deeps at 4°C had lost some of their virulence, while the lyophilized and frozen ones were only slightly attenuated (Michel and Garcia, 2003).

Physiology

Though specific aspects of the biochemical physiology of members of the genus *Flavobacterium* remain to be discovered, almost all *Flavobacterium* species are strictly aerobic and appear to lack fundamental idiosyncrasies in their carbon and energy pathways. Most species use glucose as a carbon source and probably employ the Embden-Meyerhof-Parnas pathway for their catabolism (Reichardt and Morita, 1982). Exceptions to this generalization are the species *F. succinicans* and *F. hydatis*, which can grow anaerobically when provided peptone or yeast extract, e.g., modified Shiehs medium (Anderson and Ordal, 1961; Strohl and Tait, 1978; Reichenbach, 1989; see the section Isolation and Cultivation in this Chapter). Some components of these media presumably contain so far undetermined growth factors required to drive anaerobic growth. *Flavobacterium succinicans* also requires CO_2 (which can be provided by adding 15–25 mM $NaHCO_3$ to growth media) and glucose for anaerobic growth (Chase, 1965). *Flavobacterium antarcticum* grows weakly under microaerobic conditions and poorly under anaerobic conditions (Yi et al., 2005). Capnophilic requirements, as exhibited by the related genus *Capnocytophaga* and other members of the family Flavobacteriaceae (see the chapters The Genus Capnocytophaga in this Volume and An Introduction to the Family Flavobacteriaceae in this Volume), are otherwise absent or negligible for known *Flavobacterium* spp. Anaerobic growth can occur fermentatively on carbohydrates or yeast extract or by respiration using nitrate as the electron acceptor. *Flavobacterium succinicans* can also grow by fermentation of pyruvate (converting it to mostly acetate); otherwise organic acids or amino acids are not utilized. Alternative anaerobic electron acceptors to nitrate (sulfur, ferric compounds, etc.) have yet to be tested. Fermentation products formed during growth are mostly succinate, acetate and formate. Anderson and Ordal (1961) proposed the CO_2 requirement of *F. succinicans* stems from a lack of lactate dehydrogenase; instead this species condenses CO_2 with phosphoenolpyruvate (using phosphoenolpyruvate carboxylase and guanosine 5′-diphosphate [GDP]), resulting in oxaloacetate. Oxaloacetate is then reduced further via the reduced form of nicotinamide adenine dinucleotide (NADH), forming succinate as an end product. Interesting physiological comparisons may be made between the capnophilic members of the family Flavobacteriaceae, i.e., the genera *Capnocytophaga* (see the chapter The Genus Capnocytophaga in this Volume), *Coenonia*, *Ornithobacterium* and *Riemerella* (see the chapter Capnophilic Bird Pathogens in the Family Flavobacteriaceae: Riemerella, Ornithobacterium and Coenonia in this Volume). Interestingly, *F. granuli* appears to be strictly aerobic although it was isolated from granules that had been kept under anaerobic conditions for two years (Aslam et al., 2005).

Energy metabolism can be supplemented by reduction of nitrate to nitrite by many *Flavobacterium* species, particularly freshwater species. Some strains (but not the type strains) of *F. johnsoniae* and *F. columnare* have been reported to grow by anaerobic denitrification (Stanier, 1947; Christensen, 1977; Callies and Mannheim, 1978; Nogales et al., 2002). It is possible, however, that these denitrifying strains actually belong to separate species or even genera (Reichenbach, 1989).

Carbon and nitrogen metabolism pathways are poorly understood in the genus; however, on the basis of phenotypic data, they appear quite diverse between species. This can be best seen in the capacity for carbohydrate catabolism, which varies strongly at the species level. Some species utilize a wide range of carbohydrates and polysaccharides including *F. pectinovorum*, the aptly named *F. saccharophilum*, *F. johnsoniae*, *F. hydatis* and *F. omnivorum*. On the other hand, *F. branchiophilum*, *F. columnare*, *F. psychrophilum*, *F. tegetincola* and *F. micromati* are essentially asaccharolytic or poorly saccharolytic, preferring nitrogen-containing substrates, primarily amino acids and proteins. Asaccharolytic species also lack common glycolytic enzymes (e.g., as revealed by API ZYM galleries; see Table 6 in Bernardet et al., 1996), which can be useful for their rapid discrimination from saccharolytic species. All *Flavobacterium* species except *F. branchiophilum* (which requires yeast extract) can grow on single amino acids, such as L-glutamate or L-asparagine, as sole nitrogen sources. In general, *Flavobacterium* species have little propensity to utilize other types of substrates including sugar alcohols, alcohols, organic acids, hydrocarbons and aromatics. The ability to utilize xenobiotics occasionally ascribed to *Flavobacterium* sp. (e.g., Topp et al., 1988) is almost certainly erroneous and the strains concerned are likely instead *Sphingomonas* spp., which can be confused with *Flavobacterium* owing to superficial morphological similarities.

Several other aspects pertaining to the physiology of members of the genus *Flavobacterium* are dealt with in other sections in this Chapter, particularly the section Identification.

Genetics

Besides investigations targeting the whole genome (DNA-DNA hybridization and determination of the G+C content) or particular genes (sequencing of 16S rRNA and *gyrB* genes) for taxonomic and phylogenetic purposes or for the molecular typing of bacterial strains (see the section Identification in this Chapter), genetics of members of the genus *Flavobacterium* has been poorly investigated to date. However, a group of scientists studied extensively the genetics of gliding motility in *F. johnsoniae*. Tools for the genetic manipulation of this organism were first developed: a *Bacteroides* transposon was shown to function in *F. johnsoniae* and cloning vectors based on a cryptic plasmid of *F. psychrophilum* were devised (McBride and Kempf, 1996). The system of gene transfer, the selectable marker, the suicide vector, and the transposon developed to genetically manipulate *F. johnsoniae* were also used successfully on *F. succinicans*, on other members of the family Flavobacteriaceae (i.e., *Chryseobacterium meningosepticum*), and on other members of the *Cytophaga-Flavobacterium-Bacteroides* phylum (i.e., [*Flexibacter*] *canadensis* and *Cytophaga hutchinsonii*; McBride and Baker, 1996). Recently, methods for the genetic manipulation of *F. psychrophilum* were also developed; selectable markers, plasmid cloning vectors, a *lacZY* reporter construct, and a transposon are now available and should allow for the analysis of virulence mechanisms and the development of vaccine strains (Alvarez et al., 2004). The most common plasmid in *F. psychrophilum* strains, pCP1 (see the section Molecular Typing in this Chapter), was entirely sequenced (M. J. McBride, seq. no. NC004811). Mutagenesis was used to address the genetic mechanisms of gliding motility in *F. johnsoniae*; at least eight different genes were shown to be required (Kempf and McBride, 2000; Hunnicutt and McBride, 2001; Hunnicutt et al., 2002; McBride et al., 2003, McBride and Braun, 2004). The most recently discovered genes, *gldH* and *gldI*, are required for gliding motility, chitin utilization, and infection by bacteriophages; these properties are lost in *gldH* or *gldI* mutants and restored when *gldH* or *gldI* is reintroduced in the genome via a plasmid (McBride et al., 2003). However, mechanisms responsible for gliding motility are complex and probably differ among the organisms that exhibit this kind of motility (McBride, 2001). Recently, the nucleotide sequence of the *F. aquatile* operon coding for the *Fau*I restriction-modification system was determined (Abdurashitov et al., 2003).

Pathogenicity and Epidemiology

Plant Pathogens

The decay of various fresh plants and vegetables called "soft rot" has been attributed to *F. johnsoniae*, among other bacterial species (Liao and Wells, 1986; Lelliott and Stead, 1987). The pathogenic strains were shown to produce more pectate lyase in broth medium than the non-pathogenic ones; however, *F. johnsoniae* was mostly considered an opportunistic pathogen (Liao and Wells, 1986).

Human Medicine

After several human cases of a lung disease similar to hypersensitivity pneumonitis occurred in a United States textile facility, a bacterial endotoxin was isolated from the biomass growing in

the air humidification system and shown serologically to be the cause of the clinical disease; the main representatives of the bacterial flora were isolated from the system and a *Cytophaga* strain was identified as the source of the endotoxin (Flaherty et al., 1984). Further studies showed that the bacterium was related to several *Cytophaga*, *Flexibacter*, and *Flavobacterium* reference strains; although DNA relatedness with *F. hydatis* was 78%, several biochemical discrepancies with this species led the authors to propose the name "[*Cytophaga*] *allerginae*" (Liebert et al., 1984). Fatty acid analysis, whole-cell protein profile, and DNA-rRNA hybridization (Bernardet et al., 1996), as well as a rather high DNA relatedness with *F. johnsoniae* (J.-F. Bernardet, unpublished data), confirmed the relationships of "[*C.*] *allerginae*" with members of the genus *Flavobacterium* (see the section Taxonomy in this Chapter). To our knowledge, no other case of lung disease in humans related to such organisms was reported since then. However, since bacterial strains closely affiliated to *F. johnsoniae* and *F. succinicans* were shown to occur intracellularly in amoebae retrieved from drinking water in hospitals and from a human corneal sample (Müller et al., 1999; Horn et al., 2001), other human pathology may possibly result from the close contact with such endocytobionts.

Veterinary Medicine

Although some members of the genus *Flavobacterium* are part of the normal bacterial flora in the mucus at the surface of fish and fish eggs (see the section Habitat and Ecology in this Chapter), several *Flavobacterium* species exhibit various degrees of pathogenicity for fish. To date, freshwater fish are the only animals known to be extensively affected by flavobacterial diseases, although infections in newt (Brown et al., 1997) and frog tadpole (Bullock et al., 1971) were exceptionally reported. Wild fish may be infected (Lehmann et al., 1991; Wiklund et al., 1994; Iida and Mizokami, 1996), but farmed fish are particularly exposed to these diseases owing to the high density of fish in farms and to the extensive national and international trade in fish and fish eggs. The fish-pathogenic *Flavobacterium* species are listed below in the order of decreasing economic significance. Data on cultural, phenotypical, serological, and molecular characteristics of these pathogens, as well as on their antibiotic susceptibility, are provided in other sections in this chapter and in Tables 2, 3 and 4; additional information may also be found in recent reviews (Austin and Austin, 1999; Shotts and Starliper, 1999). The terms used by fish farmers and fish pathologists to designate these bacteria reflect the great taxonomic and nomenclatural confusion that long characterized this bacterial group. Owing to the fact that spheroplasts were mistaken for microcysts and bacterial clumps for fruiting bodies (see the section Identification in this Chapter), fish pathogens were wrongly attributed to the fruiting gliding bacteria and the global term "myxobacteria" was consequently used (and still frequently is). Such generic epithets as *Chondrococcus* or *Cytophaga* were also commonly used for the most important fish pathogens until they were classified in the genus *Flexibacter* on the basis of phenotypic characteristics (Bernardet and Grimont, 1989) and finally in the emended genus *Flavobacterium* after extensive genomic and phylogenetic studies (Bernardet et al., 1996; Bernardet et al., 2002).

FLAVOBACTERIUM PSYCHROPHYLUM. Following the description of "peduncle disease" (see below) by Davis (1946), the responsible bacterium was first isolated by Borg (1948), who named it [*Cytophaga*] *psychrophila* and studied it extensively (Borg, 1960). For the following decades, the disease seemed restricted to the United States and Canada (Borg, 1960; Holt, 1988). *F. psychrophilum* was first recognized in Europe during the mid-eighties (Von Weis, 1987; Bernardet et al., 1988) and subsequently appeared in all other major areas of salmonid aquaculture (Japan, Tasmania, and Chile) during the nineties; its distribution is now considered worldwide. It is suspected that the pathogen extended its geographical range through the international trade in fish and fish eggs (Wakabayashi et al., 1994; Kumagai and Takahashi, 1997). Nevertheless, *F. psychrophilum* may also have occurred in some areas long ago, passing unnoticed because it was not responsible for serious outbreaks before intensive farming was put into practice and because media and temperature appropriate to its isolation were not commonly used. In contrast to *F. columnare* (see below), *F. psychrophilum* mostly infects salmonid fish (as well as the related species called "ayu," *Plecoglossus altivelis*, reared in Japan and Korea), although it may occasionally be isolated from eel, various cyprinids, and other fish species (Lehmann et al., 1991; Iida and Mizokami, 1996; Amita et al., 2000; Izumi et al., 2003b) in which it usually causes less severe infections. Hence, resident non-salmonid fish species as well as salmonid fish having survived an outbreak (Dalsgaard and Madsen, 2000; Madetoja et al., 2000) likely act as carriers or reservoirs of *F. psychrophilum* for salmonids in the same river. The pathogen can survive starvation outside fish hosts: although its culturability and viability declined when maintained in stream water, growth was still possible after 36 weeks provided

a resuscitation step was performed (Vatsos et al., 2003). Similarly, Madetoja et al. (2003) reported a survival capacity of more than 300 days in sterilized fresh water at 15°C even though the virulence declined much more rapidly. Consequently, *F. psychrophilum* was detected in fish-farm water, river water, and algae growing at the surface of stones on riverbeds (Amita et al., 2000; Madetoja and Wiklund, 2002; Vatsos et al., 2002). However, the main sources of infection are the high numbers of bacterial cells that are released into the water by infected and dead fish; disruption of the skin is likely a major invasion route into the fish, whereas oral contamination trials using live feed as a vector did not succeed (Madetoja et al., 2000). *F. psychrophilum* is currently one of the main bacterial pathogens in reared and wild salmonids in temperate to cold water and is responsible for considerable economic losses in salmonid culture worldwide (Izumi et al., 2003b). Besides the above-mentioned general reviews of fish-pathogenic *Flavobacterium* species, much information on the diseases caused by *F. psychrophilum* may be found in reviews focused on this pathogen (Dalsgaard, 1993; Holt et al., 1993; Nematollahi et al., 2003b).

Several different pathological entities have been described depending on the fish species and size (Holt et al., 1993; Nematollahi et al., 2003b). In the classical form observed in Northern America since the forties in the two most susceptible species, coho salmon (*Oncorhynchus kisutch*) and rainbow trout (*Oncorhynchus mykiss*), the area around the adipose fin becomes dark and eroded; pathological changes progressively extend to the whole caudal peduncle and to the tail, usually resulting in a deep ulcerative lesion exposing the spinal cord (Davis, 1946; Pacha and Ordal, 1970; Holt et al., 1993), and hence the name "peduncle disease" (Fig. 10). Similar lesions may occur around the dorsal fin; this particular location won the condition the name "saddleback disease."

The terms "bacterial cold-water disease" and "low temperature disease" are also frequently used since outbreaks usually occur when water temperature is below 10°C. When groups of experimentally infected salmonids were kept at 3–23°C, the shortest time from infection to death was reported in the group kept at 12–15°C (Holt et al., 1989). In contrast to *F. columnare* infections (see below), those caused by *F. psychrophilum* rapidly become septicemic and the bacterium may be isolated from internal organs such as the spleen and kidney. Mortality may reach up to 50% in coho salmon fingerlings and 20% in larger fish (Holt, 1988). Gill damage due to *F. psychrophilum* (which is less severe than that due to *F. columnare* or *F. branchiophilum*

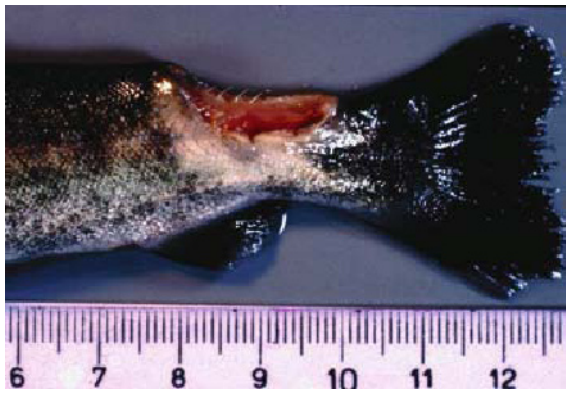

Fig. 10. "Peduncle disease" caused by *F. psychrophilum*. Extensive necrotic lesions may appear in various locations on the body of infected fish, including the caudal peduncle. On this young rainbow trout, extracellular enzymes of the pathogen have destroyed the skin, connective tissue and muscle, revealing the spinal column.

infections [see below]) has been reported in several salmonid species in Ontario (Ostland et al., 1999). Nervous forms of this disease are also known in the United States: young salmon and trout having recovered from acute infection displayed ataxia and spiral swimming behavior stemming from compression of nervous tissue by cranial lesions and spinal deformities; in such cases, osteitis, osteochondritis, meningitis and myeloencephalitis were noted (Kent et al., 1989; Meyers, 1989; Ostland et al., 1997). Such clinical signs as anemia, exophthalmia, necrotic scleritis, and skin bullae or blisters evolving into cavernous ulcers due to necrotic myositis were also reported (Lumsden et al., 1996; Ostland et al., 1997; Ostland et al., 2000). In Europe, although cases of typical cold-water disease were occasionally reported in table-size rainbow trout (Dalsgaard, 1993; Wiklund et al., 1994; Madetoja et al., 2001), *F. psychrophilum* infection is mostly a concern in rainbow trout fry and fingerlings; hence the terms "rainbow trout fry syndrome" (RTFS) and "fry mortality syndrome" (FMS; see Nematollahi et al. [2003b] and references therein). These conditions may result in high to very high mortality (i.e., 20–70%). Infection is septicemic and fish usually display only limited and nonspecific clinical signs such as anemia, lethargy, loss of appetite, dark color, and exophthalmia (Lorenzen, 1994), although fin erosion, blisters (from which *F. psychrophilum* may be isolated in pure culture; J.-F. Bernardet, unpublished data), ulcers, as well as mouth and eye lesions may also occur in fingerlings (Von Weis, 1987; Bernardet and Kerouault, 1989; Lehmann et al., 1991; Dalsgaard, 1993; Lorenzen, 1994; Martínez et al., 2004). The most consistent

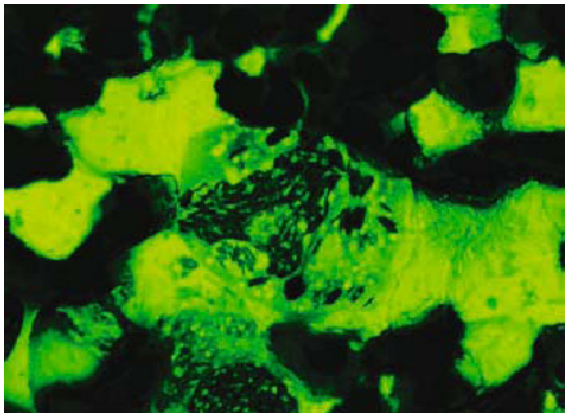

Fig. 11. *Flavobacterium psychrophilum* in a fish spleen macrophage. A spleen imprint from a rainbow trout with hemorrhagic septicemia caused by *F. psychrophilum* reveals numerous bacterial cells in the vacuoles of a macrophage (May-Grunwald-Giemsa, ×450).

internal sign is a severe splenic hypertrophy; in spleen imprints or histological preparations, numerous bacterial rods are dispersed in the parenchyma throughout the tissue (Rangdale et al., 1999; Ekman and Norrgren, 2003; Ekman et al., 2003) as well as located within phagocytes and endothelial cells in the spleen, liver, heart, and kidney (Lehmann et al., 1991; Ekman and Norrgren, 2003; Ekman et al., 2003; Fig. 11).

The presence of bacteria in the spleen tissue is considered pathognomonic for RTFS together with the replacement of the border of the spleen by a loose eosinophilic layer, fibrinous inflammation, and intercellular edema (Rangdale et al., 1999). Clinical signs and pathological findings were similar in the three salmonid species experimentally infected (Ekman and Norrgren, 2003). Following intraperitoneal injection of *F. psychrophilum* cells to rainbow trout, epifluorescence microscopy revealed that the intracellularly located bacteria in the spleen of fry were still viable and increased in number with time, suggesting that the ability of bacteria to escape from the bactericidal mechanisms of phagocytes and to be protected against the humoral defense mechanisms of the host could explain, at least partly, why fry display clinical signs and suffer mortality. Conversely, older fish displayed no sign of infection and no bacteria were detected in their spleen phagocytes (Decostere et al., 2001). Wiklund and Dalsgaard (2003) showed that 1) the *F. psychrophilum* cells associated with kidney phagocytes of large rainbow trout in vitro were rapidly destroyed, 2) the differences in association with the phagocytes were not clearly related to the serotype or virulence of the strains, and 3) a phagocyte toxin was not necessary for the virulence.

Besides the resistance to the defense mechanisms of the fish, several other factors have been suggested to explain the virulence of *F. psychrophilum* (see Dalsgaard [1993] and Nematollahi et al. [2003a] and references therein) and its wide variation among strains (Holt, 1988; Faruk, 2000). Adherence is likely the initial step of infection. The adherence of *F. psychrophilum*, studied on a gill perfusion model, was influenced by water temperature and chemical composition; also, a high virulence strain attached more readily than a low virulence one (Nematollahi et al., 2003a). The adhesion of *F. psychrophilum* to the eggs of rainbow trout (Vatsos et al., 2001) and to the body surface of ayu (Kondo et al., 2002) was also studied; initial attachment of the bacterium was shown to occur preferentially on the jaw and caudal peduncle, which are precisely the locations of some of the most typical lesions. However, the role of the slime layer of *F. psychrophilum* in the adhesion process (unlike that of *F. columnare* [see below]) has not yet been demonstrated (Nematollahi et al., 2003b). Surprisingly, when the adhesion of *F. psychrophilum* to mucus preparations from rainbow trout esophagus, stomach, intestine, gills and skin was compared to that of other fish-pathogenic bacteria, it proved to exhibit the lowest adhesion ability, a detectable adhesion being only reported to mucus from stomach and intestine (Nikoskelainen et al., 2001). The ability of *F. psychrophilum* to agglutinate and hemolyze rainbow trout erythrocytes (Lorenzen, 1994; Lorenzen et al., 1997) may explain, at least partially, the severe anemia that occurs in infected fish. Recently, a sialic acid-binding lectin was shown to be involved in the hemagglutinating properties exhibited by *F. psychrophilum* strains belonging to some serotypes (Møller et al., 2003). The extracellular proteases (Otis, 1984; Holt, 1988; Bertolini and Rohovec, 1992; Bertolini et al., 1994; Nomura and Ohara, 1994; Newton et al., 1997; Faruk, 2000; Ostland et al., 2000; Secades et al., 2001; Secades et al., 2003) and chondroitin lyase (Otis, 1984) produced by *F. psychrophilum* are certainly important virulence factors which may explain to some degree the extensive necrotic lesions displayed by diseased fish (see the section Identification in this Chapter). Scanning electron microscopy investigations of infected fin rays of Atlantic salmon revealed that erosion of the ray axis resulted from the formation of grooves and tubular boreholes likely caused by *F. psychrophilum* extracellular proteases (Martínez et al., 2004). Among the various proteolytic capacities of *F. psychrophilum*, the elastin-degrading capacity in particular has been suggested as a virulence factor, since the mortality rates in groups of rainbow trout experimentally infected

with an elastin-positive strain were significantly higher compared to those of groups infected with an elastin-negative strain; a certain correlation was also found between the elastin-degrading capacity and the serotype of the strains studied (Madsen and Dalsgaard, 1998). However, the opposite result was observed when rainbow trout eggs were injected with *F. psychrophilum* strains with or without elastin-degrading capacity, suggesting that other virulence factors are involved in the virulence of the pathogen (Ekman et al., 2003). It has also been suggested that the lytic activity displayed by *F. psychrophilum* strains against other bacterial species may constitute an advantage, indirectly contributing to its virulence (Nematollahi et al., 2003a). Wiklund and Dalsgaard (2002) showed that virulent as well as nonvirulent strains of *F. psychrophilum* were resistant to the action of the complement present in the serum of rainbow trout. Although the structure of the lipopolysaccharide of *F. psychrophilum* was recently determined (Crump et al., 2001; MacLean et al., 2001; see the section Identification in this Chapter), its role in pathogenesis has not been evaluated. A certain relationship between serotype, ribotype, and virulence was found in *F. psychrophilum* isolates; however, virulence was not clearly correlated to the plasmid content (Madsen and Dalsgaard, 2000; see the section Identification in this Chapter).

The diagnosis of *F. psychrophilum* infections usually relies on the isolation of the pathogen, preferably from internal organs (see the section Isolation and Cultivation in this Chapter), and on its identification using phenotypical and serological characteristics (see the section Identification in this Chapter). The molecular techniques available to specifically detect the bacterium in infected tissue and to identify isolates are listed in the section Identification. Serological methods such as ELISA (Rangdale and Way, 1995; Faruk, 2000), immunohistochemistry (Evensen and Lorenzen, 1996; Ekman and Norrgren, 2003), and immunofluorescence (Lorenzen and Karas, 1992; Amita et al., 2000; Faruk, 2000) have been devised to detect *F. psychrophilum* in fish tissue and to reveal antigenic differences between isolates.

F. psychrophilum has long been suspected to be vertically transmitted from brood fish to progeny, i.e., within fish eggs. If confirmed, vertical transmission associated with the international trade in fish eggs would help explain the dramatic worldwide spread of rainbow trout fry syndrome within only a few years despite disinfection procedures routinely applied to eggs (Izumi and Wakabayashi, 1997; Kumagai and Takahashi, 1997). The detection using cultivation and/or molecular methods of *F. psychrophilum* in the coelomic fluid and at the surface of the ova of infected female salmonids, as well as in the milt of certain males, is well documented (Holt, 1988; Lorenzen, 1994; Rangdale et al., 1996; Brown et al., 1997; Izumi and Wakabayashi, 1997; Kumagai and Takahashi, 1997; Ekman et al., 1999; Amita et al., 2000; Baliarda et al., 2002; Taylor, 2004). However, since *F. psychrophilum* is embedded in the mucus at the surface of the egg, a complete disinfection is difficult to achieve (Brown et al., 1997; Kumagai and Takahashi, 1997) and thus transmission within disinfected eggs rather than on their still-infected or re-infected surfaces is difficult to demonstrate. The strongest evidence for in ovo transmission of *F. psychrophilum* came from Brown et al. (1997), who reported the isolation of the pathogen from crushed steelhead trout eggs after they were disinfected using iodine compounds and after the sterility of their surface was verified by a 72-h incubation in an appropriate broth medium. The same authors also demonstrated that *F. psychrophilum* is resistant to concentrations of lysozyme greater than those found within salmonid eggs and that the pathogen is able to survive within the content of the eggs. Injection of infected females with erythromycin or tetracycline prior to fecundation did not significantly reduce the proportion of infected eggs (Brown et al., 1997; Roberts, 1998). Recent investigations by Kumagai et al. (2000) using immunofluorescence on frozen sections of experimentally infected coho salmon eggs and by Taylor (2004) using a nested PCR assay on yolk material from four different naturally infected Pacific salmonid species also succeeded in revealing *F. psychrophilum* cells within the eggs. Nanoinjection of *F. psychrophilum* in rainbow trout eggs was recently used to mimic vertical transmission and to compare the virulence of two strains (Ekman et al., 2003).

The study of the pathogenesis of *F. psychrophilum* infections and the evaluation of candidate vaccines (see below) were made possible by various experimental infection and challenge models reviewed by Nematollahi et al. (2003b). Clinical disease was successfully reproduced using subcutaneous, intramuscular, or intraperitoneal injection of bacterial suspensions, but these routes were criticized for not being natural and for bypassing the surface defense mechanisms of the fish. To better approximate the natural route of infection, other infection models were devised, using cohabitation with diseased fish or immersion in bacterial suspensions. These procedures usually failed to induce infection, except when fish were previously stressed somehow (see Madetoja et al. [2000], Busch et al. [2003], and Nematollahi et al. [2003b] and references therein); yet, skin injury or osmotic stress

did not significantly increase the mortality of rainbow trout submitted to a bath infection (Garcia et al., 2000). Presence of ectoparasites was expected to favor the penetration of *F. psychrophilum* in fish through the microlesions they cause on the skin; however, no distinct enhancement of infection could be demonstrated in rainbow trout fry bathed in a bacterial suspension and exposed to a monogenean ectoparasite compared to fry only exposed to the bacterium (Busch et al., 2003).

Although the mucus and serum of infected rainbow trout were shown to contain specific antibodies against *F. psychrophilum*, the number of bacterial cells incubated in the serum decreased only slightly, suggesting that high levels of antibodies alone do not provide protection against the pathogen and that stimulation of nonspecific immune factors is necessary to achieve nearly complete protection (LaFrentz et al., 2002; Wiklund and Dalsgaard, 2002). The inability of antibodies to provide complete protection was also demonstrated by the partial success of passive immunization experiments (LaFrentz et al., 2003). Among the vaccination attempts to prevent *F. psychrophilum* infections (see the reviews by Bernardet [1997] and Nematollahi et al. [2003b]), injection of or immersion in formalin-killed bacterial cells has met with varying degrees of success. Recently, Kondo et al. (2003) have claimed to induce protection of juvenile ayu using an oral vaccination procedure. Mortality of ayu injected intraperitoneally with formalin-killed bacterin mixed with water-soluble adjuvants was significantly lower than that of un-vaccinated fish (Nagai et al., 2003; Rahman et al., 2003). Improved vaccines could result from the identification of several immunogenic cell surface molecules (Crump et al., 2001) and from the characterization of the O-antigen of the *F. psychrophilum* lipopolysaccharide (MacLean et al., 2001). Recently, a good protection was obtained using the outer membrane protein of *F. psychrophilum* as a vaccine (Rahman et al., 2002). The major glycoprotein antigen purified from the bacterial cell membrane is another candidate for a subunit vaccine against *F. psychrophilum* (Merle et al., 2003). Following the identification of several immunogenic fractions of the bacterium using western-blot analysis of rainbow trout immune sera, immunization with the 70–100 kDa fraction resulted in a very good protection of fish (LaFrentz et al., 2004). Since antibodies in the serum of protected fish recognized high molecular weight proteins and the O-polysaccharide component of the lipopolysaccharide, these antigens may be responsible for the protective immune response and could serve as vaccine candidates. Methods for the genetic manipulation of *F. psychrophilum* are now available (Alvarez et al., 2004; see the section Genetics in this Chapter); they should facilitate the rational design of vaccine strains.

Holt et al. (1993), Austin and Austin (1999), and Nematollahi et al. (2003b) have reviewed the different antibacterial drugs (e.g., sulfonamides, furans, oxytetracycline, and florfenicol) that may be used in the control of *F. psychrophilum* infections. Although antibacterial therapy remains the most effective control method, the progressive development of resistance to oxytetracycline, oxolinic acid and amoxicillin, as well as the importance of performing in vitro antimicrobial susceptibility testing, are well documented (Soltani et al., 1995; Bruun et al., 2000; Bruun et al., 2003; Dalsgaard and Madsen, 2000; Schmidt et al., 2000; see the section Identification in this Chapter). However, a recent survey of the susceptibility of fish-pathogenic bacteria isolated in France to chloramphenicol and florfenicol found no resistant strain of *F. psychrophilum* (Michel et al., 2003). Manipulation of water temperature or salinity has also been suggested to reduce the morbidity due to *F. psychrophilum* infections in farmed fish (Soltani and Burke, 1994).

FLAVOBACTERIUM COLUMNARE. Although different generic epithets were successively used to designate it (see above and the comments to Table 1 in the chapter An Introduction to the Family Flavobacteriaceae in this Volume), *F. columnare* has long been recognized as an important fish pathogen in relatively warm freshwater worldwide, causing dramatic losses in a considerable variety of farmed and wild, food and ornamental fish. The list of fish species which may be infected and the history of "columnaris disease," as it is called by fish farmers and fish pathologists since its discovery by Davis (1922), may be found in the extensive literature devoted to this organism, particularly in recent reviews (Wakabayashi, 1993; Austin and Austin, 1999; Shotts and Starliper, 1999). Early reports of *F. columnare* from seawater or marine fish (see Bullock et al. [1971] and references therein) were subsequently invalidated following the demonstration that the bacterium was unable to survive in seawater (Chowdhury and Wakabayashi, 1988); in fact, the organism responsible for "marine columnaris" was likely *Tenacibaculum maritimum* (see the chapter The Marine Clade of the Family Flavobacteriaceae: The Genera Aequorivita, Arenibacter, Cellulophaga, Croceibacter, Formosa, Gelidibacter, Gillisia, Maribacter, Mesonia, Muricauda, Polaribacter, Psychroflexus, Psychroserpens, Robiginitalea, Salegentibacter, Tenacibaculum, Ulvibacter, Vitellibacter and Zobellia in this Volume). Even though the overall economic losses due to *F. psychrophilum* worldwide are now far higher

than those caused by *F. columnare*, the latter remains one of the most serious bacterial pathogens in commercially reared channel catfish (*Ictalurus punctatus*) in the United States (Hawke and Thune, 1992; Newton et al., 1997) and in several tropical and/or ornamental fish (Decostere et al., 1998; Michel et al., 2002; Tripathi et al., 2005).

Many environmental and host-related factors (such as water temperature and composition, skin or gill damage, stress due to handling and high stocking density, and feed or oxygen deprivation) may influence the impact of columnaris disease on fish populations (Pacha and Ordal, 1970; Becker and Fujihara, 1978; Austin and Austin, 1999). Columnaris disease is usually problematic only in the warmer periods of the year: the optimum temperature for an outbreak is 20–30°C and mortality usually does not occur below 15°C, although highly virulent strains may still be pathogenic at lower temperatures (see Wakabayashi [1991] and references therein). Field studies demonstrated that various species of feral fish serve as reservoir of infection (Pacha and Ordal, 1970; Becker and Fujihara, 1978; Wakabayashi, 1991). The survival of *F. columnare* in water depends on the concentration of various ions, on the presence of organic matter (such as particulate fish feeds on which the bacterium grows well), and on the temperature (Wakabayashi, 1991).

The pathology of columnaris disease has been extensively described (e.g., Pacha and Ordal, 1970; Amin et al., 1988; Shotts and Starliper, 1999; Decostere et al., 2002) and gross clinical signs may help achieve diagnosis (Austin and Austin, 1999). The gross pathology in young fish infected by highly virulent *F. columnare* strains is usually very limited; the gill is the major site of damage, but the body, mouth (Fig. 12), fins and tail are also frequently damaged. In adult fish, yellowish areas of necrotic tissue appear in the gills, eventually destroying completely the gill filament (Fig. 13).

Lesions on the body begin as small eroded and hyperemic areas which progressively extend to large ulcerative and hemorrhagic necrotic lesions exposing the underlying muscle tissue. A particular aspect of columnaris disease in salmonids is named "saddleback" because the lesion is typically located around the dorsal fin (Cone et al., 1980; Morrison et al., 1981). In severe cases of *F. columnare* infection, a septicemia may also occur. In tropical ornamental fish, columnaris disease is frequently called "cotton-wool" disease or "mouth fungus" since the filaments composed of numerous bacterial cells emerge from the lesions; however, recent descriptions of columnaris disease in three different tropical fish species only mentioned local skin discoloration, with or without ulceration, and degeneration of muscle fibers (Decostere et al., 1998; Michel et al., 2002). When fragments of infected fish tissue are examined under the microscope in wet mounts, great numbers of bacterial cells are

Fig. 12. Mouth lesion in fish infected by *F. columnare*. Bacteria have destroyed the floor of the oral cavity in a young rainbow trout; such necrotic lesions ("mouth rot") are common and may also affect other parts of the body ("fin rot," "tail rot," skin ulcers, etc.).

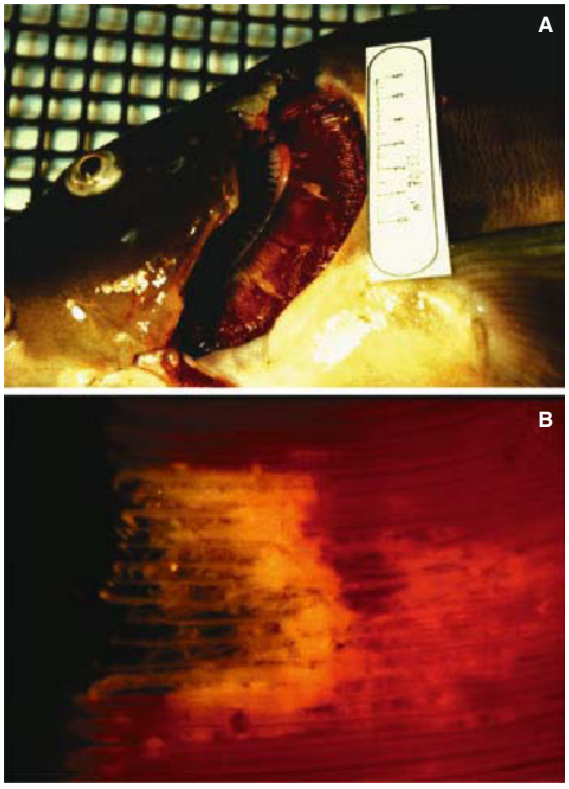

Fig. 13. Gill necrosis in carp caused by *F. columnare*. Yellowish necrotic lesions in the gills of a heavily infected common carp (A). Under the stereomicroscope (×10), gill tissue appears completely destroyed by the extracellular enzymes of *F. columnare*, and yellow bacterial growth progressively invades the gills (B).

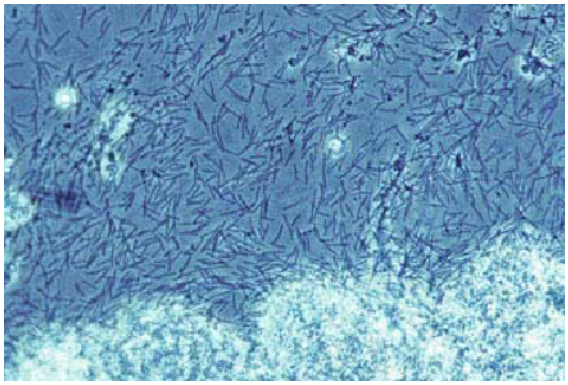

Fig. 14. Direct microscopic examination of a fragment of *F. columnare*-infected tissue. Under phase-contrast microscopy (×1000), a fragment of infected skin tissue from neon tetra (*Paracheirodon innesi*) shows numerous actively gliding bacterial cells; the dense, column-like masses of gliding bacterial cells frequently found on the surface of infected tissue are at the origin of the specific epithet "*columnare*."

observed, slowly gliding and aggregating in columnar masses, from which the specific epithet of *F. columnare* is derived (Fig. 14). Histopathology of columnaris disease was described in several fish species (Pacha and Ordal, 1967; Cone et al., 1980; Morrison et al., 1981; Amin et al., 1988; Shamsudin, 1994; Decostere et al., 1999; Tripathi et al., 2005).

Flavobacterium columnare may usually be readily isolated from external lesions, provided samples are taken from the edge of recent lesions and streaked on convenient media (see the section Isolation and Cultivation in this Chapter). When columnaris disease reaches a septicemic phase, the bacterium may also be isolated from internal organs, preferably spleen or kidney (Morrison et al., 1981; Hawke and Thune, 1992; Decostere et al., 1998; Tripathi et al., 2005). Although different colony types may occur (Song et al., 1988a; Shamsudin and Plumb, 1996), most *F. columnare* strains may be readily identified from their typical colonies on Anacker and Ordal's agar (Anacker and Ordal, 1955). These are pale greenish yellow, flat, spreading, with more or less rhizoid margins, are adherent to the agar, and may appear warty or elevated at the center (Pacha and Ordal, 1970). The gliding motility in liquid culture is also easy to observe and those who know this organism well recognize its odor. Of course, additional tests are necessary for an accurate identification (see other sections in this chapter and Table 4). Various PCR techniques have been proposed to detect *F. columnare* in the tissue of diseased fish or to identify isolates (Toyama et al., 1996; Nilsson and Strom, 2002; Tiirola et al., 2002; Darwish et al., 2004; Tripathi et al., 2005; see also the section Isolation and Cultivation in this Chapter). The typing of *F. columnare* isolates may be achieved using biochemical, serological and molecular techniques; early descriptions of bacteriocin and phage typing were also published (see the section Identification in this Chapter).

Columnaris disease was experimentally reproduced using different routes. These experiments showed *F. columnare* strains exhibit various degrees of virulence: highly virulent strains killed all experimental fish within 24 h while strains exhibiting a low virulence required over 96 h to reach 100% mortality; some of the least virulent *F. columnare* strains failed to infect the fish unless their skin was previously scarified or did not kill the fish at all (Pacha and Ordal, 1970; Amin et al., 1988; Shamsudin, 1994; Chowdhury, 1995; Decostere et al., 1999; Tripathi et al., 2005). Extensive external lesions only appear when the disease lasts several days, i.e., when it is caused by strains with low or moderate virulence. Although the virulence mechanisms of *F. columnare* are far from completely elucidated, several putative virulence factors have been studied. No correlation was found between the degree of virulence and such epidemiological markers as serotypes (Pacha and Ordal, 1970), plasmid or RAPD profiles, and ribotypes (see the section Identification in this Chapter). The various enzymes, such as extracellular proteases (Newton et al., 1997) and chondroitin AC lyase (Stringer-Roth et al., 2002), produced by *F. columnare* are presumably responsible for the extensive necrotic lesions (see the section Identification in this Chapter), and a correlation was indeed found between the degree of virulence and that of chondroitin AC lyase activity (Stringer-Roth et al., 2002). The adherence of *F. columnare* was extensively studied in vivo (Decostere et al., 1999) and ex vivo using a model of isolated gill arches (Decostere et al., 1999; Decostere et al., 1999); these studies demonstrated that 1) the adhesion of bacterial cells to the gill tissue was an important step in pathogenesis, 2) adhesion was favored by the presence of nitrite or organic matter in the water and by high water temperatures, and 3) a high virulence strain adhered more readily than a low virulence one. The role of adherence in pathogenesis was further substantiated when a decrease in virulence was observed in fish challenged with an adhesion-defective mutant of *F. columnare* obtained by serial passages on an ampicillin-enriched medium (Bader et al., 2005). Adherence ability of *F. columnare* was correlated to its hemagglutination capacity, and a lectin-like component of the capsule was responsible for the attachment of the bacterium to gill tissue; moreover, the capsule was thicker and denser in highly virulent strains than is low virulence ones (Decostere et al., 1999). Nevertheless, according

to MacLean et al. (2003), the adhesins involved have not been definitely identified; possible candidates are the lipopolysaccharide, the capsule, the fimbriae, or other appendages of the bacterium.

The control of columnaris disease is difficult to achieve and outbreaks frequently occur in the same river, lake or fish farm when environmental conditions are adequate; healthy fish may be infected by resident carrier fish, by bacteria surviving in the environment, or by recently introduced infected fish. The facts that rainbow trout surviving a columnaris disease outbreak were resistant to a re-exposure the following year (Becker and Fujihara, 1978) and that channel catfish, rainbow trout and tilapia injected with suspensions of heat- or formalin-killed virulent strains produced specific antibodies in plasma and skin mucus (Fujihara and Nakatani, 1971; Schachte and Mora, 1973, Grabowski et al., 2004) have led to various vaccination trials. Although bath or parenteral vaccination of fish against columnaris disease with killed whole-cell bacterins have shown some promise (Fujihara and Nakatani, 1971; Moore et al., 1990; Bernardet, 1997), the protection is neither strong nor long lasting, and better vaccines are needed. As suggested by Newton et al. (1997), detoxified proteases of *F. columnare* could possibly be more effective antigens. Seven outer membrane proteins, some of them common to all *F. columnare* isolates, were strongly recognized by antibodies in the serum of convalescent channel catfish; they may also prove useful in developing an improved vaccine (Davidson, 1996). Rabbit antisera raised against the outer membrane proteins of *F. columnare* were used to screen an expression library of the bacterium; two genes, encoding a zinc metalloprotease (possibly representing a new family of zincins) and a prolyl oligopetidase (Pop), both membrane-associated, were identified (Xie et al., 2004). Comparison of immunodominant antigens in whole-cell lysates of *F. columnare* showed that formalin treatment (but not pressure treatment) inactivates one of the protein antigens (Bader et al., 1997). The recently characterized lipopolysaccharide *O*-polysaccharide antigen and the glycopeptides of *F. columnare* may also provide target molecules for vaccines (MacLean et al., 2003; Vinogradov et al., 2003). The modification of water temperature and salinity has been proposed as a control method during outbreaks of columnaris disease, when possible (Holt et al., 1993; Soltani and Burke, 1994). Chemotherapy remains the most widely used control method in fish farms, but very few antibiotics are at the same time authorized for use in fish, nontoxic to fish, and actually effective in vivo despite demonstration of in vitro activity against *F. columnare* (Soltani et al., 1995; see the section Identification in this Chapter). Oxytetracycline is commonly used in feed or as a bath for external infections; oral administration of oxolinic acid, sulfonamides or florfenicol is also recommended (Wakabayashi, 1993; Austin and Austin, 1999; Shotts and Starliper, 1999). Bath, flush or dip treatments with various disinfectants (sodium chloride, copper sulfate, potassium permanganate, hydrogen peroxide, chloramine-T, quaternary ammonium compounds, Diquat, etc.) have met with varying degrees of success (Altinok, 2004; Thomas-Jinu and Goodwin, 2004). After having been advocated as a strategy to control infectious diseases of channel catfish, withholding feed has been shown to actually reduce the resistance of fish to *F. columnare* (Shoemaker et al., 2003).

FLAVOBACTERIUM BRANCHIOPHILUM. Although *F. columnare*, *F. psychrophilum* and presumably *F. hydatis* are able to cause bacterial gill disease in various fish species (see the corresponding paragraphs), a different, nongliding, yellow filamentous organism first recognized from gill disease in salmonids in Japan (Kimura et al., 1978) is actually the main causative agent. Following the identification of other, serologically different strains from similar cases in Oregon (Wakabayashi et al., 1980) and from gill disease in rainbow trout, sheatfish, and silver carp in Hungary (Farkas, 1985), comparative studies of representative isolates originating from these three geographic areas resulted in the description of the new species *Flavobacterium branchiophila* (Wakabayashi et al., 1989), which was rapidly corrected to *branchiophilum* (Von Graevenitz, 1990). The new pathogen was also recognized in Ontario, Canada, as the causative agent of gill disease, one of the most important conditions affecting the salmonid industry in this region (Ferguson et al., 1991; Turnbull, 1993; Ostland et al., 1994). More recently, cases were also identified in Korea (Ko and Heo, 1997). As for *F. psychrophilum*, it is difficult to know whether what appears to be a fast, worldwide diffusion of a new pathogen could actually be only related to improvements in the isolation and identification of a long-established bacterial species after fish pathologists became aware of the disease in other parts of the world. Bacterial gill disease was reproduced experimentally in various fish species (Wakabayashi et al., 1980; Ferguson et al., 1991; Ostland et al., 1995). Histopathological changes in infected gills were evaluated and the ability of all *F. branchiophilum* strains to attach to the gills was demonstrated, although only virulent strains were able to further colonize the gills and cause mortality (Turnbull, 1993; Ostland et al., 1995). Contrary to the two above-mentioned fish pathogens, *F. branchiophilum* is considered noninvasive and is

usually not isolated from internal organs; it is a relatively fastidious organism, easily overgrown by other bacteria (Turnbull, 1993). The virulence for gills was connected to the various enzymatic and hemagglutinating activities detected in the extracellular products (Ototake and Wakabayashi, 1985) which affect respiratory functions of rainbow trout (Wakabayashi and Iwado, 1985). Serological studies (see the section Identification in this Chapter) made possible the use of immunofluorescence and ELISA to specifically detect and quantify *F. branchiophilum* at the gill surface (Heo et al., 1990; MacPhee et al., 1995). Indirect enzyme immunoassay showed that infected fish produce serum and gill-surface antibodies (Lumsden et al., 1993); however, intermittent occurrence of gill disease outbreaks in the same fish population suggested that surviving fish are not protected against the pathogen (Heo et al., 1990). Nevertheless, immunization trials (reviewed by Bernardet, 1997) showed that the local gill immune response was probably responsible for the significant reduction in gill-associated *F. branchiophilum* and for the partial protection seen in bath-vaccinated fish challenged with relatively low numbers of bacteria (Lumsden et al., 1994). The use of NaCl (Heo et al., 1990), H_2O_2 (Derksen et al., 1999), formalin and chloramine-T (Ostland et al., 1995), and nifurpirinol (now banned; Ostland et al., 1989) was evaluated for the bath treatment of bacterial gill disease and has met with varying degrees of success (Turnbull, 1993; Shotts and Starliper, 1999).

FLAVOBACTERIUM JOHNSONIAE. [*Cytophaga*] *johnsonae* was long known as a common soil organism involved in the degradation of various biomacromolecules (Stanier, 1947; Reichenbach, 1989). It was later transferred to the genus *Flavobacterium* and its specific epithet was corrected (Bernardet et al., 1996). After strains isolated from diseased fish were first mentioned by Christensen (1977), similar strains were frequently recognized in external lesions of different fish species worldwide (Rintamäki-Kinnunen et al., 1997; J.-F. Bernardet, unpublished data). The best description of a fish disease caused by *F. johnsoniae* was published following its isolation in pure culture from extensive skin lesions in juvenile farmed barramundi (*Lates calcarifer*) in Australia (Carson et al., 1993). However, the fact that this outbreak occurred in intensive farming conditions after an increase in suspended solids in the water and a sudden drop in water temperature indicated that special conditions had to be met for *F. johnsoniae* to become pathogenic. This was confirmed when experimental infection trials in various fish species were shown to be effective only in barramundi and then only when fish were challenged after being submitted to a drop in water temperature (Soltani et al., 1994). Hence, these studies confirmed *F. johnsoniae* as an opportunistic pathogen. Although phenotypic and chemotaxonomic (i.e., whole-cell protein profiles and fatty acid analysis) investigations of a collection of fish isolates showed they were indeed highly related to *F. johnsoniae*, only rather low DNA relatedness was found between the isolates tested and the type strain (J-F. Bernardet, unpublished data). Hence, pending further research, such strains should preferably be referred to as "*F. johnsoniae*-like." Since a certain degree of heterogeneity was noticed between the strains available in culture collections (Bernardet et al., 1996), the splitting of *F. johnsoniae* into two or several species may be necessary in the future.

OTHER *FLAVOBACTERIUM* SPECIES. Several other so-called *Flavobacterium* species have been either retrieved from fish or described as fish pathogens; however, most of them have subsequently been moved to other or new genera, and they have not been involved in any outbreak since their original description.

Several *Flavobacterium*-like organisms were described from diseased marine fish; for instance, "[*Flavobacterium*] *piscicida*," isolated from various fish species in Florida, was subsequently reclassified as "[*Pseudomonas*] *piscicida*" and finally as *Pseudoalteromonas piscicida* (see Bernardet [1998] and references therein; the chapter The Genus *Alteromonas* and Related Proteobacteria in Volume 6).

[*Flavobacterium*] *balustinum* was originally isolated from the surface of dead fish; the current opinion is that this organism was a fish spoilage agent rather than a pathogen (see Austin and Austin [1999] and references therein). It was moved to the genus *Chryseobacterium* as *C. balustinum* after further taxonomic investigations (Vandamme et al., 1994).

A new bacterial species isolated from turbot (*Scophthalmus maximus*) and seawater in Scotland was first named "[*Flavobacterium*] *scophthalmum*" (Mudarris et al., 1994); this bacterium, responsible for gill disease and hemorrhagic septicemia, was also transferred to the genus *Chryseobacterium* as *C. scophthalmum* (Vandamme et al., 1994).

A related bacterium, although not isolated from fish, should be mentioned: an organism responsible for hemorrhagic septicemia in farmed bullfrog (*Rana catesbeiana*) in Taiwan was characterized and named "[*Flavobacterium*] *ranacida*" (see Faung et al. [1996] and references therein); recently, this organism was identified as *Chryseobacterium meningosepticum* (J.-F. Bernardet, unpublished data; for the three above-mentioned organisms, see

the chapter The Genus *Chryseobacterium* in this Volume).

Three strains of a facultatively anaerobic gliding bacterium were isolated from skin lesions of salmon and from a water sample in a Washington state hatchery, characterized, and named "[*Cytophaga*] *succinicans*" (Anderson and Ordal, 1961) in spite of phenotypic differences between the three strains (Reichenbach, 1989). Whole-cell protein profile and fatty acid content confirmed that one strain differs from the two others (Bernardet et al., 1996). No other strain of this bacterial species was ever described, and it was subsequently transferred to the genus *Flavobacterium* as *F. succinicans* (Bernardet et al., 1996). Also isolated from external (i.e., gill) lesions in salmon in a Michigan hatchery, another facultatively anaerobic gliding bacterium was described as the new species [*Cytophaga*] *aquatilis* (Strohl and Tait, 1978). This species was later transferred to the genus *Flavobacterium* under the new epithet *F. hydatis* (Bernardet et al., 1996). Similar strains have frequently been isolated from external lesions (i.e., gill or fin necrosis, skin ulcers, etc.) of fish since then (e.g., Austin and Austin, 1999; J.-F. Bernardet, unpublished data). As in the case of *F. johnsoniae*, the fish isolates were phenotypically and chemotaxonomically similar to *F. hydatis* in spite of rather low DNA relatedness between those that were tested and the type and only bona fide *F. hydatis* strain available in culture collections (J.-F. Bernardet, unpublished data); consequently, these strains should be referred to as "*F. hydatis*-like." The pathogenicity of *F. succinicans* and *F. hydatis* for fish was never actually demonstrated (Austin and Austin, 1999); these organisms likely act as opportunistic pathogens, invading fish already weakened by other pathogens, poor farming conditions, or environmental disorders.

Bacterial strains whose 16S rRNA gene sequence matched that of *F. frigidarium* were recently identified among the bacterial community in amoebae-infested gill tissue of salmon, but the relative implication of bacteria and parasites in the disease is not known (Bowman and Nowak, 2004).

Applications

Flavobacterium species produce a variety of enzymes (see the section Identification in this Chapter) that have potential biotechnological applications in processes involving the degradation of such biomacromolecules as agar, alginate, chitin, laminarin, pectin, xylan, etc. For instance, a keratinase-producing *Flavobacterium* sp. was recently isolated from a poultry industry (Riffel and Brandelli, 2002). This organism was able to completely degrade raw feathers and could be used to hydrolyze keratin; however, its affiliation to the genus *Flavobacterium* was only based on a scant phenotypic study. Some bona fide members of the genus have particular biotechnological potential and ecological interest because they can produce cold-active enzymes (see the section Habitat and Ecology in this Chapter).

Over the last few years, a number of algicidal bacteria were identified, especially in Japan; they have attracted much attention as possible tools to regulate the population of phytoplankton responsible for the "red tide" blooms, which frequently cause serious damage to the aquaculture industry in coastal seawaters. Some of these bacteria were attributed to the genus *Flavobacterium* thanks to their 16S rRNA sequence; though isolated from seawater, these isolates did not require NaCl for growth (Maeda et al., 1998). A whole-cell hybridization method using fluorescently labeled probes was developed for the specific detection and enumeration of another algicidal *Flavobacterium* sp. (Adachi et al., 2002).

A *F. columnare*-like organism capable of killing the cyst form of the protozoan parasite *Giardia lamblia* was recently isolated from freshwater (Rodgers et al., 2003). Provided the concentration of Ca^{2+} in the medium was high and the bacteria and cyst were in direct contact, up to 80% of the cysts were destroyed within 48 h. Hence, such strains could be used as biological control agents against *Giardia* cysts in drinking water treatment plants.

A biosurfactant-producing *Flavobacterium* sp. was isolated from samples of arid soil (Bodour et al., 2003). It produces a mixture of at least 37 compounds representing a new class of biosurfactants, named "flavolipids," exhibiting a unique polar moiety and strong and stable emulsifying and solubilizing activities; they have a variety of potential biotechnological and industrial applications, for instance, in the remediation of contaminated soils (Bodour et al., 2004).

Studying the dynamics of bacterial community in a soil contaminated with petroleum hydrocarbons, Kaplan and Kitts (2004) noticed that organisms attributed to the genera *Flavobacterium* and *Pseudomonas* from their 16S rRNA gene sequence were most abundant during the fast degradation phase. This observation supported the importance of *Flavobacterium* spp. in the bioremediation of hydrocarbon-contaminated soils already reported by previous publications (Kaplan and Kitts, 2004 and references therein), although the identification of bacterial strains may not have been based on firm grounds in all these studies.

The degradation potential of a *Flavobacterium* sp. strain on paper mill effluents was investi-

gated; degradation appeared more effective after the bacterium was pre-treated with sinusoidal magnetic fields (Aarthi et al., 2004).

A *Flavobacterium* sp. strain producing antifungal compounds may have some potential for the biocontrol of fungi responsible for the banana crown rot (Gunasinghe et al., 2004).

CHAPTER 6.5

The Genera *Bergeyella* and *Weeksella*

CELIA J. HUGO, BRITA BRUUN AND PIET J. JOOSTE

Introduction

Bergeyella and *Weeksella* have a history of being a separate group of organisms in the flavobacteria-grouping. They were originally treated as one genus (*Weeksella*) with two species, namely, *W. virosa* (Holmes et al., 1986a) and *W. zoohelcum* (Holmes et al., 1986b). Since 1994, however, they were separated into two genera in the Flavobacteriaceae family (Vandamme et al., 1994) as discussed in the introductory chapter about this family (see the chapter An Introduction to the Family Flavobacteriaceae in this Volume). Strains of both of these genera, especially *Bergeyella* with its frequent association with animal bite wounds, are found in clinical specimens.

The aim of this chapter is to provide more detail on the taxonomy, phylogeny, habitat, isolation and preservation, identification, pathogenicity and applications of these two genera.

Taxonomy and Phylogeny

Formerly known as Centers for Disease Control (CDC) groups IIf (*Weeksella*) and IIj (*Bergeyella*), these two genera were originally isolated and grouped by the late Elizabeth O. King and her successors (Tatum et al., 1974). These organisms have also been referred to as *Flavobacterium* Group 3 (Pickett and Manclark, 1970a), Group 1 (Olsen and Ravn, 1971) and "*Flavobacterium genitale*" (Price and Pickett, 1981). After Holmes and Owen (1979) emended the description of *Flavobacterium*, they found Groups IIf and IIj conformed to the emended description and later concluded that they probably should be placed in a separate genus (1981). Dees et al. (1981) were of the opinion that Group IIj and Group IIf (1986) should be accommodated in *Flavobacterium* on the basis of cellular fatty acid composition. Other authors, however, regarded Group IIj as intermediate in terms of its characteristics between the genera *Brucella* and *Moraxella* (Owen and Snell, 1973; Saphir and Carter, 1976; Bailie et al., 1978).

In 1981, Holmes and Owen allocated the flavobacteria into four groups (the recent correct names of the organisms are given in square brackets): Group A (*F. balustinum* [*Chryseobacterium balustinum*; Vandamme et al., 1994], *F. breve* [*Empedobacter brevis*; Vandamme et al., 1994], *F. indoltheticum* [*Chryseobacterium indoltheticum*; Vandamme et al., 1994], *F. meningosepticum* [*Chryseobacterium meningosepticum*; Vandamme et al., 1994], and remaining CDC Group IIb strains), Group B (*F. odoratum* [*Myroides odoratus*; Vancanneyt et al., 1996]), Group C (CDC Group IIk, type 2 and "Group IIk, type 3" [*Sphingobacterium* species; Yabuuchi et al., 1983; Takeuchi and Yokota, 1992]), and Group D (CDC Groups IIf and IIj). The organisms in Group D were then frequently referred to as *Flavobacterium*-like.

In 1986, Holmes et al. proposed the names "*Weeksella virosa*" (1986a) for strains belonging to CDC Group IIf and "*Weeksella zoohelcum*" (1986b) for strains belonging to CDC Group IIj, respectively. They also included these two species in the family Cytophagaceae, as had also been suggested earlier for the genus *Flavobacterium* (Callies and Mannheim, 1980). A number of subsequent studies (Holmes, 1992; Segers et al., 1993), however, found *W. zoohelcum* sufficiently different from *W. virosa* to constitute a different genus. After extensive genotypic, chemotaxonomic, and phenotypic studies, *Weeksella zoohelcum* was transferred to a new genus, namely *Bergeyella zoohelcum* (Vandamme et al., 1994). Although both genera currently consist only of one species each, it has been suggested by other studies that more than one species, including environmental strains, could be allocated to these two genera (Botha et al., 1989; Botha et al., 1998a; Botha et al., 1998b).

Habitat

Clinical Isolates

Both genera have had a clinical origin. They are not considered to be free-living but are regarded as constituents of the normal microflora of

mucous membranes of humans and other warm-blooded animals (Holmes et al., 1986a; Holmes et al., 1986b).

The majority of strains of *Bergeyella zoohelcum* examined by Tatum et al. (1974) was isolated from infected lesions from dog or cat bites or scratches. Other sources were blood, spinal fluid, and sputa of humans with or without a history of animal bites or scratches. The organism has also been isolated from gingival scrapings of dogs (Saphir and Carter, 1976) as well as oral and nasal fluids of dogs (Bailie et al., 1978). In a recent review, *Bergeyella zoohelcum* is considered a component of the normal oral flora of dogs and other animals (Griego et al., 1995).

Weeksella virosa has been isolated from human urine, cervix, vagina, Bartholin's gland cysts, blood, umbilical stump, ears, urethra, and spinal fluid (Tatum et al., 1974). This organism, however, seems to be predominantly associated with the female genital tract (Holmes et al., 1986a; Reina et al., 1989), and it appears to be more prevalent in sexually promiscuous women (Mardy and Holmes, 1988). There is no clear evidence of the pathogenic role of this organism.

Environmental Isolates

These two genera are not considered to be free-living in the environment, as stated above (Holmes et al., 1986a; 1986b). CDC Group IIf- and IIj-like strains have, however, been isolated from meat (Hayes, 1977) and dairy (Jooste et al., 1985) sources. In subsequent studies, these strains could not be identified as either *Bergeyella zoohelcum* or *Weeksella virosa*, but it was suggested that they could be included in one or more new species within these two genera (Botha et al., 1989; Botha et al., 1998a). *Bergeyella*- and *Weeksella*-like organisms have been isolated from raw beef, pork, chicken and lamb portions, and it was suggested that three species may be necessary to accommodate the environmental *Bergeyella*- and *Weeksella*-like bacteria (Botha et al., 1998b). *Weeksella*-like organisms were isolated from South African marine fish and were considered to be spoilage organisms because they were associated with the production of stale or pungent odors (Engelbrecht et al., 1996). A *Weeksella* strain was also isolated from petroleum-contaminated soils (see the section Applications for more details in this Chapter; Xia et al., 2000).

Isolation and Preservation

The general (nonselective) isolation, maintenance and preservation media used for culturing members of the Flavobacteriaceae are discussed in detail by Jooste and Hugo (1999) and Hugo and Jooste (2003).

Heart infusion medium containing 5% rabbit blood and other standard selective media may be used to isolate and cultivate the *Bergeyella* and *Weeksella* species (Dees et al., 1986; Jooste et al., 1985; Weyant et al., 1996). Plate count agar containing 0.5% NaCl was used to isolate *Weeksella*-like organisms from South African marine fish (Engelbrecht et al., 1996). Cultivation of *B. zoohelcum* has been reported on 5% horse blood agar (Holmes et al., 1986b).

Although no specific medium is known for the selective isolation of *Bergeyella* strains, β-hydroxybutyrate agar may be used for the enumeration of *Weeksella*, *Myroides*, *E. brevis* and *Chryseobacterium* (Bernardet et al., 1996; Jooste and Hugo, 1999). MacConkey agar has also been used for the enumeration of *Weeksella* (Bernardet et al., 1996; Jooste and Hugo, 1999), but according to Hollis et al. (1995), no *Weeksella* strains and only 2% of *Bergeyella* strains grew on MacConkey agar. This difference could presumably be ascribed to different composition of media. Selective media on which *Bergeyella* strains will not grow include β-hydroxybutyrate agar and MacConkey agar, and they exhibit only weak growth on nutrient agar (Holmes et al., 1986b; Bernardet et al., 1996; Jooste and Hugo, 1999).

For the medium-term preservation of the *Bergeyella* and *Weeksella* species, the general media used for flavobacterial maintenance may be used. These media include PMYA II (peptonized milk yeast extract agar; Christensen and Cook, 1972) and also Dorset egg medium in a screw-capped bijou bottle stored at 4°C (Cowan, 1974; Holmes et al., 1984). For longer-term preservation, isolates may be freeze dried (Holmes, 1992), or agar slant culture growth (18-h old) can be suspended in defibrinated rabbit blood placed in ampoules or other suitable containers and frozen in a mixture of dry ice and alcohol prior to storage at –50°C (Holmes et al., 1984).

Identification

When *Weeksella* and *Bergeyella* were still referred to as CDC Groups IIf and IIj, respectively, some investigators were of the opinion that they belonged to the *Flavobacterium* genus (Pedersen et al., 1970; Pickett and Manclark, 1970a; Pickett and Pedersen, 1970b; Pickett and Pedersen, 1970c; Olsen and Ravn, 1971; Price and Pickett, 1981). Others considered them intermediate in characteristics between *Flavobacterium* and *Moraxella* (Owen and Snell, 1973). In any case, these taxa may be confused with each other in the laboratory. The differen-

tial characteristics of the four groups of flavobacteria (Holmes and Owen, 1981) are given in Table 1.

For the identification of members of the Flavobacteriaceae, specific methods have been suggested (Bernardet et al., 2002). As some of these methods and characteristics are of special importance in differentiating among taxa of Flavobacteriaceae and related taxa, an update of the methods is given and discussed in detail in the introductory chapter An Introduction to the Family Flavobacteriaceae in this Volume. Only the morphological and phenotypical characteristics of importance for the differentiation of *Bergeyella* and *Weeksella* will be discussed in this chapter.

Morphology

Both genera are Gram-negative, nonsporeforming rods that are 0.6 μm wide and 2–3 μm long with parallel sides and rounded ends. They are nonmotile in hanging-drop preparations after overnight incubation in nutrient broth at either 37°C or room temperature (18–22°C). No cellular gliding movement is present (Holmes et al., 1986a; Holmes et al., 1986b; Bernardet et al., 2002).

Bergeyella and *Weeksella* colonies are nonpigmented, nonfluorescent and nonhemolytic on 5% (v/v) horse blood agar after 24 h. *Bergeyella* strains do not produce a brown, diffusible, melanin-like pigment on tyrosine agar in contrast to *Weeksella* strains. Colonies of both genera are circular, 0.5–2 mm in diameter, low convex, smooth and shiny with entire edges on nutrient agar. According to Tatum et al. (1974) and von Graevenitz (1995), *Bergeyella* colonies are sticky and, in color, are tan to yellow, while *Weeksella* colonies are butyrous to mucoid, adherent, and tan to brown. The authors did not discuss which media were used to determine these characteristics.

Phenotypic Identification and Physiology

Both genera are strictly aerobic with menaquinone 6 as the major respiratory quinone. Both genera will grow at 25°C and 37°C, but not at 5°C. The majority of *Weeksella* strains will grow at 42°C and on β-hydroxybutyrate agar, but this does not apply to *Bergeyella* strains (Holmes et al., 1986a; Holmes et al., 1986b). Divergence exists regarding the ability of the two genera to grow on MacConkey agar (Holmes et al., 1986a; Holmes et al., 1986b; Hollis et al., 1995; Weyant et al., 1996).

Both genera produce indole (Ehrlich's reagent), oxidase, catalase and phosphatase, and both degrade gelatin. Neither of the genera will produce DNase or β-galactosidase, reduce nitrate, utilize carbohydrates, or degrade starch, esculin or agar. *Bergeyella* will, however, produce urease while *Weeksella* will not (Holmes et al., 1986a; Holmes et al., 1986b; Weyant et al., 1996; Bernardet et al., 2002). Both the genera are nonsaccharolytic and will not produce acid from glucose, adonitol, arabinose, cellobiose, dulcitol, ethanol, fructose, glycerol, inositol, lactose, maltose, mannitol, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose or xylose. The general phenotypic and differential characteristics of *Bergeyella* and *Weeksella* are given in Table 2. For full descriptions and more details, the reader is referred to Holmes et al. (Holmes et al., 1986a; Holmes et al., 1986b), Hollis et al. (1995), and Weyant et al. (1996).

In contrast to the other closely related genera in the Flavobacteriaceae family (*Chryseobacterium*, *Empedobacter* and *Myroides*), *Bergeyella*

[a]From Holmes et al. (1986a, b), Weyant et al. (1996), and Bernardet et al. (2002).

and *Weeksella* are susceptible to most antibiotics such as β-lactam antibiotics, tetracycline, chloramphenicol, nalidixic acid, erythromycin and sulfamethoxazole-trimethoprim (Pedersen et al., 1970; Schell et al., 1985). They are, however, resistant to aminoglycosides (von Graevenitz, 1995; Fass et al., 1996; Goldstein et al., 1998; Goldstein et al., 1999a; Goldstein et al., 1999b; Goldstein et al., 2001; Goldstein et al., 2002).

The dominant fatty acids in *Bergeyella* are 15:0 iso, 15:0 iso 2 OH, 17:1 iso, and 17:0 iso 3OH (Vandamme et al., 1994). The DNA G+C is 35–37 mol% (Vandamme et al., 1994; Bernardet et al., 2002).

The dominant fatty acids of *Weeksella* species are 15:0 iso, 15:0 iso 2OH, 16:0, 16:0 iso 3OH, 17:1(1) iso, 17:1(2) iso, and 17:0 iso 3OH (Dees et al., 1986). The DNA G+C is 37–38 mol% (Bernardet et al., 2002).

Pathogenicity

Bergeyella zoohelcum has most frequently been isolated from the upper respiratory tract of dogs and from human wounds caused by dog and cat bites. In a study of bacteriological etiologies of 50 infected dog bites and 57 infected cat bites, *B. zoohelcum* was isolated from 4% and 7% of wounds, respectively (Talan et al., 1999). At first, there was no real evidence for its pathogenic role in humans except for a report of meningitis in a 5-year old child following a dog bite (Bracis et al., 1979) and another report of septicemia (Noell et al., 1989). In the past 10–15 years, however, the following cases were reported: leg abscesses following a dog bite (Reina and Borrell, 1992), pneumonia (Grimault et al., 1996), infectious tenosynovitis developed in a man after a Siberian tiger bite (Isotalo et al., 2000), and bacteremia after a dog bite (Montejo et al., 2001). Recently, there has been a report where *B. zoohelcum* has been associated with a necrotizing infection of the respiratory tract in a cat (Decostere et al., 2002).

Although *Weeksella virosa* has been most frequently isolated from the urogenital tract, there is little evidence for its pathogenicity (von Graevenitz, 1981; Holmes et al., 1986a). There are, however, two cases of peritonitis caused by *W. virosa* reported in the literature: one associated with peritoneal dialysis (Faber et al., 1991) and one spontaneous case (Boixeda et al., 1998).

Applications

Although Xia et al. (2000) did not clearly indicate how the organisms were identified, a *Weeksella* strain and a *Pseudomonas* strain were isolated from petroleum contaminated soils. Both strains possessed petroleum-degrading and surfactant-degrading properties. It was suggested that after the largest portion of petroleum in the contaminated zone had been removed with surfactants, these organisms could be used to degrade the residual surfactants and petroleum (Xia et al., 2000).

CHAPTER 6.6

The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella*

BARRY HOLMES

The name *Flavobacterium* was proposed in 1923 for a genus of the family Bacteriaceae encompassing the rod-shaped, nonendosporeforming, chemoorganotrophic bacteria (Bergey et al., 1923). Most of the pigmented bacteria of the family were segregated in the tribe Chromobactereae, which contained four genera of aerobic bacteria separated from each other by differences in color. These genera were *Chromobacterium*, *Flavobacterium*, *Pseudomonas*, and *Serratia*, for the purple, yellow, green fluorescent, and red strains, respectively. This emphasis on pigmentation (a character shared by genetically diverse bacteria [Weeks, 1969]) for taxonomic assignment to *Flavobacterium* has given the genus a dubious reputation in the past (McMeekin et al., 1972; Weeks, 1969), and as a consequence the genus has served too frequently as a repository for pigmented bacteria that possess the general attributes of *Flavobacterium* but had not been subjected to detailed classification studies. Taxonomic heterogeneity and general uncertainty have characterized *Flavobacterium* from its inception, and its history is a record of proposals to achieve credibility for the genus.

Stanier (1947) recognized that the cytophagas have more than a casual phenetic resemblance to pigmented, Gram-negative eubacteria such as *Flavobacterium* and the relationship to the cytophagas has dominated the taxonomic consideration of *Flavobacterium*. Differentiation of flavobacteria from cytophagas has depended primarily upon demonstration of the gliding movement and colonial translocation characteristic of the latter bacteria, but absence of these features has not deterred assignment of flavobacterial species to *Cytophaga* (Mitchell et al., 1969). Freshly isolated cytophagas have the unusual ability to use a great variety of complex natural polymers, e.g., agar, alginates, cell walls, cellulose, chitin, DNA, keratins, lipids, pectin, porphyrins, proteins, RNA, and starch, as nutrients. This ability is not a general property of flavobacterial species, although strains of some species may hydrolyze casein, chitin, gelatin, or starch.

This chapter was taken unchanged from the second edition.

The problem of differentiating *Flavobacterium* from *Cytophaga* has been discussed extensively (Christensen, 1977a; McMeekin et al., 1972; Mitchell et al., 1969; Weeks, 1969). An outcome would be more nearly possible if two issues were resolved. These are the heterogeneity of *Flavobacterium* and the differentiation of nonmotile flavobacteria from cytophagas. A primary requirement for the resolution of both issues is an acceptable definition of *Flavobacterium*. The concept of *Flavobacterium* was hardly altered in successive editions of *Bergey's Manual of Determinative Bacteriology* until the fifth (Bergey et al., 1939), which eliminated from the genus the least well-described species and the polarly flagellated strains. Those known to be Gram-positive were excluded in the seventh edition (Weeks and Breed, 1957). In the eight edition (Weeks, 1974) the genus remained heterogeneous, as evidenced by the two disparate reported ranges of GC content of the DNA: 30–42 and 63–70 mol%. Only in *Bergey's Manual of Systematic Bacteriology* (Holmes et al., 1984a) did the genus at last become reasonably homogeneous by including only nonmotile low GC strains. Interspecies DNA-DNA hybridization studies of the latter organisms showed a background level of hybridization of about 20%, which may represent a common DNA complement (Callies and Mannheim, 1980; Owen and Holmes, 1981).

Despite sharing several features, the low GC flavobacteria nevertheless show some heterogeneity and fall into four natural groups (A–D, Table 1), as previously suggested by Holmes and Owen (1981). The strains of group D, so far found only on mammalian mucus membranes, are susceptible to penicillin and are nonpigmented; they now comprise the genus *Weeksella*. Strains of the remaining groups are free-living, show resistance to a wide range of antimicrobial agents and are yellow-pigmented (Table 1). These organisms constitute the genus *Flavobacterium* and they can be divided into groups A–C on the basis of differences in indole production, oxidation of carbohydrates, and proteolytic activity (Table 1). A detailed taxonomic study of these organisms by techniques such as DNA-

Table 1. Differentiation of the flavobacteria.

Character	Habitat	Resistant to antimicrobial agents	Yellow pigment	Indole production	Oxidation of carbohydrates	Proteolytic activity
Group A: *Flavobacterium balustinum, F. breve, Flavobacterium* species group IIb *(F. gleum, F. indologenes), F. indoltheticum, F. meningosepticum*	Free-living	+	+	+	+	+
Group B: *Flavobacterium odoratum*	Free-living	+	+	–	–	+
Group C:[a] *Flavobacterium mizutaii, F. multivorum, F. spiritivorum, F. thalpophilum, F. yabuuchiae*	Free-living	+	+	–	+	–
Group D: *Weeksella virosa, W. zoohelcum*	Strict saprophyte	–	–	+	–	+

+, character present; –, character absent.
[a]Yabuuchi et al. (1983) have proposed that *F. mizutaii*, *F. multivorum*, and *F. spiritivorum* should be placed in a separate genus, *Sphingobacterium*.

rRNA hybridization is necessary to determine their phylogenetic relationships and therefore whether they all belong in the same genus. Pending such a study, it seems undesirable to divide the genus further or to admit to it taxa of uncertain affiliation, otherwise the genus is in danger once more of becoming heterogeneous. The limited data available from DNA-rRNA hybridizations (Bauwens and De Ley, 1981) indicate that *F. breve*, *F. meningosepticum*, and *F. odoratum* may not be closely related and that *F. aquatile*, the type species of the genus (and itself represented by a single strain), is not closely related to the above three species. For other reasons, *F. aquatile* had been considered unrepresentative of the genus. Consequently, Holmes and Owen (1979) requested that *F. breve* be made the type species instead. Their request was subsequently denied, and thus if the genus is further subdivided in the future the name *Flavobacterium* will remain with *F. aquatile* and the majority of organisms currently recognized as *Flavobacterium* will be transferred to one or more new genera. For the above reasons, *F. aquatile* is not considered in the tables in this paper (its characters are given by Holmes et al., 1984a). Perhaps prematurely, the genus *Sphingobacterium* has been proposed by Yabuuchi et al. (1983) for organisms in group C (Table 1) based on the fact that most of these organisms have been shown to possess novel sphingolipids in their cell walls. As this character is not easily determined routinely, and pending further study and possible revision of the genus as a whole, the group C strains are here retained in *Flavobacterium*. (Although all strains in group C have valid combinations of their specific epithets with *Flavobacterium*, there has as yet been no proposal to transfer *F. thalpophilum* or *F. yabuuchiae* to *Sphingobacterium*.)

With *Flavobacterium* better defined, it is now possible to reassess the differentiation of this genus from *Cytophaga.* It has been suggested that organisms of both these genera, which share a distinctive cellular fatty acid composition, a characteristic menaquinone system, and a low GC content, should all be included in *Cytophaga* (Oyaizu and Komagata, 1981). However, this view does not take into account the heterogeneity of the *Flavobacterium-Cytophaga* group as revealed by the preliminary DNA-rRNA hybridization results of Bauwens and De Ley (1981). More recent DNA-DNA hybridization studies (Bernardet, 1989) reveal no appreciable homology between *Cytophaga johnsonae* and *Flavobacterium* species of groups A, B, and C. Oligonucleotide cataloging (Paster et al., 1985) places *C. johnsonae* and *F. aquatile* in the same group while finding that *F. breve* is only peripherally related to the same group. Cataloging also places *Cytophaga* and *Flavobacterium* in the same eubacterial "phylum" as *Bacteroides*.

In summary, while *Flavobacterium* is now more homogeneous than it has ever been, further work is necessary to group the species into additional genera so as to reflect their phylogenetic relationships. Among the flavobacteria of clinical origin at least, these generic groupings may well be reflected by the groups A–C as defined in Table 1. While these organisms would appear to be distinct from *Cytophaga,* other flavobacteria, including *F. aquatile*, may be more closely related to *Cytophaga.* The latest arrangement of including the families Bacteroidaceae and Cytophagaceae plus a newly proposed family "Flavobacteriaceae" in the order Cytoph-

agales (Reichenbach, 1989) is a good reflection of our present knowledge of the phylogenetic relationships of these organisms.

Habitats

Yellow-pigmented, nonfermentative, Gram-negative, nonmotile, rod-shaped bacteria, which have been placed in the genus *Flavobacterium* or have been termed flavobacteria, have been isolated from fresh and marine waters, soil and ocean sediments, foods and food-processing plants, and clinical materials. These bacteria are widely distributed in nature and are especially common in water, which would explain their seeming omnipresence.

Nonclinical Sources

Flavobacterial strains have been isolated most commonly from freshwater and marine environments, and many general bacteriological surveys of such habitats have reported their presence (for example, ZoBell and Upham, 1944). The numerical taxonomic studies of Hayes (1963) and of Floodgate and Hayes (1963) used marine strains isolated from fish surfaces, sea water, and marine mud; the samples were taken from the north Atlantic region, western North American coast, and Florida. Comprehensive investigations of dairy and meat-processing industries have shown numerous flavobacteria (McMeekin et al., 1971, 1972; Jooste et al., 1985), including *Weeksella*-like organisms (Botha et al., 1989). The bacteria have also been found in chlorinated cooling water of vegetable canning plants and were the cause of characteristic spoilage following post-sterilization contamination (Bean and Everton, 1969). *F. multivorum* has been isolated from soil (Hayward and Sly, 1984; Pichinoty et al., 1985).

Clinical Sources

Flavobacteria have consistently been found among the nonfermentative, Gram-negative bacteria isolated from clinical specimens such as blood, urine, infected wounds, and feces (Pickett and Manclark, 1970; Pickett and Pedersen, 1970a, 1970b; Tatum et al., 1974). Their frequency of occurrence is usually low, 1% or less, and their pathogenicity is low-grade or doubtful. They are, however, extremely resistant to many antimicrobial agents (and so may well colonize the patient on intensive chemotherapy for an infection caused by some other organism). Such resistant strains are found in each of groups A–C: *F. breve* (Holmes et al., 1978); *F. meningosepticum* (King, 1959); Group IIb of King (Tatum et al., 1974; this taxon includes *F. gleum* [Holmes et al., 1984b] and *F. indologenes* [Yabuuchi et al., 1983]); *F. odoratum* (Holmes et al., 1977, 1979); *F. multivorum* (Holmes et al., 1981); *F. spiritivorum* (Holmes et al., 1982) and *F. thalpophilum* (Holmes et al., 1983).

F. meningosepticum, the best-known pathogen in the genus, is associated with a sometimes fatal meningitis of infants and has been isolated from their throats, spinal fluid, and blood as well as from throats of normal adults (King, 1959; Holmes, 1987). *F. odoratum* has also been a cause of ventriculitis (Macfarlane et al., 1985). Both *F. multivorum* and *F. odoratum* have been reported as a cause of bacteremia (Freney et al., 1987; Potvliege et al., 1984; Prieur et al., 1988), while both *F. odoratum* and *F. thalpophilum* have been described in wound case reports (Davis et al., 1979; Hansen et al., 1988). *Weeksella virosa* appears to be almost exclusively associated with the female genital tract (Holmes et al., 1986a; Reina et al., 1989), and it seems more prevalent in sexually promiscuous women (Mardy and Holmes, 1988). *W. zoohelcum* is commonly found in the canine oral cavity and has been isolated from human dog-bite wounds (Holmes et al., 1986b). However, one strain has been reported as a cause of meningitis in a child following a dog-bite (Bracis et al., 1979) and another as a cause of septicemia (Noell et al., 1989).

Isolation

Nonclinical *Flavobacterium*

Flavobacteria are chemoorganotrophic and not difficult to isolate, although maintenance of the cultures sometimes presents a problem.

General studies do not require enrichment procedures and usually nutrient agar-type media are used. Studies of marine, pigmented bacteria, for example, have used seawater-agar media, such as the following:

Marine *Flavobacterium* Medium (Hayes, 1963)

Beef extract (Lab Lemco)	10 g
Peptone (Evans)	10 g
Agar (Difco)	15 g
Aged seawater	750 ml
Distilled water	250 ml

Adjust pH to 7.2–7.3.

Isolation of yellow-pigmented bacteria from food and food-processing equipment used a similar medium:

Food *Flavobacterium* Medium (McMeekin et al., 1971)

Beef extract (Oxoid L20)	10 g
Peptone (Oxoid L37)	10 g
NaCl	5 g
Agar (Oxoid No. 3)	12 g
Distilled water	1 liter

Incubation temperatures were similar to that of the environment, i.e., 20–25°C, and incubation times were about 4 days.

Weeks (1955) used medium M1, which contains lesser amounts of nutrients, for both isolation and maintenance of flavobacterial cultures.

Medium M1 (Weeks, 1955)

Proteose peptone (Difco)	5 g
Yeast extract (Difco)	1 g
Beef extract (Difco)	2 g
NaCl	3 g
Agar	12 g
Distilled water	1 liter

pH 7.2–7.4.

It is not unusual to find that media containing relatively large amounts of the individual nutrients, such as those used by Hayes (1963) and McMeekin et al. (1971), are not as well suited to maintenance of flavobacterial cultures as are media with lower concentrations. A study on maintenance by Christensen and Cook (1972) dealt primarily with the isolation of cytophagas but flavobacteria were included. In general, media such as PMYA II containing small amounts of nutrients were superior.

PMYA II (Christensen and Cook, 1972)

Peptonized milk	1 g
Yeast extract	0.2 g
Sodium acetate	0.02 g
Agar	15 g
Distilleµd water	1 liter

This medium was excellent for detection of cytophagal gliding and colonial swarming, which is useful in differentiating between flavobacteria and cytophagas.

Flint (1985), when developing a selective agar medium for the enumeration of *Flavobacterium* species in water, found that on nutrient agar alone less than 10% of colonies recovered were yellow-pigmented; however, when a nutrient agar medium containing kanamycin at 50 µg/ml was used, this figure increased to 70%.

Clinical *Flavobacterium*

Tatum et al. (1974) have described in detail the procedures for isolation of flavobacteria from clinical sources, such as those of *F. meningosepticum* and Group IIb. Primary plating of a clinical specimen is usually onto blood, chocolate, eosin-methylene blue, or MacConkey agar, but other media may be used. Incubation temperature is 35–37°C, but the bacteria will grow at room temperatures (20–25°C). Other workers have found ordinary nutrient agar quite satisfactory (for example, Holmes et al., 1977, 1978).

Preservation of Cultures

Pickett and his colleagues have used cystine-trypticase agar (BBL) for maintenance of cultures of the clinical flavobacteria. Long-term preservation was carried out using brucella broth (BBL) containing 10% glycerol and the cultures were stored at –50°C (Pickett and Pedersen, 1970a). Isolates can also be stored freeze-dried.

Identification

Assignment of a culture to *Flavobacterium* now rests primarily upon the attributes ascribed to the genus (Holmes et al., 1984a). Strains are strictly aerobic, Gram-negative, nonmotile, yellow-pigmented, free-living nonfermenters with low GC content and do not show gliding motility; clinical strains at least are highly resistant to a wide range of antimicrobial agents. Since these features are quite general, the personal judgment of the investigator is a major contribution, especially for the nonclinical strains which have not been studied as thoroughly as clinical strains.

Clinical isolates can usually be identified by assigning them initially to one of the groups A–D on the basis of the characters given in Table 1 and then using the appropriate table for species determination. Methods for determining some characters useful in the differentiation of flavobacteria (indole formation, hydrolysis of DNA, starch, and urea, and pigment production) have been compared by Pickett (1989). Just as the flavobacteria may eventually comprise several genera, so new species are set to emerge from the existing recognized species. It is apparent from Tables 2–3–4 that many species are heterogeneous in phenotypic characters and such is the genomic diversity among the flavobacteria that many recognized species comprise very few known strains. Indeed, several are represented by a single strain.

Among the taxa in group A, *F. balustinum* (from heart blood of fish) and *F. indoltheticum* (from the marine environment) are represented by single strains and extensive DNA-DNA hybridization studies of phenotypically similar strains have ascribed no additional strains to the former and only three to the latter (A. G. Steigerwalt and D. J. Brenner, personal communication). Similar DNA relatedness studies reveal that in *F. breve* there is a "core" of closely related strains with other strains showing lower levels of relatedness to the "core" strains (Owen

Table 2. Characteristics for practical identification and differentiation of the *Flavobacterium* taxa of group A.

The phenotypic results were derived from previous work at the National Collection of Type Cultures, as follows: *F. balustinum, F. indoltheticum, Flavobacterium* species Group IIb (Holmes, 1983), *F. breve* (Holmes et al., 1978), and *F. meningosepticum* (Holmes, 1987). The GC values were derived as follows: *F. balustinum* and *F. breve* (Owen and Holmes, 1980), *F. meningosepticum* (Owen and Lapage, 1974; Owen and Snell, 1976), *F. indoltheticum* and *Flavobacterium* species group IIb (B. Holmes and R. J. Owen, unpublished observations).

and Holmes, 1980). Owen and Snell (1976) showed that of the strains representing the then six serovars of *F. meningosepticum*, the type strain of the species, which represented serovar A, showed much lower levels of relatedness to strains of the other serovars (B–F) than did these strains to each other. Work on this species was extended by Ursing and Bruun (1987), who found only three other strains that showed appreciable homology to the type strain; the remaining 48 strains could be divided into four subgroups. Despite the genomic differentiation of these 52 strains into two major groups, no correlation of these groups could be found with antimicrobial susceptibility (Bruun, 1987), crossed immunoelectrophoresis (Bruun and Høiby, 1987), or phenotypic characters (Bruun and Ursing, 1987). The name *F. indologenes* was proposed for all strains of group IIb (Yabuuchi et al., 1983), despite the fact that it is genomically heterogeneous (Owen and Snell, 1976). The name *F. gleum* was proposed for several group IIb strains that show a high level of DNA-DNA relatedness (Holmes et al., 1984b). More recent DNA-DNA hybridization studies of group IIb strains (A. G. Steigerwalt and D. J. Brenner, personal communication) show that, while several strains display high levels of relatedness to the respective type strains of either *F. gleum* or *F. indologenes*, as many strains again remain to be assigned to one or more genomic groups. Until this problem is further investigated, it would seem prudent to continue referring to the taxon by its original designation of *Flavobacterium* species group IIb.

Group B comprises only *F. odoratum*, easily recognized by its fruity odor (Holmes et al., 1977). Although only ten strains have been studied by DNA-DNA hybridization, there is again genomic heterogeneity in the taxon, with the strains falling into three genomic groups (Owen and Holmes, 1978).

With the exception of *F. multivorum*, all the other species in groups C and D have been examined for DNA-DNA relatedness (*F. mizutaii*, *F. spiritivorum*, and *F. yabuuchiae* [Holmes et al., 1988], *F. thalpophilum* [Holmes et al., 1983], *Weeksella virosa* [Holmes et al., 1986a], *W. zoo-*

The phenotypic results for *F. mizutaii* were taken from National Collection of Type Cultures records (B. Holmes, unpublished observations), and the GC contents for these strains were obtained from Yabuuchi et al. (1983). The results for *F. multivorum* were derived from Holmes et al. (1981), those for *F. thalpophilum* from Holmes et al. (1983), and those for *F. spiritivorum* and *F. yabuuchiae* from Holmes et al. (1988).

The phenotypic results and GC values for *W. virosa* were derived from Holmes et al. (1986a) and those for *W. zoohelcum* from Holmes et al. (1986b).

helcum [Holmes et al., 1986b]). These studies showed that the species were genomically homogeneous except for *F. spiritivorum*, which contained two strains showing high levels of relatedness to each other but lower levels to other strains of *F. spiritivorum*; these two strains now constitute *F. yabuuchiae* (Holmes et al., 1988).

Although there is clear evidence for additional genospecies in *Flavobacterium* (perhaps in *Weeksella* also [Botha et al., 1989]), some of these may not be recognized formally as new species unless phenotypic characters can be found to differentiate them. In addition, there are phenotypically discernible taxa which remain unnamed pending a full taxonomic study. These organisms are groups IIc, IIe, IIh, and IIi; they are all saccharolytic and the last three, at least, are indole producers (Rubin et al., 1985). They may therefore well be additional members of *Flavobacterium* group A, especially as strains of Groups IIe and IIh are known to contain menaquinone 6 and lack sphingolipids (Dees et al., 1986), which would also exclude them from group C (the sphingobacteria). Some differentiation of the flavobacteria can be achieved by gas liquid chromatographic analysis of volatile fatty acids produced in culture (Rasoamananjara et al., 1988). Serology has only been applied to *F. meningosepticum*, where types A–O are recognized; however, strains representing some of these serotypes are biochemically atypical of the species and may be strains of *F. breve* (Holmes et al., 1984a).

Identification of the nonclinical flavobacteria seems to be essentially a matter of deciding whether nonmotile flavobacteria are cytophagas. In this connection, it is a requirement to know whether or not an isolate demonstrates gliding movement and colonial translocation as defined by Henrichsen (1972). It is also necessary to know the DNA base composition and whether the culture can utilize a variety of complex macromolecules in its nutrition. Cultures that display properties of typical cytophagas do not present a problem since these would not be classified as flavobacteria; cultures not having such properties could be considered flavobacteria. Isolates that do not display cytophagal gliding but do demonstrate colonial translocation would not be cytophagas according to Henrichsen (1972). Cultures that are believed to display gliding motion but which do not show colonial translocation probably should not be assigned to the Cytophagaceae. Christensen (1977b) believed that colonial spreading would occur in such cultures if the correct experimental conditions were used.

It has already been stated that *F. aquatile* (from water) is not included in the identification scheme given in this chapter. Also not included are the more recently described species *F. thermophilum* (Loginova and Egorova, 1978) and *F. branchiophila* (Wakabayashi et al., 1989), the latter of which causes bacterial gill disease in freshwater fishes. The former is a thermophile, probably a *Thermus* species (see The Genus *Thermus* and Relatives in this Volume), and the latter, like *F. aquatile*, neither grows at 37°C nor grows well on nutrient agar. Two further new species, both halophiles from an Antarctic Lake, "*F. gondwanense*" and "*F. salegens*," may be proposed (T. A. McMeekin, personal communication). Whether these more recently described organisms truly belong in the genus remains to be determined. DNA-DNA hybridization studies (Bernardet, 1989) reveal that *F. branchiophila* has higher levels of relatedness to *Cytophaga* species than to *Flavobacterium* species. The other validly published species in the genus that are not mentioned here are of uncertain taxonomic position and do not belong in *Flavobacterium* for the reasons given by Holmes et al. (1984a).

Physiological Properties

Within the group A flavobacteria, the main cellular fatty acid components in *F. breve* are iso-$C_{15:0}$ and 3-OH iso-$C_{17:0}$ acids (as they are also present in *F. aquatile*); *F. meningosepticum* contains in addition significant amounts of 2-OH iso-$C_{15:0}$ and is similar to *Flavobacterium* species group IIb (Moss and Dees, 1978; Oyaizu and Komagata, 1981). *F. odoratum* (group B) differs from members of group A in containing iso-$C_{15:0}$, iso-$C_{17:1}$, 3-OH iso-$C_{15:0}$ and 3-OH iso-$C_{17:0}$ acids (Oyaizu and Komagata, 1981). Among the group C flavobacteria (or sphingobacteria), *F. multivorum* at least contains iso-$C_{15:0}$ and 2-OH iso-$C_{15:0}$ as major fatty acid components while the main cellular lipids are sphingophospholipids (Yabuuchi et al., 1981), as indeed they also are in *F. mizutaii*, *F. spiritivorum*, and *F. thalpophilum* (Dees et al., 1985; Yabuuchi et al., 1983). The group C organisms also contain major quantities of menaquinone 7 but no menaquinone 6, in contrast to the flavobacteria of groups A and B which contain major amounts of menaquinone 6 but no menaquinone 7 (Dees et al., 1985). These characters further support the case for classifying the group C organisms in the separate genus *Sphingobacterium* but they rely on characters not easily determined routinely.

Cells of all *Flavobacterium* species are nonmotile in both hanging drop preparations and in soft agar; it is generally accepted that they lack flagella. However, Weeks (1955) examined the type strain of *F. aquatile* by electron microscopy and observed structures that he thought were like "pseudoflagella." By light microscopy, Webster and Hugh (1979) observed what they thought to be nonfunctional flagella on both the type strain of *F. aquatile* and that of *F. meningosepticum*, but this was not confirmed by Thomson et al. (1981) using electron microscopy (although extracellular appendages of a nonflagellar nature, like those on gliding bacteria, were seen in *F. aquatile*).

The yellow pigments produced by these organisms are nonfluorescent and insoluble in growth media; in *F. aquatile* the pigment is carotenoid (principally zeaxanthin; O. B. Weeks, unpublished observations) whereas in *F. breve* and *F. odoratum* they are not carotenoid but are probably of the flexirubin type.

Clinical strains are generally resistant to many antimicrobial agents, including amikacin, ampicillin, carbenicillin, gentamicin, kanamycin, polymyxin B, streptomycin, and tobramycin. Although an R plasmid conferring resistance to ampicillin, carbenicillin, and erythromycin has been reported in a strain of *F. odoratum* (Kono et al., 1980), detectable plasmids have been rarely reported (Owen and Holmes, 1981) and resistance in these organisms is therefore possibly associated with chromosomal genes.

Applications

No applications for strains of the genera *Flavobacterium*, *Sphingobacterium*, or *Weeksella*

are yet known. However, suitable strains of "*Flavobacterium keratolyticus*" (isolated from soil in Japan), an organism not only without standing in nomenclature but possibly also not even a member of the genus *Flavobacterium*, naturally produce an endo-β-galactosidase. This enzyme exposes the human red blood cell cryptantigen Tk and is therefore potentially useful in blood transfusion laboratories for determining the type of end-link sugar on the red cell membrane that carries the blood group antigen (Liew et al., 1982). Growth measurements with a supposed *Flavobacterium* strain have proved useful in determining the concentration of maltose- and starch-like compounds in drinking water, where these compounds may contribute to undesirable bacterial growth in distribution systems (Van Der Kooij and Hijnen, 1985).

CHAPTER 6.7

The Order Cytophagales

HANS REICHENBACH

In the past decade much has been learnt about the order Cytophagales and about some of the organisms belonging to it, although the majority of its members are as unfamiliar as ever. On the basis of 16S rRNA studies, we can now delimit the group with some confidence and have a well-founded idea of its phylogenetic position (Paster et al., 1985; Woese et al., 1985). Accordingly, the Cytophagales appear to be distantly related to the *Bacteroides* group, and these two together comprise one of the main branches, perhaps a phylum, in the bacterial phylogenetic system. The substructure of the *Cytophaga* branch of the phylum is more difficult to evaluate. There is a main line on which we find unicellular gliders—*Cytophaga* (*Cy.**) *johnsonae, Cy. lytica, Cy. aquatilis* = *Flavobacterium (Fv.) aquatile*, and *Sporocytophaga (Sp.) myxococcoides*—but at a lower level unicellular nonmotile bacteria (*Fv. breve*, i.e., low GC, true flavobacteria) are also found. At a still lower level, a cluster branches off which comprises the unicellular gliders—*Flexibacter (Fx.) filiformis* = *Fx. elegans* Fx el, *Cy. heparina*, and *Taxeobacter* = Myx 2105) unicellular nongliding flavobacteria (*Fv. ferugineum*), but also filamentous, multicellular, gliding (*Saprospira*) and nonmotile bacteria (*Haliscomenobacter*). It is obvious from these data that our present definition of genera does not reflect the phylogenetic situation and also that the grouping in families and perhaps orders needs to be reconsidered. Before that is done, however, 16S rRNA sequences of further species should be determined.

From what has been said above it is clear that only a preliminary characterization of the order is possible at present. In this chapter, the order Cytophagales is restricted to unicellular gliding bacteria; the relevant genera are listed in Table 1. Filamentous, gliding bacteria of the genus *Saprospira* may or may not belong to the order, and they are sufficiently different to justify a separate treatment (see The Order Cytophagales in this Volume); contrary to earlier suggestions, these organisms are not apochlorotic cyanobacteria (Reichenbach et al., 1986). Unicellular, gliding bacteria of the genus *Lysobacter* have been found to be closely linked to the xanthomonads and thus belong to the gamma branch of the Proteobacteria (Woese et al., 1985); consequently they are discussed separately (see The Genus *Lysobacter* in Volume 6) It should be mentioned that, in the past, lysobacters have often erroneously been classified as cytophagas; this is discussed in The Genus *Lysobacter* in Volume 6. On the other hand, the cytophagas have been regarded as myxobacteria for some time and accordingly named; *Cy. columnaris* has even been classified in the myxobacterial genus *Chondrococcus* (now *Corallococcus*). However, as pointed out above, the two groups are not phylogenetically related. The nonmobile bacteria that cluster with the Cytophagales are discussed in The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* and The Genus *Haliscomenobacter* in this Volume.

The Cytophagales as outlined above are all unicellular, gliding, Gram-negative bacteria. All have rod-shaped cells, which may differ substantially in shape. They may be short or long, delicate or stout, with tapering or rounded ends (Fig. 1). Two genera exhibit a controlled and cyclic shape change: *Sporocytophaga* produces resting cells in the form of spherical microcysts, and some *Flexibacter* species alternate between very long and extremely agile thread cells and very short, almost spherical and nonmotile rod cells (Fig. 2). Many of the other species are more or less pleomorphic, with cell populations that consist of short and very long rods and chains of cells, particularly in older cultures.

The typical colonies are spreading swarms (Fig. 3). Sometimes they are filmlike and may cover the whole culture plate within a few days. In other cases, they only expand slowly or remain more or less compact. In a few instances there is also rhizoid growth. Many Cytophagales produce brightly colored colonies in shades of yellow, orange, or brick red. The yellow and orange colonies often change immediately into red, purple, or brown if covered with a 10% KOH solution. This color change is due to flexirubin-type pigments (Fig. 4), which have so far only been found in organisms of this group (including flavobacteria). The organisms belonging to the Cytophagales may be aerobic, microaerophilic, capnophilic (CO_2-requiring), or facultatively anaerobic. They are all organotrophs, many of them able to degrade biomacromolecules like proteins, chitin, pectin, agar, starch, or cellulose. They are ubiquitous, are abundant, and probably play a major role in

Table 1. Survey of the taxonomy of the order Cytophagales of the *Bacteriodes-Flavobacterium-Cytophaga* branch.

Order: Cytophagales
Family: Cytophagaceae
Genera: *Cytophaga*
Sporocytophaga
Unnamed *Cytophaga*-like bacteria (serveral genera)
Flexibacter
Microscilla
Flexithrix
Capnocytophaga
Taxeobacter
(Saprospira)[a]

[a]Saprospira may or may not belong to the order. It is discussed separately in The Order Cytophagales in this Volume.

In this chapter, the following abbreviations sometimes are used for the genera of the order Cytophagales: CLB, *Cytophaga*-like bacteria; *Cp., Capnocytophaga*; *Cy., Cytophaga; Ft., Flexithrix*; *Fv., Flavobacterium*; *Fx., Flexibacter*, *Mc., Microscilla; Sa., Saprospira*; *Sp., Sporocytophaga*; *Tx., Taxeobacter.*

This chapter was taken unchanged from the second edition.

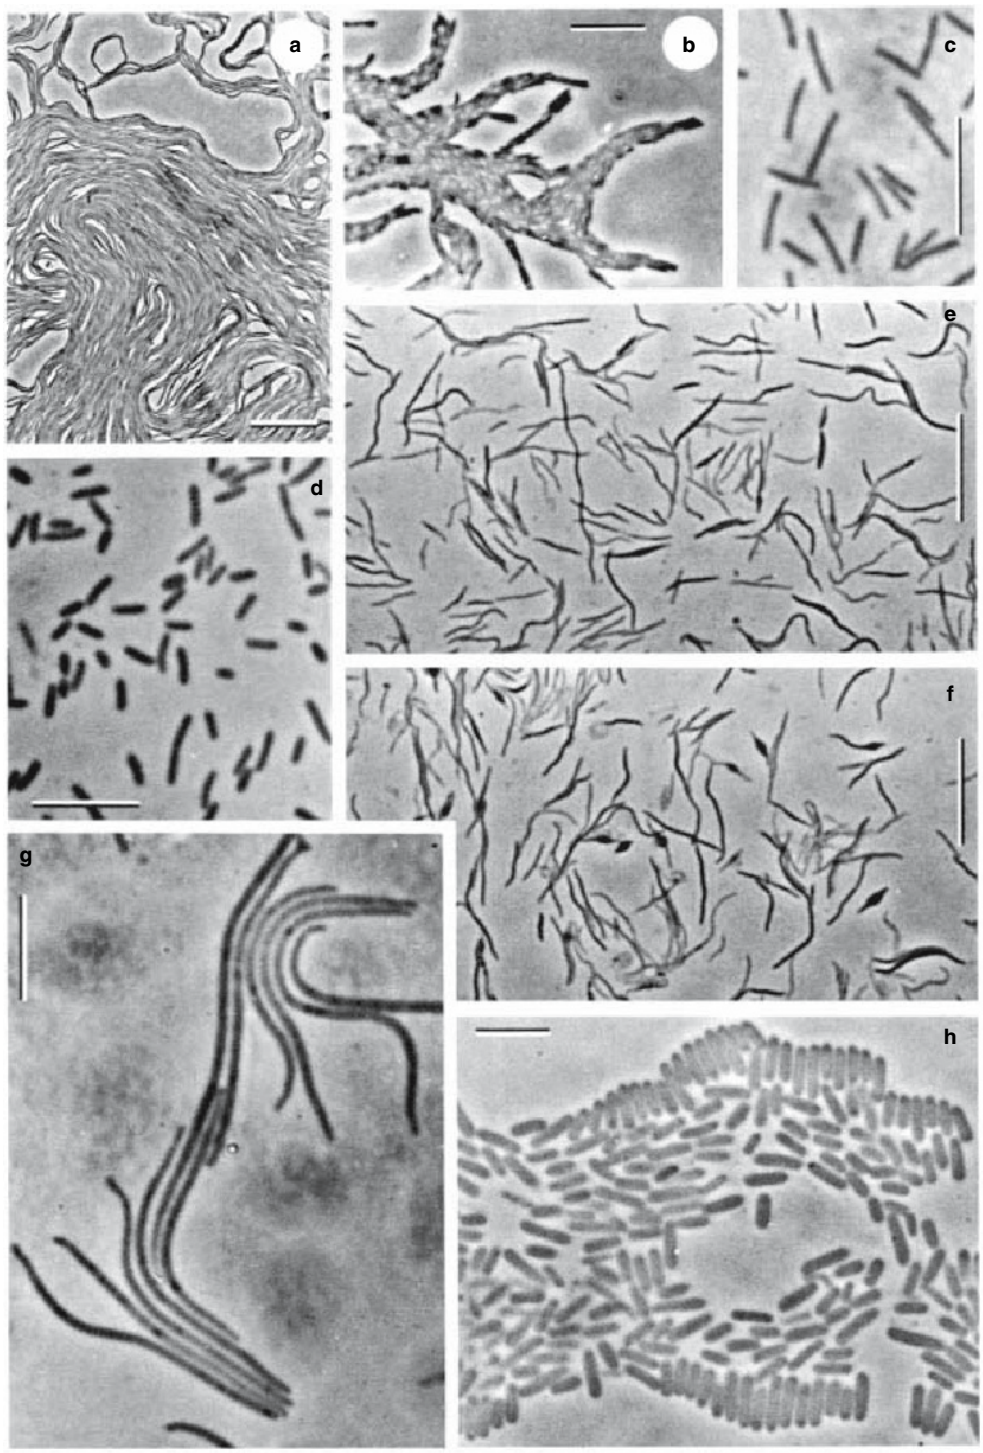

Fig. 1. Cell shape of the Cytophagales in phase contrast. (a) A brick red, marine, agar decomposer, probably a *Microscilla* species, in chamber culture; the long, flexible, thread cells have tapered ends. Bar = 25 µm. (b) CLB from soil, in chamber culture, showing the typical arrangement of cells at the swarm edge. Bar = 10 µm. (c) *Cytophaga lytica*, a yellow, marine, agar-digesting CLB, from SP2 liquid medium. Bar = 5 µm. (d) *Cytophaga succinicans*, a facultatively anaerobic freshwater CLB, from AO agar. Bar = 5 µm. (e and f) *Cytophaga aurantiaca* type strain, a cellulose-degrading true *Cytophaga*, from glucose-glutamate agar. The population in (e) consists of delicate, flexible rods, which are pleomorphic with very long and with slightly swollen cells; in (f), cells from older parts of the colony begin to produce dark, lemon-shaped inflations, which later degenerate to spheroplasts. Bar = 10 µm in both pictures. (g) *Flexibacter flexilis* type strain, from starch agar; one of the thread cells (top edge of the photograph) shows the beginning of branching at one end. Such branching is not uncommon among the Cytophagales. Bar = 5 µm. (h) *Taxeobacter* species, cells in situ on water agar with a streak of living *E. coli*, showing a characteristic palisade pattern. Bar = 25 µm.

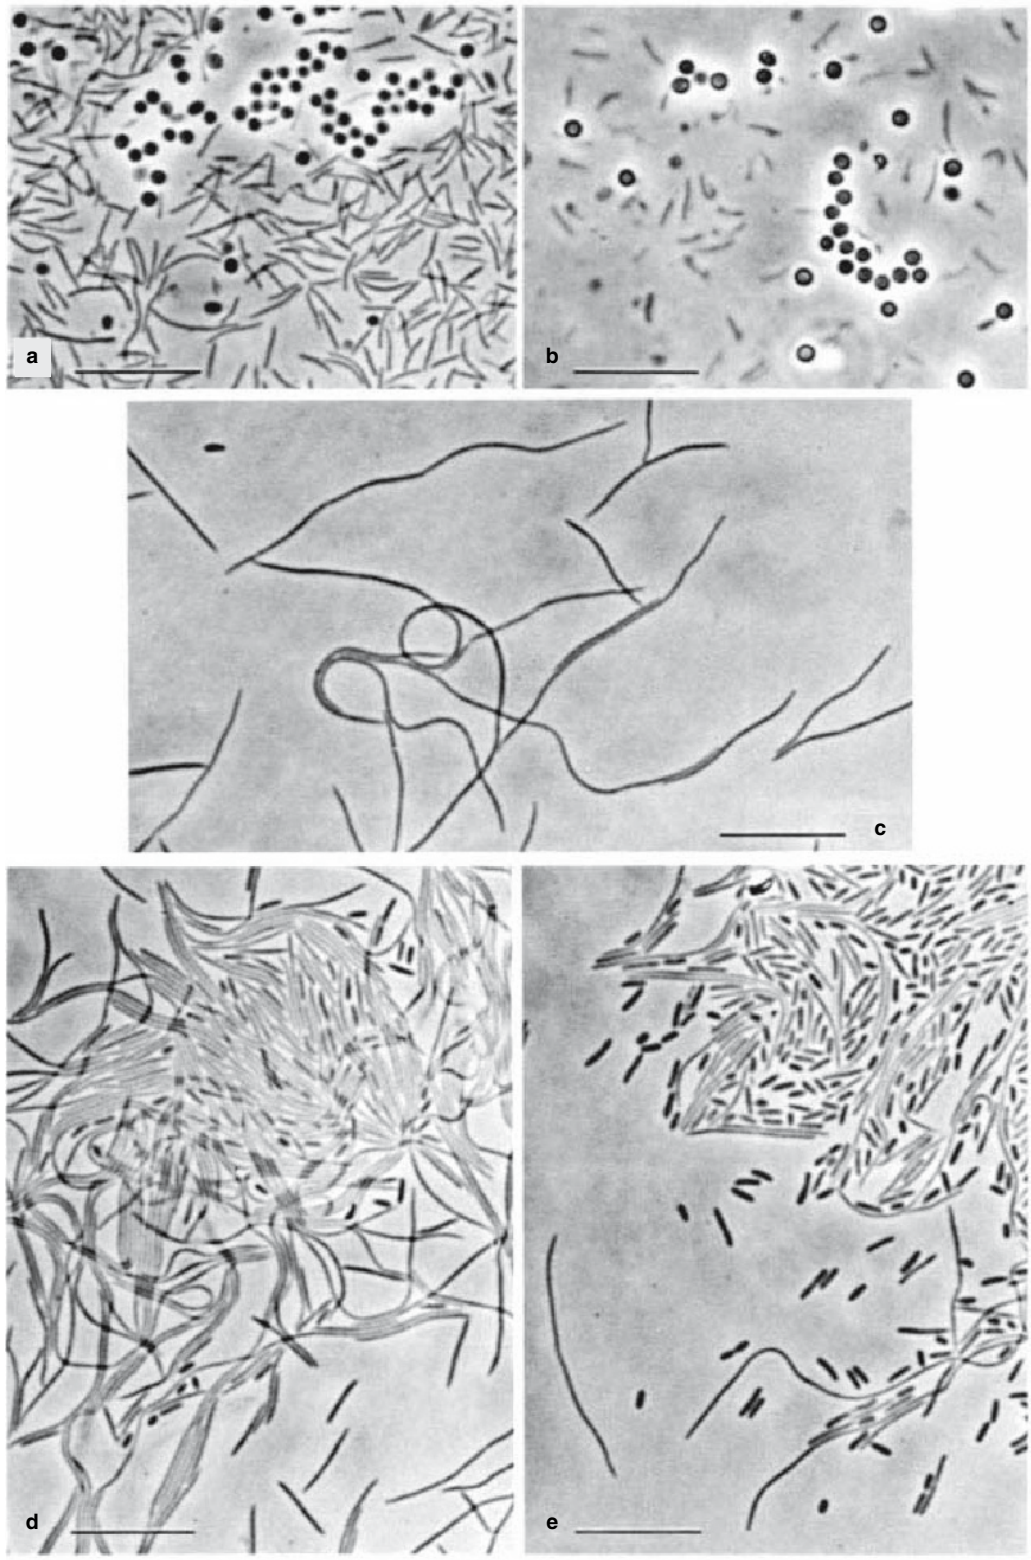

Fig. 2. Cytophagales with a cyclic change in cell shape, shown in phase contrast. (a and b) *Sporocytophaga myxococcoides* from a membrane of regenerated cellulose on ST6 agar; in (a), most cells are still vegetative rods, but young microcysts and intermediary stages of cell conversion can already be seen; in (b), mature, otpically refractile microcysts are present. (c to e) *Flexibacter filiformis* (formerly called *Fx. elagans* Fx el) from VY/2 agar; (c) a slide mount from the very edge of the swarm colony shows very long, delicate, flexible, and extremely agile thread cells without, or with only very few, cross walls; (d) at some distance from the edge, the thread cells have become much shorter by fragmentation; (e) finally, the cell population consists mainly of very short rods which are also clearly fatter and darker and are no longer motile. Bars = 10 μm.

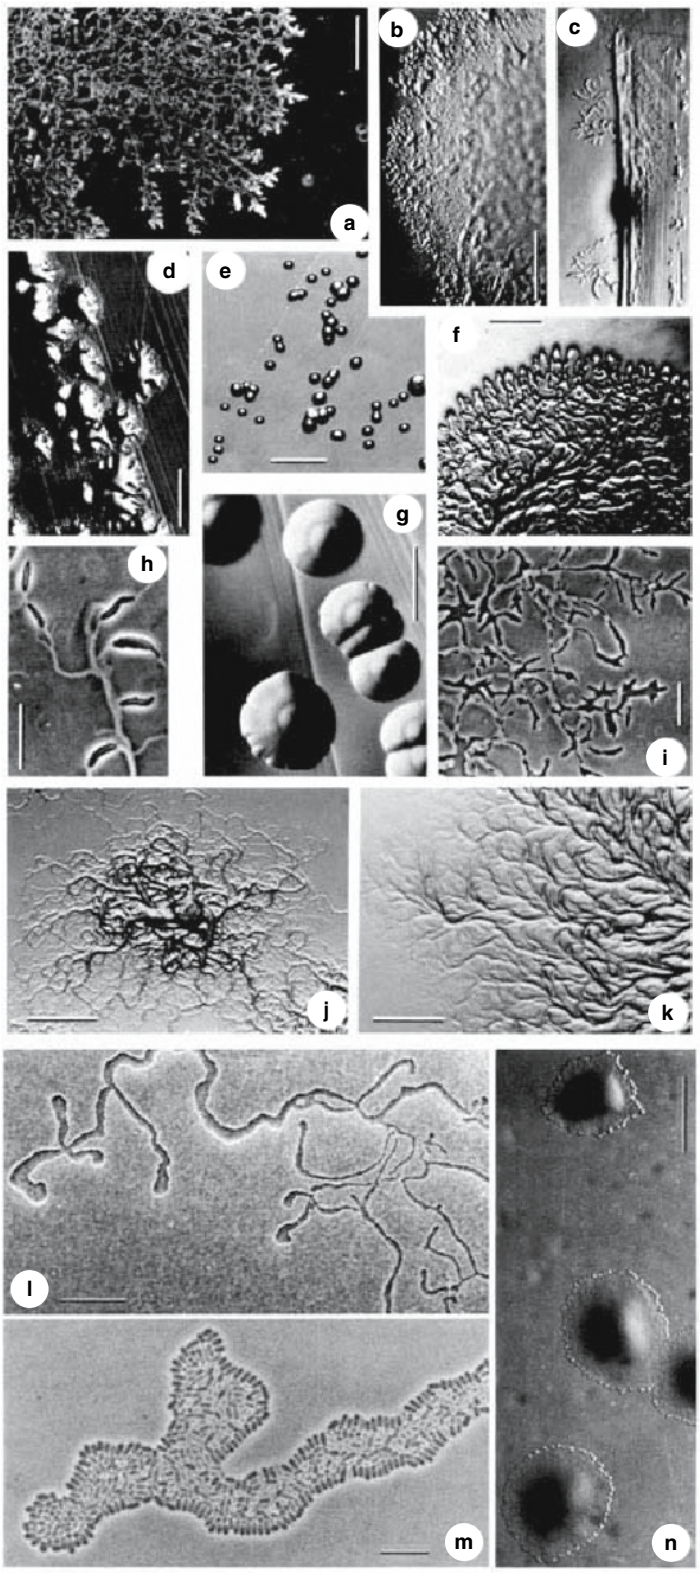

Fig. 3. Colonies of various diverse Cytophagales. (a) Spreading colony of a CLB from soil, growing in chamber culture, dark field. Bar = 100 µm. (b) *Flexibacter filiformis* Fx el, swarm colony on agar plate. Bar = 3 mm. (c) CLB from soil; typical swarm colonies emerge at the side of a streak on an agar surface. Bar = 1 mm. (d and e) CLB from soil growing on two different agar media. (d) On the poorer substrate, the colonies are relatively large and show some spreading; (e) they remain small and compact on the rich medium. Bar = 1 mm in both. (f) CLB from soil, swarm colony on CY agar showing a distinct surface pattern. Bar = 1 mm. (g) *Cytophaga flevensis*, an agar-digesting CLB from freshwater; as a relatively rich agar substrate was used, the colonies remained rather compact. Bar = 2 mm. (h) *Flexibacter filiformis* Fx el, chamber culture; dense clusters of cells are sitting in conspicuous slime tracks; phase contrast. Bar = 30 µm. (i) CLB from soil, chamber culture, edge of a swarm colony with a network of slim tracks; phase contrast. Bar = 30 µm. (j and k) *Cytophaga columnaris*, a fish-pathogenic CLB from freshwater; swarm colonies on MYX agar (j) and AO agar (k), showing the typical growth pattern of the organism. Bar = 1 mm in both. (l to n) *Taxeobacter ocellatus* Tx ol (= Myx 2105): (l and m) on water agar with a streak of living *E. coli*, the organism typically spreads out, producing long, tendril-like strips; (m) at a higher magnification, the unusual palisadelike arrangement of the cells becomes apparent; both phase contrast; (n) after plating on CY agar, relatively compact, brick red colonies begin to spread out. Bar = 100 µm in (l), 10 µm in (m), and 2 mm in (n).

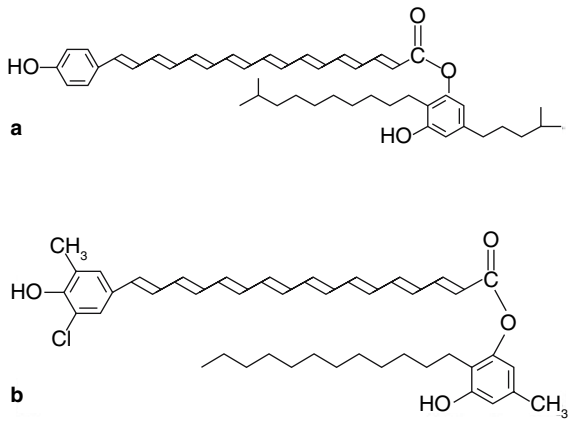

Fig. 4. Flexirubin-type pigments characteristic for members of the Cytophagales. (a) *Cytophaga*-flexirubin from CLB. (b) Chloroflexirubin from a *Flexibacter* species.

the turnover of matter in nature (e.g., Ruschke, 1968; Ruschke and Rath, 1966). Some may also be of practical interest.

A few reviews on the Cytophagales and their subgroups have been published since the first edition of *The Prokaryotes* and can be recommended here for further information (several chapters in *Bergey's Manual of Systematic Bacteriology*, vol. 3, 1989, for detailed discussions of the taxonomic problems; also, Reichenbach and Weeks, 1981; Shewan and McMeekin, 1983; and on practical aspects: Reichenbach, 1988; see also: Bernardet, 1989; Jooste, 1985; Kath, 1990).

Habitats

The Cytophagales are by far the most common of all gliding bacteria. They are found in enormous numbers in certain habitats, mainly those rich in organic material. They can adapt, however, to rather low nutrient levels (Höfle, 1982, 1983) and probably usually subsist on biomacromolecules, which they are specialized to degrade. The main habitats of the Cytophagales, and thus convenient sources for their isolation, are soils at or close to neutral pH, decaying plant material, and dung of animals, particularly that of herbivores. In freshwater environments, they are found on river banks and lake shores, in estuaries, in aerobic bottom sediments, and in algal mats. Certain *Cytophaga*-like bacteria (CLB) have also been found in large numbers freely floating in water, especially during the cold season, e.g., in Lake Constance, the Mindelsee, and the Feldsee in southwestern Germany (Gräf, 1962a; Reichardt, 1974; Ruschke and Rath, 1966). The principal cellulose decomposers in southern Canadian lakes appear to be cytophagas (Hoeniger, 1985). CLB are common in sewage plants where, in the aerobic regions, CLB may constitute 5 to 10% of the total cultivatable bacterial population (Güde, 1980). Here, too, a seasonal variation in the number of CLB can be observed, with a maximum in the winter months. Typically, the CLB are particularly enriched in those stages at the end of the purification process, where only recalcitrant organic molecules remain.

In marine environments, the Cytophagales are abundant near the shores: on living and dead seaweeds, in aerobic and anaerobic bottom sediments, and on decaying sea animals, such as crustaceans with their chitin exoskeleton. Marine cellulose degraders have been found on fishing nets in Japan, where they once were a serious problem in the deterioration of the fabric (Kadota, 1956). Cellulose degraders seem, however, not to be common in marine habitats; at least we have failed so far to isolate any from European coasts. Little is known about the distribution of CLB in the open sea, and a careful investigation of this point would be desirable. As CLB are not likely to form spreading colonies on rich media, the "flavobacteria" that are often observed in ecological studies of various aquatic environments perhaps may frequently really be CLB instead.

In estuarine habitats in the upper Chesapeake Bay, CLB were found to constitute a substantial proportion of the chitin-degrading bacterial flora (Reichardt et al., 1983), among them many facultatively anaerobic, flexirubin-positive strains resembling *Cy. johnsonae* and *Cy. aquatilis*. These organisms tolerated various levels of salt, but did not depepnd on elevated salt concentrations.

However, the boundaries between land and sea appear in general to be rather sharp for CLB. This may be concluded from the observation that virtually all strains of CLB and *Flexibacter* isolated by us from terrestrial and freshwater habitats contain, in addition to carotenoids, flexirubin-type pigments, while strains isolated from the sea coast usually produce carotenoids exclusively and only exceptionally produce flexirubin-type pigments (Reichenbach et al., 1981). Since enormous numbers of terrestrial CLB must constantly be washed or blown into the sea, this can only mean that terrestrial strains cannot easily adapt to and become established in the marine environment. An interesting exception may be *Cy. flevensis*. This is an agar-decomposing organism that does not produce flexirubin-type pigments, both characteristics which would speak for a marine origin. It has, however, been isolated from fresh water of the Isselmeer in the Netherlands (van der Meulen et al., 1974). Since the Isselmeer is a part of the North Sea that has been separated from the open sea for decades and has gradually become constituted with fresh water, marine bacteria would have had ample time to adapt to gradually changing conditions and thus may have had a chance to survive. These

observations also suggest that marine and terrestrial CLB may be less closely related than was thought before; this is indeed supported by 16S rRNA analyses (Paster et al., 1985).

In recent years, it has been discovered that CLB may also occur in milk and dairy products and perhaps occasionally contribute to deterioration (Jooste, 1985; Jooste et al., 1985). Even more serious are sporadic reports of CLB as human pathogens. CLB in the air humidifier system of a textile plant were found to be responsible for a hypersensitivity pneumonitis of workers; they were later described as a new species, *Cy. allerginae* (Flaherty et al., 1984; Liebert et al., 1984). The *Capnocytophaga* species live in the tooth pockets of humans (Leadbetter et al., 1979). Although a role for them in periodontic disorders has been discussed, it seems that the contribution of capnocytophagas to that disease is only a minor one at the most. But life-threatening septicemias and other kinds of general infections have been observed repeatedly and not only in immunocompromised patients as has originally been thought (e.g., Forlenza et al., 1980; Paerregaard and Gutschik, 1987; Shlaes et al., 1982). Fortunately, the organisms respond well to antibiotics (Forlenza et al., 1981; Gräaf and Morhard, 1966).

An economically serious problem are the fish-pathogenic CLB. These organisms are gaining even more importance as fish cultivation is intensified. First discovered in aquarium fishes in the USA (Davis, 1922), infections with CLB became a major concern in the 1940s in the western USA, where they caused severe losses among salmonid fishes in rivers and lakes and in fish hatcheries. The infections were then intensively studied, and it was discovered that more than one species of CLB were involved, causing several different diseases with diverse symptoms. The two most important diseases were columnaris disease, brought about by *Cy. columnaris* (= *Fx. columnaris* = *Chondrococcus columnaris*), and cold water disease by *Cy. psychrophila.* One factor that may have contributed to these outbreaks may have been the warming of the water by electric power plants, mainly along the Columbia River. It appears that, as a rule, unfavorable living conditions for the fish, like confinement, crowding, and suboptimal water temperature, favor infections by CLB (e.g., Anacker and Ordal, 1959; Becker and Fujihara, 1978; Bullock, 1972; Colgrove and Wood, 1966; Collins, 1970; Davis, 1949; Fujihara and Hungate, 1972; Fujihara et al., 1971; Garnjobst, 1945; Ordal and Rucker, 1944; Pacha, 1968; Pacha and Ordal, 1970; Pacha and Porter, 1968; Rucker et al., 1953; Snieszko and Bullock, 1976). Fish diseases caused by CLB are now known worldwide, and they often are a serious threat to fish culturists (e.g., Ajmal and Hobbs, 1967; Bootsma and Clerx, 1976; Deufel, 1974; Ghittion, 1972; Lehmann, 1978; Song et al., 1988; Wakabayashi and Egusa, 1974; Wakabayashi et al., 1970a, 1970b). In Europe, CLB diseases have been observed only since about 1965, but it is not clear whether the pathogens were there before but had previously been overlooked or whether infections have finally become established on a larger scale because environmental conditions have deteriorated. It appears that in the past few years *Cy. psychrophila* has begun to spread through Europe; again, the reasons are not known (Bernardet, 1989; Bernardet and Kerouault, 1989). Very recently, flavobacteria have also been found to be involved in fish diseases (*Fv. branchiophila*), and it will be interesting to see if they are related to fish pathogenic CLB. The data on DNA-DNA hybridization with *Cy. columnaris* were insignificant (Wakabayashi et al., 1989). Further, CLB diseases have been encountered in marine environments (e.g., Anderson and Conroy, 1969; Bullock, 1972; Campbell and Buswell, 1982; Hikida et al., 1979), apparently due to infections by *Fx. maritimus* (Bernardet et al., 1990; Wakabayashi et al., 1986). CLB and flavobacteria obviously belong to the bacterial flora that colonize the eggs of cod and halibut, but in this case detrimental effects have not been demonstrated (Hansen and Olafsen, 1989). However, CLB may have a role in disorders of other marine animals; they have been linked to the destruction of the hinge ligaments of cultivated oysters (Dungan et al., 1989). Based on what is known so far, it may be concluded that the infection mechanism of the CLB pathogenic for fish is connected to their very strong protease activity and, in some, also DNase activity.

Isolation

There are no selective methods that are universally applicable for the enrichment and isolation of the diverse members of the Cytophagales. The general strategy for their isolation is to provide conditions that promote spreading growth on surfaces and then to pick organisms that produce spreading colonies or swarms (Fig. 3) for subcultivation. The nutrient level is usually kept low in the medium used for crude and enrichment cultures in order to stimulate gliding motility and delay development of contaminants. By combining this approach with the use of special substrates in the isolation medium, nutritional specialists among the Cytophagales may be enriched more specifically, e.g., cellulose and chitin degraders. The isolation procedure thus always requires the use of plate cultures. Liquid

media have only been used successfully for baiting cellulose decomposers (see below).

With some experience, it will often be possible to recognize members of the Cytophagales microscopically, because many have a characteristic cell morphology (Fig. 1 and 2). If that is not the case, the appearance of the colonies may provide a clue. The property of swarming presents some difficulties since some organisms cannot be or, only with difficulty, can be induced to form spreading colonies, even when gliding motility can be recognized unequivocally by microscopic examination of wet mounts or by the occurrence of slime trails in chamber cultures. This is why quite a few CLB were originally classified as *Flavobacterium* species. On the other hand, spreading growth is, of course, shared by other gliding bacteria. But there are only two other groups of organotrophic, unicellular gliders: the myxobacteria, which usually show a totally different swarm morphology and typically produce fruiting bodies in crude cultures (see The Genus *Pelobacter* in this Volume), and the lysobacters, which have a peculiar cell morphology, which is, however, shared by some CLB (see The Genus *Lysobacter* in Volume 6). In many cases, pigmentation may be a useful criterion. As already mentioned, many, although not all, members of the Cytophagales are bright yellow, orange, or red. These pigments are always cell-bound (in contrast to some or all of the *Lysobacter* pigments, which, in addition, are usually much paler). If growth is heavy, pigmentation can already be easily recognized in the colonies; alternatively it may be observed after the cells have been concentrated by scraping them together. A large group of soil and freshwater strains of *Cytophaga*, *Sporocytophaga*, CLB, and *Flexibacter* produce flexirubin-type pigments that, upon addition of alkali, turn from orange to purple (Achenbach et al., 1978; Reichenbach et al., 1974). This test can easily be applied to culture plates. In this case, the yellow or orange colonies will turn a much deeper color, either red, purple-violet, or brown, when spotted with 10% KOH solution. The color change differs from that of the pure pigments because of the presence of other pigments, usually carotenoids, which alter the flexirubin absorption spectrum. The color change reaction is reversible upon addition of HCl. If a gliding bacterium gives a positive result with this color test, one can be certain that it belongs to one of the above-mentioned groups of organisms. The only nongliding bacteria known to contain flexirubin-type pigments are the phylogenetically related, low GC (true) flavobacteria (Reichenbach et al., 1980; Weeks, 1981). It should be understood, however, that the described color change is a phenolate reaction that can also be observed with other pigment types. In fact, a similar color reaction has been found in *Brevibacterium linens*, which contains the phenolic carotenoid 3,3′-dihydroxy-isorenieratene (Kohl et al., 1983). Nonmotile, Gram-positive *Brevibacterium*, of course, cannot easily be confused with the organisms discussed here.

Sources for the isolation of Cytophagales will be found in the section on "Habitats." If a broad representation of those organisms is desired, the samples should be processed soon after collection, especially if the samples are from aquatic or humid environments, because in such samples, oxygen depletion and desiccation in particular can quickly lead to the elimination of sensitive species. Thus, in my experience, the cellulose-degrading *Cytophaga* species are easily lost in this way. On the other hand, many species of Cytophagales are completely desiccation resistant; I have been able to isolate strains of *Sporocytophaga*, *Flexibacter*, CLB, and *Taxeobacter* from samples that had been air-dried and stored for 5 to 10 years at room temperature.

Methods for the Isolation of Cytophagales

Small samples of promising natural material are inoculated either as individual spots or as one to three well-separated streaks onto the surface of dry water agar (WAT agar) plates. For marine samples, seawater agar (MS1 or SW2 agar) is used. Alternatively, media with a very low nutrient content may be used (CYT, MS4, SP2, SP6 agar). Finely divided samples such as soil may also be sprinkled over the plate, as a way of multi-spot inoculation. This can be advantageous because the organisms tend to stick to tiny particles and thus may be distributed in the sample very unevenly. To reduce the growth of fungi, cycloheximide (2.5 mg/100 ml) should be added to the isolation medium (not necessary with marine samples).

WAT Agar and WCX Agar

$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved. After autoclaving, 25 µg cycloheximide may be added per ml from a filter-sterilized stock solution for WCX agar.

MS1 Agar

Agar	1.5%

In natural seawater.
The pH is not adjusted. The medium is autoclaved.

SW2 Agar

Na acetate	0.002%
NH_4Cl	0.1%
Agar	1.5%

In artificial seawater (see below).
The pH is adjusted to 7.2. The medium is autoclaved.

Artificial Seawater (Dawson et al., 1969)

NaCl	24.7 g
KCl	0.7 g
$MgSO_4 \cdot 7H_2O$	6.3 g
$MgCl_2 \cdot 6H_2O$	4.6 g
$CaCl_2$ anhydrous	1.0 g
$NaHCO_3$	0.2 g

Dissolve in 1 liter water. To prevent precipitation, $CaCl_2$ and $NaHCO_3$ are autoclaved as separate stock solutions.

CYT Agar

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$CaCl_2 \cdot 2H_2O$	0.05%
$MgCl_2 \cdot 7H_2O$	0.05%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved.

MS4 Agar

$(NH_4)_2SO_4$	0.1%	(autoclaved separately)
Glucose	0.2%	(autoclaved separately)
Agar	1.5%	

In natural seawater.
The pH is not adjusted. The medium is autoclaved.

SP2 Agar

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.02%
Na acetate	0.002%
Agar	1.5%

In artificial seawater.
The pH is adjusted to 7.2. The medium is autoclaved.

SP6 Agar

Casitone (Difco)	0.03%
Yeast extract (Difco)	0.01%
Agar	1.5%

In artificial seawater.
The pH is adjusted to 7.2. The medium is autoclaved.

The plates are incubated at 30°C, at room temperature, or at 12°C, depending on the origin of the samples. Cultures started from aquatic sources are usually incubated at the lower temperature range because many aquatic CLB will not grow above 25 to 27°C.

The cultures are checked at regular intervals of 1 to 2 days for spreading colonies. It takes between 24 h and several weeks for spreading organisms to appear, depending on the organism, the incubation temperature, and the nutrient concentration in the culture, which may have been substantially augmented by the introduced sample material. As the spreading swarms are often filmlike and extremely delicate, the plates must be examined with a dissecting microscope equipped with a tiltable mirror so that side illumination can be used from below. Some experience is required before gliding organisms can be reliably distinguished from flagellated bacteria, which occasionally also spread out (Fig. 3b and 3d). A good distinguishing characteristic is usually the pattern of the swarm edge which, for gliding bacteria, is usually dentate with fine flamelike projections, while for flagellated organisms, it tends to be entire or coarsely lobed. However, certain *Bacillus* strains that form long filaments may also spread out with flamelike tongues at the edge of their colonies. Amebae or, in marine samples, gliding diatoms like *Nitzschia putida* may mislead the investigator. Usually a look through the microscope will quickly dispel all doubts; thus, e.g., no gliding bacterium is known that is able to swim actively (that is, move without being in contact with a surface).

The baiting technique used for the isolation of myxobacteria (see The Genus *Pelobacter* in this Volume) also often yields members of the Cytophagales. Living cells of *Escherichia coli* are streaked cross-wise or in three parallel lines onto water agar and inoculated with a suitable sample. The organisms develop along the *E. coli* streaks, often without lysing them, and spread as an extremely thin film, usually a monolayer, far out over the agar surface between the streaks. The technique is in essence nothing else than an enrichment in a low nutrient medium.

If the Cytophagales are present in sufficiently high numbers, the samples can be suspended in sterile water, diluted, and plated. Media with low nutrient concentrations, like CYT and SP6 agar, are well suited. Media with a somewhat higher nutrient concentration, like CY, SP2, and SAP2 agar, may also be used. They result in higher colony counts, but spreading of the gliding bacteria may be reduced or suppressed completely (Fig. 3i and 3j). Here, the color of the colonies may provide a useful lead. It should be kept in mind, however, that dilution plating is often not very successful, because the organisms tend to stick to particles and may be lost during the first few dilution steps.

CY Agar, CYG2 Agar, and CYCX Agar

Casitone (Difco)	0.3%
Yeast extract (Difco)	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved. The medium may be supplemented with 0.3% glucose, which is separately autoclaved, for CYG2 agar. If the medium is used for plating of dilution steps, 25 µg cycloheximide may be added per ml after autoclaving from a filter-sterilized stock solution, for CYCX agar.

SAP2 Agar

Tryptone (Difco)	0.1%
Yeast extract (Difco)	0.1%
Agar	1.5%

In artificial seawater.
The pH is adjusted to 7.2. The medium is autoclaved.

Water samples may be plated directly or upon dilution. Often, however, it will be necessary to concentrate the bacteria by passing the sample through a membrane filter. The filter is then incubated right-side up on a suitable culture plate, either as a whole or after having been cut into several sectors; the latter approach increases the chance of isolating several different organisms. If media with somewhat higher nutrients are used, like CY or SAP2 agar, the incubation time is shortened and, thus, the danger of overgrowth reduced. But spreading of the organisms may become more or less suppressed, so that members of the Cytophagales can only be recognized by their color and cell shape. The strategy that is best applied depends on the load of contaminants expected. Some of the smallest gliding bacteria can move through the filter pores (at 0.3- to 0.5-µm pore size) and form colonies on the agar surface below. This can be used as a selective technique. In this case, the filter should be removed from the agar surface after about one day to prevent contaminants from also moving through the filter.

Isolation of Nutritionally Specialized Organisms

AGAR DECOMPOSERS. Agar decomposers are very common in marine environments and can be obtained by the methods outlined above. They are easily recognized, because their colonies rest in shallow craters or in deep pits, and are surrounded by large, uncolored, "gelase" zones if the plate is flooded with iodine solution (Stanier, 1941; Veldkamp, 1961). Some organisms liquify the agar very quickly so that they can only be isolated if widely separated colonies are obtained after plating. Here, the filter migration technique described above is sometimes useful. A few agar-decomposing CLB have also been found in freshwater habitats near the sea coast, viz. *Cy. flevensis* (van der Meulen et al., 1974) and *Cy. saccharophila* (Agbo and Moss, 1979).

CHITIN DECOMPOSERS. Chitinolytic bacteria are very common among the Cytophagales. Samples are streaked out on chitin agar, e.g., CT6 or CT7 agar (for marine strains, on CT8 or CT9 agar). The chitin is only added in a thin top layer in order to conserve chitin, which is relatively laborious to prepare, and to prevent the chitin from settling on the bottom of the dish out of reach of the organisms; in addition, superior results are obtained in this way because the cleared zones in the opaque chitin layer appear sooner and become more pronounced (Stanier, 1947; Veldkamp, 1955, 1965). Good sources for chitin decomposers are soil, material from sewage plants, and the shells of dead crustaceans. All known chitin-degrading Cytophagales can also grow very well without chitin, e.g., on CY agar, and they can be isolated by the general techniques described above. Thus, they can be purified by plating on, e.g., CY or SAP2 agar.

CT6 Agar

Top layer:

$MgSO_4 \cdot 7H_2O$	0.1%
K_2HPO_4	0.02%
Agar	1.5%

The pH is adjusted to 7.5. After autoclaving, enough chitin is added to give an easily recognizable turbidity, which should be achieved with about 0.5% chitin. The chitin is taken from an autoclaved stock suspension of reprecipitated material; the suspension must be dense enough so that the volume to be added to the medium does not exceed 30%. The preparation of the chitin is described in The Genus *Lysobacter* in this Volume 6. The medium is poured as a thin layer on top of the following:

Base agar:

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved.

CT7 Agar

Top layer as for CT6 agar. The base agar is WAT agar. On this medium only organisms that can use chitin as the only carbon and nitrogen source are able to grow.

CT8 Agar

Top layer:

K_2HPO_4 (autoclaved separately)	0.02%
Agar	1.5%

In artificial seawater.

The pH is adjusted to 7.5. After autoclaving, chitin is added, as for CT6 agar. The medium is poured on SW2 agar plates.

CT9 Agar

Top layer as for CT8 agar; base agar is SP2 agar.

CELLULOSE DECOMPOSERS. Decaying plant material or soil is sprinkled on filter paper that has been placed on mineral salts agar, e.g., ST6 agar (for marine organisms, SW5 agar may be used).

ST6 Agar and ST6CX Agar

$(NH_4)_2SO_4$	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$MnSO_4 \cdot 7H_2O$	0.01%
$FeCl_3 \cdot 6H_2O$	0.02%
Yeast extract (Difco)	0.002%
Agar	1%
K_2HPO_4	0.1% (autoclaved separately)

After autoclaving, a filter-sterilized trace element solution is added, and, for crude cultures, 25 µg cycloheximide per ml from a filter-sterilized stock solution is added, for ST6CX agar. A recipe for a trace element solution is found in The Genus *Pelobacter* in this Volume.

SW5 Agar

$(NH_4)_2SO_4$	0.1%
Yeast extract (Difco)	0.02%
Agar	1%
K_2HPO_4 (autoclaved separately)	0.1%

In artificial seawater.

The medium is autoclaved.

It appears that the type of filter paper used does not make much difference; we get good results with thin, moderately dense, high-quality filter paper (68 g/m^2, ash 0.1 to 0.2%, more than 95% α-cellulose). Growth of cytophagas on mineral salts agar with cellulose is usually considerably stimulated by Ca^{2+}, Mn^{2+}, and $Fe^{2+/3+}$ (Bortels, 1956). While media with NO_3^- as the nitrogen source are often recommended in the literature, in my experience, media with NH_4^+ are far superior for the isolation of cytophagas and sporocytophagas, at least on agar media.

As an alternative, enrichment cultures may be started with strips of filter paper immersed in a mineral salts solution, e.g., Dubos medium or ST5 medium, in test tubes, so that part of the filter paper remains above the surface of the liquid. The tubes are then inoculated. After incubation for 1 to 3 weeks, glassy, translucent yellow to orange or red spots on the paper at the air-liquid interface indicate growth of cellulose-decomposing cytophagas and sporocytophagas. The yellow and orange spots usually give the flexirubin reaction when a drop of 10% KOH solution is added, but some (terrestrial) *Cytophaga* strains are flexirubin-negative. It appears that, in general, enrichment on plates gives better results because it allows the use of a heavier inoculum. However, an enrichment in liquid medium may be useful when habitats are investigated that are poor in cellulose degraders, such as marine environments. For the latter, good results have been reported with KM7 mineral medium and incubation at 25°C (Kadota, 1956). As already mentioned, fresh samples should be used for isolating *Cytophaga* strains.

Dubos Mineral Medium (Dubos, 1928)

$NaNO_3$	0.05%
K_2HPO_4 (autoclaved separately)	0.1%
$MgSO_4 \cdot 7H_2O$	0.05%
KCl	0.05%
$FeSO_4 \cdot 7H_2O$	0.001%

The pH is adjusted to 7.2. The medium is autoclaved.

ST5 Mineral Medium (Stanier, 1942)

$(NH_4)_2SO_4$	0.1%
K_2HPO_4 (autoclaved separately)	0.1%
$MgSO_4 \cdot 7H_2O$	0.02%
$CaCl_2 \cdot 7H_2O$	0.01%
$FeCl_3$	0.002%

The pH is adjusted to 7.0 to 7.5. The medium is autoclaved. For enrichment cultures, 25 µg cycloheximide is added per ml from a filter-sterilized stock solution.

KM7 Mineral Medium (Kadota, 1956)

$NaNO_3$	0.05%
K_2HPO_4	0.1%
$MgSO_4 \cdot 7H_2O$	0.05%
$FeSO_4 \cdot 7H_2O$	0.01%

In natural seawater.

The pH is adjusted to 7.2. The medium is autoclaved. This medium was originally developed for a different purpose, which explains the inclusion of relatively small amounts of $MgSO_4$ in a seawater medium.

The purification of cellulose decomposers may be a tedious procedure that requires skill and considerable patience, and it almost always takes several weeks or months. The first subcultures are best started on filter paper placed on mineral salts agar. Now, however, small (about 10×15 mm) rectangular filter strips are usually used and inoculated independently from different sites of the crude culture. The filter paper pieces, three or four per plate, are kept well separated to prevent the passage of contaminants from one to the other. Of course, organisms such as flagellated bacteria, amebae, ciliates, and nematodes will spread quickly within the water-soaked filter pad. Before further purification is attempted, they should first be eliminated. To get rid of amebae, which are almost always abundant in cultures started from soil, the plate is exposed to the vapors of a 5% ammonia solution for 2 min (M. Aschner, personal communication). After another one to two minutes of incubation, the cytophagas are transferred to a fresh plate. If there are very many amebae, the procedure may have to be repeated after the cellulose decomposers have grown up. If nematodes are still there, the plate is frozen at –80°C for 2 days. The cellulose decomposers are transferred to a fresh plate as soon as possible after thawing. Next, contaminating bacteria have to be removed, which is the most difficult step. After the load of contaminants has been reduced by repeated transfers to filter paper on mineral salts agar, the cellulose decomposer may be transferred to cellulose overlay agar; we have often had good results with CEL1 agar.

CEL1 Agar

Top layer:

$(NH_4)_2SO_4$	0.1%
Cellulose powder	0.5%
Agar	1.0%

Cellulose powder MN300 from Macherey and Nagel (Düren, Germany) works well.

The pH is adjusted to 7.2. The medium is autoclaved and then poured as a thin layer on top of ST6 agar plates.

The cellulose decomposers penetrate the agar medium and spread within the cellulose layer, concommitantly producing a clear lysis zone. Most or all of the contaminants stay close to the inoculation site, so that after 1 to 3 weeks, a pure, or at least improved, inoculum can be obtained from the edge of the lysis zone.

Favorable results are sometimes obtained by inoculating a small rectangle of filter paper that has been placed on top of cellulose overlay agar, preferably close to one side of the plate. In this case, the cellulose decomposers grow profusely on the filter paper, and from there they spread within the cellulose agar, while the contaminants tend to remain in the macerating filter paper where they find higher nutrient concentrations.

We also find carboxymethyl cellulose media, like ST10 agar, useful for purification of cellulose decomposers. On this medium, too, they spread within the substrate; this can be recognized from a slowly increasing, shallow depression in the surface of the plate. Growth is usually very thin and can barely be seen, if at all; but bacterial cells are found under the microscope if slide mounts are made from the depressed area. Transfers are made from the edge of the depression zone after some time.

ST10 Agar

$(NH_4)_2SO_4$	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$FeCl_3$	0.02%
K_2HPO_4 (autoclaved separately)	0.1%
Casitone (Difco)	0.2%
Carboxymethyl cellulose	1.5%
Agar	0.6%

Carboxymethyl cellulose Sigma no. C-5013, sodium salt, high viscosity, works well.

After autoclaving, standard trace elements (see The Genus *Pelobacter* in this Volume) and, if used for contaminated strains, 25 µg cycloheximide per ml are added from filter-sterilized stock solutions.

Another technique for purification is to transfer the cellulose decomposers to a membrane filter (cellulose nitrate, 0.3 to 0.4 µm pore size) on cellulose overlay agar or, better, on a membrane of regenerated cellulose (e.g., no. 11604/50/N, pore size 0.8 µm, from Sartorius, Göttingen, Germany) on ST6 agar. The cytophagas will migrate through the membrane filter and produce colonies on the substrate below. If regenerated cellulose is used, these colonies appear particularly early and show a sharp margin. It may, however, still take from 1 to 3 weeks before colonies develop. They are often bright yellow and spread very slowly. With this technique, the time of removal of the top membrane is crucial, because other bacteria may soon grow through the membrane and contaminate the cellulose degraders again. Therefore, it is best to start several parallel cultures and to remove the top membrane at various different times, e.g., after incubation at 30°C overnight, for 1 day, and for 2 days.

With sporocytophagas, final purification is often possible by cautious heating of microcysts suspended in water. The heat resistance seems to vary substantially from strain to strain and probably also depends on the maturation stage. For example, the thermal death point was reached after 10 min at 68°C with one strain of *Sp. myxococcoides*, while another strain survived 10 min at 70°C; a strain of *Sp. ellipsospora* was killed after 10 min at 58°C (Imshenetsky and Solntseva, 1936; Sijpesteijn and Fåhraeus, 1949). We found that occasionally a strain may even survive boiling for 10 min. Results are usually satisfactory in our laboratory if we incubate microcysts at 58°C and take samples after 10, 20, and 40 min. The heated samples may be streaked on CEL1 agar, on filter paper on CY agar, or on CA2, CA13, or HP18 agar.

CA2 Agar (Mullings and Parish, 1984)

Base agar:

Agar	1.5%

Stock solution A:

KNO_3	7.5 g
K_2HPO_4	7.5 g

Dissolved to give 100 ml.

Stock solution B:

$MgSO_4 \cdot 7H_2O$	1.5 g

Dissolved to give 100 ml.

Stock solution C:

$CaCl_2 \cdot 2H_2O$	0.27 g
$FeCl_3$	0.15 g

Dissolved to give 100 ml.

After autoclaving, the base agar is supplemented with: (a) 1% (v/v) of each of the three stock solutions; (b) 1% (w/v) of glucose (from an autoclaved 20% stock solution); and (c) standard trace elements (see, e.g., The Genus *Pelobacter* in this Volume).

CA13 Agar

As for CA2 agar, but the KNO_3 in stock solution A is replaced by 0.5 g of $(NH_4)_2SO_4$.

HP18 Agar

Na glutamate	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.5%

The pH is adjusted to 7.2. After autoclaving, 0.1% glucose (from an autoclaved stock solution) and standard trace elements are added.

Of course, plating of diluted cell suspensions would seem to be the method of choice for the purification of cellulose-degrading cytophagas. However, this can only be done if the organisms are already enriched to near purity since colonies composed of single cells are apparently not produced by these organisms, not even on glucose-containing media, such as those just mentioned, that allow massive growth of pure cultures. Whenever isolated colonies are obtained upon plating, these colonies probably always start from cell clusters, and these are normally contaminated when heavily contaminated cultures are used to prepare the suspension. Further, the cellulose degraders produce a lot of slime which makes it difficult to suspend the cells uniformly in a liquid. After plating on cellulose-overlay agar, colonies which are surrounded by a lysis zone appear only after weeks of incubation, and this gives contaminants ample time to develop and overgrow the cellulose degraders. Gliding and spreading bacteria become a particular nuisance under such conditions. It may be mentioned here that, when glucose is used in a medium, care has to be taken to sterilize the glucose separately, either by filtration or by autoclaving, since cellulose-degrading cytophagas are extremely sensitive to toxic products arising when glucose is autoclaved together with other medium compounds (Stanier, 1942). Cellulose-degrading sporocytophagas and cytophagas have been known for many years (Hutchinson and Clayton, 1919; Winogradsky, 1929), but relatively few pure strains are available. They are very common in soil and decaying plant material (for their occurrence, isolation, and cultivation, see Fåhraeus, 1947; Imschenezki, 1959; Imshenetski and Solntseva, 1936; Kadota, 1956; Krzemieniewska, 1930; Krzemieniewska, 1933; Stanier, 1942; Stapp and Bortels, 1934; Veldkamp, 1965).

Pectin Decomposers. Pectin-decomposing CLB can be obtained by plating samples, e.g., lake water, on pectin overlay agar like PEK1 agar or on PEK7 agar. Pectolytic organisms cause shallow depressions in the pectin gel or liquefaction; on PEK7 agar, the colonies are surrounded by clearing zones in a background of finely divided, dispersed pectin flakes or granules, which may be clearly seen, however, only under a dissecting microscope. If such plates are flooded with iodine solution, colonies of pectolytic organisms are surrounded by light yellow halos in a brown plate. The preparation of pectin media is somewhat tricky, and the results depend decisively on the type of pectin used. We found pectin from apple, 38% esterified (from Roth, Karlsruhe, Germany), useful.

PEK1 Agar (Güde, 1973)

Base agar:

Part A:

NH_4Cl	1 g
$CaCl_2 \cdot 2H_2O$	3 g

In 100 ml water.

Part B:

K_2HPO_4	0.5 g

In 50 ml water.

Part C:

$MgSO_4 \cdot 7H_2O$	0.2 g
Agar	15 g
Tris HCl buffer, 1 M, pH 8.0	100 ml

In 750 ml of water.

After autoclaving the solutions are combined, standard trace elements (see The Genus *Pelobacter* in this Volume) are added, and plates are poured.

Top layer:

12 g pectin is slowly dissolved in 300 ml water of 70°C, the pH is adjusted to 7.2, and the medium is autoclaved for exactly 10 min at 110°C. The solution is poured as a thin layer on base agar plates and will form a gel within 5 h. During autoclaving, the medium may become dark, but this does not interfere with its usefulness.

PEK7 Agar

Top agar:

Casitone (Difco)	0.2%
Pectin	0.5%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved and poured on CY agar plates.

Pectolytic CLB are very common in freshwater (Güde, 1973). They have also been isolated from soil samples after enrichment by percolation of a 1% pectin solution through the samples (Dorey, 1959; his *Fv. pectinovorum* is actually a CLB: Christensen, 1977b). The pectolytic CLB do not depend on pectin but may be stimulated by the presence of a carbohydrate like glucose. They can easily be purified by plating a diluted cell suspension on, e.g., CY agar + 0.3% glucose (= CYG2 agar) or on MYX agar.

MYX Agar

Na glutamate	0.5%
Yeast extract (Difco)	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%

Glucose (autoclaved separately)	0.2%
Agar	1.5%

The pH is adjusted to 7.2. The medium is autoclaved.

Fish Pathogens. CLB pathogenic for fish can usually be isolated and cultivated on relatively simple media. For freshwater strains, AO agar has been used with good results (e.g., Anacker and Ordal, 1955; Bullock, 1972; Pacha and Ordal, 1967; Snieszko and Bullock, 1976).

AO Agar (Anacker and Ordal, 1955)

Tryptone (Difco)	0.05%
Yeast extract (Difco)	0.05%
Beef extract	0.02%
Na acetate	0.02%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved.

The agar concentration may be varied depending on the purpose for which the medium is used; a reduction to 0.9% is recommended for the first isolation from fish (for AOW agar) and to 0.4% for stock cultures (for AOS agar).

Infested material from gills, skin lesions, or internal organs, such as kidney or spleen, is streaked on agar plates and incubated at 12 to 18°C or at 30°C depending on the origin of the fish. Initially, media containing diluted fish infusion were used for isolation (Ordal and Rucker, 1944), but this seems not to be required, at least not in all cases, because similar results have been obtained with beef extract (Bernardet, 1989). However, sometimes, the fish pathogens grow very slowly at first and need an adaptation period before they can conveniently be handled (Ordal and Rucker, 194). This is not totally unusual, for it has been observed that a CLB that had been growing for a long time in a chemostat lost its ability to grow on plates, so that the plate count dropped to 20% of the viable cell count (Höfle, 1983). The medium used for isolation is, of course, not exclusive for pathogenic CLB, or CLB at all, and many kinds of saprophytic bacteria will grow on it as well. This may become a problem especially if the fish has already been dead for some time, because it is quickly colonized by putrefying organisms. A study of the drug resistance of a collection of *Cy. columnaris* strains revealed that the organism is resistant to a number of antibiotics (Fijan and Voorhees, 1969), and by the addition of neomycin (5 μg/ml) + polymyxin B (10 units/ml) to AO agar, the isolation yields could be improved (Fijan, 1969). The pathogenic CLB can be recognized on the plate by their yellow to orange colonies, which give a positive flexirubin reaction, and, in the case of *Cy. columnaris*, by a very typical, rhizoid-colony morphology. Spreading of the colonies is not always well pronounced, especially with *Cy. psychrophila*, but this organism can easily be recognized, because it does not grow at 30°C and, in contrast to environmental CLB, does not utilize sugars.

For isolating CLB pathogenic for marine fish AOW agar prepared with artificial seawater (= MAOW agar) or, for estuarine sources, with one-third-strength artificial seawater (= BAOW agar) is useful. Also, a richer medium, Marine Agar (Difco), which is a peptone (0.5%)-yeast extract (0.1%) agar (1.5%) in artificial seawater, has been used with good results (Hikida et al., 1979; Campbell and Buswell, 1982). In another case, the pathogen proved more fastidious and could only be isolated and cultivated on an agar medium containing 5% of an enzymatic digest of fish muscle in addition to peptone (0.1%) and yeast extract (0.1%) in seawater (Anderson and Conroy, 1969). In this case it was also shown that the organism depended on a high salt concentration and that a NaCl solution could not replace seawater. In fact, the fish—rainbow trout with severe lesions on the jaws and snout ("erroded mouth disease")—could be healed simply by transfer to fresh water. *Cy. columnaris*, on the other hand, is completely inhibited by 1% NaCl (Fijan and Voorhees, 1969; Pacha and Ordal, 1970).

The Genus *Capnocytophaga*. The capnocytophagas are normal inhabitants of the human oral cavity, where they can be found in tooth pockets and in the dental plaque. They may also occur in large numbers in periodontal disorders and infected lesions in the mouth. The genus was established by Leadbetter et al. 1979, but the organisms are very probably identical with the fast-gliding, anaerobic, slender rods discovered 20 years earlier during a study of fusospirilloses of the human oral cavity, which were described under the name *Sphaerocytophaga* (Gräf, 1961). In fact, they were known even before that time, but as *Bacteroides* species. Although the capnocytophagas have a strictly fermentative metabolism, they are not particularly sensitive to oxygen and grow both in the presence and in the absence of oxygen, provided an elevated level of CO_2 is supplied. The capnocytophagas are not fastidious at all and can easily be isolated and cultivated (Forlenza and Newman, 1983; Gräf, 1961; Leadbetter et al., 1979). Originally they were isolated on 10% sheep's blood agar. The samples were streaked onto the agar surface, and the cultures were incubated for 7 to 8 days at 37°C in Fortner plates, i.e., a co-culture with a facultative anaerobe. Spreading colonies were obtained, which showed a reddish hue and consisted of cells that were more or less yellow when scraped together (Gräf, 1961).

Leadbetter et al. 1979 recommended the following procedure: The sample material is quickly transferred to a screw-cap tube containing a modified Ringer's solution (NaCl, 0.9%; KCl, 0.042%; $CaCl_2 \cdot 2H_2$, 0.025%). Plaque material may be homogenized by a short burst of ultrasound (5 to 10 sec). Within 30 min after sampling, streaks are made on trypticase soy broth agar (TSB agar), which may be supplemented with 5% sheep's blood; the blood is, however, not essential. The cultures are incubated at 37°C in an atmosphere of $H_2 + CO_2 + N_2$ (GasPak, Baltimore Biological Laboratories = BBL). After 2 to 3 days, spreading colonies may be observed, but higher yields are obtained after 5 days (100% rather than 45%; Forlenza and Newman, 1983). There are three types of colonies—grey, pink, and yellow—but the cell masses of all three are yellow when scraped together. The shapes of the colonies depend critically on the ingredients used for preparing the medium: With stocks from other suppliers than BBL, nonspreading, small, compact colonies were obtained on the same type of medium (variations of this kind could, however, also be a result of using different batches of a medium component from the same supplier). The strains are purified by repeatedly streaking out material from swarm edges.

TSB Agar (Leadbetter et al., 1979)

Trypticase soy broth (BBL)	3%
Agar	3%

The pH is 7.3 (unadjusted). The medium is autoclaved.

Trypticase soy broth consists of:

Trypticase peptone	1.7%
Phytone peptone	0.3%
NaCl	0.5%
K_2HPO_4	0.25%
Glucose	0.25%

TSB agar may be supplemented with 5% sheep's blood (for TS-blood agar).

The capnocytophagas may also be first enriched by suspending sample material in trypticase soy broth without glucose in screw-cap tubes. After tightening the lids, the tubes are incubated at 37°C for 3 days. After that, large numbers of slender fusiform rods may be found in the liquid. Isolates are obtained by streaking the cell suspension on the media mentioned above.

It may be mentioned here that free-living CLB are also known that require CO_2 for fermentative growth on glucose—for example, the facultative anaerobe *Cy. succinicans* (Anderson and Ordal, 1961a, 1961b).

In addition to capnocytophagas, CLB that are not obligatory fermentative and that do not require CO_2 have also been found in dental plaque (London et al., 1982). The organisms could be isolated on blood agar media similar to those mentioned above, e.g., Columbia blood agar (BBL) or modified Schaedler agar with 5% defibrinated horse blood. The plates were incubated at 37°C in a GasPak atmosphere, but the bacteria can grow equally well in a normal atmosphere. The organisms were recognized by their spreading swarm colonies.

Purification

Purification of most members of the Cytophagales is relatively uncomplicated. It is usually sufficient to suspend, dilute, and plate samples from enrichment cultures by conventional methods. In some instances, e.g., with *Cy. columnaris*, the preparation of homogeneous suspensions may be difficult because the cells are embedded in a tenacious, sticky slime, but use of a small tissue homogenizer normally solves this problem. The plating medium should contain somewhat higher nutrient concentrations than the enrichment medium contains because high plating efficiency is desirable, and spreading growth is not required and should in fact be repressed. Some suitable media are CY agar, sometimes better with glucose (e.g., CYG2 agar); MYX agar; and, for marine strains, SAP2 agar. Often, pure strains are quickly obtained by repeatedly transferring material from the edges of spreading swarm colonies. These transfers should be made carefully, preferably by cutting out a little block of agar with the swarm edge using the sharp needle of a 1-ml disposable syringe. For this technique, media that favor gliding motility are, of course, preferable. The specific problems encountered with certain groups of the Cytophagales have already been discussed.

Cultivation

Most bacteria of the order Cytophagales can be cultivated on relatively simple media. VY/2 agar and CY agar have proved useful for all terrestrial and freshwater organisms except the cellulose decomposers. Cultures usually remain viable longer on VY/2 agar because growth is lighter and the pH is not changed as much as on CY agar. VY/2 agar is also useful for deciding whether an organism is a glider because it stimulates spreading growth. If heavier growth is desirable, CY agar may be enriched with glucose as, e.g., in CYG2 agar. Growth of some CLB is much stimulated by the presence of a carbohydrate. The cellulose decomposers grow very well on filter paper placed on CY agar. Other media suitable for their cultivation are listed above. If these gliding bacteria are cultivated on mineral

salts-glucose media (CA2 and CA13 agar) they often grow only if a heavy inoculum is applied.

VY/2 Agar

Bakers' yeast (by fresh weight of commercial yeast cake) 0.5%
$CaCl_2 \cdot 2H_2O$ 0.1%
Cyanocobalamin 0.5 µg/ml
Agar 1.5%

The cyanocobalamin is usually not required.

The pH is adjusted to 7.2. The medium is autoclaved. The yeast may be stored as an autoclaved stock suspension for several weeks. A uniform distribution of the yeast is obtained if the medium is melted before the yeast is added.

Many bacteria of the *Cytophaga* group produce heavy growth on HP6 agar, MYX agar, and similar media. Many will also grow well on mineral salts-glucose media like CA2 and CA13 agar. Special media that allow the detection of the ability of a strain to decompose certain macromolecules have already been mentioned. A medium useful for the demonstration of starch decomposition is STK2 agar.

HP6 Agar

Na glutamate	1%
Yeast extract (Difco)	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
Cyanocobalamin	0.5 µg/ml
Glucose (autoclaved separately)	0.5%
Agar	1.5%

The cyanocobalamin is usually not required.

The pH is adjusted to 7.2. The medium is autoclaved.

STK2 Agar

Base agar:

Casitone (Difco)	0.1%
Yeast extract (Difco)	0.05%
$MgSO_4 \cdot 7H_2O$	0.1%
Agar	1.2%

The pH is adjusted to 7.2. The medium is autoclaved.

Top agar:
As base agar, but agar concentration increased to 1.5%. The medium is prepared with only about 85% of the total water volume. In the remaining water are dissolved, referring to the total volume of the top agar, the following:

Soluble starch	0.2%
K_2HPO_4	0.02%

The starch solution should be heated on a water bath before autoclaving in order to prevent clumping of the starch. The two solutions are combined after autoclaving, and the mixture is poured as a thin layer on plates of the base agar. Starch degradation can be discovered if, after a suitable incubation time, the culture plates are flooded with an iodine solution, e.g., Lugol's solution diluted 1 : 5.

The fish pathogens can be cultivated on AO agar but usually also grow well on CY, MYX, and HP6 agar. Most strains do not utilize carbohydrates at all. The capnocytophagas grow on TSB agar with or without sheep's blood.

The same types of media can be used for the marine Cytophagales, only prepared with natural or artificial seawater instead of distilled water. No case is known in which the latter would not do, but a simple NaCl solution is often not suitable (e.g., Anderson and Conroy, 1969). The tolerated salinity range differs depending on the organism and often depends on the origin of the strain (e.g., Lewin and Lounsbery, 1969; Reichardt et al., 1983). Marine cellulose decomposers may be cultivated on filter paper placed, e.g., on SW5 agar. Alternatively, the mineral salts-glucose media as described for the terrestrial organisms may be used, when prepared with seawater.

The type of peptone added to a medium is not as crucial in the case of the Cytophagales as it is for myxobacteria; nevertheless, very different results may be obtained with different preparations and even with different batches. An example has already been given for the capnocytophagas. In our experience, enzymatic digests of casein, e.g., casitone (Difco) or peptone from casein (Marcor, Merck, and Oxoid), are the most universally useful peptones. Soy peptones also often give excellent results. Addition of yeast extract may stimulate growth appreciably. Again, not all preparations are equally satisfactory; good results are obtained, e.g., with Difco yeast extract. Further, it should be kept in mind that quite a few bacteria of this group grow on inorganic nitrogen sources, and it is always worthwhile to test an isolate for that possibility.

As a rule, members of the Cytophagales immediately produce homogeneous cell suspensions when inoculated into liquid media and shaken. Typically, the liquid shows a silky shimmer when rotated. Rarely, the bacteria grow in tiny granules or flakes, and then they probably always are surrounded by thick capsules or slime layers. The medium sometimes becomes more or less viscous, especially when sugars are included, and harvesting the cells by centrifugation may then make difficulties. In one such case, the addition of 10% $(NH_4)_2SO_4$ (w/v) resulted in satisfactory separation (Verma and Martin, 1967).

Most Cytophagales grow well in liquid media that contain peptone, e.g., CAS liquid medium or FXA liquid medium and, for marine organisms, SP5 liquid medium. Addition of a sugar, such as in FXAG liquid medium, may stimulate growth considerably and may even be a prerequisite for cultivation. Glucose, galactose, mannose, saccharose, and maltose are often readily utilized. The sugar has two effects: it is a convenient carbon and energy source, and it is partly transformed into acids that delay the rise of pH of the medium that results from ammonia production. Shifts of pH may cause problems in

shake cultures. Concentrations of buffers high enough to stabilize the pH reliably are often inhibitory to growth. With *Fx. filiformis* (former *Fx. elegans* Fx el), appreciable inhibition was observed at the following buffer concentrations (at a pH of about 7.0): citrate above 15 mM; phosphate, Tris HCl, and Tris-maleic acid-KOH above 20 mM; 3-morpholino-propane sulfonic acid (= MOPS) above 50 mM (E. Fautz, personal communication).

CAS Liquid Medium

Casitone (Difco)	1%
$MgSO_4 \cdot 7H_2O$	0.1%

The pH is 6.8 and needs no adjustment if Difco casitone is used. The medium is autoclaved.

FXA Liquid Medium

Casitone (Difco)	1%
Yeast extract (Difco)	0.2%
$MgSO_4 \cdot 7H_2O$	0.1%

Other similar, enzymatically digested, casein peptones may also be used, e.g., Peptone from casein, tryptically digested (Merck, Darmstadt, Germany).

The pH is adjusted to 7.0. After autoclaving, 0.2% of separately autoclaved glucose may be added, for FXAG liquid medium.

SP5 Liquid Medium

Casitone (Difco)	0.9%
Yeast extract (Difco)	0.1%

In artificial seawater.

The pH is adjusted to 7.2. The medium is autoclaved.

The fish pathogens can be cultivated in the same media mentioned for their isolation, e.g., AO broth (AO agar without agar) (e.g., Bernardet and Kerouault, 1989; Bullock, 1972; reference is not an exact match Pacha, 1968). A supplement to AO broth of 5% fish peptone, prepared from brook trout, has been recommended and gave superior results with some isolates, although it was not strictly required; it may sometimes be useful with fresh isolates (Kincheloe, 1962). For marine fish pathogens, AO broth in seawater or TCY liquid medium may be used (e.g., Hikida et al., 1979).

TCY Liquid Medium (Hikida et al., 1979)

Tryptone (Difco)	0.1%
Casamino acids, technical (Difco)	0.1%
Yeast extract (Difco)	0.02%
NaCl	3.13%
KCl	0.07%
$MgCl_2 \cdot 2H_2O$	1.08%
$CaCl_2 \cdot 2H_2O$	0.1%

In distilled water.

The pH is adjusted to 7.0 to 7.2. The medium is autoclaved.

One study showed that growth of *Cy. columnaris* can be substantially improved by a fine-tuning of the medium formulation (Song et al., 1988). The optimal medium was SO broth, which was a modification of a medium used by Shieh (1980), from which glucose, pyruvate, and citrate have been omitted, because these compounds had no effect on growth. The medium was much superior to tryptone-yeast extract and tryptone-yeast infusion broth. The generation time was reduced to 150 min compared to 210 min in the next-best medium.

SO Liquid Medium (Song et al., 1988)

Peptone	0.5%
Yeast extract	0.05%
Na acetate	0.001%
$BaCl_2 \cdot H_2O$	0.001%
K_2HPO_4	0.01%
KH_2PO_4	0.005%
$MgSO_4 \cdot 7H_2O$	0.03%
$NaHCO_3$	0.005%
$CaCl_2 \cdot 2H_2O$	6.7 mg/liter
$FeSO_4 \cdot 7H_2O$	1.0 mg/liter

The capnocytophagas are obligatory fermenters and grow luxuriantly in trypticase soy broth (TSB agar without agar) supplemented with 1% glucose; the cultures are incubated under the exclusion of oxygen (Forlenza et al., 1981).

Many Cytophagales can also be cultivated in simple synthetic media, e.g., SY liquid medium. Stabilization of the pH is especially difficult in this case and is effectively achieved only in bioreactors.

SY Liquid Medium

KH_2PO_4	0.07%
$Na_2HPO_4 \cdot 2H_2O$	0.14%
$(NH_4)_2SO_4$	0.2%
$MgSO_4 \cdot 7H_2O$	0.02%
$FeSO_4$	5 mg/l
$MnSO_4$	5 mg/l

After autoclaving, 1% glucose is added from a separately autoclaved stock solution.

Cellulose decomposers grow well in liquid media with powdered cellulose, e.g., in CEL1 liquid medium or in Dubos liquid medium with 0.5% cellulose. We use, with good success, a peptone-mineral salts medium with cellulose powder (= M9 liquid medium). Also, CAS liquid medium with cellulose powder (0.5%) often allows good growth. Further, many strains of cellulose degraders may be cultivated in glucose-containing liquid media such as GLU liquid medium (Kath, 1990; Verma and Martin, 1967).

CEL1 Liquid Medium

ST5 liquid medium is supplemented with 0.1% powdered cellulose (e.g., MN300 for chromatographic purposes from Macherey and Nagel, Düren, Germany), autoclaved separately as a stock suspension.

M9 Liquid Medium

Base medium:

NH_4Cl	0.1%
K_2HPO_4	0.075%
Casitone (Difco)	0.3%
Yeast extract (Difco)	0.09%

Supplement A:

$MgSO_4 \cdot 7H_2O$	4.5%

Supplement B:

$CaCl_2 \cdot 2H_2O$	0.2%
$FeCl_3 \cdot 6H_2O$	0.15%
$MnSO_4 \cdot H_2O$	0.15%

Supplement C:

Cellulose powder	10%

After autoclaving all solutions, 1% (v/v) of supplements A and B, 5% (v/v) of supplement C, and filter-sterilized standard trace elements (see, e.g., The Genus *Pelobacter* in this Volume) are added to the base medium.

GLU Liquid Medium (Kath, 1990)

The percentages indicated for each ingredient are with respect to the final volume of the medium.

Solution A:

NH_4Cl	0.1%
K_2HPO_4	0.075%
Casamino acids (Difco)	0.3%
Na-Fe^{III}-EDTA	0.002%
HEPES	1.19%

In 90% of the total volume.

The pH is adjusted to 7.2.

Solution B:

$MgSO_4 \cdot 7H_2O$	0.045%
$CaCl_2 \cdot 2H_2O$	0.01%
Glucose	0.5%

In 10% of the total volume.

After autoclaving, solutions A and B are combined, and standard trace elements are added from a filter-sterilized stock solution (see, e.g., The Genus *Pelobacter* in this Volume).

Most members of the Cytophagales can be grown without difficulties on a large scale in bioreactors. In ordinary batch cultures, typical yields obtained are between 10 and 15 g wet weight, or 2 and 4 g dry weight, per liter on peptone media with sugar; the ratio of dry to wet weight is 0.20 to 0.25. Generation times are in the range of one to several hours. Thus, e.g., *Fx. filiformis* Fx el grows in peptone media at 30°C with a doubling time of 2 h and 15 min; in mineral salts-glucose medium (SY liquid medium) it grows with a doubling time of 6 h and 20 min (H. Fink, personal communication). *Tx. ocellatus* grows at 30°C with generation times of 1 h and 50 min in peptone liquid medium, 2 h in dilute peptone medium, and 3 h and 30 min in casamino acids-glucose medium.

Little is known about specific mineral and vitamin requirements by members of the Cytophagales. At least, they appear not to be particularly fastidious in that respect. In a study on trace element effects on cellulose-degrading *Sporocytophaga* growing in a mineral salts-cellulose medium, a stimulation of cellulose decomposition by Ca^{2+}, Fe^{2+}, Mn^{2+}, and sometimes Cu^{2+} was demonstrated (Bortels, 1956). Certain Zn salts (ZnO, ZnS, 0.1%) were found to encourage growth of a series of cytophagas and CLB; $ZnSO_4$ (0.1%) suppressed swarming and slime production on plates, and its use in isolation media was suggested (Mehra et al., 1967). In a comparative study of a large number of different marine Cytophagales, a dependence on thiamine and cyanocobalamin was found in a few instances (Lewin and Lounsbery, 1969).

Except for the capnocytophagas, the Cytophagales are strict aerobes. Those that are known to grow anaerobically are usually facultative anaerobes. Some are able to respire on nitrate. Not one of the tested strains could use fumarate as an electron acceptor (Callies and Mannheim, 1978). Several Cytophagales require carbon dioxide for fermentative metabolism, so that care should be taken that enough CO_2 is present in the atmosphere when strains are being tested for anaerobic growth (GasPak, candle jar, Fortner plates, carbonate in the medium). The only strictly fermentative Cytophagales known so far are the capnocytophagas, which are, however, not oxygen sensitive but do require an increased level of CO_2; if that is provided, they can grow even under aerobic conditions (Leadbetter et al., 1979). They need CO_2 because they depend on the activity of phosphoenolpyruvate carboxykinase for growth (Kapke et al., 1980). There seem also to be *Capnocytophaga* strains that grow at CO_2 levels found in air. The existence of strictly anaerobic Cytophagales is not yet excluded.

All known Cytophagales are restricted to pH values between 6 and 8. Their temperature range is wide, from about 0°C to more than 40°C. On plates, most strains will grow more or less at 30°C. In contrast, liquid cultures of many strains, particularly those isolated from aquatic environments, grow only, or grow much better, at lower temperatures (usually between 18 and 26°C).

Preservation

Agar cultures of many Cytophagales stay viable for months when stored at low temperatures (2 to 8°C). At room temperature or higher, plate cultures can usually be kept for 2 to 6 weeks. In general, organisms from aquatic environments are more sensitive than those from soil. Media that are rich in peptone or contain higher concentrations of a sugar are always less suitable for

stock cultures, because they produce heavier growth and lead to unfavorable pH shifts. Good media for stock cultures are often VY/2, CYT, and SAP2 agar. For the fish pathogens, a reduction of the agar concentration in AO medium to 0.4% is advantageous. Cellulose decomposers are kept best on filter paper on top of CY or ST6 agar.

For long-term storage, essentially all standard methods for the preservation of bacteria can be applied to the Cytophagales. In our experience, the following methods give excellent results.

Drying in Skim Milk

From a young plate culture, a heavy cell suspension is prepared in about 0.7 ml of sterile skim milk. Three to five drops of this suspension are placed on a plug of skim milk predried by lyophilization in an ampule. The plug must not become solubilized but only wetted by the amount of added cell suspension. The loaded ampules are stored at 4 to 6°C until the whole set has been finished (not longer than one h) and are then dried in a desiccator over silica gel at a good vacuum for about 4 h at room temperature. The desiccator is kept overnight under vacuum, then pumped again for 15 min, and filled with nitrogen gas (preferably by attaching it to a nitrogen-filled balloon). Then the ampules are sealed and stored at room temperature or at 4 to 6°C (we do not yet know whether there is a difference in survival times). So far, organisms have been revived by us after up to 10 years of storage at room temperature. Successful lyophilization is also reported for *Cy. columnaris* (Anacker and Ordal, 1959). Lyophilized cultures of *Cy. columnaris* and *Cy. psychrophila* which had been kindly supplied to us by Dr. R.E. Pacha (Ellensburg, Washington) could be reactivated without problems after 26 and 20 years, respectively.

Skim Milk Preparation (for Preservation)

> 40 g of powdered skim milk (e.g., Oxoid L31; must be free of antibiotics) are dissolved in 200 ml water and filtered through gauze. The solution is distributed into tubes (5 ml per tube) or ampules (1 ml per 5-ml ampule) and autoclaved at exactly 115°C for 15 min. May be stored in the cold for several weeks.

Storage at Ultra-Low Temperatures

From a dense liquid culture, e.g., in FXA or CAS liquid medium, 2-ml amounts are pipetted into screw-cap tubes and placed directly into a deep freeze at –70 to –80°C. Samples of marine organisms, e.g., in SP5 liquid medium, should be kept in an inclined position during freezing to prevent cracking of the tubes. Cellulose decomposers have been successfully frozen in CEL1 liquid medium.

Alternatively, a heavy loopful of cells from a plate culture is deposited in 1 ml of a peptone-containing liquid medium, like the ones mentioned above, and frozen in the same way. The peptone medium can also be used for cellulose decomposers. Fish pathogens can be frozen at –70°C as agar cultures in AO agar with 0.9% agar; they were found to remain viable for at least one year (Fijan and Voorhees, 1969). Of course, all cultures for preservation should be young, well-growing cultures in an optimal state.

Alternatively, cell suspensions in peptone liquid media may be stored frozen in liquid nitrogen. A special freezing program is not required. We routinely add 5% dimethyl sulfoxide (DMSO) to the suspension medium, although our experience suggests that this is not necessary. In a systematic study on cryopreservation of Cytophagales, mainly marine ones, good survival in liquid nitrogen was demonstrated when the cells were suspended in a medium containing 10% glycerol, while 10% DMSO proved less suitable. Also without additives, at least one cycle of freezing and thawing was usually well tolerated. Many strains remained viable even for some weeks at –22°C without additives, but eventually, after varying storage times, most strains died (Sanfilippo and Lewin, 1970).

For revival, the frozen tube or ampule is quickly thawed, best by placing it into cold water. Immediately after the medium has become liquid, the bacteria are transferred to a suitable growth medium. For reviving a culture, it is advisable to use several different agar and liquid media in parallel, because one or the other may be more appropriate depending on the organism. Also, we found that facultative anaerobes are occasionally better reactivated under anaerobic conditions; they sometimes refuse to start to grow in an aerobic atmosphere, even when they thrive ordinarily very well under such conditions. Thus far we have tested survival at –80°C for up to 15 years and in liquid nitrogen for up to 10 years and have not yet observed any losses.

Storage in 50% Glycerol at –25°C

Using a young plate culture, a heavy cell suspension is prepared in 50 mM phosphate buffer, pH 7.2. Of this suspension, 1 ml is transferred to a screw-cap tube that contains 2 ml of 87% glycerol precooled to –25°C. The suspension is thoroughly mixed and stored at –25°C in an ordinary household deep freeze. Marine organisms may be suspended in SP5 liquid medium; 1 ml of the suspension is then transferred to 2 ml of precooled 87% glycerol. Alternatively, a heavy

loopful of cells is suspended directly in precooled SP5 liquid medium + 87% glycerol (1:2, vol/vol).

To start an active culture, a loopful of the suspension is streaked on a suitable agar medium. The remaining suspension may be returned to the deep freeze, provided the temperature was kept low during handling. CLB preserved by this method may survive for at least several years (I. Hirsch, personal communication), but we have in some cases observed losses, particularly with marine strains, so this technique is advisable for long-term storage, especially when better alternatives are available.

Storage in 0.9% Saline or in Distilled Water

Starting from young plate cultures, cell suspensions are prepared in 0.9% saline or in distilled water. The cell density should not be very high; we usually prepare a suspension of about 10^7 to 10^8 cells/ml (a suspension just faintly turbid), and this stock suspension is then diluted fivefold. Then, 0.5-ml amounts of both suspensions are transferred in parallel to 1-ml ampules, which are sealed under air and stored at room temperature (18 to 22°C) in the dark. Marine organisms may be suspended in artificial seawater. In our laboratory, a number of *Flexibacter* and CLB strains stored in saline for 7 years could be reactivated with ease and produced heavy growth within 2 days; it is likely that they would have survived for even longer periods. However, the organisms probably are not completely at rest in such suspensions and continue to grow, even if extremely slowly, so that over a long period variant strains may arise.

Characterization

Cell Morphology and Cytology

The cells of all Cytophagales without exception are rod-shaped (Fig. 1 and 2). The proportions and dimensions of the rods vary, however, over a wide range. The CLB have very short to moderately long rod cells; the short ones are often relatively fat, and the longer ones may be rather slender; they typically measure 0.5 to 1.0 × 2 to 8 μm; the cell ends are usually slightly tapered. The cells of *Capnocytophaga* resemble those of CLB with moderately long rods. *Taxeobacter* has relatively plump cylindrical rods with rounded ends. The rod cells of the cellulose decomposers (*Sporocytophaga*, *Cytophaga*) tend to be moderately long and very delicate, measuring 0.3 to 0.7 × 3 to 8 μm; *Cytophaga* cells are often spindle-shaped. *Flexibacter* and (*Microscilla*) have long thread cells which contain either very few or no cross-walls and typically measure 0.4 to 0.8 × 10 to 50 μm. Many species readily form spheroplasts. Especially in cultures of cellulose-decomposing true cytophagas, large numbers of lemon-shaped intermediary forms can often be seen (Fig. 1f). This was a source of much confusion for the early investigators (who had no phase contrast microscopes), and fancy developmental cycles have been constructed on such observations (for a review, see Imschenezki, 1959). Inflated, spindle-shaped rods may still be motile and viable and may recover, but it is doubtful whether such stages are of any advantage for the organism, e.g., for a rearrangement of the genetic apparatus, as has been suggested. Lemon-shaped degeneration forms are also typical for *Taxeobacter.* Under starvation, a *Cy. johnsonae* strain was observed to produce coccoid cells which looked like spheroplasts, did not show a peptidoglycan layer, often had lost most of their cytoplasm, and were osmotically stable (Reichardt and Morita 1982). Nevertheless, they were found to be viable, and at least some of them could grow out again into rods. It was suggested that they represent survival forms. Spheroplastlike cells have also been interpreted as resting stages in several other Cytophagales (e.g., Gräf, 1961, 1962; Bauer, 1962), and generic names have even been proposed based on such observations ("*Sphaerocytophaga,*" "*Sphaeromyxa*"). But the evidence for a function as resting forms is not convincing in any of those cases.

Several Cytophagales change their cell morphology in response to environmental conditions. Marine *Flexithrix dorotheae* is described to grow quasi-mycelially with long, sheathed filaments that release short, gliding fragments, which may again grow into filaments (Lewin, 1970). Unfortunately, the type strain, which is the only known strain of that organism, does not show this behavior any more; at least I have not been able to verify it in spite of many efforts.

The vegetative cells of *Sporocytophaga* may convert by shortening and fattening into small (diameter 1.2 to 1.4 μm), spherical, optically refractile microcysts. The microcysts are desiccation resistant; we have isolated strains from dry soil samples that had been stored for up to 9 years at room temperature. Their high heat tolerance, which allows them to survive at 60°C, in some cases even at 100°C for a short time, has already been mentioned.

Fx. filiformis (Fx el) and related species go through a spectacular shape change in the course of culture development (Fig. 2c to 2e). When inoculated into a liquid medium, e.g., CAS or MD1 liquid medium, the organism grows into long (15 to 50 μm and more), slender, flexible cells. These cells are not the usual filaments or

trichomes, for they contain no cross-walls or septa, or only very few widely separated ones (10 to 30 μm); I therefore call them thread cells. The thread cells are extremely agile and can glide, bend, twist, and wriggle like little worms. When the culture ages, the cells become shorter and shorter and may finally end up as very short coccobacilli (this stage is not always reached). The shorter rods also become slightly fatter and darker, which clearly indicates that the shortening is not simply a fragmentation of the thread cells. Under certain conditions the organism may grow exclusively in the long or in the short form. One factor that determines the length of the cells is obviously population-density connected. The same cycle can also be observed in plate cultures, e.g., on VY/2 agar, on which fast-spreading swarms are produced. Here, agile thread cells are found at the edge, while shorter and shorter rods are found moving towards the center of the colony. Below a certain length, the rods become nonmotile. The same developmental cycle has been described for *Chitinophaga*, only there the coccobacilli were interpreted as microcysts (Sangkhobol and Skerman, 1981); this appears, however, not to be correct. A study on the length control of *Flexibacter* strain FS-1 revealed that the long thread cells grew exponentially with a generation time of 90 min at 30°C. When the culture was shifted to 35°C they divided into three or four cells within the following 120 min. The culture continued to grow exponentially with about the same growth rate, but with shorter cells. When the culture was shifted back to 30°C, the shorter cells stopped dividing immediately but continued to grow, and the thread cells reappeared. When the thread cells divided, the constriction always occurred in the middle of the cell. The biochemical and genetic mechanisms that control all these fascinating morphogenetic processes are not at all understood and have not been thoroughly studied. In particular, *Fx. filiformis* should provide a beautiful model system for such investigations (Humphrey and Marshall, 1980; Poos et al., 1972; Reichenbach et al., 1974; Simon and White, 1971).

The fine structure of the cells of the Cytophagales is essentially that of typical Gram-negative bacteria, with a few remarkable peculiarities. The outer surface of the cells is usually corrugated or undulated and densely covered with cushionlike knobs and folds (e.g., Bovallius, 1979; Follett and Webley, 1965; Humphrey et al., 1979; Oyaizu et al., 1982; Strohl, 1979; van der Meulen et al., 1974). Often, vesicular and long, uneven, tubular extensions of the outer membrane and LPS can be seen (e.g., Follett and Webley, 1965; Holt et al., 1979a; Kuhrt and Pate, 1973; London et al., 1982; Martin et al., 1968; Pate and Ordal, 1967a; Pate et al., 1967; Simon and White, 1971). These strands may become as long as 0.5 μm and have been shown to contain LPS components, like 2-keto-3-deoxyoctonate (Humphrey et al., 1979). All Cytophagales excrete slime, sometimes in substantial quantities, and this slime can usually be distinguished as a dense network of fine fibril surrounding the cells (e.g., Bovallius, 1979; Humphrey et al., 1969; Martin et al., 1969; Pate and Ordal, 1967b; Ridgway and Lewin, 1973; Ridgway et al, 1975; Strohl and Tait, 1978; Verma and Martin, 1967). The microcysts of *Sp. myxococcoides* are encased in a massive, fibrillar capsule, about 180 nm thick (Holt and Leadbetter, 1967; the diameter of the microcysts as determined in this study was an astonishing 2 to 2.5 μm, which is much greater than is usually measured in the light microscope [1.2 to 1.4 μm]).

The cell envelope of the Cytophagales consists of a thin peptidoglycan layer and the usual outer membrane. In marine, filamentous *Fx. polymorphus* (clearly different from *Flexibacter* as defined here and of uncertain taxonomic position), an unusual S-layer was discovered on top of the outer membrane (Ridgway, 1977; Ridgway and Lewin, 1973, 1983; Ridgway et al., 1975). The layer consists of densely packed, goblet-shaped subunits, which have a complicated structure and are perhaps rooted in the cytoplasmic membrane. Another very interesting structural detail has been detected in the cell envelope of certain CLB (Pate and Chang, 1979). Here, tiny rings were seen and could be isolated from cell lysates. The rings were about 20 nm wide and 10 nm thick and were arranged in long chains that seem to form a large, regular, netlike superstructure. It was hypothesized that these rings might be homologous with the flagellar rotors and that their rotation would somehow propel the cell. It may be added here that the mechanism of gliding motility has been studied for many years with several Cytophagales, but so far without a clear answer (e.g., Burchard, 1984; Chang et al., 1984; Duxbury et al., 1980; Glaser and Pate, 1973; Godwin et al., 1989; Lapidus and Berg, 1982; Pate, 1985; Speyer, 1953; Wolkin and Pate, 1984). What can be said is that there is some motility apparatus in the cell surface, because latex beads move along the surface of immobilized cells (Lapidus and Berg, 1982); that the excreted slime is essential for gliding because it acts as a Stefan adhesive allowing easy translocation but preventing efficient detachment of the cells from the substrate (Humphrey et al., 1979); that the cells rotate around their long axis during gliding (Godwin et al., 1989); and that the energy for gliding may not be provided by ATP, at least not exclusively (Pate and Chang, 1979; Ridgway, 1977). The speed of gliding may be on the order of 100 to 150 μm/min, with large deviations in

both directions, depending both on the organism and on environmental conditions (e.g., Duxbury et al., 1980; Garnjobst, 1945; Lapidus and Berg, 1982; Speyer, 1953; Stanier, 1942).

Fine longitudinal fibrils, which were arranged in wide bands just below the outer membrane, have been discovered in *Cy. columnaris* (Pate and Ordal, 1967b). They were suggested to represent the machinery of gliding motility. The fibrils could indeed not be seen in nonmotile mutants (Glaser and Pate, 1973). In freeze-etched preparations, tiny beads of about the same diameter as the fibrils can be seen on the inner surface of the outer membrane (Burchard and Brown, 1973). When the cells are fixed with glutaraldehyde before being fractured, those beads arrange themselves in long lines which resemble fibrils. Thus it seems possible that the fibrils seen in ultrathin sections are merely fixation artifacts.

Lysing cells of *Cy. columnaris* release unusual tubular structures that appear to derive by invagination from the cytoplasmic and mesosomal membranes (Pate et al., 1967). They are composed of lipid and protein, although the number of protein bands is much reduced in comparison with the cytoplasmic membrane (Kuhrt and Pate, 1973). Similar tubules are also known from other Gram-negative bacteria including *Sporocytophaga* (e.g., Holt and Leadbetter, 1967; Martin et al., 1968; Yamamoto, 1967); they are not identical with rhapidosomes as has occasionally been suggested. The latter were originally observed in *Saprospira* (see The Order Cytophagales in this Volume for a detailed discussion); they were later found also in other bacteria, e.g., *Sp. myxococcoides* (Pate et al., 1967), and may be phage tails.

The cells of the Cytophagales divide in the usual way by formation of a septum, which is normally connected with a mesosome (e.g., Holt and Leadbetter, 1967; Poos et al., 1972; Ridgway et al., 1975).

Appendages like fimbriae and pili seem never to have been observed with Cytophagales. Pili were, however, isolated from *Fv. branchiophilum*, where they supposedly are important for the attachment of this fish pathogen to gill filaments (Heo et al., 1990).

In several *Capnocytophaga* strains, acid and alkaline phosphatases could be localized by cytochemical and immunochemical reactions in the periplasmic space; in fact the enzymes were associated with the outer membrane, probably the LPS, and about 12% of the activity was exposed on the outer cell surface. Most of the enzyme molecules were released from the cells when the cultures became older, a good part of them in a membrane-bound form (reference is not an exact match Poirer and Holt, 1983b, reference is not an exact match 1983c). While the bacteria normally cannot penetrate the periodontal tissue it seems conceivable that enzymes like the phosphatases may do so and thus are responsible for damage inflicted to the host by *Capnocytophaga*.

Chemical Composition

The peptidoglycan appears as a clearly distinguishable layer in ultrathin sections of all Cytophagales studied in this respect; it is between 2 and 5 nm thick, but increases to 9 nm in *Sporocytophaga* microcysts (e.g., Pate and Ordal, 1967a; reference is not an exact match Verma and Martin, 1967a). The murein sacculus has been isolated from *Cy. hutchinsonii* and *Sp. myxococcoides* and chemically analyzed (Verma, 1970; Verma and Martin, 1967a, 1967b). It had the composition of a typical Gram-negative peptidoglycan with L-Ala, D-Glu, *m*-DAP, D-Ala, and 70% direct cross-linking between *m*-DAP and D-Ala. Diaminopimelic acid (0.2 to 0.3% of the dry weight) was also observed in an early study on two flexibacters; the diamino acid came most probably from the cell wall (Holm-Hansen et al., 1965). The same organisms appear also to contain bound ornithine (0.08 to 0.7% of the dry weight); the origin of that amino acid is obscure (Holm-Hansen and Lewin, 1965; it could come from an ornithine-containing lipid, see below). Also, the lipopolysaccharide (LPS) of the Cytophagales seems to closely resemble that of the enterobacteria. The LPS of *Fx. filiformis* Fx el (= Fx $^{1}/_{2}$) was found to contain mannose, galactose, glucose, rhamnose, ribose, glucosamine, galactosamine, and small quantities of xylose, arabinose, 2-keto-3-deoxyoctonate (KDO), and heptose (Rosenfelder et al., 1974). From 17 strains of CLB and one strain each of *Cy. aurantiaca* and *Sp. myxococcoides*, the LPS was extracted with phenol, and its sugar composition was subsequently analyzed (Sutherland and Smith, 1973). LPS yields were between 0.4 and 3.4% of the dry weight (in addition, substantial amounts of polysaccharide could be harvested from the culture supernatant by ultracentrifugation). The LPS of all strains contained a high proportion of ribose (in the absence of an appreciable ultraviolet [UV] absorption at 260 nm), mannose, and glucosamine; further, most LPS preparations yielded glucose, galactose, and galactosamine, and 7 out of 19 also rhamnose. The hexosamines remained after removal of lipid A by mild hydrolysis. Because of analytical problems, KDO and heptose could not be determined reliably; but KDO always appeared to be present, whereas heptose remained questionable and was

there in very small amounts, if at all. The LPS of *Flexibacter* BH3 contained galactose, glucose, arabinose, rhamnose, glucosamine, deoxysugar, and KDO, but heptose could not be detected (Humphrey et al., 1979). An endotoxin, which was highly active immunologically as well as in the *Limulus* test, was isolated from a CLB; its main carbohydrate constituents (above 0.5% of the total) were rhamnose, fucose, mannose, galactose, glucose, glucosamine, galactosamine, and an astonishing 34% of (tentatively identified) heptose; KDO is not mentioned (Flaherty et al., 1984). The inner and outer membrane of *Cy. johnsonae* were separated and showed densities of 1.18 and 1.14 g/cm^3, respectively; the outer membrane contained the sulfonolipids that will be discussed later, but little or no KDO (Godchaux and Leadbetter, 1988). Occasionally, members of the Cytophagales produce copious amounts of extracellular slime. In the case of *Cy. hutchinsonii* and *Sp. myxococcoides*, that slime was found to be an acidic heteropolysaccharide consisting of xylose, arabinose, mannose, glucose, and glucuronic acid; the slime of *Sporocytophaga* also contains galactose (Martin et al., 1968; Verma and Martin, 1967b). This slime seems to be broken down enzymatically in the later stages of the culture. *Flexibacter* BH3 produces an extracellular, water-soluble, glycoprotein slime with glucose, fucose, galactose, and some uronic acid in the carbohydrate part (Humphrey et al., 1979). The extracellular slime of *Cy. columnaris* was determined to consist of a homopolymer of α-(1-4)-linked D-galactosamine (Johnson and Chilton, 1966).

The fatty acid patterns of the Cytophagales consistently show two peculiarities (Collins et al., 1982; Fautz et al., 1979; Godchaux and Leadbetter, 1984; Kath, 1990; Liebert et al., 1984; Oyaizu and Komagata, 1981; Walker, 1969):

1. The dominant species are branched fatty acids, mainly 15:0 (15 to 45% of the total; in *Capnocytophaga* up to 77%; Collins et al., 1982). Branching is mostly of the iso type, but small amounts of anteiso fatty acids are usually also present. Only *Cy. hutchinsonii* contains larger quantities of anteiso fatty acids, almost exclusively 17:0 (26% of the total), but as the identification was tentative, this should be reinvestigated (Walker, 1969). It was also stated that *Capnocytophaga* and *Sporocytophaga* exclusively contain anteiso fatty acids (Holt et al., 1979a), but at least for *Capnocytophaga* this could not be corroborated (Collins et al., 1982). In one study, 1 to 3% of the total fatty acids from CLB have been identified with (delta 17)-cyclopropane fatty acids (Oyaizu and Komagata, 1981). Other major fatty acids are straight chain 16:1, 16:0, and 15:0, usually in that order. The double bond has been found to be in the *cis* configuration and in the C-11 to C-12 position (Kath, 1990; Oyaizu et al., 1982; Walker, 1969).

2. There are always substantial quantities (15 to 55% of the total fatty acids) of 2- and 3-hydroxy fatty acids (Collins et al., 1982; Fautz et al., 1979, 1981; Kath, 1990; Liebert et al., 1984; Oyaizu and Komagata, 1981; Oyaizu et al., 1982). In *Capnocytophaga*, only 3-hydroxy fatty acids could be identified (Collins et al., 1982). Only a small part of these hydroxy fatty acids seem to rise from LPS, where, in addition, exclusively 3-hydroxy fatty acids are found (Rosenfelder et al., 1974).

Most of them rather appear to have their origin in novel sulfonolipids, the capnoids, which were originally discovered in *Capnocytophaga* but have since been isolated from many other Cytophagales and may indeed be a chemosystematic marker for that group (Godchaux and Leadbetter, 1980, 1983, 1984). The capnoids are essentially sulfonated sphingolipids, in which the hydroxyl on C-1 of the sphinganine base, capnine, is replaced by a sulfonic acid group. Free capnine was found only in *Capnocytophaga*; normally the amino group on C-2 bears an amide-bonded, long-chain, fatty acid as in true ceramides. The sulfonilipids may comprise as much as 20% of the cell's total lipids and are localized in the outer membrane (Godchaux and Leadbetter, 1988). It appears that there is a connection between sulfonolipids and gliding motility, for capnoid-negative mutants of *Cy. johnsonae* are no longer able to glide, but gliding may recover when sulfonolipid synthesis is restored (Abbanat et al., 1986). The biosynthesis of the capnines is presumably due to the reaction of cysteine or, more likely, of cysteic acid with a matching fatty acyl-CoA compound (Abbanat et al., 1985; White, 1984).

The fatty acid pattern of marine *Fx. polymorphus* is unique among the Cytophagales in that it consists of relatively low amounts of (mainly iso-) branched species and large quantities of polyunsaturated fatty acids, viz. 18% 20:5 (Johns and Perry, 1977). This, together with the ultrastructural details discussed above, suggests that this organism may not be correctly classified among the Cytophagales.

It is interesting to note that very similar lipid patterns to those just discussed have been demonstrated in nonmotile but phylogenetically related flavobacteria, i.e., a high proportion of branched and of 2- and 3-hydroxy fatty acids (e.g., Dees et al., 1979; Fautz et al., 1981; Moss and Dees, 1978; Oyaizu and Komagata, 1981; Yabuuchi et al., 1983; Yano et al., 1976) and the occurrence of capnoids (Godchaux and

Leadbetter, 1983) and typical sphingophospholipids and ceramides (e.g., Asselineau and Pichinoty, 1983; Yabuuchi et al., 1983; Yano et al., 1983).

The complex lipids of the Cytophagales are still incompletely known. In all organisms that have been investigated (*Capnocytophaga*, *Cy. hutchinsonii*, *Sp. myxococcoides*) phosphatidylethanolamine was by far the major phospholipid (Collins et al., 1982; Holt et al., 1979c; Iizuka et al., 1987; Walker, 1969). The phospholipid content of the capnocytophagas was between 30 and 36% of the total cellular lipids when estimated as acetone-soluble lipid. The organisms also contained an ornithine lipid, some phosphatidylserine, substantial amounts of a polyprenol, and 5% squalene; two laboratories report the absence of phosphatidylglycerol (Collins et al., 1982; Holt et al. 1979a) while in a third laboratory (Iizuka et al., 1987), this compound was detected along with phosphatidylinositol and cardiolipin. In *Cy. hutchinsonii*, 45% of the dominating 16:1 fatty acid was recovered from phosphatidylethanolamine; no other phospholipid could be demonstrated in this organism, but it contained substantial quantities of two unidentified glycolipids (Walker, 1969).

The respiratory quinones of the Cytophagales are exclusively menaquinones (Callies and Mannheim, 1978; Collins et al., 1982; Kleinig et al., 1974; Oyaizu and Komagata, 1981). Different species contain either MK-6 or MK-7, and the distribution of the two types may be of taxonomic significance. Thus, all cellulose decomposers contain MK-7 and differ in that respect neatly from most terrestrial CLB, which are presently classified with them in the same genus but contain MK-6 (M.D. Collins, personal communication). The respiratory quinone of *Capnocytophaga* is MK-6 with traces of MK-5 (Collins et al., 1982), and that of *Flexibacter* is MK-7 (Kleinig et al., 1974). Again, the true flavobacteria are also menaquinone organisms (Callies and Mannheim, 1978; Oyaizu and Komagata, 1981).

Most Cytophagales synthesize pigments. Apart from an occasional strain that produces a dark, diffusing, probably melaninlike substance (e.g., "*Cy. krzemieniewskae*": Stanier, 1941; *Fv.* (*Cy.*) *uliginosum*: ZoBell and Upham, 1944), the pigments are always cell-bound. Chemically they are of two kinds, either carotenoids or flexirubin-type pigments. The two pigment types may occur in the same organism but then are typically localized in different places: the carotenoids in the cytoplasmic and the flexirubins in the outer membrane (Irschik and Reichenbach, 1978).

It had been suggested for many years that the yellow and orange pigments that can be extracted from many Cytophagales might be carotenoids (e.g., Anderson and Ordal, 1961a; Fox and Lewin, 1963; Lewin and Lounsbery, 1969; Verma and Martin, 1967a). Unequivocal proof of zeaxanthin (4,4′-dihydroxy-β,β-carotene) could be provided for the yellow pigment of marine *Ft. dorotheae* (Aasen and Liaaen-Jensen, 1966c); the same pigment was demonstrated by chromatographic comparison in marine *Cy. lytica* (Lewin and Lounsbery, 1969), and it was later chemically identified also in a terrestrial CLB (*Cy. johnsonae*: Achenbach et al., 1978b). Two monocyclic ketocarotenoids, flexixanthin and deoxyflexixanthin, have been isolated from a flexibacter (probably *Fx. roseolus*: Lewin and Lounsbery, 1969); their chemical structures have been elucidated (Aasen and Liaaen-Jensen, 1966b). *Cy. diffluens* appears to contain the monocyclic dihydroxy carotenoid saproxanthin (Lewin and Lounsbery, 1969), which was originally isolated from *Saprospira grandis* and identified by chemical methods (Aasen and Liaaen Jensen, 1966a).

A novel pigment type, the flexirubins, which later turned out to be of considerable chemosystematic relevance, has been discovered in *Fx. filiformis* (formerly *Fx. elegans* Fx el: Achenbach et al., 1974, 1976; Reichenbach et al., 1974). The chromophore is an omega-phenyloctaenic acid which is connected via an ester bond to a resorcinol bearing two hydrocarbon chains (Fig. 4). This basic chemical structure may be modified by variation of the length and branching of the hydrocarbon chains on the resorcinol and by the introduction of additional substituents on the omega-phenyl ring, specifically methyl and chlorine; actually, for all pigment species, chlorinated counterparts are found in every flexirubin-producing organism (for reviews of their chemistry and biosynthesis, see: Achenbach, 1987; Achenbach et al., 1978). In this way, a large variety of different flexirubin-type pigments arise, and one single strain may synthesize more than 25 different compounds (Achenbach et al., 1979). Still, certain structural types seem to be characteristic for certain taxa, e.g., a methyl in the *meta* position on the omega-phenyl ring seems to occur only in *Flexibacter*. Biosynthetically, the omega-phenyl ring with the first three carbon atoms of the chain derives from tyrosine, the rest of the chain from acetate, and the resorcinol ring with its hydrocarbon substituents derives from acetate and various starter molecules, like propionate or isovalerate, via an orsellinic acid homologue; only the methyl on the omega-phenyl comes from methionine; the linking of the two halves of the molecule is the last biosynthetic step (Achenbach et al., 1972, 1982, 1983). A total synthesis of flexirubin has also been performed (Achenbach and Witzke, 1977). Flexirubin-type pigments have been found so far only in the Cytophagales and in the

true flavobacteria (Achenbach et al., 1981; Reichenbach et al., 1981; Weeks, 1981). However, not all Cytophagales contain flexirubin-type pigments, and even closely related species, and perhaps even strains of the same species, may differ in that respect. Still, the presence of these pigments in a strain appears to be a reliable criterion that the isolate belongs to the Cytophagales and flavobacteria. The existence of flexirubin-type pigments in a strain can be demonstrated in three ways: 1) As already mentioned, the colonies show a reversible color shift when covered with a 20% KOH solution (see color plate I in *The Prokaryotes*, 1st edition). 2) This preliminary test can be confirmed by a simple thin-layer chromatography of an acetone extract of the bacteria, with an extract of a known flexirubin-producer as a reference; this test can be made even more reliable by recording the absorption spectra of the eluted spots and by performing the alkali reaction in the cuvette (Reichenbach et al., 1974). 3) Finally, as the only other bacterial pigments that give a similar color reaction appear to be aromatic carotenoids (Kohl et al., 1983), the pigments may be specifically labeled by feeding radioactive tyrosine (flexirubins) or mevalonic acid (carotenoids); the result is analyzed by autoradiography of the chromatograms (Fautz and Reichenbach, 1980). Incidentally, the color reaction of cellulose-decomposing cytophagas or sporocytophagas with alkali was already observed long ago, although its meaning was not understood at the time (Fåhraeus, 1947; Walker and Warren, 1938).

Occasionally, strains of CLB with a thin, film-like growth show a striking greenish-reddish iridescence (see color plate I in *The Prokaryotes*, 1st edition). This is probably a physical color due to interference effects. Also, it has been suggested that the greenish color that is sometimes observed in cultures of Cytophagales may arise from the combination of a yellow cell mass and dark melaninlike pigments (Lewin and Lounsbery, 1969).

Pigment production by Cytophagales may be influenced by environmental conditions. Thus, *Cy. succinicans* is colorless when grown anaerobically, but yellow-orange under aerobic conditions (Anderson and Ordal, 1961a). Illumination may stimulate carotenoid synthesis; but the synthesis of the flexirubins is light-independent. In the latter case, however, the specific pigment content of the cells varied substantially with some other culture parameters; in particular, a high phosphate content and a low pH appear to reduce pigment synthesis (Reichenbach et al., 1974).

Little else is known about the chemical composition of the Cytophagales. The amino acid composition of the protein of a cellulose-decomposing cytophaga was analyzed and found to be rich in nutritionally valuable, essential amino acids (Chang and Thayer, 1975). The GC content of the DNA of the Cytophagales varies over a wide range from 28 to 65 mol% (e.g., Behrens, 1978; Kath, 1990; Mandel and Leadbetter, 1965; Mandel and Lewin, 1969; Oyaizu and Komagata, 1981). The base sequences of large chunks of the 16S rRNA of a series of *Cytophaga*, *Sporocytophaga*, and CLB strains have been determined (Kath, 1990). An unusual multicopy, single-stranded DNA-RNA species (msDNA) discovered in myxobacteria (see The Genus *Pelobacter* in this Volume) was also found in *Fx. filiformis* (= *Fx. elegans* Fx el), but it was ruled out for *Cy. johnsonae* and *Tx. ocellatus* (Dhundale et al., 1985); it should be interesting to reinvestigate the isolated occurrence of msDNA in *Flexibacter* with the inclusion of other strains.

Phages and Bacteriocins

Phages have been reported for several CLB and appear not to be difficult to obtain (Anacker and Ordal, 1955; Kingsbury and Ordal, 1966; Pate et al., 1979; Richter and Pate, 1988; Stürzenhofecker, 1966; Valentine and Chapman, 1966). There is considerable morphological variability. Most of the phages bear a tail, which usually seems to be contractile. However, two temperate phages have been isolated from *Cy. johnsonae* strains that appear to have no tails; these phages also were sensitive to chloroform, and their plaque formation was inhibited by agar (Richter and Pate, 1988). In all cases that have been investigated, the phages contained double-stranded DNA. A phage of *Cy. columnaris* could not be propagated in the presence of streptomycin (70 μg/ml), probably because the antibiotic prevented the injection of the phage DNA into the host, which for its part was resistant to streptomycin (Kingsbury and Ordal, 1966). Much higher phage yields were often observed when $CaCl_2$ (1 to 4 mM) was present during infection. Interestingly, nonmotile mutants of *Cy. johnsonae* were completely resistant to all phages tested on them (Pate et al., 1988; Wolkin and Pate, 1986).

A bacteriocinlike activity was discovered in a strain of *Sp. myxococcoides* (Tchan and Giuntini, 1950). The strain inhibited other *Sp. myxococcoides* strains, but not *Cy. aurantiaca*; the activity could not be propagated, and no phage particles could be demonstrated under the electron microscope. Bacteriocin activity was found in many strains of the fish pathogen *Cy. columnaris* (Anacker and Ordal, 1959b). The target specificity of the bacteriocins produced by different *Cy. columnaris* strains varied, so that with the aid of seven selected bacteriocin preparations, 134 strains could be grouped into nine sensitivity

classes. No connection could be seen between a certain bacteriocin class and its distribution in nature. The same results were observed for serological classes of *Cy. columnaris* (Anacker and Ordal, 1959a). Bacteriocin activities were recorded in 20 out of 30 tested strains of *Cy. johnsonae* (Richter and Pate, 1988). The activities were destroyed by protease treatment and acted bactericidally on sensitive strains. With respect to their specificity, two types could be distinguished: 1) bacteriocins that acted on motile and nonmotile strains and 2) ones that, like the phages discussed above, attacked only motile strains. With the latter, nonmotile mutants could be selected.

The occurrence in various members of the Cytophagales of rhapidosomes, which appear to be tails of defective phages, has already been mentioned.

Colony Morphology

The colonies of the Cytophagales typically are spreading swarms (Fig. 3). Spreading growth depends, however, on several environmental factors, so that organisms that are well able to move by gliding still may not produce swarms (e.g., Chang et al., 1984; Perry, 1973; Wolkin and Pate, 1984). Thus, e.g., 70% of yellow bacteria isolated from sewage plants showed gliding motility under the microscope, but only 25% also formed spreading colonies (Güde, 1980). It has been found in many cases that low nutrient concentrations favor swarming (e.g., Agbo and Moss, 1979; Bauer, 1962; Garnjobst, 1945; Wolkin and Pate, 1984). Therefore, if spreading is to be observed, agar media with a low peptone content (0.1% or less) should be used; also, VY/2 agar stimulates swarming in many cases. Other factors that may influence the spreading behavior are the kind of nutrients supplied, temperature, and humidity. No general rules can be given; however, often a relatively low temperature and a high humidity favor spreading.

The morphology of the swarm colonies varies very much, as is to be expected with such a large assembly of widely differing organisms. Often the swarms are almost unstructured, thin sheets; sometimes their surface is covered with flat mounds, tiny warts, or veins or it appears fibrous and feltlike; or the swarms form a network which may become confluent towards the center of the colony. While the swarm sheet is always somewhat slimy, the production of copious amounts of slime is relatively rare; it is observed, e.g., when the cellulose decomposers are grown on a glucose-containing agar (see also Strohl and Tait, 1978). The slime is usually soft, so that the cells can easily be scraped off the plate; but sometimes it becomes very tough, and the cell mass can hardly be removed from the agar surface, e.g., with *Cy. columnaris* (Garnjobst, 1945) and *Cy. uliginosa.* The organisms also often penetrate the agar, and some species even grow and spread preferentially within the plate, e.g., microaerophilic and agar-attacking organisms (e.g., Veldkamp, 1961). Colony variations have been reported for several species (Anderson and Ordal, 1961a; Bachmann, 1955; Oyaizu et al., 1982; Pacha, 1968; Stanier, 1942, 1947; Veldkamp, 1961). In one case, migrating microcolonies were observed (Strohl and Tail, 1978). The colonies of the cellulose decomposers on filter paper are slowly expanding, glassy, unstructured, slimy patches that are usually bright yellow to orange. Grey areas in the colonies of *Sporocytophaga* usually signal generous microcyst formation.

A sickening odor has been reported for *Cy. columnaris* on nutrient agar (Garnjobst, 1945). On peptone-containing media, and particularly with liquid cultures, a strong, cheesy smell is produced by many CLB. The cellulose degraders produce a pleasant sour-fruity odor when growing on glucose agar.

Physiology and Enzymology

With a few exceptions, the physiology and enzymology of the various members of the Cytophagales have not been thoroughly investigated, and virtually no information is available about most basic biochemical pathways. Further, many of the studies were published a long time ago, and a reevaluation of the data in the light of modern biochemical insights would be desirable. On the other hand, nothing discovered so far suggests that the metabolism of these bacteria would differ in some basic manner from the metabolism of other comparable organisms.

Most Cytophagales are strict aerobes, but there also are microaerophilic species, facultative anaerobes, and organisms with a strictly fermentative metabolism (Anderson and Ordal, 1961a, 1961b; Bachmann, 1955; Hirsch, 1980; Leadbetter et al., 1979; Stanier, 1947; Veldkamp, 1961). It appears that all Cytophagales that are capable of fermentative growth require elevated CO_2 levels (optimum 0.3 to 1% $NaHCO_3$: *Cy. fermentans, Cy. succinicans, Cy. salmonicolor, Capnocytophaga*). For strictly fermentative *Capnocytophaga* it has been shown that CO_2 is necessary because the organism depends on phosphoenolpyruvate carboxykinase (PEPCK) in order to synthesize ATP and the terminal electron acceptor, oxalacetate; the latter is reduced under regeneration of NAD to the level of succinate, which is then excreted as the major fer-

mentation product. Obviously PEPCK replaces in that organism the more usual pyruvate kinase. The enzyme is regulated by the energy charge of the cell: low ATP levels stimulate, high ones inhibit PEPCK activity (Kapke et al., 1980). A condensation of CO_2 with phosphoenolpyruvate was also suggested for fermentatively growing *Cy. succinicans* (Anderson and Ordal, 1961b). The reaction was stimulated by GDP. A CO_2-independent fermentation of fructose-1,6-diphosphate could be performed in cell extracts supplemented with lactate dehydrogenase. The data could be well reconciled with the mechanism outlined for *Capnocytophaga*. As *Cy. succinicans* is a facultative anaerobe, it is likely to have alternative pathways starting from PEP. The fermenting organisms may utilize various sugars, mannitol, and polysaccharides such as agar or starch; however, as a rule, organic acids are not suitable fermentation substrates; one exception is *Cy. succinicans*, which grows anaerobically on pyruvate. Fermentation products are mainly succinate and acetate, usually also propionate and formate, and sometimes small quantities of lactate and ethanol. *Cy. salmonicolor* produces CO_2 and H_2 during fermentative growth (Veldkamp, 1961).

Nitrate respiration allows vigorous growth of *Cy. johnsonae* var. *denitrificans* (Stanier, 1947). More recently, a CLB was isolated that grew anaerobically with NO_3^-, NO_2^-, and N_2O as terminal electron acceptors (Adkins and Knowles, 1984, 1986). If small quantities of sulfide (0.4 μM) were available, this organism was able to reduce N_2O even in the presence of acetylene in concentrations (4 kPa) that normally inhibit N_2O reduction. This is also of interest because acetylene-inhibited N_2O reduction is generally accepted as a measure of denitrification in soils. However, other denitrifying CLB (*Cy. johnsonae* strains) did not show acetylene-insensitive N_2O reduction (Adkins and Knowles, 1986). The strains differed in their ability to reduce various nitrogen compounds. In one case, N_2O reduction turned out to be inducible by nitrite, but not by nitrate. Anaerobic growth under reduction of nitrite or N_2O has also been found among flavobacteria (Pichinoty et al., 1976). Growth with fumarate as the terminal electron acceptor was not possible with any of the Cytophagales and flavobacteria tested, but several of the organisms, e.g., *Cy. hutchinsonii* and *Cy. johnsonae*, could use fumarate for limited NAD regeneration under anaerobic conditions (Callies and Mannheim, 1978). As already mentioned, no strict anaerobes are known among the Cytophagales.

It appears that all Cytophagales, including the cellulose decomposers, grow on organic nitrogen compounds, e.g., peptones, as the sole nitrogen source. Many also use the same compounds for carbon and energy and grow vigorously on peptone media, even if, as a rule, carbohydrates are the preferred carbon and energy sources. Some organisms, however, require the addition of a carbohydrate, e.g., apparently all cellulose decomposers. On the other hand, there are also organisms that cannot utilize carbohydrates at all, e.g., *Cy. psychrophila* (Pacha, 1968) and many *Cy. columnaris* strains (e.g., Song et al., 1988a).

Many Cytophagales can be cultivated on inorganic nitrogen compounds. NH_4^+ is usually preferred to NO_3^-. The latter can sometimes not be utilized at all, thus by *Cy. fermentans* (Bachmann, 1955). The spectrum of utilizable carbon compounds is wide and varies with the individual organisms. Glucose is almost always accepted. One exception is the *Cy. diffluens* group: These bacteria require some other sugar like galactose or sucrose (Lewin and Lounsbery, 1969). Acid is often produced from carbohydrates even under aerobic conditions (e.g., Oyaizu and Komagata, 1981; van der Meulen et al., 1974). *Sp. myxococcoides* metabolizes glucose via the Embden-Meyerhof-Parnas pathway (Hanstveit and Goksøyr, 1974), as does *Cy. johnsonae* (Reichardt and Morita, 1982a).

Many of the Cytophagales are able to degrade biomacromolecules, particularly all kinds of polysaccharides, like agar, starch, cellulose, yeast cell-wall β-glucan, succinoglycan (Oyaizu et al., 1982), pectin, alginate, and heparin. As many of the responsible exoenzymes potentially are of some practical interest, these activities will be discussed under "Practical Aspects," this chapter.

DNA and RNA are efficiently degraded by many Cytophagales (e.g., Greaves et al., 1970; Mitchell et al., 1967). A particularly strong DNAse activity is observed with *Cy. columnaris*. It seems, however, that no organism is able to grow solely on nucleic acids. Phosphatases are very common among the Cytophagales (e.g., Christensen, 1977a; Hirsch, 1980; Reichardt et al., 1983). An alkaline and an acid phosphatase of *Cp. ochracea* have been isolated and studied in detail (Poirier and Holt, 1983b). The enzymes are able to remove phosphate from phosphoseryl residues of phosvitin and may play a role in the dephosphorylation of phosphoproteins. CLB are able to grow on washing-powder polyphosphates as phosphate sources; the polyphosphates are well tolerated up to 0.0025% and are rapidly hydrolyzed (Ruschke and Köhn, 1970). Lipolytic activities are also known from Cytophagales, e.g., cleavage of tributyrin and of Tweens (e.g., Christensen, 1977a; Hirsch, 1980; Jooste et al., 1985; Oyaizu et al., 1982; Reichardt et al., 1983), but the responsible enzymes seem never to have been characterized.

The patterns of antibiotic sensitivities have been determined for many members of the Cytophagales, although the data often are not really comparable because of differences in methods (e.g., Agbo and Moss, 1979; Arlet et al., 1987; Christensen, 1977a; Forlenza et al., 1981; Gräf and Morhard, 1966; Reichardt et al., 1983; van der Meulen et al., 1974; Warke and Dhala, 1968). It appears that many organisms are relatively resistant to penicillins, polymyxin B, aminoglycosides, and chloramphenicol. Kanamycin resistance has been used in the isolation of cellulose-decomposing *Cytophaga* and *Sporocytophaga* strains (2.5 to 10 mg kanamycin sulfate per liter); but it is not known whether these organisms are always resistant to that antibiotic (Rivière, 1961a). Capnocytophagas respond to several conventional antibiotics and are thus easy to control.

A genetics of the Cytophagales is still nonexistent.

Classification and Identification

As mentioned in the introduction, 16S rRNA studies have shown that the Cytophagales are a main branch, or phylum, of their own in the bacterial phylogenetic system (Paster et al., 1985). They are found there together with some other, phenotypically rather different bacteria; although our current knowledge suggests that some common characteristics may indicate connections between those groups, on this basis, probably, nobody would have dared earlier to propose the existence of a natural relationship among all those bacteria. Thus, e.g., *Capnocytophaga* resembles *Bacteroides* morphologically and metabolically to such a degree that it was formerly classified in this genus. Also, sphingolipids, in general rare in bacteria, are found in *Bacteroides* and in certain flavobacteria (but also in nonrelated myxobacteria). Further, the 16S rRNA tree of descent demonstrates unequivocally that the present genera of the Cytophagales are heterogeneous and that we may even need new definitions for families and perhaps orders.

The order Cytophagales is defined here using conventional phenotypic characteristics so that new isolates can be classified relatively easily and reliably. As discussed in the introduction, only part of the group of phylogenetically related bacteria is included in the phenotypically defined order. As defined here, the order Cytophagales contains unicellular, Gram-negative, rod-shaped, gliding bacteria that often exhibit a pronounced cellular shape change or at least pleomorphism. Most species produce more or less brightly colored, yellow, orange, pink, or red colonies. The yellow and orange ones often give a positive flexirubin reaction. The respiratory quinones are exclusively menaquinones.

This definition presents us with two problems: First, a practical one—how to distinguish cytophagas from *Lysobacter*, which shares many of the above-mentioned characteristics. Differences in cell shape and pigmentation, as mentioned in the introduction, would quickly differentiate most, but unfortunately not all, Cytophagales from *Lysobacter*. In case of doubt, more subtle characteristics have to be examined. It seems that all lysobacters degrade chitin, while many Cytophagales do not. The GC content of *Lysobacter* DNA is high, between 65 and 70 mol%, values that are only reached by red *Taxeobacter* among the Cytophagales. The respiratory quinones of *Lysobacter* are ubiquinones (Q-8), while all Cytophagales appear to contain menaquinones exclusively (M.D. Collins, personal communication). Finally, no marine and no parasitic lysobacters have been found so far.

The second problem is how to integrate the flavobacteria into the order Cytophagales. The old genus *Flavobacterium* was plainly heterogeneous, but after exclusion of the high-GC-content species, the remaining, low-GC-content (30–45 mol%) species appear to be naturally related among themselves and with the Cytophagales. Those species of flavobacteria for which 16S rRNA catalogs exist are connected to the phylogenetic tree of the Cytophagales at various levels and are often found close to the gliding species. This suggests that the genus *Flavobacterium* is still heterogeneous and that a gliding species may be more closely related to a nonglider than to another glider. The situation became even more confusing after several organisms that were originally described as nonmotile and consequently classified as *Flavobacterium* species were later discovered to glide; they would therefore have to be classified among the cytophagas. This is the case for the type species of *Flavobacterium*, *Fv. aquatile*, and for *Fv. pectinovorum*, *Fv. uliginosum*, and *Fv. heparinum*. The (nonmotile) flavobacteria also have, in common with the Cytophagales, menaquinones as the only respiratory quinones and often have flexirubin-type pigments. Therefore, most probably, gliding motility will lose its determining character in this taxonomic group, and eventually there may be order(s), families, and perhaps even genera that comprise motile and nonmotile species, just as there are in groups of flagellated bacteria. But before the new boundaries can be defined, more data, especially molecular and chemosystematic ones, are needed.

As set out above, the Cytophagales are restricted here to gliding organisms which can be differentiated into genera according to the following key:

Key to the Genera of the Cytophagales

1. Cellulose decomposers that grow on filter paper as the only carbon source; may utilize inorganic or organic N sources; cannot grow on peptone alone but require in addition a carbohydrate, like cellulose (filter paper) or a suitable sugar (e.g., glucose) 2

1′. Do not attack filter paper cellulose; usually grow well on peptones, but some are much stimulated by carbohydrate or depend on it for fermentative growth 3

2. Produce microcysts . . . . . *Sporocytophaga*

2′. Do not produce microcysts, terrestrial . . . . . *Cytophaga*

2″. Do not produce microcysts, marine . . . . . *Cytophaga* (?)

3. Strictly fermentative; require CO_2 and carbohydrate for growth; inhabitants (mainly) of the oral cavity of man and mammals . . . . . *Capnocytophaga*

3′. Strict aerobes or facultative anaerobes . . . 4

4. Vegetative cells in young cultures are long (20 to 100 μm) thread cells 5

4′. Vegetative cells in young cultures are short to moderately long (2 to 15 μm) rods 6

5. Soil and freshwater bacteria; several species show a very conspicuous (cyclic) cellular shape change: in young cultures, long (20–30 μm), extremely agile thread cells; in older cultures, short immotile rods or coccobacilli; many strains contain flexirubins; GC content, 40 to 50 mol% . . . . . *Flexibacter*

5′. Marine organisms; cellular shape change not observed . . . . . *Microscilla*

5″. Marine organisms; very long (sometimes multicellular and nonmotile) filaments which may or may not have a sheath and release shorter, but often still rather long, gliding thread cells; colonies yellow due to zeaxanthin, no flexirubins; GC content, 37 mol% . . . . . *Flexithrix dorotheae*

6. Short, stout rod cells with rounded ends, often arranged at the edges of the colonies in a palisadelike fashion; colonies more or less brick red; GC content, 55 to 65 mol% . . . *Taxeobacter*

6′. Cell shape very variable: short to very short, but sometimes also moderately long (5 to 15 μm) rods, delicate or plump, with rounded or tapering ends; colonies often fast spreading, filmlike swarms, yellow to orange, marine organisms sometimes pink; many terrestrial isolates contain flexirubin-type pigments, marine isolates usually do not; in soil, freshwater, and marine habitats; some are fish pathogens; GC content, 30 to 40 mol% . . . . . *Cytophaga*-like bacteria (CLB)

(6″.) Cells are relatively short, cylindrical rods with rounded ends, but often long thread cells or cell chains are also found in cultures; colonies (slowly) spreading, often rather slimy, pale grey to greenish yellow, brick red, or brown due to diffusing pigments; respiratory quinone is Q-8; GC content, 65 to 70 mol%: *these organisms do not belong to the Cytophagales* . . . (*Lysobacter*)

The cellulose decomposers were historically the first cytophagas described, and thus taxonomically they represent the type of the whole group. For many years it has been suggested that these cellulose decomposers are rather specialized organisms that are not closely enough related to the other organisms of the group to be united with them in one genus. Experimental evidence for this hypothesis has been provided recently: Surveys of the respiratory quinones of gliding bacteria showed that many CLB contain MK-6, but all cellulose decomposers contain MK-7 (Oyaizu and Komagata, 1981; M.D. Collins, personal communication). Quantitative fatty acid analyses, DNA-DNA hybridization data, and especially comparisons of 16S rRNA base sequences suggest that the two type strains of the named species of the cellulose-decomposing cytophagas and of several new isolates are relatively closely related among themselves. Further, it could be shown that *Sporocytophaga* strains are equally closely related among themselves and, finally, that the latter are relatively closely related to the cellulose-decomposing cytophagas, but that other CLB, like *Cy. johnsonae* and *Cy. heparina*, are much farther off from both (Kath, 1990). The conclusion is that the genus *Cytophaga* should indeed be restricted to the cellulose decomposers. New genera will have to be defined for the other organisms hitherto classified in the genus *Cytophaga*, but this should not be done until after the boundaries between the various groups have been clearly established by molecular taxonomy. In the present situation it may be best to follow the practice used in the present review and to group these other organisms under the label *Cytophaga*-like bacteria (CLB). *Sporocytophaga* appears to be a separate and equally natural genus, at least as far as cellulose decomposers are concerned. Sporocytophaga isolates can easily be recognized by the presence of microcysts; these are usually pro-

duced in enormous numbers in enrichment cultures, and their formation can also be reliably induced with pure strains that no longer produce them in ordinary plate cultures when the strain is grown in M9 liquid medium (Kath, 1990). *Sp. cauliformis* appears to be a misnomer (Gräf, 1962a): It seems neither to decompose cellulose nor to form microcysts and probably belongs to the large assembly of CLB.

Another source of confusion is the distinction between *Flexibacter* and *Cytophaga.* The definition of the genus *Flexibacter* given here is based on the original description by Soriano (1945, 1947), but it is in disagreement with that used in *Bergey's Manual*, eighth edition (Leadbetter, 1974). The definition of *Flexibacter* has recently been changed again in *Bergey's Manual of Systematic Bacteriology* (Reichenbach, 1990), where it is now placed in accordance with the ideas presented here. (A detailed explanation of the rather complex taxonomic situation may be found in the latter reference, but it will not be repeated here.) The organisms united in the present genus *Flexibacter* have long, highly flexible cells. The organisms also have in common a somewhat higher GC content of 40 to 50 mol% (Behrens, 1978; Mandel and Lewin, 1969) and they all seem to contain MK-7 as respiratory quinone (M.D. Collins, personal communication). The type species is *Fx. flexilis*, which shows rather sluggish movements and is flexirubin negative. Much more fascinating is *Fx. elegans* Soriano (1945), which for many years was regarded as the typical *Flexibacter* and about which many details have been published, especially about strain Fx el (e.g., Achenbach et al., 1978; Behrens, 1978; Fautz et al., 1979, 1981; Hirsch, 1979; Paster et al., 1985; Poos et al., 1972; Rosenfelder et al., 1974; Reichenbach et al., 1974, 1981; Simon and White, 1971). In young cultures and at the edges of spreading swarms, the organism has long and extremely agile thread cells. These cells change their shape in the later stages of the culture, becoming shorter and shorter and finally becoming nonmotile (Fig. 2; Poos et al., 1972; Simon and White, 1971). Under certain conditions, the organism may grow exclusively in the short form, but the cells readily grow out into thread cells again if conditions are changed. Soriano (1945) did not mention any shape change, perhaps because he did not observe it, perhaps because he thought his cultures were contaminated, or perhaps because he regarded his organisms to consist of multicellular filaments and therefore judged fragmentation to be commonplace. But his description of *Fx. elegans*, and especially of the movements of the thread cells, leaves no doubt that his and our organisms are at least closely related. It was later discovered that there existed in the literature an even earlier description that exactly fitted *Fx. elegans* as outlined above, shape change, color, and physiology included—that of *Myxococcus filiformis* by Solntseva (1940), whose only mistake was to misinterpret the short cells as myxospores. Unfortunately, the situation was further confounded by the description under the name of *Fx. elegans* of an organism that quite obviously was not identical with Soriano's species (Lewin, 1969; Lewin and Lounsbery, 1969). As the name *Fx. elegans* has been conserved with Lewin's stain as the type species, it has been proposed to change the name of the organisms discussed above into *Fx. filiformis* (Reichenbach, 1990). To complicate things even more, an organism has been described more recently under the name of *Chitinophaga*, without any reference to the publications cited above, which is clearly closely related or identical with *Fx. filiformis* (Sangkhobol and Skerman, 1981). In this case, microcysts have again been postulated, but the published pictures are not at all convincing, and when studying the type strain the present author has never observed anything even remotely resembling a microcyst (H. Reichenbach, unpublished observations). In the 16S rRNA phylogenetic tree, *Fx. filiformis* Fx el is found in a side branch far away from *Sporocytophaga* and the CLB (Paster et al., 1985). It remains to be established whether the genus *Flexibacter* in its present state is really homogeneous. The genus is restricted so far to soil and freshwater organisms; many, but not all, contain flexirubin pigments, which have in fact been discovered in strain Fx el. The marine counterpart of *Flexibacter* may be *Microscilla*; no cellular shape change is known for this genus (Lewin, 1969; Lewin and Lounsbery, 1969; Pringsheim, 1951). It has not been well studied, and the status of the genus and its relation to the other Cytophagales are unknown.

The CLB are unquestionably a very large and heterogeneous assembly of terrestrial and marine bacteria. They will probably have to be distributed over several new genera, as discussed above. In the absence of a sound taxonomy, it is not even remotely possible at the moment to estimate the number of existing species. From DNA-DNA hybridization data and other studies it may be deduced that there are many more genera than are named so far. Some efforts have been made to establish a reliable taxonomy for the fish pathogens, which would obviously be of great practical importance. DNA-DNA hybridization data showed that the fish pathogens *Cy. columnaris*, *Cy. psychrophila*, and *Cy. maritima* are all well-separated, homogeneous, genomic species, which show little relatedness among themselves or to the many environmental species included in the studies (Baxa et al., 1987; Bernar-

det and Grimont, 1989; Bernardet and Kerouault, 1989; Bernardet et al., 1990). There are, however, strong indications that these are not the only fish pathogens among the CLB and that there are still other, hitherto undescribed species (Kent et al., 1988; Pyle and Shotts, 1981). Further, the data seem to suggest that the fish pathogens are restricted to fish and cannot be isolated as free-living, environmental strains, although the latter possibility is difficult to rule out definitely. Information about an environmental reservoir of the fish pathogens would, of course, be of central importance for epidemiological considerations and control measures. Serological data speak also against a close relationship between fish-pathogenic and environmental CLB (Pacha and Ordal, 1970; Pacha and Porter, 1968). Serological tests have therefore been very useful for a quick diagnosis of the fish pathogens, which is important for practical reasons. Early studies showed that species-specific antigens exist in *Cy. columnaris* and *Cy. psychrophila* (Anacker and Ordal, 1959; Bullock, 1972; Pacha and Porter, 1968). *Cy. columnaris* has in addition at least seven type-specific antigens, which can be used to subdivide a collection of 325 strains into four serological groups; no link could be seen between those serological groups and levels of virulence (Anacker and Ordal, 1959; Pacha and Ordal, 1970). Fluorescence-labeled specific antibodies against *Cy. maritima* could be used to demonstrate the presence of the pathogen in various tissues (Baxa et al., 1988). Incidentally, the fish themselves develop antibodies against *Cy. columnaris,* and these seem to limit natural infection and can be applied to protection by vaccination (e.g., Becker and Fujihara, 1978; Liewes et al., 1982).

In another study, the isoenzyme patterns of 106 strains of spreading and nonspreading, yellow-pigmented bacteria from fish and other habitats were used to classify CLB. While one group coincided neatly with isolates that had been identified with *Cy. columnaris*, the other three groups were clearly heterogeneous, one of them even containing other *Cy. columnaris* isolates (Starliper et al., 1988). Thus, the results were inconclusive, and isoenzyme studies do not appear promising for taxonomic purposes.

The recently discovered genus *Taxeobacter* (H. Reichenbach, unpublished observations) has a special position among the soil Cytophagales. It is distinguished from the CLB by its cell morphology, the arrangement of the cells in spreading colonies (Figs. 1 and 3), and the brick red color of the latter. It is a common organism that can be cultivated without difficulties and has probably only been overlooked because it is not easily isolated by conventional techniques. By 16S rRNA cataloging, *Taxeobacter* (= Myx 2105) has been located in the *Fx. filiformis* side branch close to *Cy. heparina* (Paster et al., 1985).

As already mentioned, *Capnocytophaga* has been known for many years under different names. It is a fermenter requiring an atmosphere with 5% CO_2, at least for isolation, and produces mainly acetate and succinate from glucose. Initially only known from the human oral cavity, related species have since been found also in animals, e.g., in dogs (Brenner et al., 1989) and in the rice rat (Shklair and Ralls, 1988). The genetic homogeneity of the three human species and the identity of one of them with *Bacteroides ochraceus* (type strain) has been established by DNA-DNA hybridization (Williams and Hammond, 1979; Williams et al., 1979).

Practical Aspects

The Cytophagales are of considerable practical interest. Their importance becomes even more impressive if we take also into consideration the many isolates classified as *Flavobacterium* in the literature, which would be justified because those strains may often have been CLB with unrecognized gliding motility, and even if they were true flavobacteria, they would be closely related organisms. A general review of the practical aspects of gliding bacteria including the Cytophagales has been published (Reichenbach, 1988).

Bacteria belonging to this large complex of species are found virtually everywhere in nature, at least in aerobic and microaerobic environments. They definitely play a major role in the turnover of matter. Their activities are, of course, not always beneficial for humans. Some undesired effects with respect to the dairy industry (see also Cousin, 1982; Guamis et al., 1987) and the rotting of cellulose fabrics have already been mentioned. Other examples of this less pleasant side are the participation of pectolytic CLB in the spoilage of vegetables (Liao and Wells, 1986; Lund, 1969) and of proteolytic CLB in the putrefaction of fish, although in the latter case, gliding bacteria may be associated with freshly caught fish and are gradually replaced by other bacteria during deterioration (Cho et al., 1984; Gennari and Tomaselli, 1988; Liston, 1960; Shewan, 1971). Also in nature the actions of CLB are not always beneficial. Thus, e.g., CLB have been found tunneling in the cell walls of seagrass leaves, apparently killing the leaves in the process (Porter et al., 1989). A case of symbiosis was discovered in calcareous sponges of the genus *Clathrina;* the bacterium may be sponge-specific and has been associated with the sponge for a long time (Burlando et al., 1988). There may yet be many more examples of similar symbioses to be discov-

ered. One such case may be the yellowish-brown bacterium living in the mycetomes of the granary weevil *Sitophilus granarius* (Bhatnager and Musgrave, 1970).

In a different context, the destruction of organic molecules may become a positive asset. The occurrence of large populations of CLB in sewage plants has already been discussed (see also Bauer, 1962). Cellulolytic *Cytophaga* and *Sporocytophaga* seem to play a role during composting of cattle manure (Godden and Penninckx, 1984). Many articles describe the decomposition by flavobacteria of recalcitrant chemicals such as pesticides, and, as just explained, some of these could really have been CLB. Thus, flavobacteria have been found to attack chlorobenzoic acid (Baggik, 1985), pentachlorophenol (Brown et al., 1986; Crawford and Mohn, 1985), parathion (Mulbry et al., 1986), nylon oligomers (Negoro and Okada, 1982), biphenyl and phenanthrene (Stucki and Alexander, 1987), and aliphatic diols (Willetts, 1983), to give just a few examples. The digestion of hardwood mesquite (*Prosopis* sp.) with a cellulose-decomposing *Cytophaga* strain has been studied with the aim of improving the feed quality of the plant material for cattle (Chang and Thayer, 1975). It was shown that the *Cytophaga* protein is particularly rich in essential amino acids, but feeding experiments with mice gave unsatisfactory results.

The production by members of the Cytophagales of special enzymes for technical application could be another field of practical interest. Not too much is known about such enzymes, but a number of potentially useful hydrolases and lyases has indeed been discovered and more or less characterized. The following examples may illustrate this. The *Cytophaga* and *Sporocytophaga* species are very active cellulose decomposers and have been studied since the beginning of the century (e.g., Berg et al., 1972; Fåhraeus, 1947; Hutchinson and Clayton, 1919; Imshenetski and Solntseva, 1936; Krzemieniewska, 1930, 1933; Rivière, 1961; Sijpesteijn and Fåhraeus, 1949; Stanier, 1942; Winogradsky, 1929). Initially it was believed that enzymatic attack required close contact between cell and fiber, but later it was found that in the culture supernatant of *Sp. myxococcoides* there were also enzymes that could solubilize cellulose, at least to a certain degree (Kauri and Kushner, 1985; Osmundsvåg and Goksøyr, 1975; Vance et al., 1980). With other organisms, however, cell-free cellulases could not be demonstrated (Chang and Thayer, 1977). Also, transglycosylations to β-1-3 and β-1-6 oligosaccharides (Charpentier, 1965) and a conversion of β-D-glucose into α-D-glucose by the activity of an exoglucanase (Charpentier and Robic, 1974) have been demonstrated. Relatively little is known about enzymes themselves, and a reinvestigation using modern methods would be desirable.

Another group of enzyme producers known for some time are the pectolytic CLB (e.g., Donderski, 1982; Dorey, 1959; Güde, 1973). The responsible enzyme is a randomly cleaving polygalacturonate lyase, which catalyzes a trans-elimination reaction; a pectin methyl esterase could not be found (Kurowski and Dunleavy, 1976; Sundarraj and Bhat, 1971). Only one single enzyme was found in *Cy. johnsonae*, and this enzyme was the smallest one (35 kDa) of all pectate lyases characterized (Liao, 1989). The pectolytic activity of *Cy. johnsonae* made water-stored spruce logs more permeable for preservatives and was therefore considered to be of practical relevance (Kurowski and Dunleavy, 1976; Ward and Fogarty, 1974).

Although chitin degradation is often observed among CLB and flexibacters, relatively little is known about the enzymes (Donderski, 1984; Reichardt et al., 1983; Stanier, 1947; Sundarraj and Bhat, 1972). The enzymes of *Cy. johnsonae*, a chitinase and a chitobiase, may be excreted or cell-bound. Deacetylation seems to be the first degradation step. The chitinolytic strain of *Cy. johnsonae* studied by Veldkamp (1955) was either a *Lysobacter*, judging from the strain deposited at NCIB (no. 8501), or a *Flexibacter*, as may be concluded from the published description of the organism.

Several enzymes from CLB that degrade polysaccharides derived from marine algae have been characterized, mainly agarases (Duckworth and Turvey, 1969a, 1969b, 1969c; van der Meulen and Harder, 1975, 1976), but also a porphyranase (Turvey and Christison, 1967) and a large (100 kDa) extracellular carrageenase (Sarwar et al., 1987).

Many Cytophagales efficiently hydrolyze starch (e.g., Christensen, 1977a), but the enzymes never seem to have been studied. In two cases, special enzymes have been found in CLB because they had been screened for them for an application in structural studies. A strain was found and identified with *Cy. johnsonae* that produced endo-β-glucanases, which could then be used to study the composition of yeast cell walls (Bacon et al., 1970; Webley et al., 1967). The discovery of a strain that attacked heparin (Payza and Korn, 1956a, 1956b) proved a decisive contribution to the elucidation of the chemical structure of this complex heteropolysaccharide (e.g., Dietrich, 1969). The organism was first classified as *Flavobacterium heparinum* but later recognized to be a CLB (Christensen, 1980). Enzyme production has to be induced by the addition of heparin, and yields are not particularly good. Later, another

(tentatively classified) *Flavobacterium* strain was isolated that produced heparinase constitutively and at a 10-fold higher level (Joubert and Pitout, 1985). The enzyme may be of considerable practical interest for the deheparinization of blood.

Many Cytophagales excrete strong proteinases. A few of these enzymes have been further characterized because of their unusual specificities. In a screening, strains were discovered that solubilized autoclaved feathers and wool and could grow on these substrates as the only C and N sources; they did not attack the native material (Christison and Martin, 1971; Martin and So, 1969). The organisms resembled *Cy. johnsonae* in their characteristics but were never clearly classified. The keratinolytic enzyme appears to be associated with acidic polysaccharides on the surface of the cells. *Capnocytophagas* show strong aminopeptidase activities (e.g., Nakamura and Slots, 1982). In a screening for arylaminopeptidases among oral bacteria, several different activities at high levels were discovered in capnocytophagas, including monopeptide-, dipeptide-, and tripeptide-cleaving enzymes, some of which were only seen in capnocytophagas, e.g., enzymes attacking ala-, leu-, his-, lys-, and met-β-naphthylamines (Suido et al., 1986). Such proteolytic enzymes could contribute to the occasional pathogenicity of the organisms. Also the fish-pathogenic CLB show very strong proteolytic activities, which may be responsible for at least part of their infectivity. In an effort to prepare compounds with immunoadjuvant activity from cell walls of *Staphylococcus epidermis*, an interesting endopeptidase was isolated from the culture supernatant of the gliding bacterium *Cytophaga* B-30 (Kawata et al., 1984). The identity of the organism is not unequivocally established, and the description does not rule out the possibility that it was really a lysobacter. The enzyme released long-chain polysaccharide peptides from *Staphylococcus*, but little or nothing from *Streptococcus* and *Micrococcus* peptidoglycan. In cells and in the culture supernatant of *Cytophaga* NCMB 1314, an agent was discovered, presumably an enzyme, that solubilized active cholinesterase from fish muscle (plaice, *Pleuronectes platessa*). Again, the identity of the organism is not completely clear. Release of this "S-factor" into the medium was stimulated by cultivation under magnesium limitation (Bovallius, 1978, 1979; Lundin, 1968; Lundin and Bovallius, 1966).

Substantial phospholipase A_2 activity has been seen in *Capnocytophaga (Cp.) ochracea* strains; it has been suggested that this enzyme is a factor contributing to the pathogenic potential of the organism (Sandholm et al., 1988).

Interesting immunological effects may be produced with certain cell components of the Cytophagales. The allergenic activity of *Cytophaga allerginae* endotoxin, leading to humidifier fever, a lung disorder, has already been mentioned; the chemical composition of the endotoxin has been determined (Flaherty et al., 1984; Liebert et al., 1984). The purified endotoxin proved to be a novel mitogen that induced peripheral blood lymphocytes in vitro to synthesize IgG and IgA; as the immunoglobin induction is not inhibited by cyclosporin A, it seems to be T-cell independent (Alevy and Compas, 1987). Another potent mitogen called gliding bacteria adjuvant (GBA) was recovered in relatively large quantities (140 to 400 mg/l) from the culture supernatant of the *Cytophaga* GB-2. The psychrotrophic bacterium was first isolated from contaminated fetal calf serum. GBA was free of endotoxin and protein and perhaps consisted of a complex slime polysaccharide. It stimulated mouse B lymphocyte proliferation in vitro, the production of immunoglobulins, and the release of colony-stimulating factor and interleukin 1 by macrophages (Shiigi et al., 1977; Usinger et al., 1985). Purified exopolysaccharide from *Capnocytophaga* cultures activated the human complement system in vitro (maximum effect at 28 μg/ml plasma); this activation may be a factor leading to tissue destruction in periodontal lesions (Bolton and Dyer, 1986). A large (155-kDa), lectinlike protein was isolated from the outer membrane of *Cp. gingivalis* (Kagermeier and London, 1986). The lectin appears to be specific for neuraminic acid, *N*-acetylgalactosamine, and *N*-acetylglucosamine, and it is probably responsible for coaggregation with other bacteria, like *Actinomyces israelii*, in the formation of dental plaque. Similar adhesins with specificities for rhamnose and fucose were found on *Cp. ochracea* (Weiss et al., 1987). A lactose-specific, lectinlike receptor was demonstrated on *Cp. sputigena* and *Cp. gingivalis* (Saito et al., 1988).

Some members of the Cytophagales have been found to produce very interesting secondary metabolites. In a screening for antibiotic activities, about 20% of the 270 tested strains showed inhibitory effects (Reichenbach et al., 1984). Several β-lactams were isolated from *Flexibacter* strains, including new monobactams with oligopeptide side chains (Cooper et al., 1983; Sing et al., 1983) and monobactams with formylamino- and glucuronic acid substituents, the formacidins (Hida et al., 1985; Katayama et al., 1985). Monobactams with a dehydroasparagine residue were obtained from *Cy. johnsonae* (Kato et al., 1987a, 1987b), and deacetoxycephalosporin C and 7-formylamidocephalosporins were obtained from a *Flavobacterium* (Shoji et

al., 1984; Singh et al., 1982, 1984). *Cy. uliginosa* (formerly *Fv. uliginosum*) contributed marinactan, a heteropolysaccharide with marked antitumor activity in mice (Umezwawa et al., 1983).

Finally, there are some important medical and veterinary aspects of the Cytophagales: Flexibacteria are able to pass through membrane filters of 0.1-μm pore size used for sterilizing seawater; the contaminants could be eliminated only by pasteurization (Little et al., 1987). Immunological effects of cell components and products of diverse Cytophagales and resulting health problems have already been reviewed. A further example are the mitogenic and immunomodulatory effects exerted by cell wall fractions from a *Capnocytophaga* strain which had been isolated from a patient with juvenile periodontitis; the effects were also given by fractions that were free of LPS and peptidoglycan (Murayama et al., 1982). It is not known to what extent or whether *Capnocytophaga* contributes to periodontal disorders. Cytopathogenic effects were observed for "*Sphaerocytophaga*" (Gräf, 1962b, 1962c). These bacteria were present in large numbers in acute and chronic inflammations in the human oral cavity. In cell cultures (calf kidney cells), they caused cell lysis, and they destroyed human leukocytes in vitro. When inoculated subcutaneously into guinea pigs, they produced inflammations and ulcerations, but were not pathogenic for mice and rabbits when applied intraperitoneally and intravenously, respectively. It was found that neutrophils from patients with large *Capnocytophaga* populations in dental infections showed abnormal behavior and that such behavior could be induced in normal neutrophils when they were exposed to sonic extracts of *Capnocytophaga* (Shurin et al., 1979). Sonic extracts of *Cp. sputigena* showed moderate toxicity for human gingival fibrablasts as indicated by inhibition of cell proliferation and thymidine incorporation (Stevens and Hammond, 1988). Heat-killed *Cp. gingivalis* cells elicited strong endotoxin reactions in the *Limulus* and the Shwartzman test (e.g., Fumarola et al., 1981). As capnocytophagas are usually found in large numbers in cases of severe destructive periodontitis, especially in juvenile periodontitis, and as they produce similar symptoms when inoculated into healthy gnotobiotic rats, they may indeed not be completely harmless, even if they are always present in the normal buccal flora (Forlenza and Newman, 1983). Perhaps they also play a certain role in the "piggyback" transport of nonmotile bacteria into periodontal pockets. While the situation appears complex and somewhat controversial with periodontal pathogenicity, the case is clear when general infections occur (see also Hawkey et al., 1984). Newly described *Cp. canimorsus* and *Cp. cynodegmi* have been considered to be responsible for septicemia and localized wound infections in humans after dog bites; the organisms seem occasionally also to be transmitted by cats (Brenner et al., 1989). Capnocytophagas respond well to antibiotics, like various β-lactams, quinolones, chloramphenicol, and tetracycline (see also Arlet et al., 1987).

As already discussed in the section on "Habitats," the fish-pathogenic CLB are showing a steadily increasing economic impact on fish cultivation and, to a lesser extent, also on wildlife, in fresh water as well as in seawater. *Cy. columnaris*, *Cy. psychrophila*, *Cy. maritima*, and *Fv. branchiophilum* appear to be the major pathogens and have been reported worldwide, but other species are probably also involved (see also Amin et al., 1988; Farkas and Oláh, 1984; Kuo et al., 1980, 1981; Kusuda and Kimura, 1982; Ostland et al., 1989; Spangenberg, 1975). The outbreaks of disease may follow a seasonal pattern (e.g., Kuo et al., 1981). This is easily understandable, for the fish, as well as the pathogen, usually have well-defined temperature optima; thus, for example, *Cy. columnaris* is a typical warm-water, *Cy. psychrophila* a cold-water pathogen (e.g., Snieszko, 1974). Losses due to infections by CLB can be severe and sometimes approach 100% within a few days. Individual strains of the same species may differ substantially in their virulence. It seems that the pathogens become a problem mainly when the fish are kept under suboptimal conditions. The bacteria are sensitive to certain antibiotics, e.g., chloramphenicol, tetracyclines, and erythromycin, but better suited for practical application are chemotherapeutics like nifurpirinol or Mefarol. As pointed out already, control of the disease may also be effected by vaccination or transfer of the fish to water with a higher or lower temperature or salinity, depending on the specific case. Numerous studies on the various aspects of fish diseases caused by CLB have been published in the last 40 years, and some references to specific topics are *preconditioning by environmental factors:* Chen et al., 1982; Chowdhury and Wakabayashi, 1989a, 1989b; Hanson and Grizzle, 1985; Snieszko, 1974; *experimental infection:* Baxa et al., 1987b, Chowdury and Wakabayashi, 1989a; Kuo et al., 1987b; *histopathology:* Pacha and Ordal, 1967; and *control measures:* Amin et al., 1988; Deufel, 1974; Liewes et al., 1982; Ostland et al., 1989; Snieszko, 1953, summarizes the older literature.

Finally, it seems safe to predict that, beyond the examples given earlier, more diseases and disorders of aquatic animals other than fish will be discovered that are connected to CLB.

CHAPTER 6.8

The Genus *Saprospira*

HANS REICHENBACH

Gram-negative gliding bacteria that form helical, multicellular filaments are grouped in the genus *Saprospira* (Fig. 1). All known species live in aquatic environments. They are moderately common but relatively difficult to isolate and therefore have not been studied very well, although some of them can be cultivated without problems. Relatively little has been added to our knowledge of *Saprospira* since the first edition of *The Prokaryotes* (Reichenbach and Dworkin, 1981).

The genus *Saprospira* was defined by Gross (1911). He described two marine species, *S. grandis* and *S. nana*, of which only the former has since been isolated by other investigators. The two organisms differed considerably in their dimensions, as shown in Table 1, which lists some characteristics of the known strains of the genus.

It seems, however, that at least three other investigators had observed saprospiras before Gross. Kolkwitz (1909) described a freshwater saprospira under the name of *Spirulina albida.* He obviously believed his organism to be an apochlorotic blue-green "alga" (cyanobacterium).

In 1875, van Tieghem (1880) observed a delicate white scum that resembled *Beggiatoa* covering the mud in the water course of an old mill. Under the microscope, he discovered that the organism consisted of long, fine, helical filaments that were so tightly wound up that the coils touched. The helices moved by rotation around their long axis. The long filaments were also actively bending. He called this organism *Spirulina alba,* thereby deliberately emphasizing its close affinity to the blue-green algae of the same genus. Although his description is rather scant, it seems almost certain that he was dealing with a *Saprospira* species.

In the same year, Warming (1875) observed a very large helical organism in marine debris from the Danish coast and named it *Spirochaeta gigantea*. From his careful description, one can deduce that this organism, too, may have been a *Saprospira* species.

Not much was published in the five decades following the definition of the genus. In addition, until the middle of the 20th century, *Saprospira* was regularly regarded as belonging to the spirochetes, which caused considerable confusion. Gross (1912) himself stressed the similarity between *Cristispira*, which was also first defined by him, and *Saprospira*. To him and most other investigators at the time, the latter was essentially a spirochete without a crista or an axial filament. Unfortunately, in stained preparations, both organisms also showed a multichambered aspect, which was in fact a staining artifact but obscured the difference in organization of the two bacteria. Dobell (1912) described a new freshwater species, *Saprospira flexuosa*. From the careful description given by Dobell, one may deduce that his organism really was a *Saprospira*, perhaps *S. albida* as suggested by Lewin (1962), although this point cannot be decided because we do not know how many different freshwater saprospiras exist. During a study on helical bacteria in the digestive tract of oysters, Dimitroff (1926) observed several types of organisms which he regarded as saprospiras. One he identified with *S. grandis*, the others he described as new species, *S. lepta* and *S. puncta*. His account of the movements of his isolate of *S. grandis* leaves considerable doubt whether the bacterium was really *Saprospira*. On the other hand, he observed true cristispiras under the microscope and distinguished their very fast movements quite clearly from those of *Saprospira*. If one takes into account the fact that before the days of the phase contrast microscope, it was not so easy to observe living bacteria, it is easier to understand this uncertainty. It might be worthwhile to investigate again for the presence of saprospiras in shellfish. The two new species could never be observed by Dimitroff in the living state so their motility behavior is not known. They both had long, tapering ends with a sharp point, which is not known for any *Saprospira* species. The giant, gliding "spirochete" observed by Soriano in an enrichment culture and very briefly mentioned by him in the legend to a rather suggestive drawing (Soriano, 1945), was probably a (freshwater) saprospira. Dyar (1947) described the isolation and cultivation of a freshwater "spirochete." This organism resembled *Saprospira* in many respects and indeed was later identified with *S. albida* by Pringsheim (1963). Skuja (1948) described the new species, *Achroonema spiroideum,* from Swedish lakes. The organism was later equated with *S. albida* (Lewin, 1962), but the very lax coils typical for *Achroonema spiroideum* leave some doubts whether this assignment is correct.

Many details about the morphology and physiology of the saprospiras were elucidated between 1960 and 1970 through the research of Lewin and his collaborators, who also defined several new species and emended the taxonomic position of the genus (Lewin, 1962, 1965a, 1965b, 1969, 1972; Lewin and Lounsbery, 1969; Lewin and Mandel, 1970). The phylogenetic relationship of *Saprospira grandis* was recently established by 16S rRNA oligonucleotide cataloging: The organism belongs to the *Bacteroides-Flavobacterium-Cytophaga* phylum (Paster et al., 1985). A relationship with the cyanobacterium *Spirulina* has specifically been ruled out (Reichenbach et al., 1986).

A short review of the genus *Saprospira* has recently been published (Reichenbach, 1989). A movie showing the movements and the development of the swarm colonies of *Saprospira* is also available (Reichenbach et al., 1975/1976; Reichenbach, 1980).

This chapter was taken unchanged from the second edition.

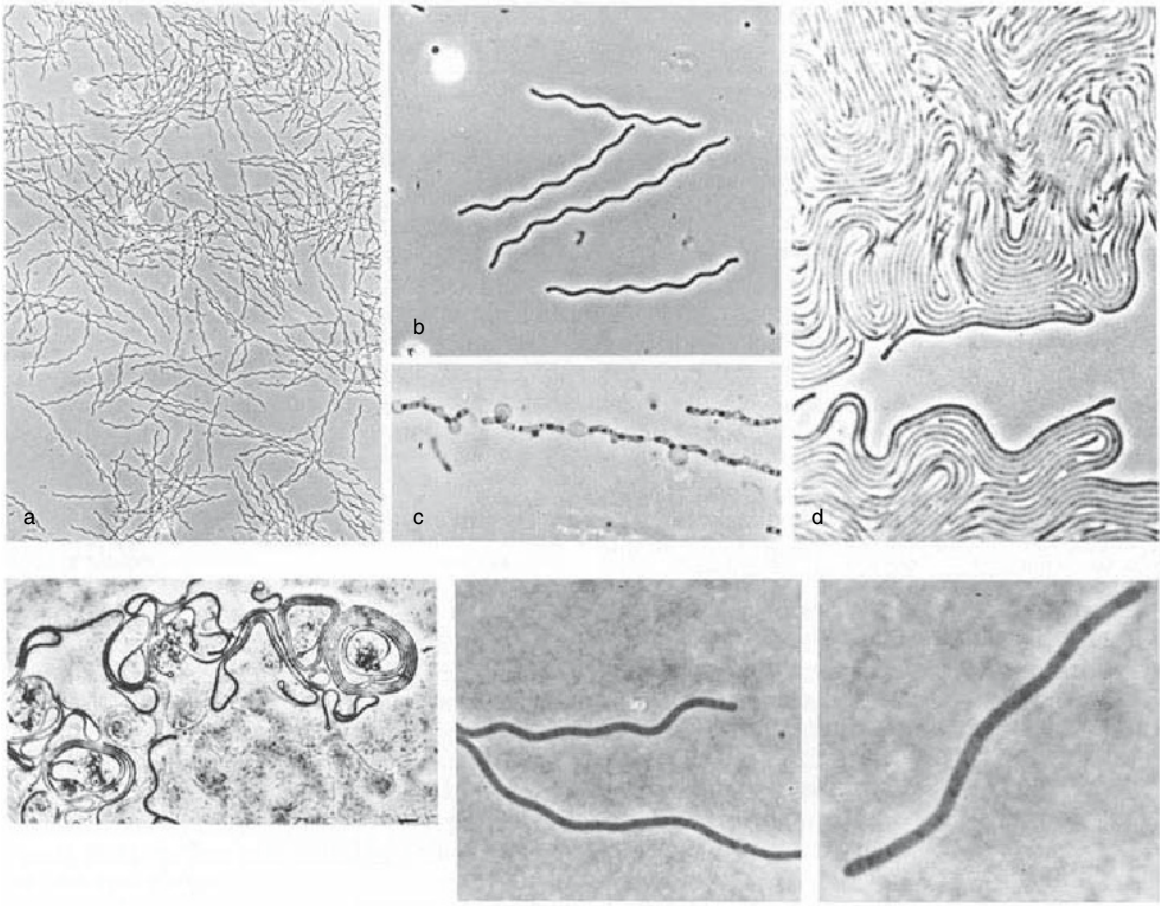

Fig. 1. Phase contrast photomicrographs of *Saprospira grandis*. (a) Helical filaments from a 1-day-old liquid culture, survey picture; ×180. (b) Filaments at higher magnification; ×500. (c) Decaying filament showing the individual cells; ×900. (d) Growing in the narrow space between agar and cover glass in a chamber culture, the filaments have lost most of their helical shape and concomitantly their ability to glide; ×920. (Lower left) Nonhelical filaments in a chamber culture with large, optically refractile, terminal bulbs; ×470. (Lower center and lower right) At very high magnification (×1000 and × 1200; Zeiss Axiomat) the cross-walls in the filaments are visible. The lower filament shows a constriction near one end, perhaps one possible way of filament fragmentation.

Habitats

The saprospiras appear to live exclusively in aquatic environments. *S. grandis* and other marine species have been isolated from sand and mud and collected at the sea coast at many different locations all over the world (Gross, 1911; Lewin and Lounsbery, 1969; Lewin and Mandel, 1970). One strain of *S. grandis* has been obtained from a rotting crab carapace (Reichenbach, 1980). As discussed above, several species may possibly be found within oysters (Dimitroff, 1926). Saprospiras are common also in fresh water (Lewin, 1965b). They seem to prefer eutrophic conditions and are often associated with algae. Saprospiras have been obtained from the mud in rivers and lakes (Kolkwitz, 1909; Pringsheim, 1963), from planktonic algae and cyanobacteria, as well as from the upper layers of surface waters, in which the filaments may be free-floating (Dobell, 1912; Skuja, 1948; Brunel, 1949; Ashton and Robarts, 1987), from decaying organic matter in a sulfur spring (Dyar, 1947), from a bog (Jarosch, 1967), and from sewage plants, including activated sludge (Kolkwitz, 1909; Cyrus and Sladká, 1970; Sladká and Ottová, 1973). *S. thermalis* was first isolated from a hot spring in Iceland, but the organism is not thermophilic and in fact not even thermotolerant, for its maximum temperature is 35–37°C (Lewin, 1965a). Only one strain of *S. albida* was ever isolated from soil. The sample came from Canada, but unfortunately nothing was said about the water conditions of that soil (Lewin, 1965b).

Interesting details about the interaction of a saprospira species with the cyanobacterium

Table 1. Characteristics of the *Saprospira* strains.

Strain	Morphological characteristic (μm)[a]					GC content (mol%)	Habitat
	Length of filament	Diameter of filament	Width of helix	Pitch of helix	Length of cell		
S. grandis, Gross 1911	6–100	0.8		6–6.5	1.5–2.2		Marine
S. grandis, Lewin 1962	10–500	0.8–1.2	1.5–2	4–10	1–2.5	46–48	Marine
S. grandis, Dimitroff 1926[b]	50–90	1.2–1.4[c]		20–28			Oyster, marine
S. grandis, Reichenbach 1980	15–450	0.8–0.9	1.4–1.8	5–6.5	2.7–5.5	47	Marine
S. nana, Gross 1911	36	0.5		2.3–3	1.5–3		Marine
S. gigantea, Warming 1875	About 400	1.5–3	5–9	25–40			Marine
S. toviformis, Lewin and Mandel 1970	10–500	0.8	1.5	4–9	1–2.5	38	Marine
S. lepta, Dimitroff 1926[b,d]	54–92	0.5	1.6–4.8	5–13			Oyster, marine
S. puncta, Dimitroff 1926[b,d]	60–100	0.9–1.2		4–8			Oyster, marine
S. albida, Kolkwitz 1909		1	4–5				Fresh water
S. albida, Dyar 1947	About 400		2	3–6.5			Fresh water
S. albida, Lewin 1965b	10–500	0.8–1.2	1.5–2	3–7	2–3	40–43	Fresh water
S. albida, Ashton and Roberts 1987	10–450	0.8–0.9	1.4–1.6	2.9–4.9	2.1–2.7		Fresh water
S. flexuosa, Dobell 1912[e]	3–50	0.8	2	3			Fresh water
S. spiroidea, Skuja 1948[f]	10–250	0.3–0.5	2.8–5.7	9–25	3–15		Fresh water
S. flammula, Lewin 1965b	10–500	1.0	1.5	3–4	2–3	48	Fresh water
S. thermalis, Lewin 1965a	10–500	1.0	1.5–2.5	7–17	2–5	35–37	Fresh water

In the older literature, measurements were often taken from fixed and stained specimens which may have been considerably distorted.
From the description by Dimitroff it cannot be decided with confidence whether his organisms were true saprospiras.
It is not clear whether Dimitroff was talking about the width of the filament or the width of the helix.
With tapering ends.
Probably actually *S. albida*.
Achroonema spiroideum was equated with *S. albida*, but it forms a very lax helix, and, in this respect, it resembles *S. thermalis* more closely than *S. albida*.

Microcystis aeruginosa in a South African reservoir have been published (Ashton and Robarts, 1987). Usually *Saprospira* is found in the surface layers of the lake at a very low density of less than 10 filaments per liter, but during *Microcystis* blooms, its density increases to more than 10,000 filaments per liter, and the saprospiras colonize and lyse the floating colonies of the cyanobacterium. Curiously, the *Saprospira* seems selectively to attack a toxic variant of *M. aeruginosa,* which is dominant at the site for most of the year. It has been suggested that saprospiras could be useful to control this undesired organism.

Isolation

No specific enrichment methods are known for saprospiras. Gross (1911) described a collection technique that makes use of the tendency of *Saprospira* to attach itself to a substrate surface. He filled a large petri dish with a sample of marine sand, covered it with sea water, placed coverslips on the water surface, and left them floating overnight. Most of the saprospiras stuck to the glass surface and could be removed from the crude culture.

To isolate saprospiras, samples are taken from appropriate habitats (see above) and placed as well-separated streaks or spots onto the surface of dry agar plates. To prevent excessive growth of contaminants, the media should contain nutrients in low concentrations only. For marine samples, MS1, SW2, or SP6 agar can be used. It appears that for saprospiras, natural and artificial seawater are equivalent, so that the following media could be prepared with either one.

MS1 Agar

Agar 1.5%

Natural seawater

The pH is not adjusted. The medium is autoclaved.

SW2 Agar

Agar	1.5%
NH_4Cl	0.1%
Na acetate	0.002%

Artificial seawater (see below)

The pH is adjusted to 7.2. The medium is autoclaved.

Artificial Seawater (Dawson et al., 1972)

The following recipe has been used by us with good results: NaCl, 24.7 g; KCl, 0.7 g; $MgSO_4 \cdot 7H_2O$, 6.3 g; $MgCl_2 \cdot 6H_2O$, 4.6 g; $CaCl_2$ (anhydrous), 1.0 g; $NaHCO_3$, 0.2 g. Bring to 1 liter with water. To avoid precipitation, $CaCl_2$ and $NaHCO_3$ are autoclaved as separate stock solutions.

SP6 Agar

Casitone (Difco)	0.03%
Yeast extract (Difco)	0.01%
Agar	1.5%

Artificial seawater (see above)
The pH is adjusted to 7.2. The medium is autoclaved.

The freshwater saprospiras are often more fastidious, and most investigators were only able to maintain their isolates for longer periods in mixed cultures, e.g., in fouling soil suspensions such as soil enriched with proteinaceous material in water (Pringsheim, 1963). Repeatedly, it has been found that small quantities of H_2S are stimulatory, although the organisms do not really depend on it (Dobell, 1912; Dyar, 1947). Perhaps the good results with Pringsheim's technique were also due to the production of H_2S from the added protein. Dyar (1947) seems to have been the first to succeed in isolating and cultivating a strain of *S. albida*. She used a leaf-infusion agar with a few drops of blood for isolation.

Several freshwater saprospiras were isolated by Lewin using LEW1 agar (Lewin 1965a, 1965b).

LEW1 Agar (Lewin, 1965b)

$Ca(NO_3)_2 \cdot 4H_2O$	0.05%
$MgSO_4 \cdot 7H_2O$	0.01%
K_2HPO_4	0.01%
Tryptone (Difco)	0.01%
Agar	1%

Yeast extract (Difco) can also be used in place of tryptone.

The crude cultures are incubated at 30°C, at room temperature, or in the refrigerator, depending on the starting material. For freshwater strains, 23–27°C is recommended (Lewin, 1965a). Although marine *S. grandis* has a temperature optimum around 30°C, it is useful to keep crude and enrichment cultures at 6°C, since the organism still grows and spreads reasonably well at that temperature, while the growth of contaminants is considerably reduced (H. Reichenbach, unpublished observations). The crude cultures are examined from time to time under a dissecting microscope. Oblique illumination should be applied to make delicate, spreading colonies also visible. Already after 3 to 4 days or, at lower temperatures, after a longer interval of up to 2 to 3 weeks, spreading colonies with long, rootlike tongues (Fig. 2) or with irregular, flamelike edges may be found. This is the typical appearance of colonies of gliding bacteria. *Saprospira* colonies often also show a very regular striped pattern (Dyar, 1947; Reichenbach et al., 1975/76; Reichenbach, 1980), which is seen with other screw-shaped bacteria, e.g., *Methanospirillum hungatii* (Ferry et al., 1974). A microscopic control should show the typical *Saprospira* filaments (Fig. 1) and their characteristic movements (Reichenbach et al., 1975/76). Further purification is achieved by making transfers from the spreading edges of the swarm colonies; it is best to cut out a piece of the colony using the sharp point of a 1-ml disposable syringe. The material is streaked on the same medium as before or, as soon as the colonies appear sufficiently pure, also on a richer medium, e.g., SAP2 agar for marine and LEW2 and LEW3 agar for freshwater strains.

SAP2 Agar

Tryptone (Difco)	0.1%
Yeast extract (Difco)	0.1%
Agar	1.5%

Artificial seawater (see above)
The pH is adjusted to 7.2. The medium is autoclaved.

LEW2 and LEW3 Agar (Lewin, 1965a)

The recipe is the same as for LEW1 agar, but the tryptone concentration is raised to 0.03% and 0.3%, respectively.

Finally, diluted filament suspensions may be plated on the richer versions of the above-mentioned media. The most troublesome contaminants are other gliding bacteria and, in marine samples, agar decomposers. Both groups should be eliminated at the very beginning of the enrichment process.

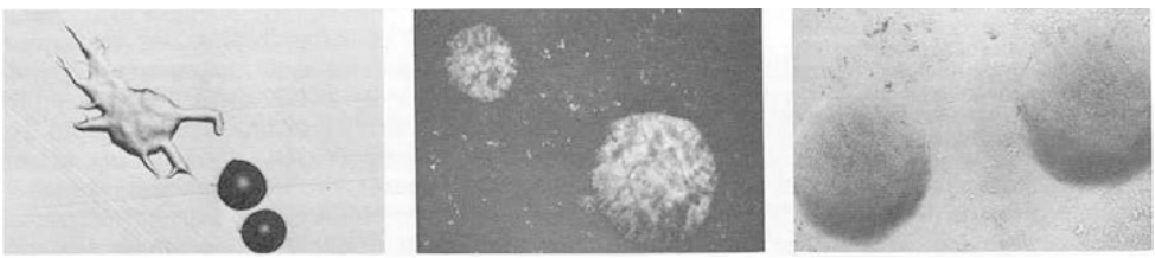

Fig. 2. Colonial morphology of *Saprospira grandis*. (Left) Colony on peptone-seawater agar together with two colonies of a nongliding organism. The *Saprospira* colony is rather tough and remains relatively compact; it spreads mainly along the grooves scratched into the agar surface by the inoculation loop. Leitz Aristophot; ×7.2. (Middle) Compact colonies on SP2 agar, in dark field; ×33. (Right) Colonies under oblique illumination; ×33. In both cases, the appearance of the colonies suggests some orderly arrangement of the filaments; in bright field, a pattern of fine, parallel, concentric stripes can be seen; Zeiss Axiomat.

Cultivation

All *Saprospira* strains that have been studied so far are strictly aerobic organotrophs and seem to prefer amino acids as carbon, nitrogen, and energy sources, often without an alternative. Many marine strains grow well on relatively simple media, such as SAP1 or SAP2 agar.

SAP1 Agar (Lewin, 1962)

Tryptone (Difco)	0.5%
Yeast extract (Difco)	0.5%
Agar	1.5%

Artificial seawater (see above)
The pH is adjusted to 7.2. The medium is autoclaved.

The marine saprospiras can be cultivated without difficulties and with good yields in liquid media, such as SP5 liquid medium or SAP1 liquid medium (as for SAP1 agar, but without agar). They usually form homogeneous suspensions in shake cultures.

SP5 Liquid Medium

Casitone (Difco)	0.9%
Yeast extract (Difco)	0.1%

Artificial seawater (see above)
The pH is adjusted to 7.2. The medium is autoclaved.

An almost fully defined medium is reported for *S. grandis* (Lewin, 1972). It is composed of nine essential amino acids, mineral salts, and an unknown growth factor present in yeast nucleic acid hydrolysate. The marine saprospiras almost always require at least half-strength sea water, but *S. toviformis* and a few *S. grandis* strains also grow at freshwater salt concentrations (Lewin and Lounsbery, 1969).

Among the freshwater saprospiras, *S. thermalis* is the least fastidious one and can be grown on relatively simple media, e.g., LEW3 agar (see above), and in LEW4 liquid medium. A synthetic medium also has been developed (Lewin, 1965a).

LEW4 Liquid Medium (Lewin, 1965a)

Casamino acids (Difco)	0.1%
Sodium glutamate	0.1%
Glucose (sterilized separately)	0.1%
Tris (hydroxymethyl) aminomethane	0.1%
$MgSO_4 \cdot 7H_2O$	0.01%
KNO_3	0.01%
$CaCl_2 \cdot 2H_2O$	0.01%
Sodium glycerophosphate	0.01%
Thiamine	1 mg/liter
Cobalamine	1 µg/liter
Fe	0.5 mg/liter
Zn	0.3 mg/liter
B, Co, Cu, Mn, Mo each	0.1 mg/liter

The pH is adjusted to 7.5. The medium is autoclaved.

Good growth was also obtained in a medium containing the mineral salts (and glycerophosphate) of LEW4 liquid medium plus tryptone (Difco) 0.02% and glucose 0.02%. If the tryptone is replaced by casamino acids, the addition of the vitamins became necessary (as in LEW4 liquid medium). The casamino acids in turn can be replaced by 0.2% sodium glutamate and three essential amino acids, i.e., leucine (50 mg/liter), isoleucine (50 mg/l), and valine (100 mg/liter). Growth was substantially faster when tyrosine (100 mg/liter) or phenylalanine (250 mg/liter) was also added.

The freshwater saprospiras of the *S. albida* type are more difficult to cultivate. Dyar (1947) could grow pure cultures on blood agar containing 5–10% erythrocytes and 1–1.5% agar. The organism did not grow if blood serum or heat-sterilized blood was used, which seems to indicate that it required either a heat-labile growth factor or enzyme in erythrocytes. Lewin (1965b) recommended a semisolid medium, LEW5 agar, for those strains, but even then they grow rather slowly.

LEW5 Agar (Lewin, 1965b)

Tryptone (Difco)	0.1%
Yeast extract (Difco)	0.1%
Gelatin (Difco)	0.1%
Glucose (sterilized separately)	0.1%
Tris buffer	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
KNO_3	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
NaCl	0.1%
Sodium glycerophosphate	0.01%
Fe	0.5 mg/liter
Zn	0.3 mg/liter
B, Co, Cu, Mn, Mo	0.1 mg/liter each
Agar	0.25%

The pH is adjusted to 7.5. The medium is autoclaved.

Unlike the other freshwater saprospiras, *S. flammula* is stimulated by 0.3% NaCl. It does not grow on casamino acids alone, but can be cultivated on a medium containing 0.5% tryptone, 0.3% NaCl and 0.25% agar (Lewin, 1965b).

Most saprospiras grow well at 30°C. Many strains even grow at 40°C (Lewin and Lounsbery, 1969). The temperature optimum is near 25°C for (marine) *S. toviformis* (Lewin and Mandel, 1970), 26°C for (freshwater) *S. albida* (the range is still 15–34°C; Dyar, 1947), and about 37°C for (marine) *S. grandis* (Lewin, 1962). *S. grandis* survives 46°C for 30 min (Lewin, 1972). This high temperature optimum of *S. grandis* is somewhat surprising, for the organism usually is found in a relatively cold environment. Thus, strain Sa gl was isolated at Roscoff, Brittany, where the Atlantic Ocean rarely reaches 17–18°C and is much colder most of the year. This strain also

grows rather well at 6°C and thus has a very wide temperature range.

The optimal pH is around neutral, and the range in which growth is possible is 6.5 to 7.5 and occasionally slightly beyond. The doubling time of *S. grandis* is 2 to 3 h at 30°C in SAP1 liquid medium (Lewin, 1962, 1972), and that of *S. thermalis* is 6 to 7 h at 30°C (Lewin, 1965a). A yield of about 250 mg dry cell mass per liter has been found with *S. thermalis* (Lewin, 1965a). With *S. grandis* in SP5 liquid medium at 30°, after 24 h of cultivation we obtained 12.5 g bacteria per liter by wet weight, corresponding to 2.5 to 3 g dry weight. Aasen and Liaaen-Jensen (1966a) harvested 400 g wet cells, giving 51.5 g freeze-dried bacteria, from 200 liters of culture broth after 20 h at 30°C.

Preservation

Cultures of *S. grandis* strain Sa gl on SAP2 agar remain viable for 2 to 3 weeks at room temperature (21°C). Lysis within 3 days at 30°C and within a few weeks at 25°C, on all tested liquid and agar media, has been reported for other strains (Lewin, 1962). Dyar (1947) found that her *S. albida* survived on blood agar for about one month but died after a short time in the refrigerator.

Filaments of *S. grandis* strain Sa gl can be suspended in SP5 liquid medium and frozen at –80°C or in liquid nitrogen without any further precautions. We were able to revive both cultures without difficulty after 2.5 years, the longest period tested so far. They will certainly survive for a much longer time. We had no success with drying in skim milk (H. Reichenbach, unpublished observations).

Sanfilippo and Lewin (1970) tested several freezing techniques with 27 strains of five *Saprospira* species. The longest survival times they found for cultures frozen at –22°C was 2 to 3 weeks (only marine species). In media containing 10% glycerol, all marine strains survived in liquid nitrogen for 1 year, the longest period tested. Of the freshwater species, only some strains of *S. thermalis* could be preserved in this way. Dimethyl sulfoxide (DMSO, 10%) proved toxic for all saprospiras: all strains were killed within 24 h at room temperature.

Characterization

The saprospiras form helical, multicellular, unbranched filaments (see Fig. 1) that move by gliding when in contact with a substrate surface. The length of the filaments is not fixed and varies considerably, even within one culture. The filaments tend to be longer in liquid media than on agar plates. *S. grandis* strain Sa gl, e.g., measures 15–130 μm when grown on a plate and 20–450 μm when grown in a liquid medium of the same composition. Similar figures have been reported for other strains and species (see Table 1). The diameter of the filaments is relatively constant and usually around 1 μm.

The filaments are composed of cylindrical cells that are 1–5 μm long and closely attached to one another. No constrictions are visible at the surface of the filaments at the sites of the septa. The cells at the ends of the filaments are rounded, but otherwise do not seem different from the rest. (As mentioned above, two dubious species with pointed filaments have been described from oysters; Dimitroff, 1926.) The length of the cells within one filament is variable, which suggests that the cells divide along the whole filament and independently from one another. With a good microscope and applying phase or interference contrast, the cross-walls can be seen in the living filament. Also, dark-field microscopy shows the septa clearly (Dyar, 1947; Jarosch, 1967). The cell boundaries become more apparent when the filaments begin to disintegrate (see Fig. 1c). Drying of the filaments to the slide may be sufficient to induce fragmentation (Dyar, 1947). Further, the multicellular nature of the screws can be seen after staining, e.g., with an I-KI solution (Skuja, 1948) or with Heidenhain's hematoxylin (Gross, 1911). Other staining methods often used in the older literature, e.g., with safranine, borax carmine, or methylene blue, also produced chambered filaments in *Saprospira*, but this may sometimes have been an artifact due to shrinkage of the protoplast, for true spirochetes also showed such a chambered appearance (Dobell, 1912; Dimitroff, 1926). Another identified artifact was an "axial filament" in heavily stained mounts of *S. albida* (Dyar, 1947). Of course, the septa are easily recognizable in thin sections under the electron microscope (Lewin, 1962). Also, in the election microscope, a typical Gram-negative cell wall with a thin peptidoglycan layer and an outer membrane can be seen. As usual, the septa consist only of the two cytoplasmic membranes and the peptidoglycan layer. The filaments multiply by breaking in two, apparently sometimes at the sites of necridia, i.e., dead cells (Gross, 1911; see also The Genus *Herpetosiphon* in this Volume). It seems that reproduction by simultaneous fragmentation into many short, one- or few-celled pieces can also take place (Gross, 1911, 1912; Dobell, 1912; Lewin, 1962, 1965b). The short pieces move only very slowly if at all, but with growing length their movements speed up again (Dobell, 1912; Skuja, 1948).

The helix of *Saprospira* usually is relatively loose (Fig. 1). Its pitch is 3–10 μm, and its width

is 1.5–2.5 μm. Some species show especially lax helices, e.g., *S. thermalis* and *S. (Achroonema) spiroideum*. But pitch and width are not constant features of a strain and can vary somewhat even within one culture. With the freshwater species, the helices appear usually to be coiled sinistrally (Lewin, 1965b), while the marine strains are coiled dextrally (Lewin and Mandel, 1970). The screw shape of the filaments may completely disappear during cultivation, in which case the organism would be difficult to recognize as a *Saprospira* (Dyar, 1947; Lewin, 1965b). Thus, the very long filaments seen in liquid cultures generally form only rudimentary and irregular helices. Also after improper fixation (e.g., with picric acid) the filaments tend to straighten out (Gross, 1911). In chamber cultures when restricted to the narrow space between the agar surface and the cover glass, *S. grandis* grows in the shape of very long, meandering filaments that are completely straight and, interestingly, also nonmotile (Fig. 1d; Reichenbach et al., 1975/1976; Reichenbach, 1980).

In such chamber cultures of *S. grandis*, filaments can sometimes be seen with the end cells inflated into spherical, optically refractile bulbs of 1.4–3 μm diameter (Fig. 2; Reichenbach, 1980). Those bulbs are probably a degeneration phenomenon but should not be confused with the spheroplasts that are found in old cultures all along the filament (Dyar, 1947) or can be produced by adding a 5 to 10% NaCl solution ("blisters"; Dobell, 1912). Filaments of *S. grandis* from liquid cultures appear to be very sensitive to changes in environmental conditions. Simply mounting them on a slide is sufficient to induce a decay of the filament and the formation of spherical protrusions at the surface of the cells (Fig. 1c).

Inside the cells of *S. albida* many highly refractive granules can be seen, sometimes extending from one side of the cell to the other (Dobell, 1912; Dyar, 1947). Dyar distinguishes two types: 1) volutin granules, i.e., polyphosphate, which show metachromatic staining with methylene blue and dissolve in (hot) water or in 0.02% $NaHCO_3$ solution, and 2) lipid globules, which stain with Sudan black B. The latter could well consist of poly-β-hydroxybutyrate. The inclusions are also seen under the electron microscope (Dyar, 1947). They appear to be relatively rare in *S. grandis* (Lewin, 1962; Lewin and Kiethe, 1965).

Gross (1911) mentioned that, in aging cultures of *S. grandis*, series of cells with increased stainability could occasionally be seen within filaments. Such cells later became spherical and surrounded themselves with a heavy wall. He suggested that those cells were spores, although he could not observe any further development. This observation has not yet been corroborated by other investigators.

A DNA phage of *S. grandis* with an icosahedral head, a contractile tail sheath, and rigid tail spines has been isolated and characterized (Lewin et al., 1964). Peculiar rod-shaped particles with long, wicklike tails, found in lysing cultures of *S. grandis* (Lewin, 1963; Lewin and Kiethe, 1965; Reichle and Lewin, 1968) and of the freshwater species *S. albida* and *S. flammula* (Lewin, 1965b), have been described as "rhapsidosomes." The preparations showed no infectivity whatsoever. Initially it was thought that the particles consisted of a ribonucleoprotein containing a highly 2′-*O*-methylated RNA (Correll and Lewin, 1964; Correll, 1968). This, however, turned out to be an analytical error, for the particles are composed exclusively of protein (Delk and Dekker, 1969, 1972; Price and Rottman, 1970). Very similar particles were later found in a myxobacterium and identified as the tails of a defective phage (Reichenbach, 1967). The *Saprospira* particles very probably have the same origin (Delk and Dekker, 1972). In fact, defective phage tails are rather common in bacteria, and many examples are known today. Unfortunately, the term rhapidosome was later also used for rod-shaped particles of a totally different morphology and nature, leading to unnecessary confusion (e.g., Pate et al., 1967; Yamamoto, 1967; Baechler and Berk, 1972).

In autolysed cultures of *S. thermalis*, but not of any other *Saprospira*, cell-wall fragments with a periodic hexagonal substructure are seen under the electron microscope, obviously remnants of a surface layer (Lewin, 1965b).

The helical filaments of *Saprospira* move by gliding when in contact with a suitable substrate surface, e.g., an agar or glass surface. The speed of *S. grandis* at room temperature (25°C) is 50–120 μm/min, and the movement is thus very obvious (Lewin, 1962). A speed of 120–180 μm/min has been determined for *S. thermalis* (Lewin, 1965b), one of 600 μm/min for *S. spiroidea* (Skuja, 1948), and one of only 14 μm/min for *S. flexuosa* (Dobell, 1912). The gliding screws rotate around their long axis and are also able to bend actively. Bending is particularly conspicuous when the filaments are suspended in a liquid. The helices move equally well in both directions and may quickly and frequently reverse the sense of their movement. As already mentioned, loss of the helical arrangement of the cells leads to a loss of translocation. The locomotory machinery still seems to be operative, however, since tiny particles stuck to the surface of the filaments can be seen to migrate back and forth over a limited distance, presumably the length of a cell (Reichenbach et al., 1975/1976). Obviously, the proper spatial arrangement of the cells in the

helix is a prerequisite for their efficient cooperation during movement (Reichenbach, 1980). As with all other gliding bacteria, the mechanism of locomotion is not understood in *Saprospira*. A movement of Indian ink particles on a helical path along the surface of filaments of *S. albida* has been explained by the movement of a helical slime belt that could also be responsible for the translocation of the filaments (Jarosch, 1967), but what moves the slime is still an open question. A sticky surface is, no doubt, essential for gliding motility, and the surface of *Saprospira* is indeed very sticky (Gross, 1911). Slimy material has been isolated from viscous, nonlysing liquid cultures of *S. thermalis* (27 mg/liter), and various sugars have been provisionally identified in the hydrolysate (glucose, xylose, rhamnose, traces of galactose and mannose; Lewin, 1965a).

The colonies of *S. grandis* on rich agar media are compact with entire edges and of a rather tough consistency (Fig. 2). On dilute media, however, the colonies spread, albeit often slowly and to a much lesser extent than that sun with the swarms of many other gliding bacteria. Long, unbranched, rhizoidal tongues may radiate from the edges of those colonies (Fig. 2). In other cases, the swarms are thin and filmlike (e.g., *S. grandis* on SP6 agar). The spreading colonies and, less so, also the compact ones show a surprising and very regular pattern of narrow stripes (Fig. 3). The striations are particularly impressive under dark-field illumination. As already mentioned, the phenomenon was first described for *Saprospira* by Dyar (1947) and is also known for other, unrelated, helical bacteria. It may be explained by an exact alignment of the screws (Fig. 3d). The optical pattern seems to arise from differences in light scattering in the rising and falling gyres of the helices, perhaps in combination with an interference effect. Colonies of *S. grandis* Sa gl show a periodicity of the stripes of 7.6 to 8.6 μm, while the pitch of the helices in suspension is 4.9 to 6.5 μm. Apparently, the helices are slightly distorted on the plate.

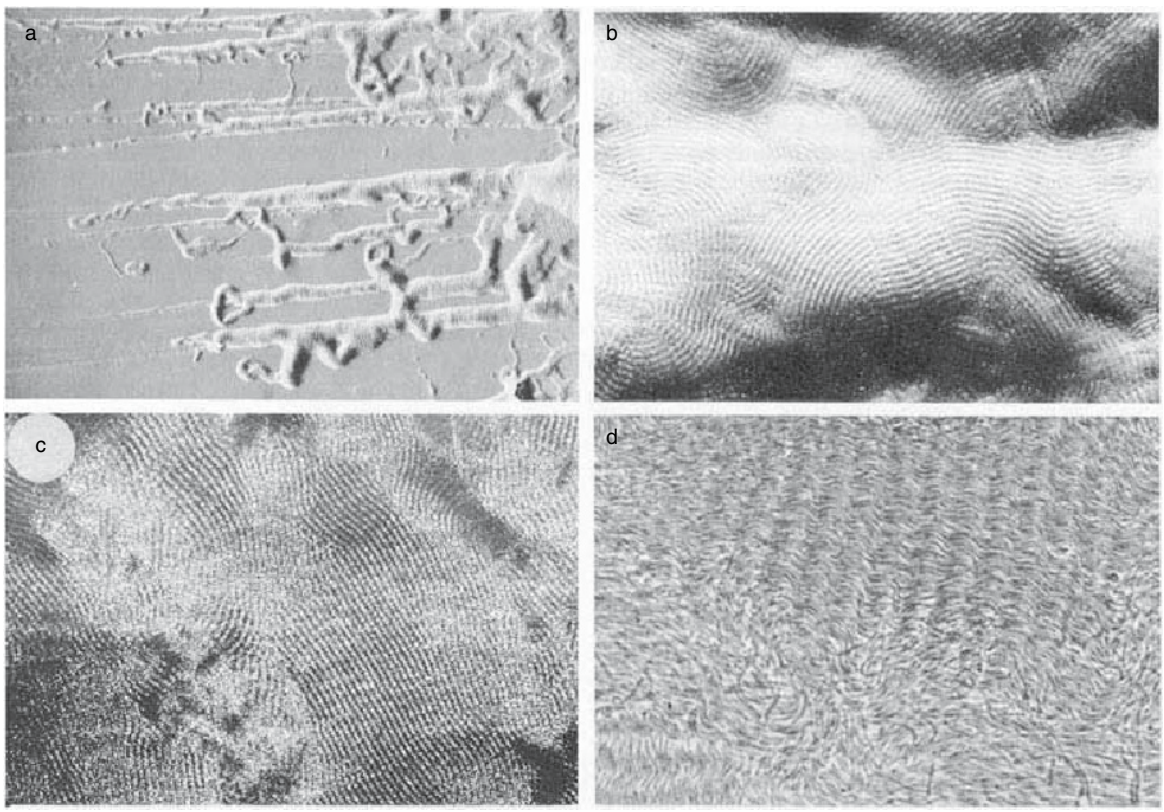

Fig. 3. Striated colonies of *Saprospira grandis*. (a) Colony spreading along grooves in the agar surface; the stripes run almost perpendicular to the direction of the spreading movement; Zeiss Standard Microscope, with oblique illumination; ×60. (b) Surface of a colony under oblique illumination; the filaments are just recognizable as a very delicate striation perpendicular to the stripes; Zeiss Axiomat; ×120. (c) Under dark-field illumination, the pattern of stripes becomes even more distinct; Zeiss Axiomat; ×120. (d) At high magnification it can be seen that in the striated areas the filaments lie strictly parallel, with the screws "in phase"; Zeiss Axiomat; ×580.

Relatively little is known about the chemical composition of *Saprospira*. The respiratory chain contains menaquinone MK-7 exclusively (M. D. Collins, personal communication). While initial studies seemed to indicate an *o*-type cytochrome as the terminal oxidase (Webster and Hackett, 1966), it was later found that *S. grandis* has four functional cytochromes, one of which has an unusual maximum at 603 nm (77°K) in the difference spectrum, and that an a,a_3-type cytochrome is most probably the oxidase (Dietrich and Biggins, 1971). NADH-oxidation by *Saprospira* particles is insensitive to antimycin A, rotenone, and amytal, but it is inhibited by cyanide and HOQNO.

The GC content of the DNA of the various species is 35–48 mol% (see Table 1).

The saprospiras are colored in shades of yellow, orange, pink, and red. The pigments are cell-bound. Initial studies provided a preliminary characterization of the pigment patterns by thin-layer chromatography and of the pigment type by absorption spectra of chromatographic fractions (Fox and Lewin, 1963; Lewin and Lounsbery, 1969). It soon became apparent that the pigments were probably carotenoids, but so far only one, the new xanthophyll saproxanthin (a modified 3,1′-dihydroxy-γ-carotene) from *S. grandis*, has been chemically characterized (Aasen and Liaaen-Jensen, 1966a). The pigment content was 0.02% of the freeze-dried cells. From *S. thermalis*, a single carotenoid, apparently a keto-carotenoid, was obtained, but because of very low yields (0.002% of the dry weight) its chemical structure could not be determined (Aasen and Liaaen-Jensen, 1966b). The early investigators described *S. albida* as completely unpigmented (however, they may have thought mainly of chlorophylls), but when a sufficiently high cell density is obtained, the organism shows a pale yellow tint (Fox and Lewin, 1963). Carotenoid synthesis by *S. thermalis* is stimulated by light, by suboptimal concentrations of cobalamine or tyrosine, and by subinhibitory concentrations of thiamine or sodium thiosulfate (Lewin, 1965a).

As already mentioned, *S. grandis* depends entirely on amino acids for growth (Lewin, 1972). It can be cultivated on various peptones, such as tryptone, casitone, phytone, or yeast extract. It can also be grown on casamino acids, but only if the medium is supplemented with tryptophan, asparagine, and a small quantity of yeast nucleic acid hydrolyzate (the growth factor supplied by the latter could not be identified). In that case, the casamino acids could be replaced by a mixture of essential amino acids, i.e., arginine, histidine, isoleucine, leucine, valine, methionine, phenylalanine, threonine, and perhaps lysine. Curiously, asparagine cannot be substituted by aspartate or glutamine. In nature, *S. grandis* may provide itself with the required amino acids by the degradation of proteinaceous matter. Gelatin liquefaction, the clotting and digestion of milk casein, and the decomposition of bacterial cells by *S. grandis* have been reported. In accordance with the metabolic restrictions outlined above, polysaccharides like starch, alginate, carboxymethyl cellulose, and agar are not hydrolyzed (Lewin and Lounsbery, 1969). Strain Sa gl also does not attack chitin and yeast cells. Marine *S. toviformis* differs from *S. grandis* in that it grows on casamino acids alone and does not require asparagine. Also, it is stimulated by lactate and acetate and depolymerizes carboxymethyl cellulose. It, too, does not utilize any of the tested sugars (Lewin and Lounsbery, 1969).

S. thermalis, the only freshwater species studied in some detail, utilizes glucose but none of the other tested sugars, sugar alcohols, ethanol, or acetate (Lewin, 1965a; Lewin and Lounsbery, 1969). This organism also hydrolyzes starch. *S. thermalis* grows well in a mineral salts/glucose medium with tryptone. The latter can be replaced by 1) yeast extract; 2) casamino acids plus the vitamins cobalamine and thiamine; or 3) glutamate plus the essential amino acids valine, leucine, and isoleucine and the vitamins. Much better growth is obtained if phenylalanine or tyrosine is also added to the synthetic medium. The main nitrogen source in the latter medium, glutamate, can be substituted by asparagine, methionine, or threonine, to a certain extent also by NH_4^+ or urea, but not by NO_3. *S. thermalis* too is proteolytic. The organism appears to operate a citric acid cycle (Lewin, 1965a). A fructose-bisphosphate aldolase has been purified 240-fold from *S. thermalis* (Willard and Gibbs, 1968). It is a type II aldolase, as is characteristic for bacteria, requiring cysteine, Zn^{2+}, and K^+ for maximum activity.

All saprospiras are catalase negative and produce ammonia from amino acids; none reduces nitrate to nitrite. Only *S. thermalis* produces H_2S and minor amounts of indole.

Taxonomy

An extensive study on the taxonomy of flexibacteria, including several types of saprospiras, was performed in the late 1960s (Lewin, 1969; Lewin and Lounsbery, 1969). The study was based mainly on a set of about 70 morphological and physiological features, but the GC content of the strains was also determined (Mandel and Lewin, 1969; in case of a discrepancy between data in the literature, the GC values given in Table 1 were taken from this study). The data were pro-

cessed in two different ways: by an Adansonian analysis (Colwell, 1969) and by a recurrent group analysis (Fager, 1969). While in both schemes, the strains of *S. grandis*, *S. thermalis*, and *S. toviformis* turn out as coherent and clearly separated groups, the connections between those groups, and between them and other flexibacteria, differ substantially. Considering the limitations of such a phenotypic classification it may, however, be too early to conclude that the various saprospiras are not closely enough related to be included in one genus.

The phylogenetic relationship of *S. grandis* with the cytophagas and flavobacteria has already been mentioned. The branching point is, however, relatively low, and the connection to the other members of the group is consequently weak.

At present, only one species of *Saprospira* is accepted, *S. grandis* (Reichenbach, 1989). Although there are no conclusive arguments to prove it, at least some of the various organisms classified as saprospiras in the past (Table 1) may indeed represent other *Saprospira* species. Apparently, a similar situation exists with *Saprospira* as with *Beggiatoa*, for which strains or species of widely different dimensions have also been reported. Unfortunately, with the exception of *S. grandis*, no other *Saprospira* seems to be currently available for comparison in a public culture collection, so that all planned studies will have to start with new isolates.

Applications

Apart from the remote possibility discussed earlier for using saprospiras for the control of freshwater cyanobacteria, no other practical interest in the saprospiras is obvious at the moment.

CHAPTER 6.9

The Genus *Haliscomenobacter*

EPPE GERKE MULDER AND MARIA H. DEINEMA

In the 1st edition of *The Prokaryotes,* the genus *Haliscomenobacter* was considered together with bacteria of the genera *Sphaerotilus* and *Leptothrix*, but *Haliscomenobacter* is not closely related to these other Gram-negative sheathed bactera.

Habitats

Strains of *Haliscomenobacter hydrossis*, the only species of the genus *Haliscomenobacter* isolated so far, are nearly always present in activated sludge flocs, sometimes in large amounts. The conditions for such an abundant development, which gives rise to bulking sludge, are not understood.

Straight, thin, needle-shaped, sheath-forming chains of cells protruding from the sludge flocs (Fig. 1) may interfere with clumping and compacting of the solids.

Isolation

The following procedure (van Veen, 1973) can successfully be used to isolate *Haliscomenobacter* sp. from bulking activated sludge.

I Medium (g/liter of distilled water)

Glucose	0.15
$(NH_4)_2SO_4$	0.5
$Ca(NO_3)_2$	0.01
K_2HPO_4	0.05
$MgSO_4 \cdot 7H_2O$	0.05
KCl	0.05
$CaCO_3$	0.1
Vitamin B_{12}	10^{-5}
Thiamine	4×10^{-4}
Agar (Oxoid)	10

S.C.Y. Medium (g/liter of distilled water)

Sucrose	1.0
Casitone (Difco)	0.75
Yeast extract (Difco)	0.25
Trypticase soy broth without dextrose (BBL)	0.25
Vitamin B_{12}	10^{-5}
Thiamine	4×10^{-4}
Agar (Oxoid)	10

The vitamins are sterilized separately by filtration.

A sample of 0.10–0.50 ml of sludge with a relatively large amount of *Haliscomenobacter* threads is pipetted into tubes containing 10 ml sterile tap water. The tubes are stirred for several minutes with a tube mixer and the flocs allowed to settle. The settling time depends on the characteristics of the sludge and especially on the degree of bulking. This treatment of the sludge is repeated until sufficient filamentous organisms are observed microscopically in the upper layers of the supernatant. During moderate agitation and rotating movements of the dilute floc suspensions, fragments of threads are severed from the protruding filaments. The low total numbers of organisms and the favorable ratio between filamentous and other bacteria in the upper liquid layers permit a direct inoculation of the plates without further dilution of the suspension. The time of agitation of the flocs in the tubes appears to be related to the mechanical properties of the stirrer and to the nature and number of filamentous organisms present in activated sludge.

Very small droplets containing sufficient numbers of filamentous bacteria are transferred to the previously dried surfaces of 30 to 40 agar plates containing I medium. The cells are regularly spread over the whole surface of the agar plates by rubbing firmly with a sterile glass rod. The plates are incubated for 3 to 4 weeks at a temperature between 17 and 20°C.

The small colonies that develop from filamentous bacteria are often difficult to detect with a stereomicroscope, but recognition of the poorly contrasting, filamentous microcolonies on the agar is facilitated by low-magnification (150×) phase-contrast microscopy. Isolation is performed by transferring bacterial cells to S.C.Y. medium using sterile capillary tubes.

Preservation of Cultures

Stock cultures of *Haliscomenobacter hydrossis* can be maintained in the following way. Three milliliters of sterile tap water are pipetted onto the surface of the S.C.Y. agar slopes. The inoculated tubes are incubated at 20–25°C until turbid growth has developed in the liquid layer on the agar. The cells remain viable during 3 months' storage at 4°C.

Identification

The main characteristics of *Haliscomenobacter* spp. are presented in Table 1. Pinkish, smooth, or slightly filamentous colonies about 1–3 mm in diameter are formed on S.C.Y. medium. The cells

[a]Electron microscope observations.

are nearly always enclosed by a narrow, hardly visible, hyaline sheath (Fig. 2). A holdfast, as may be present in *Sphaerotilus natans*, has never been detected. The sheaths do not attach to glass walls of culture flasks; occasionally single cells are liberated from the sheaths in fast-growing, aerated cultures. Flagella have not been detected by electron microscope examinations, and motility in liquid or hanging-drop cultures has never been observed. Glucose, glucosamine, lactose, sucrose, and starch have been found to be excellent carbon and energy sources. The cells grow very well with $(NH_4)_2SO_4$, KNO_3, glutamate, or casamino acids as the nitrogen source. Both vitamin B_{12} and thiamine are required for growth. Maximum growth was generally obtained after an incubation period of 4–6 days on a rotary shaker at 25°C (Krul, 1977; van Veen et al., 1973).

Instead of poly-β-hydroxybutyrate (present in *Sphaerotilus* and *Leptothrix* spp.), polysaccharide globules are present in cells from media with a high C/N ratio (Fig. 3) (Deinema et al., 1977). Strains of *Haliscomenobacter* isolated so far belong to one species, *H. hydrossis* (Crombach et al., 1974; Eikelboom, 1975; van Veen et al., 1973).

The GC content of the DNA of *H. hydrossis* strains was found to be 49.0 ± 0.7 mol% (Crombach et al., 1974). This value, together with the other properties of this sheathed bacterium (Table 1), confirms the theory that except for the presence of a sheath, bacteria of the genus *Haliscomenobacter* are entirely different from those belonging to the genera *Sphaerotilus* and *Leptothrix*.

Three strains of *Haliscomenobacter hydrossis* have been deposited with the American Type Culture Collection (ATCC 27775–7) in Rockville, Maryland, and with the Deutsche Sammlung für Mikroorganismen (DSM 1100) in Göttingen.

CHAPTER 6.10

Sphingomonas and Related Genera

David L. BALKWILL, J. K. FREDRICKSON AND M. F. ROMINE

Introduction

The genus *Sphingomonas* was defined by Yabuuchi et al. (1990) as a group of Gram-negative, rod-shaped, chemoheterotrophic, strictly aerobic bacteria that possess ubiquinone 10 as the major respiratory quinone, contain glycosphingolipids (GSLs) instead of lipopolysaccharide in their cell envelopes, and typically produce yellow-pigmented colonies. By 2001, the genus included more than 20 species that were quite diverse in terms of their phylogenetic, ecological, and physiological properties. As a result, Takeuchi et al. (2001) subdivided *Sphingomonas* into four genera: *Sphingomonas*, *Sphingobium*, *Novosphingobium* and *Sphingopyxis*. These genera are referred to collectively as "sphingomonads" in this chapter. The sphingomonads are widely distributed in nature, having been isolated from many different aqueous and terrestrial habitats, as well as from plant root systems, clinical specimens, and other sources. Sphingomonads are metabolically versatile and, thus, are able to utilize a wide range of naturally occurring organic compounds as well as many types of refractory environmental contaminants. Because of this, there has been much interest in the metabolic pathways of these organisms, the properties of the enzymes involved with those pathways, and the genetics of their catabolic processes. Some of the sphingomonads (especially *Sphingomonas paucimobilis*) also play a role in human disease, primarily by causing a range of mostly nosocomial, non-life-threatening infections that typically are easily treated by antibiotic therapy. Owing to their remarkable biodegradative and biosynthetic capabilities, sphingomonads have been utilized for a wide range of biotechnological applications, from bioremediation of environmental contaminants to production of extracellular polymers such as sphingans used extensively in the food and other industries.

Taxonomy and Phylogeny

The genus *Sphingomonas* was defined by Yabuuchi et al. (1990) as a group of Gram-negative, rod-shaped, chemoheterotrophic, strictly aerobic bacteria that possess ubiquinone 10 as the major respiratory quinone, contain glycosphingolipids (GSLs) in their cell envelopes, and typically produce yellow-pigmented colonies. Other characteristics, such as presence of certain lipids and the utilization of various substrates, were also included in the definition of the genus. However, it was the presence of GSLs that most clearly distinguished *Sphingomonas* from other members of the α-subclass of the Proteobacteria (Woese, 1987; Stackebrandt et al., 1988) at that time. Yabuuchi et al. (1990) characterized 16 strains of bacteria in the Japan Collection of Microorganisms (JCM) that had been received as *Pseudomonas paucimobilis* (including the type strain, JCM 7516^T; Holmes et al., 1977), *Xanthomonas* sp., *Flavobacterium* sp., *Flavobacterium devorans*, *Flavobacterium capsulatum* (Leifson, 1962), or *Sphingobacterium* sp. On the basis of physiological, biochemical, and phylogenetic evidence, 14 of these strains were classified into five species of the new genus: *Sphingomonas paucimobilis* (the type species), *Sphingomonas parapaucimobilis*, *Sphingomonas adhaesiva*, *Sphingomonas capsulata* and *Sphingomonas yanoikuyae*.

Between 1990 and 1999, various research groups added 15 more novel species to the genus. Takeuchi et al. (1993) defined *Sphingomonas macrogoltabidus*, *Sphingomonas sanguis* and *Sphingomonas terrae* after examining several strains known to degrade polyethylene glycol (PEG), as well as two *Sphingomonas* strains that were included in the Yabuuchi et al. (1990) study but not assigned to any species. Two years later, Takeuchi et al. (1995) defined four more species that consisted of strains isolated from plant roots: *Sphingomonas asaccharolytica* (from apple tree roots), *Sphingomonas mali* (also from apple tree roots), *Sphingomonas pruni* (peach tree roots), and *Sphingomonas rosa* (rose roots). Nohynek et al. (1995) proposed *Sphingomonas chlorophenolica*, based on a reexamination of four strains (originally described as *Arthrobacter, Flavobacterium* or *Pseudomonas* species; Edgehill and Finn, 1982; Saber and Crawford, 1985; Radehaus and Schmidt, 1992; Resnick and Chapman, 1994) known to degrade

polychlorinated biphenyls (PCBs). A *Flavobacterium* strain (strain MH; Horvath et al., 1990) that degrades the herbicide 2-(2,4-dichlorophenoxy)-propionic acid (Mecoprop™) was reclassified as *Sphingomonas herbicidovorans* (Zipper et al., 1996). Similarly, Nohynek et al. (1996) reclassified three strains of *Pseudomonas saccharophila* that can degrade polychlorinated biphenyls (PCBs; Puhakka et al., 1995) as *Sphingomonas subarctica*. Strains from deep terrestrial subsurface environments (Atlantic coastal plain aquifer sediments) were added to the genus by Balkwill et al. (1997a), who described *Sphingomonas aromaticivorans*, *Sphingomonas stygia* and *Sphingomonas subterranea*. Kämpfer et al. (1997) then reclassified "*Pseudomonas azotocoligens*" (Anderson, 1955; Hill and Postgate, 1969) as *Sphingomonas trueperi*, and Denner et al. (1999) renamed *Pseudomonas echinoides* (Heumann, 1962) *Sphingomonas echinoides*. Yrjälä et al. (1998) reclassified *Pseudomonas* strain HV3 (which degrades aromatic and chloroaromatic compounds; Kilpi et al., 1980) as *Sphingomonas* HV3, but this strain was never recognized as a distinct species.

By 1999, the genus *Sphingomonas* included no fewer than 20 recognized species. It was obvious from phylogenetic analyses of 16S rRNA gene sequences that this group of bacteria was genetically rather diverse, forming several distinct clusters of strains within the α-4 subclass of the Proteobacteria in phylogenetic trees. As a result, several authors speculated that the genus was too diverse and might best be separated into two or more distinct genera at some point in the future (e.g., Van Bruggen et al., 1993; Segers et al., 1994; Takeuchi et al., 1994; Takeuchi et al., 1995; Balkwill et al., 1997a). Moreover, Kämpfer et al. (1997) reported that *Sphingomonas* species with *sym*-homospermidine as the major polyamine formed a relatively homogeneous subgroup within the genus. Nevertheless, Yabuuchi et al. (1999) expanded the genus even further by transferring in three more species from other genera because their cell envelopes contain GSLs. *Blastomonas natatoria* (Sly and Cahill, 1997), *Erythromonas ursincola* (Yurkov et al., 1997), and *Rhizomonas suberifaciens* (Van Bruggen et al., 1990) were renamed *Sphingomonas natatoria*, *Sphingomonas ursincola* and *Sphingomonas suberifaciens*, respectively. This change added phytopathogenic and photosynthetic organisms to *Sphingomonas*, thereby creating an unusually diverse genus in terms of its physiological and ecological characteristics. Shortly after the Yabuuchi et al. (1999) proposal, Hiraishi et al. (2000) emended the description of the genus *Blastomonas*, redefining it as a photosynthetic genus and proposing that *Erythromonas ursincola* (*Sphingomonas ursincola* in Yabuuchi et al., 1999) be transferred to it as *Blastomonas ursincola*. This proposal has been recognized, removing one species from *Sphingomonas*, but the other two species transferred by Yabuuchi et al. (1999) remain in the genus at this time (see Table 1).

Takeuchi et al. (2001) carried out a thorough reevaluation of the then-recognized species of *Sphingomonas* to better define the genus and, if necessary, subdivide it into additional genera. An important conclusion of this study was that, though the presence of GSLs in the cell envelope is significant, species should not be assigned to the genus *Sphingomonas* solely on the basis of this characteristic. *Rhizomonas* and *Blastomonas* (including the former *Erythromonas ursincola*) nested in the overall *Sphingomonas* cluster during phylogenetic analyses of 16S rRNA gene sequences. However, they were clearly separated, along a distinct line of descent, from any of the four monophyletic clusters of *Sphingomonas* species seen in phylogenetic trees (see below and Fig. 1 in Takeuchi et al., 2001). This was also true for *Erythrobacter* and *Porphyrobacter*, two other genera in the α-4 subclass of the Proteobacteria that possess GSLs. *Rhizomonas* and *Blastomonas* also differed from the *Sphingomonas* clusters in possessing phytopathogenic or photosynthetic properties, which are generally considered to be taxonomically very significant. Therefore, it was suggested that *Blastomonas* and *Rhizomonas* be left as they were prior to the Yabuuchi et al. (1999) revision and not be included in the genus *Sphingomonas*, a proposal that has not yet been recognized in the case of *Rhizomonas suberifaciens* and *Blastomonas natatoria* (see Table 1).

Takeuchi et al. (2001) found that phylogenetic analyses separated the remaining species of *Sphingomonas* into four monophyletic and genetically distinct clusters (in phylogenetic trees) that were supported by high levels of confidence (>86%) in bootstrap analyses. These clusters could also be distinguished on the basis of certain physiological and biochemical characteristics. Therefore, it was proposed that the four monophyletic clusters of species represent four distinct genera, including *Sphingomonas* and three novel genera: *Sphingobium*, *Novosphingobium* and *Sphingopyxis*. The principal traits of these four genera, as reported by Takeuchi et al. (2001), are summarized in Table 2. *Sphingomonas* differs from the other three genera primarily in its lipid composition (major fatty acids and major 2-OH fatty acids), the presence of homospermidine as the major polyamine, and signature nucleotide bases at certain positions within the 16S rRNA gene. *Sphingobium* and *Novosphingobium* are

Table 1. Reorganization and subdivision of the genus *Sphingomonas* by Takeuchi et al. (2001).

Original *Sphingomonas* species name	Taxonomy reference	Proposal by Takeuchi et al. (2001)	Current taxonomic status

Sphingomonas HV3	Yrjälä et al., 1998	Not examined	Not recognized as species

[a]Type species.
[b]Reclassified as *Blastomonas ursincola* by Hiraishi et al. (2000).

virtually identical in terms of lipid composition, signature nucleotide bases, and various other traits, but can be distinguished by the presence or absence of nitrate reductase activity (in addition to the clustering patterns in phylogenetic trees). *Sphingopyxis* differs from the other three genera primarily in its lipid composition and signature nucleotide bases (see Table 2). The Takeuchi et al. (2001) proposal to redefine and subdivide the genus *Sphingomonas* was accepted and the current taxonomic positions of the species examined in this study are summarized in Table 1.

At present, the genus *Sphingomonas* officially includes ten species (Table 3) that were not examined by Takeuchi et al. (2001) because the papers describing them were incomplete at the time of that study or have appeared since it was published. On the basis of the phylogenetic analyses presented in the respective publications, it appears that five of these recently described species are members of the genus *Sphingomonas* as redefined by Takeuchi et al. (2001): *Sphingomonas pituitosa* (an extracellular slime producer; Denner et al., 2001), *Sphingomonas roseiflava* (from plant roots; Yun et al., 2000), *Sphingomonas cloacae* (a nonylphenol-degrading strain; Fujii et al., 2001), and *Sphingomonas aquatilis* and *Sphingomonas koreensis* (isolated from natural mineral water sources in Korea; Lee et al., 2001). Three of the recently described species appear to be members of the genus *Sphingobium* on the basis of their positions in phylogenetic trees. These are: *Sphingomonas chungbukensis* (an aromatic degrader; Kim et al., 2000), *Sphingomonas wittichii* (which degrades dibenzo-*p*-dioxin; Yabuuchi et al., 2001), and *Sphingomonas xenophaga* (two strains that degrade xenobiotics; Stolz et al., 2000). *Sphingomonas alaskensis*, an oligotrophic organism isolated from seawater (Vancanneyt et al., 2001), clusters with *Sphingopyxis* species in phylogenetic trees and thus is most likely to be a member of that genus. The remaining species, *Sphin-*

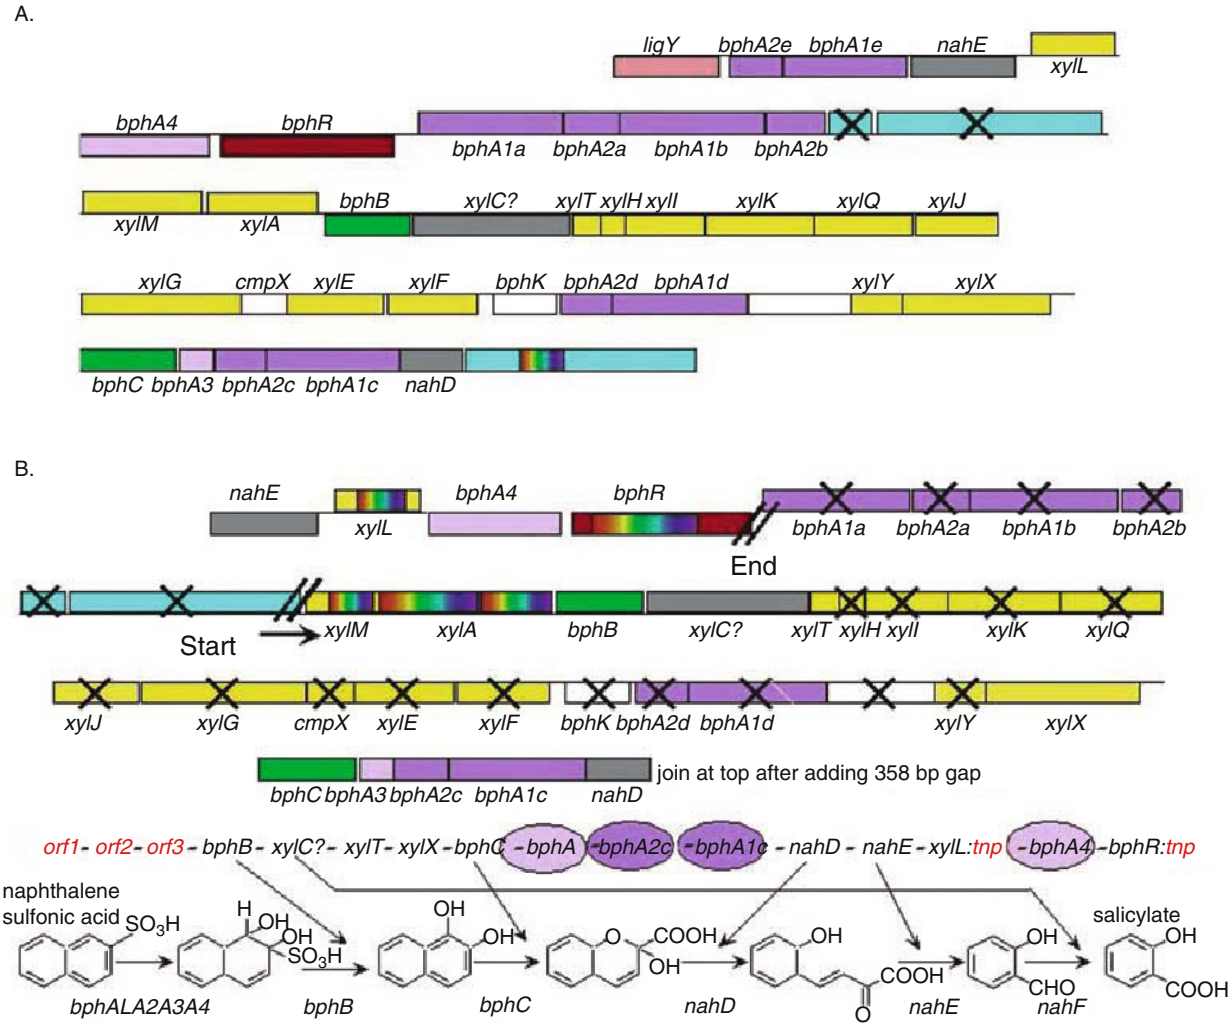

Fig. 1.

gomonas taejonensis, was described by Lee et al. (2001) and could be a member of either *Sphingopyxis* or *Sphingomonas*. The clusters in the phylogenetic tree published by Lee et al. (2001) are not in complete agreement with those described by Takeuchi et al. (2001) and this makes it difficult to speculate about the correct taxonomic placement of this species without additional information. At some point, the official taxonomic status of the 10 species listed in Table 3 will need to be clarified. Moreover, new *Sphingomonas* species proposed in the future should be characterized specifically in regard to their placement within the genera described by Takeuchi et al. (2001).

The subdivision of the genus *Sphingomonas* into four genera (Takeuchi et al., 2001) is a rather recent development, and very few reports since then have focused on the redefined genus or on any of the three new genera as separate entities. Moreover, many strains of *Sphingomonas* described in the literature were never assigned to a species and, therefore, are referred to simply as "*Sphingomonas* sp." At this time, it is not known whether these strains are members of the redefined genus *Sphingomonas* or one of the three new genera. Consequently, this chapter treats all members of the four genera proposed by Takeuchi et al. (2001) as a single group of organisms (i.e., as they were prior to reorganization of the genus). The new names proposed by Takeuchi et al. (2001) are used when the actual taxonomic position of an organism is reasonably certain. The phrase "*Sphingomonas* and related genera" refers to the four genera proposed by Takeuchi et al. (2001), and the term "sphingomonads" refers in general to the members of all of those genera.

[a]In many cases, it has not been confirmed that the strain is a member of the indicated genus and/or species.

can occupy a broad range of different types of environments. Aqueous habitats in which they have been shown to occur include freshwater environments such as river water, pond water, and groundwater, as well as marine environments such as seawater near the coasts of Alaska and Japan. Sphingomonads also have been isolated from soils and freshwater, marine, or deep terrestrial subsurface sediments.

Many strains of *Sphingomonas* and related genera have been isolated from comparatively pristine environments, but a considerable proportion of them (e.g., one third of those in Tables 4 and 5) were discovered in contaminated (sometimes rather badly contaminated) environments. The contaminants in these environments include a variety of potentially toxic and/or recalcitrant compounds, such as PCBs, creosote, pentachlorophenol, herbicides, etc. Many of the strains isolated from contaminated habitats were able to utilize one or more of the contaminants as sole carbon sources, a reflection of the exten-

sive biodegradative versatility of these organisms (see the section Physiology in this Chapter). Given their versatile degradative abilities, it seems likely that natural enrichments have occurred for species of *Sphingomonas* and related genera in some of the contaminated habitats cited in Tables 4 and 5.

Many of the sphingomonads described to date were isolated from low-nutrient habitats (e.g., soils and sediments), some of which may be very oligotrophic (e.g., seawater and deep subsurface environments). In fact, the type strain of *Novosphingobium capsulatum* (ATCC 14666^T) was isolated from stored distilled water (Leifson, 1962). In contrast, various strains of *Sphingomonas*, *Sphingobium* and *Novosphingobium* have been isolated from roots or other parts of plants, where one would expect the concentrations of organic carbon to be much higher than in soils, sediments, or seawater. *Sphingomonas* and *Sphingobium* also have been isolated from clinical specimens with relatively high concentrations of organic nutrients, such as blood and sputum. Some of these isolates, especially strains of *Sphingomonas paucimobilis*, have been implicated in certain types of (mostly nosocomial) infections in humans (see the section Disease in this Chapter). These findings indicate that sphingomonads can survive and function over a rather wide range of nutrient concentrations.

In all likelihood, the complete range of habitats that can be occupied by *Sphingomonas*, *Sphingobium*, *Novosphingobium* and *Sphingopyxis* has yet to be determined. In any case, it is obvious from the research reported to date that these organisms are exceedingly widespread in nature and that this is due primarily to their physiological and metabolic versatility, especially their extensive catabolic capabilities.

Isolation

To the best of our knowledge, no one has published a protocol designed specifically for the isolation of *Sphingomonas*, *Sphingobium*, *Novosphingobium* and/or *Sphingopyxis* species. Virtually all strains of these genera reported to date were isolated more or less fortuitously, in studies that were carried out for various reasons but with no intent to concentrate specifically on *Sphingomonas*-like organisms. The primary objective of some of these studies was to examine the composition of culturable aerobic microbial communities in certain types of environments, in which case environmental samples typically were diluted (if necessary) and plated on commonly available microbiological media. Comparatively dilute media have been used in most studies in which sphingomonads were isolated. Examples include R2A agar (described by Reasoner and Geldreich [1985] and used by Christner et al. [2001]; see also Rickard et al., 2002); a dilute peptone-tryptone-yeast extract-glucose (1% PTYG) medium (Balkwill, 1989; Fredrickson et al., 1995) and PYGV, a dilute peptone-yeast extract-glucose medium with vitamins described by Staley (1968) and used by Männistö et al. (1999). However, sphingomonads have also been isolated using media that have higher concentrations of nutrients, such as Czapek-Dox agar with sucrose (30 g/liter; Denner et al., 2001) and blood agar (Morrison and Shulman, 1986). In all of these studies, sphingomonads just happened to be among the bacteria detected and isolated. Several researchers have mentioned the growth of yellow-pigmented colonies, and this could serve as an initial indication that these types of bacteria may be part of the community being examined. Interestingly, Lee et al. (2001) focused on yellow-pigmented bacteria in natural mineral water sources in Korea because earlier studies had focused on nonpigmented forms. As a result, they isolated several new strains of *Sphingomonas* that were shown to represent three novel species (*S. aquatilis*, *S. koreensis* and *S. taejonensis*).

Many strains of *Sphingomonas* and related genera have been isolated in studies in which enrichment cultures were used to investigate bacteria that degrade specific organic compounds, most often compounds that are important as environmental contaminants. The inoculum for the enrichment in these studies usually is water, soil, or sediment from a contaminated environment. The enrichment itself typically is carried out in some type of mineral-salts medium (which may or may not include vitamins), with the target compound serving as the sole source of carbon and energy. Examples of target compounds used in enrichments that have resulted in the isolation of sphingomonads include 6-aminonaphthalene-2-sulfonic acid (Nörtemann et al., 1986), biphenyl (Furukawa et al., 1983), dibenzo-*p*-dioxin (Wittich et al., 1992), *N*,*N*-dimethylaniline (Schmidt, 1994), fluoranthene (Mueller et al., 1990), 4-fluorodiphenyl ether (Schmidt et al., 1992), Orange II (an azo dye; Coughlin et al., 1999), 2-methylphenanthrene (Gilewicz et al., 1997; Sabaté et al., 1999), nonylphenol (Fujii et al., 2001), pentachlorophenol (Saber and Crawford, 1985; Radehaus and Schmidt, 1992), phenanthrene (Dutta et al., 1998), the herbicide Isoproturon™ (Sørensen et al., 2001), tetralin (Hernáez et al., 1999), and several others.

To isolate organisms that degrade compounds like those listed above, it usually has been nec-

essary to run the initial enrichment culture for an extended period of time and to subculture at least twice in fresh batches of the enrichment medium. While isolating a 2-methylphenanthrene-degrading *Sphingomonas* strain (2MPII), for example, Gilewicz et al. (1997) incubated an initial enrichment for one month and then made two successive transfers into fresh medium, incubating each of the transfers for another month. Sørensen et al. (2001) used 15 successive subcultures in fresh medium during the isolation of a *Sphingomonas* strain (SRS2) that degrades the phenylurea herbicide Isoproturon™. Variations on the enrichment approach have included the use of multiple substrates instead of a single target compound (Puhakka et al., 1995), a soil column (Horvath et al., 1990), and/or a continuous-flow fluidized-bed bioreactor (Puhakka et al., 1995). Regardless of the details, enrichment and subculturing may yield a mixed culture, in which case one still has to isolate the strain that actually degrades the compound of interest, assuming the reactions are carried out by a single strain as opposed to a consortium. This is most often done by plating the mixed culture on a general growth medium, isolating the different colony types by re-streaking on fresh medium, and then testing each of the pure cultures for their ability to degrade the target compound. However, some authors have developed indicator media on which the colonies that degrade the target compound are recognized by a change in the appearance of the surrounding medium (e.g., Saber and Crawford, 1985; Sabaté et al., 1999). This approach greatly lessens the time required to detect and isolate the desired strain(s).

A few strains of *Sphingomonas* have been obtained by using very specialized procedures for isolation of organisms with certain types of physiological traits other than the ability to use a specific compound as a carbon source. For example, Eguchi et al. (2001) and Vancanneyt et al. (2001) used extinction dilution techniques and enrichments in filter-sterilized seawater to isolate oligotrophic strains of *Sphingomonas alaskensis* from seawater near Cape Muroto in Japan and Resurrection Bay in Alaska, respectively. Ashtaputre and Shah (1995) isolated a *Sphingomonas paucimobilis* strain (GS1) that produces a viscous, gel-forming exopolysaccharide by plating soil from Baroda, India, on a nitrogen-free sucrose agar medium and looking for viscous colonies.

Cultivation

The types of media that have been used to cultivate sphingomonads are nearly as varied as the habitats from which they have been isolated (see the section Habitat in this Chapter). A variety of complex media can be utilized for routine cultivation of most species. For example, many of them have been cultured for phylogenetic and biochemical studies on various combinations of peptone, yeast extract, and a source of carbon and energy (e.g., glucose; Takeuchi et al., 1993; Takeuchi et al., 1995; Balkwill et al., 1997a). However, other complex media have also been used. Examples include trypticase soy broth (TSB) or agar (TSA; Zipper et al., 1996; Denner et al., 2001; Lee et al., 2001; Yabuuchi et al., 2001), Luria broth (Kim et al., 2000), nutrient agar (Lee et al., 2001), and brain-heart infusion agar (for pathogens; Takeuchi et al., 1993).

As a group, sphingomonads are metabolically very diverse and able to degrade both a broad range of naturally occurring organic compounds and many different types of refractory environmental pollutants. As a result, a variety of chemically defined media have been used to cultivate these organisms, typically for enrichment cultures using a single organic compound as the sole source of carbon and energy (e.g., Saber and Crawford, 1985; Katayama et al., 1988; Mueller et al., 1990; Schmidt et al., 1992; Wittich et al., 1992; Takeuchi et al., 1993; Parsons et al., 1998; Wittmann et al., 1998; Fukuda et al., 2002). Our laboratory utilized a defined mineral salts medium designed for cultivation of aerobic pseudomonads to grow aromatic-degrading isolates from subsurface sediments (Fredrickson et al., 1995). Similar media have been used by others (Fortnagel et al., 1990) and often contain phosphates (which also serve to buffer pH), $(NH_4)_2SO_4$, magnesium and calcium salts, and a trace element solution (for examples, see Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ) media 457 and 465; http://www.dsmz.de/media). Mineral media are sometimes supplemented with peptone and/or vitamins to enhance growth (Zipper et al., 1996).

Most strains of sphingomonads are mesophiles and, therefore, are routinely cultured at 30°C. Although some strains have been isolated from low-temperature environments and some are even psychrotrophic (Eguchi et al., 1996), they also grow well at mesophilic temperatures (Christner et al., 2001). No thermophilic sphingomonads have been isolated to our knowledge. All known species are obligate aerobes; to date, no facultative strains been described. Some of the marine-derived strains have been grown in media containing NaCl at concentrations similar to those in seawater, but it is not clear whether these strains actually require salt (Eguchi et al., 1996).

Identification

There is no currently available rapid-kit-based or automated method for identification of all of the various species of *Sphingomonas*, *Sphingobium*, *Novosphingobium* and *Sphingopyxis* described to date. One might suspect that a new strain (depending on the conditions under which it was isolated) is a member of one of these genera if it is a Gram-negative, rod-shaped organism that forms yellow, off-white, or whitish brown colonies on general media such as nutrient agar or trypticase soy agar. Perhaps the easiest way to establish whether the isolate is very likely to be a member of one of these genera is to determine its 16S ribosomal RNA gene sequence (or partial sequence) and then analyze that sequence phylogenetically to determine the strain's evolutionary relatedness to previously described species. Standard approaches for doing this have been detailed by many of the authors who have proposed new *Sphingomonas* species in recent years (e.g., Takeuchi et al., 1995; Takeuchi et al., 2001; Balkwill et al., 1997a). The clustering patterns in the resulting phylogenetic trees and the signature nucleotide bases at certain positions in the 16S rRNA gene (see Table 2) will indicate whether the isolate is highly likely to be a member of one of the four *Sphingomonas*-related genera described by Takeuchi et al. (2001).

Following phylogenetic analysis, several additional analyses should be done to confirm that an isolate is a member of *Sphingomonas*, *Sphingobium*, *Novosphingobium* or *Sphingopyxis* on the basis of the distinguishing characteristics of these genera (Table 2) described by Takeuchi et al. (2001). At a minimum, one should show that glycosphingolipids (GSLs) are present in the cell envelope and that ubiquinone Q10 is the principal respiratory quinone. GSLs can be detected and identified by extraction with chloroform:methanol, followed by thin layer chromatography (TLC; Kawahara et al., 1991). Isoprenoid quinones can be extracted with chloroform:methanol, separated by TLC, and identified by high-performance liquid chromatography (HPLC) analysis (Takeuchi et al., 1993). Lipid composition, especially the major fatty acids and 2-hydroxy fatty acids, should also be determined and various methods can be used to do this (for examples, see Balkwill et al. [1997a], Yabuuchi et al. [1999], and Takeuchi et al. [2001]). Some authors have utilized the Microbial Identification System (MIDI Inc., Newark, DE, USA) for lipid analysis (for examples, see Nohynek et al. [1995] and Lee et al. [2001]).

To identify an isolate to the species level within one of the *Sphingomonas*-related genera, it generally would be necessary to perform substrate-utilization and other physiological analyses. For details, the reader is referred to the species descriptions and techniques cited in the taxonomy papers for each recognized species in Tables 1 and 3. It may appear from these analyses that an isolate is a new species. If so, one would then have to establish this by showing either that 16S rRNA gene sequence similarities are below 97% or that chromosomal DNA-DNA reassociation values are below 70% when the isolate is compared to the phylogenetically most closely related established species (see Stackebrandt and Goebel, 1994).

Preservation

Strains of *Sphingomonas* and related genera are readily preserved by lyophilization, and culture collections routinely supply these organisms in the form of freeze-dried stocks. To provide an extra measure of insurance for long-term preservation, however, they should also be frozen in a cryoprotectant and stored at very low temperature. Cultures typically are frozen in their usual growth medium containing either 20–25% glycerol or 7% dimethylsulfoxide (DMSO) as the cryoprotectant. In our laboratory, we grow broth cultures to the late exponential phase, concentrate the cells by centrifugation, and resuspend them in a relatively small volume of fresh medium containing 7% DMSO prior to freezing. After freezing by placement in a –80°C freezer or dry ice-methanol bath, the frozen stocks can be stored at –80°C and/or under liquid nitrogen.

Physiology

Catabolism of Organic Compounds

Sphingomonas, *Sphingobium*, *Novosphingobium* and *Sphingopyxis* species are aerobic (nonfermentative), yellow-pigmented, nonsporeforming Gram-negative bacteria that either are nonmotile or contain a single polar flagellum. Glucose is assimilated by most strains (Balkwill et al., 1997a) and is frequently used as a growth substrate in both complex and defined media. A wide variety of other sugars including arabinose, fucose, galactose, lactose, mannose, melibiose, sucrose, trehalose, and xylose also are commonly assimilated (Balkwill et al., 1997a; Denner et al., 2001; Fujii et al., 2001). Many sphingomonads can degrade polysaccharides in addition to mono- and disaccharides. For example, *Sphingomonas* strain A1 can use high-molecular-weight alginate for growth by depolymerizing the polymer with an intracellular alginate lyase

(Momma et al., 1999). This organism has developed a novel pit-dependent endocytosic uptake system for the metabolism of macromolecules (Hashimoto et al., 2001).

Sphingomonads are well recognized for their metabolic versatility and ability to degrade a broad range of environmental contaminants in addition to various natural organic compounds primarily of plant origin. Some strains have even been isolated from arsenic-contaminated mine tailings and can reduce arsenate to arsenite under aerobic conditions (Macur et al., 2001). They are particularly adept at degrading aromatic compounds including single and multi-ring structures with various substitutions and functionality. Examples of the classes and types of organic compounds that can be degraded by sphingomonads are provided in Table 6. Because of their metabolic versatility, the metabolic pathways of sphingomonads have been studied in detail (e.g., Schmidt et al., 1992; Wittich et al., 1992; Zylstra and Kim, 1997), as have the properties of their associated catabolic enzymes (Bünz and Cook, 1993a; Bünz et al., 1993b; Bertini et al., 1995; Armengaud and Timmis, 1998; Hynkova et al., 1999; Xun et al., 1999; Byun et al., 2001; Vuilleumier et al., 2001; Oakley et al., 2002).

Extracellular Biopolymers

Sphingomonas strains are known to produce extracellular biopolymers, including certain gellan-related exopolysaccharides (Lobas et al., 1992; Martins et al., 1996; Hashimoto and Murata, 1998). For example, some strains of *S. paucimobilis* produce a gellan-related polysaccharide that forms a gel if deacetylated (Anson et al., 1987). Gellan-related polysaccharides synthesized by strains of *Sphingomonas* are collectively referred to as "sphingans" (Pollock, 1993). They share the same carbohydrate backbone structure (–X-glucose-glucuronic acid-glucose-X–) in which X is either L-rhamnose or L-mannose. The yield, molecular structure, and properties of sphingans are significantly affected by growth medium composition (Fialho et al., 1999). *Sphingomonas paucimobilis* GS1 produces an anionic heteropolysaccharide with a viscosity that is 5.5-fold greater than that of xanthan gum. This compound is stable over a pH range of 2–10 and in the presence of NaCl con-

Table 6. Organic compounds metabolized by members of the genus *Sphingomonas*.

Compound class or compound	Representative strain(s) (reference)
Nonylphenol	*Sphingomonas cloacae* (Fujii et al., 2001)
Dibenzo-*p*-dioxin, dibenxofuran	*Sphingomonas wittichii* strain RW1 (Wittich et al., 1992)
Diphenyl ethers	*Sphingomonas* sp. strain SS3 (Schmidt et al., 1992)
Polychlorinated hydrocarbons:	
Pentachlorophenol	*Sphingomonas* sp. strain ATCC 39723 (Crawford and Ederer, 1999);
Polychlorinated	*S. chlorophenolica* RA2 (Witmann et al., 1998)
biphenyls	*S. paucimobilis* BPSI-3 (Davison et al., 1996)
Monoaromatics:	
toluene, xylene, cresol	*S. aromaticivorans* F199 (Balkwill et al., 1997a);
	S. yanoikuyae B1 (Zylstra and Kim, 1997)
Polyaromatic hydrocarbons:	
naphthalene, anthracene,	*S. yanoikuyae* B1 (Gibson, 1999)
phenanthrene	*S. paucimobilis* EPA 505 (Mueller et al., 1990)
fluoranthene	*S. paucimobilis* 2322 (Dutta et al., 1998);
substituted naphthalenes	*Sphingomonas* sp. strain BN6 (Riegert et al., 1999)
Pesticides:	
lindane	*S. paucimobilis* UT26 (Nagata et al., 1999)
diclofop-methyl	*S. paucimobilis* (Adkins, 1999)
2,4-D, mecoprop	*S. herbicidovorans* MH (Kohler, 1999)
carbofuran	*Sphingomonas* sp. strain CF05 (Feng et al., 1997)
isoproturon	*Sphingomonas* sp. strain SRS2 (Sørensen et al., 2001)
Lignin monomers & dimers:	*S. paucimobilis* SYK-6 (Masai et al., 1999)
Triterpenoids (resin acids): dehydroabietic acid, abietic acid, palustric acid, dichlorodehydroabietic acid	*S.* spp. DhA-33 (Mohn and Stewart, 1997; Mohn et al., 1999)
Polymers:	
Polyethers (polyethylene glycol)	*S. macrogoltabidus* strain 203,
	S. terrae E-1-A (Kawai, 1999; Takeuchi et al., 1993)

centrations up to 50 g · liter^{-1}, has a gel strength four times that of agar, and is able to withstand autoclaving (Ashtaputre and Shah, 1995). Functions of extracellular polysaccharides produced by sphingomonads include the attachment of cells to surfaces (Azeredo and Oliveira, 2000), the formation of biofilms (Johnsen et al., 2000; Kuehn et al., 2001), and the probable enhancement of pathogenicity (Pollock, 1993). In addition to sphingans, some sphingomonads can produce enzymes that are involved in the depolymerization of polysaccharides (Hashimoto et al., 1996; Sutherland and Kennedy, 1996; Hashimoto and Murata, 1998). Some strains of *Sphingomonas* exhibit a planktonic/sessile dimorphism, with the sessile state being marked by production of a viscous exopolysaccharide capsule (Pollock and Armentrout, 1999). The factors that control these behaviors in *Sphingomonas* are complex and poorly understood, but it is clear that culture conditions, such as the level of aeration, can influence shifts between the planktonic and sessile states and, hence, exopolysaccharide production.

In an effort to increase gellan yield in "*Sphingomonas elodea*," Vartak et al. (1995) noted that mutants deficient in 6-phosphogluconate dehydrogenase were unaffected in CO_2 production or gellan yield from glucose. This result combined with other enzyme analyses indicated that "*S. elodea*" utilizes the Entner-Doudoroff and pentose-phosphate pathways, rather than the Embden-Meyerhof glycolytic pathway, for glucose metabolism.

Membrane Structure

Sphingomonads are nearly unique among Gram-negative bacteria in that they are devoid of lipopolysaccharides (LPS) that can carry endotoxins. Instead, the cell envelope structure of *S. paucimobilis* includes a cell membrane that consists of proteins, phospholipids, and respiratory quinones and an outer membrane that contains glycosphingolipids (GSLs) with the carbohydrate moiety facing away from the cell surface (Kawasaki et al., 1994). The GSLs therefore occupy a position similar to that of LPS in other Gram-negative bacteria and likely provide many of the same functions (White et al., 1996), such as a barrier to bactericidal substances. *Sphinogomonas paucimobilis* GSLs include a glycosyl portion consisting of D-mannose-*p*-(1→2)-α-D-galactose-*p*-(1→6)-α-D-glucosamine-*p*-(1→4)-α-D-glucuronic acid-1-α-(18:0)/(18:1) ω5 dihydrosphingosine with an amide-linked 2-hydroxy (14:0) at the 2 position of the long-chain base (Kawahara et al., 1991). The structure of GSLs can vary from species to species (Kawahara et al., 1999; Kawahara et al., 2001). Because the carbohydrate part of a GSL is far shorter than that of LPS, the cell surface of sphingomonads is more hydrophobic that that of other Gram-negative bacteria (Kawahara et al., 2001). This hydrophobicity likely contributes to the ability of sphingomonads to degrade hydrophobic polycyclic aromatic hydrocarbons (PAHs; Mueller et al., 1990; Ye et al., 1996; Ryeom et al., 2000; Daane et al., 2001) and susceptibility to hydrophobic antibiotics (Smalley et al., 1983).

Oligotrophy

Sphingomonas species such as *S. alaskensis* appear to be the dominant members of the picoplankton and important contributors to the total biomass and nutrient recycling in some low-nutrient marine environments (Eguchi et al., 2001). The type strain of *S. alaskensis* (RB2256) was isolated from Resurrection Bay in Alaska using a dilution-to-extinction method (Schut et al., 1997) and produces ultramicrocells (<0.08 μm^3) in dilute or rich medium (Eguchi et al., 2001). *Sphingomonas alaskensis* RB2256 appears to be well-adapted for survival under oligotrophic conditions as it can grow in liquid sea water medium containing less than 1 mg · liter^{-1} of dissolved organic carbon (Schut et al., 1997) and has an intermediate sized genome (~3.25 Mbp; Eguchi et al., 2001) with a single copy of the rRNA operon (Fegatella et al., 1998). Moreover, gene expression in this strain is highly regulated in response to starvation, including considerable co- and post-translational modification of proteins (Fegatella and Cavicchioli, 2000). Both growing and starved cells were remarkably resistant to stresses such as elevated temperature and high concentrations of ethanol and hydrogen peroxide, indicating that strain RB2256 has stress-resistance mechanisms that are distinct from those of other non-differentiating bacteria (Eguchi et al., 1996). Maximum growth rates were reached almost immediately when carbon-limited or starved cells of strain RB2256 were exposed to excess glucose, indicating that protein synthesis was constitutively regulated and that this organism is well adapted to life in seawater.

Genetics

Genetic systems have been used primarily to study aromatic catabolic metabolism and sphingan biosynthetic pathways in sphingomonads. Conjugation of broad host range plasmids

pUFR042 (IncW; De Feyter and Gabriel, 1991) into *N. aromaticivorans* F199 (M. F. Romine, unpublished results) and pSEB24 (IncQ; Yamazaki et al., 1996) or pRK311 (IncP; Ditta et al., 1985) into *Sphingomonas* S88 (Yamazaki et al., 1996) have been successful. Sphingomonads are inherently resistant to polymyxin B, which inhibits proper cytoplasmic membrane formation in most other Gram-negative bacteria, including *Escherichia coli*, and therefore makes an excellent selectable marker to discriminate against donor cells in conjugation experiments. The majority of the genetic studies on sphingomonads have focused on the construction of transposon mutants generated either with *Tn10* (Pollock et al., 1998) or with *Tn5* (Kim and Zylstra, 1995; Feng et al., 1997; Zylstra and Kim, 1997; Bünz et al., 1999; Romine et al., 1999; Kaneko et al., 2000; Bastiaens et al., 2001; Story et al., 2001).

Deletion mutants in *Sphingomonas* strain S88 have been constructed by standard double crossover exchange, utilizing a narrow host range plasmid, pSEB26, which contains the pMB1 (pUC12/13) replication origin. The ability of many sphingomonad strains to metabolize sucrose suggests that use of the sucrose sensitivity phenotype that is conferred by levansucrase (*sacB*) as a selectable marker for the second crossover event will not be suitable for most wildtype strains of these organisms. Indeed, a *sacB* homolog was found in the genome sequence of the sucrose-metabolizing *Novosphingobium aromaticivorans* strain F199.

The aromatic catabolic properties of many sphingomonads reside on large plasmids (>50 Kb). Plasmids have been cured from *Sphingomonas* sp. strain CF06 by growing cells at elevated temperature (42°C) for 2 days (Feng et al., 1997). In *Tn5* mutants selected for their inability to metabolize carbofuran, these plasmids were found to have undergone rearrangements, deletions, or loss. Because of their large size, specialized techniques are required to isolate sphingomonad plasmids (Furukawa and Chakrabarty, 1982; Stillwell et al., 1995; Feng et al., 1997). Transfer of the *N. aromaticivorans* pNL1 conjugative plasmid to *Sphingomonas* strain S88m260 has been demonstrated. The *sspB*$^{-}$ phenotype of the recipient strain makes it resistant to the peptidoglycan synthesis inhibitory antibiotic, bacitracin (Pollock et al., 1998), to which other sphingomonads are sensitive. Stringent starvation protein B (SspB) is required for biosynthesis of capsular polysaccharide (Pollock et al., 1998). Similar spontaneous bacitracin-resistant recipient strains for conjugal transfer can be isolated by selection in the presence of bacitracin (T. J. Pollock, personal communication).

Genomics

Novosphingobium aromaticivorans F199 harbors a 185,457-bp conjugative, aromatic catabolic plasmid, pNL1, that has been completely sequenced (Romine et al., 1999). The entire genome of this organism was sequenced to near completion by the United States Department of Energys Joint Genome Institute, and the data are available at (the Joint Genome Institute website). Draft annotations of the genome sequence are available at (Oak Ridge National Laboratory Computational Biology website (DB1)) and at PEDANT (Protein Extraction, Description, and Analysis Tool) website). To date, this is the only publicly available genomic sequence information for a sphingomonad. Strain F199, which was isolated from deep subsurface sediments Fredrickson et al., 1995), has an additional plasmid, designated "pNL2" (~480 kbp) and an estimated genome size of 2.86 Mb (R. Schneider, unpublished data), but genome sequence analyses suggested that the genome size is closer to 3.8 Mb. The average G+C content of pNL1 is 62 mol% and that of the genome is 65.1 mol%. Genome sizes of other *Novosphingobium* strains from terrestrial subsurface environments were estimated to be approximately 2.9 Mb (*N. subterraneum* B0478), 3.76 Mb (*N. aromaticivorans* B0522), 3.82 Mb (*N. aromaticivorans* B0695), and 3.81 Mb (*N. stygium* B0712), whereas those for the type strains of *N. capsulatum* (ATCC 14666) and *S. paucimobilis* (ATCC 29837) were estimated to be 4.18 Mb and 2.6 Mb, respectively (Fredrickson et al., 1999). Extrachromosomal elements hosted by these strains ranged between 48 Kb and 750 Kb (150, 230, 420, and 630 Kb for strain B0478; 50, 130, and 270 Kb for strain B0712; 180 and 650 Kb for strain B0522; 48, 150, and 750 Kb for strain B0695; 230 and 600 Kb for ATCC 14666; and 360 Kb for ATCC 29837). These genome sizes are comparable to those of *S. alaskensis* strains RB2256, AF01, and KT-1, whose genome sizes have been estimated to range between 3.11 and 3.25 Mb, with a G+C content between 64.8 and 65.3 mol% (Eguchi et al., 2001).

Over one-third of *N. aromaticivorans* plasmid pNL1 (83 open reading frames) is devoted to aromatic catabolic genes. The remainder of the plasmid encodes for genes that are necessary for conjugation and replication. The replication region includes two transposons and two group II intron-associated maturases. Group II introns commonly have been found in the genomes of eukaryotic organelles in fungi and plants and, more recently, in bacteria. In bacteria, they are most often associated with insertion sequence elements (Ferat et al., 1994; Knoop and Brennicke, 1994; Kulaeva et al., 1998; Martínez-

Abarca et al., 1998), conjugative transposons (Mullany et al., 1996), conjugative plasmids (Mills et al., 1996), and chromosomal sex factors (Shearman et al., 1996), suggesting that these elements can be disseminated via horizontal transfer. Homing by mobile group II introns results in unidirectional, lateral transposition of the intron to a specific site within an intron-less copy of the intron's normal host gene. Group II homing is unique in that it does not require recombinase activity, is not critically dependent on exon homology, and occurs without marker conversion in flanking exons (Cousineau et al., 1998). These properties are conducive to interspecies spread of the introns, which may account for the wide distribution in prokaryotes and eukaryotes. A possible role for group II introns in the transfer and evolution of biodegradative functions is suggested by studies by Yeo et al. (1997), who demonstrated that when a conjugative plasmid was utilized to capture genes responsible for 2,5-xylenol catabolism, a group II intron was concurrently trapped on the plasmid. Mobile group II introns can be re-targeted and used for highly specific chromosomal gene disruption. Consequently, these introns have been proposed as a useful tool for genetic engineering and functional genomics (Karberg et al., 2001).

The aromatic catabolic cluster includes genes responsible for catabolism of naphthalene, biphenyl, and *m*-xylene. Seven sets of oxygenase large and small subunits are present on pNL1. Enzymes belonging to this family typically catalyze the initial ring oxidation step in aromatic catabolic pathways. The duplication of these genes, but not those that encode enzymes needed for further conversion of oxygenase catabolic products to catechol, suggests that the enzymes they encode may be responsible for the broad substrate specificity of *N. aromaticivorans* strain F199. Analysis of the genome sequence also showed duplication of genes encoding cytochrome *c* and flavocytochrome methylhydroxylase components of enzymes that likely catalyze the initial oxidation of substrates such as *p*-cresol, vanillyl alcohol, and eugenol.

Surprisingly, instead of being clustered by the catabolic pathway in which their products participate, catabolic genes in *N. aromaticivorans* F199 plasmid pNL1 are co-located with those for other types of catabolic enzymes within eleven putative operons. The DNA sequences in the catabolic gene-encoding region of pNL1 have approximately 70% identity to sequences available for *S. yanoikuyae* B1 (Kim, 1996a) and *S. xenophaga* BN6 (GenBank accession number U65001). While the gene order and orientation of the compared genes in strains B1 and F199 are identical, two genes that encode putative membrane proteins are absent in strain B1 and a third membrane-encoding gene in strain B1 has an insertion sequence (Fig. 1a). In strain BN6, gene deletions, insertions, and rearrangements relative to pNL1 result in inactivation or deletion of the catechol extradiol cleavage genes and *m*-xylene catabolic genes (Fig. 1b). Unlike strain F199, strains B1 (Gibson et al., 1973) and BN6 (Stolz et al., 2000) were isolated from waters contaminated with anthropogenic aromatic hydrocarbons. One can speculate that these strains share a common ancestor with F199 and that the selective pressures produced by the pollutants resulted in genetic recombinatorial events that improved the ability of these strains to compete and to grow on man-made aromatic hydrocarbons. The Middendorf formation sediments from which strain F199 was isolated are estimated to have been deposited about 100 million years ago, and the groundwater that flows through this formation has been dated at 4,000 years of age (Fredrickson et al., 1999; Murphy et al., 1992). The primary carbon and energy source available to microorganisms living in these sediments is recalcitrant sedimentary organic matter or lignite. The heterogeneity of lignite and the extremely slow rates of carbon exchange in these sediments may explain why strain F199 maintains so many aromatic catabolic genes and the absence of transposons or similar mobile elements in the regions that encode them.

Ecology

Although sphingomonads have been isolated from a wide range of environments and the physiological and metabolic properties of select strains have been examined in detail, relatively little is known regarding the ecology of this diverse group of microorganisms. Two aspects of their metabolism probably contribute to their widespread distribution in the environment: their ability to utilize a wide range of organic compounds and their ability to grow and survive under low-nutrient or starvation conditions. *Sphingomonas* is a dominant member of the picoplankton population in some marine environments, as evidenced by the isolation of *S. alaskensis* from a 10^5 dilution of seawater from near Cape Muroto, Japan, where the standing bacterial count was 3.1×10^5 cells $\cdot$ ml^{-1} (Eguchi et al., 2001). Similarly, seven phylogenetically related strains of *S. alaskensis* were isolated from a 10^6-fold dilution of seawater from Resurrection Bay, a deep fjord of the Gulf of Alaska (Vancanneyt et al., 2001). The physiological properties of these strains, as described ear-

lier, showed that they are well adapted to life in oligotrophic marine environments. *Sphingomonas* isolates were also among psychrotrophic bacteria cultured from Antarctic sea ice (Bowman et al., 1997) and from water collected at the mouth of Yaquina Bay, Oregon (Suzuki et al., 1997). The widespread distribution and numerical abundance of these organisms suggest that they play an important role in the cycling of carbon and other nutrients in marine environments. In addition to general ecological roles in nutrient cycling, *Sphingomonas* has also been identified as the pathogenic agent of coral plague, a disease that was first identified on coral of the Florida Reef Tract in 1995 and has spread rapidly since (Richardson, 1997; Richardson et al., 1998). A strain of *S. paucimobilis* served as a host for several temperate marine phage (Jiang et al., 1998). Although the extent of this association in nature is unknown, the interactions between marine viruses and their hosts likely have a significant impact on the genetic diversity and composition of marine microbial communities. Additional investigations will most likely reveal even more extensive ecological roles of *Sphingomonas* in marine environments.

Consistent with the idea of sphingomonads being adapted to oligotrophic environments and having the ability to assimilate a wide range of organic compounds was the isolation of three new species of *Sphingomonas* (now renamed "*Novosphingobium*" species) from deeply buried (>200 m below land surface) sediments of the Atlantic Coastal Plain (ACP) of the eastern United States (Fredrickson et al., 1995). The organic carbon content of the groundwater from ACP aquifers is generally very low, <0.5 mg · liter^{-1}, but sedimentary organic carbon can be as high as 1.7% (wt/wt; Fredrickson et al., 1999). We have previously suggested that the extensive catabolic capabilities (e.g., assimilation of aromatic compounds) of these deep subsurface strains might be a result of their adaptation to growth on a range of structurally diverse organic compounds that are only slowly released from solid phase carbon associated with buried sediments. Although the distribution of sphingomonads in the deep subsurface has not been investigated extensively, they have also been isolated from deep sediments from the United States Department of Energys Hanford Site in south-central Washington (Balkwill et al., 1997b; Chandler et al., 1998). Even less is known about the ecology of sphingomonads in the terrestrial subsurface than in marine environments, but they likely fill a similar niche as oligotrophic heterotrophs that contribute to the turnover of organic carbon and perhaps other nutrients.

Many strains of sphingomonads with novel biodegradative properties have been isolated from contaminated soils and sediments (see Tables 4 and 5). They have also been detected in contaminated sediments with molecular-based techniques (Kasai et al., 2001). These findings suggest that the sphingomonads have an important ecological role in contaminated environments, but specific information in this regard is limited. There is some evidence, however, that organic contaminant-degrading strains of sphingomonads are able to compete effectively for resources in contaminated environments and, in some cases, may be the primary organisms responsible for removal of the contaminants. A fluidized bed reactor that was utilized to treat polychlorophenol-contaminated groundwater in Finland for over six years was dominated by *Novosphingobium* sp. strain M1, which could biodegrade the three main contaminants at the in situ temperature of 8°C (Tirola et al., 2002). A strain of *S. paucimobilis* that degrades 2,4-dichlorophenoxyacetic (2,4-D) acid (strain 745) was the second most dominant population (after a genetically constructed strain of *Pseudomonas cepacia*) in a Kansas prairie soil that was treated with 2,4-D and inoculated with four strains of 2,4-D-degrading bacteria (Ka et al., 1994; Kim et al., 1996b). Although a strain of *S. paucimobilis* that degrades hexachlorocyclohexane was observed to survive poorly after it was inoculated into an unamended control soil, it survived and grew in contaminated soil, especially inside of soil aggregates less than 0.025 mm in diameter (Nishiyama et al., 1992). Contaminant-degrading sphingomonad strains have been shown to effectively degrade organic contaminants when inoculated into subsurface sediment (Fredrickson et al., 1999) or soil (Halden et al., 1999). They also maintained higher population densities in the presence of the contaminant than in its absence. These findings indicate that sphingomonads can utilize contaminants as a growth and energy source and that they can compete successfully with the indigenous organisms in complex environments.

Disease

Although it is widespread in other environments (Table 5), *Sphingomonas paucimobilis* (formerly *Pseudomonas paucimobilis*) also has a long history of being associated with equipment in hospitals and with various types of clinical specimens. When Holmes et al. (1977) described *Pseudomonas paucimobilis*, 22 of 28 strains included in the new species had come from hospital equipment, liquid solutions used in hospitals, or clinical specimens. At least one strain of three additional *Sphingomonas* species (*S.*

adhaesiva, *S. parapaucimobilis* and *S. sanguinis*) and one strain of *Sphingobium yanoikuyae* have also been isolated from various clinical sources (Tables 4 and 5). Strains of *S. paucimobilis* are thought to be widespread and endemic members of the microbiota in hospitals (Reina et al., 1991). Equipment and other sources from which they have been isolated include various types of respiratory therapy items, humidifiers, water, air, bedside water bottles, sinks, temperature probes, etc. (Holmes et al., 1977; Crane et al., 1981; Faden et al., 1981; Reina et al., 1991; Lemaitre et al., 1996). Clinical specimens from which strains of *S. paucimobilis* have been obtained include blood cultures, vaginal swabs, urine, sputum, tracheal secretions, sinus washings, spinal fluid, etc. (Holmes et al., 1977; Crane et al., 1981; Faden et al., 1981; Morrison and Schulman, 1986; Lemaitre et al., 1996).

The occurrence of *S. paucimobilis* in a clinical specimen does not necessarily mean that the organism is causing an infection. For example, Faden et al. (1981) investigated an incident in a hospital in which *P. paucimobilis* was isolated from maxillary sinus washings four times in five weeks. There was no indication that the patients examined in this incident had active cases of sinusitis. Rather, the bacterium appeared to be present as a noninfectious contaminant. The source of the contamination was identified as a leaking sink, under which a saline solution used to cleanse sinuses was stored. Similarly, Lemaitre et al. (1996) investigated a situation in which *S. paucimobilis* was isolated from the tracheal secretions of 85 mechanically ventilated babies in a neonatal intensive care unit. Fortunately, none of the neonates developed pneumonia or sepsis. The source of the contamination was traced to the temperature probes of respiratory ventilators used in the hospital.

Although *S. paucimobilis* is sometimes present in clinical specimens as a noninfectious contaminant, it is capable of causing active infections in humans, albeit somewhat infrequently. Through 1991, at least 18 cases of infections attributed to *S. paucimobilis* were described in the literature (see reviews by Morrison and Schulman [1986] and Reina et al. [1991]). Among these infections were six cases of bacteremia (bacterial infections of the bloodstream), two leg ulcers, four cases of peritonitis (in patients undergoing chronic ambulatory dialysis), a brain abscess, a cervical adenopathy, a splenic abscess, a respiratory infection, a urinary infection, and a single case of meningitis. Sporadic reports of *S. paucimobilis* infections (mostly cases of bacteremia, but also urinary, respiratory, and wound infections) have continued to appear since the Reina et al. (1991) review (e.g., Lemaitre et al., 1996; Martino et al., 1996; Gorricho et al., 1998; Hsueh et al., 1998; de Otero et al., 1998; Paster et al., 2002; Perola et al., 2002).

Fortunately, infections by *S. paucimobilis* are seldom serious or life threatening, so long as they are treated properly. Apparently, *S. paucimobilis* has limited virulence in comparison to *Pseudomonas* and other genera that have been associated with similar infections and sources of contamination (Morrison and Shulman, 1986; Reina et al., 1991; Hsueh et al., 1998). The reason for this is not known, although it has been suggested that the relative lack of virulence is a result of the absence of lipopolysaccharide (LPS) and its associated endotoxins in *Sphingomonas* and other genera with GSLs in their envelopes (Hsueh et al., 1998). In any event, infections caused by *S. paucimobilis* can be treated effectively with antibiotics. Antibiotic susceptibility patterns have been studied in some detail (Gilardi, 1984; Reina et al., 1991), and these should be kept in mind when deciding on a specific course of treatment.

As noted elsewhere in this chapter, *Sphingomonas paucimobilis* and related species are able to survive in a rather broad range of environments. This is consistent with their appearance as contaminants in many different hospital-related reservoirs of infection (equipment, solutions, water systems, etc.). Given the near ubiquity and considerable adaptability of these organisms, it might be almost impossible to prevent occasional *S. paucimobilis*- related nosocomial infections of humans, even when treatment facilities exercise rigorous precautionary measures.

The ability of *S. paucimobilis* to infect humans is now well established, but it remains to be seen whether members of *Sphingomonas*, *Sphingobium*, *Novosphingobium* and *Sphingopyxis* can cause diseases in plants. Several strains of these genera were isolated from the root systems of various plants (see Tables 4 and 5), but there is little or no detailed information on the nature of the relationship between these bacteria and the plants from which they were isolated. To the best of our knowledge, there are no indications that the bacteria are pathogenic to the extent that they are harmful to the plants with which they are associated; they are likely to be saprophytic. *Sphingomonas suberifaciens* is the only confirmed plant pathogen in the four *Sphingomonas*-related genera described by Takeuchi et al. (2001). However, these authors recommended that this species be transferred back to its former designation (*Rhizomonas suberifaciens*) because the inclusion of phytopathogenic forms created a genus that was too broad in terms of its ecological and physiological characteristics (see the section Taxonomy and Phylogeny in this Chapter).

Given that strains isolated from root systems were left in the genus, it appears that Takeuchi et al. (2001) did not consider these organisms to be plant pathogens.

Biotechnological Applications

Their metabolic diversity and ability to produce extracellular gellan-like polysaccharide (sphingans) has generated much interest in sphingomonads for biotechnological applications, and numerous patents utilizing members of this group exist world-wide. General categories of these patents include novel catalyses, bioremediation, fossil fuel desulfurization, novel enzymes, biotin production, and polysaccharide production.

Sphingans have a wide range of applications in the food, pharmaceutical, petroleum and other industries (Sutherland, 1999). One interesting and novel application of the extracellular polysaccharide (EPS) produced by *S. paucimobilis* GS-1 is as a drilling fluid component in oil exploration because its relative stability of viscosity under extremes of pH, temperature and salinity, as well as emulsification properties (Shah and Ashtaputre, 1999). *Sphingomonas* will likely continue to be an important source of organisms for research and development of novel exopolysaccharides.

Biocatalytic transformations, including the degradation of hazardous organic compounds and the conversion of commonly occurring organics to novel or specialty chemicals, have also been among the important applications of sphingomonads. A two-phase partitioning bioreactor containing *S. aromaticivorans* achieved complete biodegradation of naphthalene, phenanthrene, acenaphthene and anthracene at volumetric consumption rates of 90 $mg \cdot liter^{-1} \cdot h^{-1}$ (Janikowski et al., 2002). A strain of *S. paucimobilis* has also been used to bioremediate hexachlorocyclohexane-contaminated soil, in which case greater than 95% removal of the contaminant occurred within two months after inoculation (Senoo et al., 1996). Sphingomonads appear to be ideally suited for bioremediation applications because of their ability to complete and proliferate in contaminated soils and sediments.

Sphingomonas sp. strain HXN-200 has proven to be an excellent biocatalyst for the regio- and stereoselective hydroxylation of pyrrolidines (Li et al., 1999; 2001), *N*-substituted azetidines and piperidines (Chang et al., 2002) and pyrrolidin-2-ones (Chang et al., 2000). Because of their extensive intrinsic catabolic capabilities and amenability to genetic manipulation, sphingomonads are amenable to genetic engineering to obtain strains with improved properties (Vartak et al., 1995; Van Kranenburg et al., 1999).

CELIA J. HUGO, BRITA BRUUN AND PIET J. JOOSTE

Introduction

Formerly belonging to the genus *Flavobacterium*, the genera *Empedobacter* and *Myroides* have now been included in the family Flavobacteriaceae as set out in the introductory chapter on Flavobacteriaceae of this edition (see An Introduction to the Family Flavobacteriaceae in this Volume by Bernardet and Nakagawa). Both these genera are known to have a clinical origin and to be resistant to a wide range of antimicrobials. The aim of this chapter is to give the reader more detail on the taxonomy, phylogeny, habitat, isolation and preservation, identification, pathogenicity and applications of these genera.

Taxonomy and Phylogeny

Members of both genera, *Empedobacter* and *Myroides*, were formerly included in the genus *Flavobacterium*, family Bacteriaceae, tribe Chromobacterieae, and were known as *Flavobacterium breve* (Bergey et al., 1923) and *Flavobacterium odoratum* (Stutzer and Kwaschnina, 1929), respectively. These genera have now been included as two of the 25 genera of the family Flavobacteriaceae (Reichenbach, 1989). The phylogeny and taxonomy of this family are discussed in detail by Bernardet and Nakagawa in Introduction to Flavobacteriaceae in this Volume.

Empedobacter

This organism was isolated for the first time in 1888 by Mori from canal water and was simply known as "the short canal bacillus" (Mori, 1888). In 1890, Lustig named it "*Bacillus brevis*," the only validly published name of this organism until 1994. This name was also used by Frankland and Frankland (1894). After that, this organism was given a variety of names which, unfortunately, were not validly published, namely "*Bacillus canalicolis brevis*" (Cornil and Babes, 1890), "*Bacillus canalis parvus*" (Eisenberg, 1891), "*Bacterium canalis parvus*" (Chester, 1897), "*Bacterium canale*" (Mez, 1898), "*Pseudobacterium brevis*" (Krasil'nikov, 1949), and "*Empedobacter breve*" (Prévot, 1961).

In 1923, Bergey et al. transferred *Bacillus brevis* to the color genus *Flavobacterium* (which they created) as *F. brevis*; this name was used by Stutzer and Kwaschnina (1929) for their isolates. In the eighth edition of *Bergey's Manual*, Weeks (1974) corrected the epithet to *Flavobacterium breve*. In conjunction with an emended description of the genus, Holmes and Owen (1979a) made a request to reject *Flavobacterium aquatile* and to replace it with *F. breve* as the type species of the genus. The Judicial Commission of the International Committee on Systematic Bacteriology, however, denied this request, stating that there was no real potential for confusion if *F. aquatile* was retained, nor were there strong arguments found in the *International Code of Nomenclature of Bacteria* for rejecting *F. aquatile* as the type species of the *Flavobacterium* genus (Wayne, 1982).

Lustig (1890) did not designate the type strain of *B. brevis*, and no neotype strain appears to have been proposed for this species until Holmes et al. (1978) proposed NCTC 11099, isolated from bronchial secretions, as the neotype strain of *F. breve*. Despite being phenotypically homogeneous, strains of *F. breve* were found to be genomically heterogeneous (Owen and Holmes, 1980; Ursing and Bruun, 1991).

In 1994, Vandamme et al. proposed new genus names for some of the species in *Flavobacterium* after extensive genotypic, chemotaxonomic and phenotypic studies. Instead of proposing a new name for *F. breve*, they proposed reviving the name *Empedobacter* (Prévot, 1961) and renamed *F. breve* "*Empedobacter brevis*."

Myroides

Isolated for the first time in 1923, members of the genus *Myroides* have historically been classified as *Bacterium faecale aromaticum* (Stutzer, 1923) and later as *Flavobacterium odoratum* (Stutzer and Kwaschnina, 1929). No further mention of this organism was made in the literature until

1977, when Holmes et al. examined nine clinical isolates and identified them as *F. odoratum*. They gave a revised description of *Flavobacterium* and proposed a neotype strain for *F. odoratum* (NCTC 11036 = ATCC 4651). In this and a subsequent study (Holmes et al., 1979b), it was found that three strains of CDC Group M-4f (Tatum et al., 1974) were identical to *F. odoratum*. These strains were originally assembled and placed into groups by the late Elizabeth O. King and her successors (King, 1959; Tatum et al., 1974). *Flavobacterium odoratum* was, however, not included in the list of species of flavobacteria in the *Bergey's Manual of Systematic Bacteriology* until 1984 (Holmes et al., 1984).

It was suggested by several authors that *F. odoratum* should be classified in a separate genus on the basis of phenotypic and phylogenetic differences (Holmes and Owen, 1981; Holmes et al., 1984; Gherna and Woese, 1992; Nakagawa and Yamasato, 1993; Bernardet et al., 1996). Heterogeneity on the basis of colonial morphology, nutritional features, fatty acid profiles, and genomic relatedness among *F. odoratum* strains, were, however, also observed (Owen and Holmes, 1978; Rasoamananjara et al., 1986; Rasoamananjara et al., 1987). It was only in 1996 that Vancanneyt et al. performed an extensive polyphasic taxonomic analysis and reclassified *F. odoratum* into a new genus as *Myroides odoratus* (type strain, ATCC 4651). They also described an additional species, namely *Myroides odoratimimus* (NCTC 11180).

Habitat

Clinical Isolates

Although originally isolated from canal water, *Empedobacter* is mainly known to have a clinical origin, although it accounts for less than 0.1% of all clinical isolates of nonfermentative Gram-negative bacteria (G. L. Gilardi, personal communication, cited in Pickett et al., 1991). Stutzer and Kwaschnina (1929) were the first investigators to report the isolation of this organism from a clinical source, namely feces from a patient with relapsing fever. Since then, *Empedobacter* strains have been isolated from human eyes (swabs), bronchial secretions, peritoneal fluid, dialysis fluid, serous cavity fluid, cervixes and vaginas (swabs), wounds, blood, and urine (Holmes et al., 1978; Bruun, 1982).

Although it is not regarded as a component of the human microflora, *Myroides* accounts for 0.2% of all clinical isolates of nonfermentative, Gram-negative bacteria (Pickett et al., 1991). The first *Myroides* strains isolated were from the human intestine (Stutzer, 1923; Stutzer and Kwaschnina, 1929). Since then this organism has been isolated from human urine, feces, wound discharge, sputum and blood (Holmes et al., 1979b; Bruun, 1982; Shewan and McMeekin, 1983; Rubin et al., 1985; Pickett et al., 1991). Although the source is uncertain, water in the hospital environment is frequently suspected of carrying this organism. It was speculated that the strain that caused necrotizing fasciitis and bacteremia in a 71-year-old female farmer in Taiwan gained access via a trivial wound contaminated with soil or water (Hsueh et al., 1995).

Environmental Isolates

Although the first *Empedobacter* and *Myroides* strains were primarily isolated from clinical sources, a number of recent studies have indicated that they are widely distributed in the environment, especially water. This accounts for their apparent presence in many habitats (e.g., Herman [1981] and Shewan and McMeekin [1983]).

Empedobacter brevis and *Flavobacterium odoratum* (*Myroides odoratus*) together with other bacteria were isolated from stable fly eggs and were found to be necessary to complete the development of stable fly larvae (Lysyk et al., 1999). These organisms were also isolated from South Atlantic fish species at the processing site and were considered potential active spoilers of the fish (i.e., producers of off-odors; Engelbrecht et al., 1996). An *Empedobacter* strain and two *Myroides odoratus* strains were also isolated from freshwater fish skin, the water of the sampling site, and the air during chill storage of the freshwater fish, but were not considered important contributors to the spoilage of these fish (González et al., 2000).

In the food environment, *Myroides* strains have been isolated from dairy sources and shown to produce thermostabile proteases and lipases which may play a role in the spoilage of dairy products (Griffiths et al., 1981; Zahran and Al-Saleh, 1997). They could, however, not be isolated from dairy sources by Jooste et al. (1985). In a study by Hebbar et al. (1991), *F. odoratum* was isolated from roots and crowns of the sunflower plant (*Helianthus annuus*), where it acted as one of the antagonistic bacteria to fungal pathogens. Chourasia (1995) isolated this organism from the geocarposphere of peanuts (*Arachis hypogaea*).

It was found that in food processing plants, welding of stainless steel surfaces has no significant influence on short-term accumulation of *Listeria monocytogenes* or a three-member bacterial consortium (including two *Myroides odoratus* strains) that was isolated from weldments in a seafood processing plant (Tide et al., 1999).

In a study by Bremer et al. (2001), it was, however, found that the attachment of *Listeria monocytogenes* to stainless steel increased significantly in the presence of *Myroides odoratus* strains as contaminating organisms of food surface areas.

Isolation and Preservation

The flavobacteria in general are not difficult to isolate, since they are chemo-organotrophic (Holmes, 1992). The general (nonselective) isolation, maintenance and preservation media used for culturing members of the Flavobacteriaceae are discussed in detail by Jooste and Hugo (1999) and Hugo and Jooste (2003).

Plate count agar containing 0.5% NaCl was used to isolate *Empedobacter* and *Myroides* strains from Cape marine fish (Engelbrecht et al., 1996) while tryptone soya agar (Oxoid) was used to isolate *Empedobacter* and *Myroides odoratus* from freshwater fish (González et al., 2000).

For the isolation of *Myroides odoratus* from the geocarposphere of peanut, 5% trypticase soy agar (Bacto tryptone, 17 g; Bacto soytone, 3 g; Bacto dextrose, 2.5 g; sodium chloride, 5 g; dipotassium phosphate, 2.5 g; Bacto agar, 20 g; and distilled water, 1 liter) and PAF (Bacto peptone, 10 g; proteose peptone, 10 g; potassium phosphate, 1.5 g; magnesium sulfate, 1.5 g; Bacto agar, 15 g; and distilled water, 1 liter) were used (Chourasia, 1995).

Cultivation of *Empedobacter* and *Myroides* strains has been reported on nutrient agar (Holmes et al., 1978; Yagci et al., 2000) and heart infusion medium with 5% rabbit blood (Dees et al., 1986). Cultivation of *Myroides* species has been reported in nutrient broth No. 2 (Oxoid; Owen and Holmes, 1978) and trypticase soy agar (BBL; Vancanneyt et al., 1996).

Although no specific medium is known for the selective isolation of *Empedobacter* and *Myroides* species, β-hydroxybutyrate agar and MacConkey agar may be used for the enumeration of *Myroides*, *E. brevis*, *Chryseobacterium* and *Weeksella* (Bernardet et al., 1996; Weyant et al., 1996; Jooste and Hugo, 1999). Selective media on which *Empedobacter* and *Myroides* species will not grow include nutrient broth containing 6% NaCl and Simmons citrate agar (Holmes et al., 1977; Jooste and Hugo, 1999). *Empedobacter* strains will also not grow on Salmonella-Shigella agar (Tatum et al., 1974; Holmes et al., 1978; Weyant et al., 1996; Jooste and Hugo, 1999).

For the preservation of *Empedobacter* and *Myroides* species, the general media used for flavobacterial maintenance may be used. These media include PMYA II (peptonized milk yeast extract agar; Christensen and Cook, 1972) and Dorset egg medium in a screw-capped bijou bottle stored at 4ºC (Cowan, 1974; Holmes et al., 1984). For longer periods of preservation, isolates may be freeze-dried (Holmes, 1992), or agar slant culture growth (18-h old) can be suspended in defibrinated rabbit blood placed in suitable containers and frozen in a mixture of dry ice and alcohol prior to storage at –50ºC (Holmes et al., 1984).

Identification

Methods for the identification of members of the Flavobacteriaceae are described by Bernardet et al. (2002). General identification methods and characteristics (chemotaxonomically significant components [respiratory quinones, fatty acids, etc.], production of enzymes, pigments, gliding motility, salt requirement, and capnophilic metabolism) of the Flavobacteriaceae are also discussed in detail in An Introduction to the Family Flavobacteriaceae in this Volume by Bernardet and Nakagawa. Only the morphological and phenotypical characteristics of *Empedobacter* and *Myroides* will be discussed in this chapter, since they play such an important role in differentiating the two genera.

Morphology

Members of both genera are Gram-negative, nonsporeforming rods that are 0.5 μm in diameter and 1–2 μm long with parallel sides and rounded ends. Longer rods of *Empedobacter* may be observed (Holmes et al., 1984; Vandamme et al., 1994). In *Myroides* species, longer rods and long chains (containing 4–10 cells) may occur in broth medium (Holmes et al., 1977).

They are nonmotile (i.e., cellular gliding and swarming of colonies are absent). Cells lack flagella (Holmes et al., 1978; Holmes et al., 1979b; Bernardet et al., 2002).

Pigmentation is light yellow (in both genera), of the flexirubin type, nonfluorescent, and insoluble in solid media (Holmes, 1992; Bernardet et al., 2002). The yellow hue of *Empedobacter* does not change with variation of medium or temperature (Holmes et al., 1984). *Empedobacter* colonies on nutrient agar at 30°C are pinpoint (to 2.0 mm), low convex, circular, smooth and shining and have an entire edge. On blood agar the colonies are pinpoint (to 2.5 mm; Holmes et al., 1984; Vandamme et al., 1994; Bernardet et al., 2002).

In *Myroides* species, four colony types may occur after incubation for 24 h on nutrient agar (Holmes et al., 1979b). Colony type 1 produces

effuse, spreading colonies (3–4 mm in diameter) with raised, shiny centers and dull, matt, spreading edges. On further incubation, the whole colony becomes smooth and shiny. Colony type 2 shows the same appearance after 24 h as colony type 1 shows, but the colonies are smaller, about 1.0–1.5 mm in diameter. Colony type 3 is smooth, shiny, and convex with no spreading edge and with a diameter of 0.5–1.0 mm after 24 h. Colony type 4 is mucoid. A characteristic fruity odor is produced by most strains (Holmes et al., 1977; Bruun, 1982; Rubin et al., 1985; Vancanneyt et al., 1996).

Phenotypic Identification and Physiology

Empedobacter

Both genera are strictly aerobic with menaquinone 6 as the major respiratory quinone. Both genera will grow at 25°C and 30°C, but not at 5°C or 42°C. All *Myroides* and most *Empedobacter* strains will grow at 37°C, but most *Empedobacter* strains will only produce acid from carbohydrates when incubated at 30°C. Prolonged incubation may then be necessary (up to 17 days; Holmes et al., 1978; Bruun, 1982; Bernardet et al., 2002).

Strong proteolytic activity occurs in both genera. Both genera will grow on MacConkey agar as well as on β-hydroxybutyrate agar. Both genera produce DNase, urease, oxidase, catalase and phosphatase. Indole is produced in *Empedobacter* but not in *Myroides*. Both genera degrade gelatin. While starch is not degraded by *Myroides*, results vary for *Empedobacter*. Neither of the genera produces β-galactosidase, reduces nitrate, or degrades agar and esculin. *Myroides* species reduce nitrite. In *Empedobacter*, several carbohydrates (not glycerol or trehalose) are oxidized. In *Myroides* there is no carbohydrate utilization (Holmes et al., 1978; Holmes et al., 1979b; Holmes et al., 1984; Bernardet et al., 2002). The differential characteristics of *Empedobacter* and *Myroides* are given in Table 1.

Table 1. Differential characteristics of *Empedobacter* and *Myroides*.

Characteristic	*Empedobacter*	*Myroides*
Growth at		
37°C	+a	+

+, positive reaction; (+), weak positive reaction; –, negative reaction; V, varies within and/or between species: V, varies between references; and Pen G, penicillin G.
From Holmes et al. (1978, 1979, 1984) and Bernardet et al. (2002).

Both genera are known for their resistance to a wide range of antimicrobials (Holmes et al., 1984; Vandamme et al., 1994). *Myroides* in particular are resistant to the following groups of antimicrobials (although variability exists between reported cases): β-lactams, aminoglycosides, tetracyclines, quinolones and trimethoprim-sulfamethoxazole (Holmes et al., 1979b; Strandberg et al., 1983; Macfarlane et al., 1985; Hsueh et al., 1995; Yagci et al., 2000). Although an R plasmid conferring resistance to ampicillin, carbenicillin, and erythromycin has been reported in a strain of *M. odoratus* (Kono et al., 1980), plasmids have not been detected in *Myroides* species since then. Resistance in these organisms is, therefore, possibly associated with chromosomal genes (Holmes, 1992).

The dominant fatty acids in *Empedobacter* are 15:0 iso, 16:1γ7c, 16:1γ5c, 16:0, 16:0 3OH and 17:0 iso 3OH (Oyaizu and Komagata, 1981; Dees et al., 1986; Vandamme et al., 1994). The DNA contains 31–33 mol% G+C (Vandamme et al., 1994; Bernardet et al., 2002).

The dominant fatty acids of *Myroides* species are 15:0 iso, 15:0 iso 3OH, 16:0 3OH, 17:0 iso 3OH, and 17:1 iso γ9c (Oyaizu and Komagata, 1981; Dees et al., 1986; Vancanneyt et al., 1996). The DNA contains 30–38 mol% G+C (Vancanneyt et al., 1996; Bernardet et al., 2002).

The two species of *Myroides*, *M. odoratus* and *M. odoratimimus*, are difficult to differentiate phenotypically. Small differences were, however, found in carbon source assimilation (Biotype 100, bioMérieux) and oxidation (Biolog GN MicroPlate assays; Vancanneyt et al., 1996). The differential characteristics between the two species are given in Table 2.

Pathogenicity

Empedobacter

This organism was isolated for the first time in 1888 from canal water and found to be pathogenic to laboratory animals such as guinea pigs, mice and rabbits, but not pigeons (Holmes et al., 1978). Stutzer and Kwaschnina (1929) and

Table 2. Differential characteristics between *M. odoratus* and *M. odoratimimus*.

Characteristic	*M. odoratus*	*M. odoratimimus*
Growth on Biotype 100 carbon sources	Negative for all	Positive for L-aspartate, L-glutamate and L-proline Variable for L-malate, succinate and fumarate
Biolog GN MicroPlate oxidation of 95 carbon sources	Positive for all	Positive for Tween 40, Tween 80, methylpyruvate, monomethylsuccinate, acetic acid, α-hydroxybutyric acid, α-ketovaleric acid, DL-lactic acid, propionic acid, succinic acid, bromosuccinic acid, succinamic acid, alaninamide, L-alanine, L-alanylglycine, L-asparagine, L-aspartic acid, L-glutamic acid, glycyl-L-aspartic acid, glycyl-L-glutamic acid, L-leucine, L-ornithine, L-proline, L-serine, L-threonine, inosine, uridine and thymidine Variable for L-Fucose, formic acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-ketoglutaric acid, L-histidine, L-phenylalanine, D-serine, urocanic acid, phenyl ethylamine, 2,3-butanediol, and glycerol
Major fatty acids	15:0 iso, 15:0 iso 3OH, 15:0 anteiso, 16:0 3OH, 17:0 iso 3OH, and 17:1 iso ω9c	13:0 iso, 15:0, 15:0 iso, 15:0 iso 3OH, 16:0 3OH, 17:0 iso 3OH, 17:1 iso ω9c, and summed feature 4

Abbreviations: 15:0, pentadecanoate; 15:0 iso, 13-methyl-tetradecanoic acid; 15:0 iso 3OH, 3-hydroxy-13-methyl-tetradecanoic acid; 13:0 iso, 11-methyl-dodecanoic acid; 16:0 3OH, methyl 3-hydroxyhexadecanoate; 17:0 iso, 15-methyl-hexadecanoic acid; 15:0 anteiso, 12-methyl-tetradecanoic acid; 17:1 iso ω9c, 15-methyl-cis-delta-7-hexadecanoic acid; summed in feature 4: 15:0 iso 2OH, 2-hydroxy-13-methyl-tetradecanoic acid; 16:1 ω7c; 16:1 ω7t and 17:0 iso 3OH, 3-hydroxy-15-methyl-hexadecanoic acid.
From Vancanneyt et al. (1996).

Holmes et al. (1978), however, found their clinical isolates did not cause disease. The resistance of this organism to a wide range of antimicrobial agents (including carbenicillin and gentamicin) suggested, however, that *Empedobacter* infections would be difficult to treat (Holmes et al., 1978).

Empedobacter brevis was easily recovered from clinical material (Weyant et al., 1996). Recently, it was shown that *E. brevis* together with strains of other bacterial species is a common contaminant of contact lens care systems. These species may facilitate *Acanthamoeba* growth and thus cause keratitis of the eyes (Bottone et al., 1992). In 1997, *E. brevis* was found to cause meningitis in a dog, but the source of the organism was not known (Haburjak and Schubert, 1997).

Myroides

Stutzer (1923) speculated that the strains he isolated played only a saprophytic role in the human intestine. He could not demonstrate any animal pathogenicity since intradermal, intraperitoneal, and intravenous injections of *Bacterium faecale aromaticum* into mice, guinea pigs and rabbits produced no pathogenic response. Stutzer and Kwaschnina (1929) isolated strains of *F. odoratum* from the feces of patients with typhoid fever, acute gastroenteritis, and relapsing fever. Although not considered to be pathogenic, this organism was isolated in a way that might reflect the pathological processes in the intestine.

Holmes et al. (1979b) first suggested a possible pathogenic role for *F. odoratum* isolated from soft tissue infections, including an amputation site and urinary tract infections. Davis et al. (1979) isolated the organism from an amputation site, but the pathogenic role of the organism in this connection was uncertain. In 1985, Macfarlane et al. reported ventriculitis caused by *F. odoratum*, which was treated with intraventricular cefotaxime. Hsueh et al. (1995) reported the first necrotizing fasciitis and bacteremia caused by *F. odoratum* (*M. odoratus*) and argued that this organism should be added to the list of etiologic agents that can cause severe skin and soft-tissue infections. Since then, a case of recurrent cellulitis with bacteremia was reported in a corticosteroid-treated patient with multiple skin lesions (Bachman et al., 1996).

In 2000, an outbreak of a *Myroides* spp. urinary tract infection was reported among urology patients with catheters in a Turkish hospital (Yagci et al., 2000). *Myroides odoratimimus* was identified as the organism causing this outbreak over a three-year period. All of the 22 affected patients, including two with bacteremia, had

pyuria, calculi and neoplasia. Yagci et al. (2000) speculated that the outbreak was maintained by contamination from an unknown source, but could not identify a single measure that ended the outbreak.

The resistance of *Myroides* to a wide range of antimicrobial agents commonly used against Gram-negative nonfermentative bacterial infections, including β-lactams (penicillins, cephalosporins, aztreonam, and carbapenems) and aminoglycosides, suggests that any infection by this organism would prove difficult to treat (Holmes et al., 1979b; Strandberg et al., 1983; Hsueh et al., 1995; Yagci et al., 2000).

Applications

No literature on applications of *E. brevis* is available. In the past 10–15 years, some applications of *Myroides* spp. have been reported. *Myroides* spp. have been used as biological control agents against bacterial and fungal pathogens of the sunflower plant (Hebbar et al., 1991). *Flavobacterium odoratum* (*M. odoratus*) has been able to colonize the geocarposphere of peanuts, resulting in the inhibition of aflatoxin production by *Aspergillus flavus* (Chourasia, 1995). In a study by Lysyk et al. (1999), *Myroides* isolated from the eggs of stable flies was considered essential, together with other bacteria, for the development of the larvae. This study evaluated a rearing procedure for the larvae to study insect-microbe interactions and evaluating microbial control agents.

The enzymes of *Myroides* spp. may also be useful. *Flavobacterium odoratum* (*M. odoratus*) was found to produce elastase, which is a commercially useful enzyme having clinical therapeutic applications and food processing applications as a meat-tenderizing agent or protein hydrolytic catalyst (Yan et al., 1994). An isoamylase from *F. odoratum* (*M. odoratus*) was found to greatly enhance the production of maltose, maltotriose, maltotetraose and trehalose under industrial conditions for starch processing in the presence of respective auxiliary enzymes (Takahashi et al., 1996). According to Labuschagne et al. (1997), the lipase of *F. odoratum* (*M. odoratus*) may be useful for industrial applications such as the hydrolysis of insoluble acylglycerols.

CHAPTER 6.12

The Genera *Chryseobacterium* and *Elizabethkingia*

JEAN-FRANÇOIS BERNARDET, CELIA HUGO AND BRITA BRUUN

Introduction

Together with the genera *Bergeyella* and *Empedobacter*, the genus *Chryseobacterium* Vandamme, Bernardet, Segers, Kersters, and Holmes 1994 was built on the ruins of the genus *Flavobacterium*, shortly before the latter was thoroughly emended following extensive phylogenetic investigations (Vandamme et al., 1994; Bernardet et al., 1996; see also the following chapters in this edition: The Genus Flavobacterium in this Volume, The Genera Empedobacter and Myroides in this Volume, and The Genera Bergeyella and Weeksella in this Volume). For reasons that are explained in the section Phylogeny, the splitting of the genus *Chryseobacterium* was proposed very recently (Kim et al., 2005b); the organismpreviously known as *Chryseobacterium meningosepticum* and *C. miricola* were allocated to the new genus *Elizabethkingia* under the epithets *Elizabethkingia meningoseptica* and *E. miricola*. Among the currently recognized *Chryseobacterium* and *Elizabethkingia* species, those that were already described in the previous editions of *Bergey's Manual of Systematic Bacteriology* and *The Prokaryotes* were dealt with in the chapters Genus *Flavobacterium* Harrison, Breed, Hammer and Huntoon 1923 (Holmes et al., 1984) and The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* (*The Prokaryotes*, second edition and in this Volume), respectively.

The genera *Chryseobacterium* and *Elizabethkingia* belong to the family Flavobacteriaceae, the history and structure of which are presented in another chapter in this Volume: An Introduction to the Family Flavobacteriaceae. Currently, Flavobacteriaceae comprise 25 other valid genera; following extensive bacteriological surveys of various, mostly marine and polar environments, several additional genera are about to be published in the *International Journal of Systematic and Evolutionary Microbiology*. Taxonomic and nomenclatural issues concerning the family are dealt with by the Subcommittee on the taxonomy of *Flavobacterium* and *Cytophaga*-like bacteria of the International Committee on Systematics of Prokaryotes. This subcommittee has issued minimal standards for the description of new taxa in the family Flavobacteriaceae (Bernardet et al., 2002).

Many *Chryseobacterium* and *Elizabethkingia* strains occur in soil, freshwater, and marine environments, while others are found in dairy products; others are opportunistic pathogens of humans and animals. Most of the environmental species have not been extensively studied and some of them are only represented in culture collections by one or very few strains. Conversely, the clinical and dairy isolates have received more attention owing to their medical or economic significance, and collections comprising a reasonable number of strains are available.

Phylogeny

The 16S rRNA gene sequences of at least the type strains of all valid *Chryseobacterium* and *Elizabethkingia* species are now available, as well as the sequences of representative isolates of the taxa that are not validly published yet (see the section Taxonomy in this Chapter). The position of the genera within the family Flavobacteriaceae and the position of the family within the phylum "Bacteroidetes" (Garrity et al., 2003) or "Cytophaga-Flavobacterium-Bacteroides phylum" are presented in Figs. 1 and 2 in the chapter An Introduction to the Family Flavobacteriaceae in this Volume, together with comments on the denomination and delineation of higher taxa in the phylum. Figure 1 below is an updated phylogenetic tree of members of the genera *Chryseobacterium* and *Elizabethkingia*.

Since the 16S rRNA gene sequences of *Chryseobacterium balustinum*, *C. gleum* (the type species), *C. indologenes*, *C. indoltheticum* and *Elizabethkingia meningoseptica* deposited in databases and used to draw previously published phylogenetic trees were of poor quality, new sequences were recently determined and deposited by O. Matte-Tailliez, J.-F. Bernardet and B. Kerouault. These sequences were used to draw the current tree in combination with the high

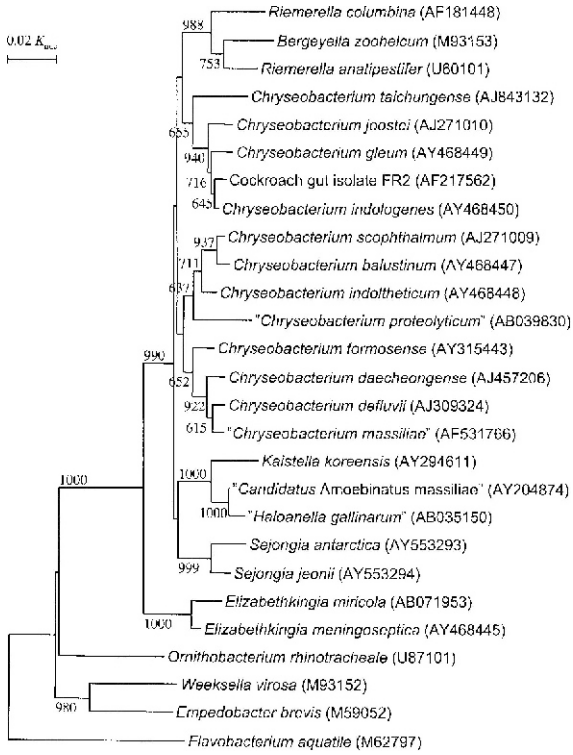

Fig. 1. Phylogenetic relationships among representatives of the genera *Chryseobacterium* and *Elizabethkingia* and of related organisms established on 16S rRNA gene sequence comparisons using the neighbor-joining method (Saitou and Nei, 1987). Sequences were taken from the GenBank nucleotide database; accession numbers of the sequences are given in parentheses. Scale bar, 0.02 *Knuc* (Kimura, 1980). The numbers on the branches represent the confidence limits (expressed as percentages rounded up to whole numbers) estimated by a bootstrap analysis (Felsenstein, 1985) of 1000 replicates; confidence limits less than 50% are not shown. Sequences were aligned using the CLUSTAL W version 1.8 software package (Thompson et al., 1994). The alignments were modified manually against the 16S rRNA secondary structure of *Escherichia coli* (Brosius et al., 1978). All species are included and represented by their type strain (except *Empedobacter brevis*). Representatives of invalid taxa for which the 16S rRNA sequences are available have also been included for information; their names are in quotation marks. *Flavobacterium aquatile* was used as outgroup.

quality sequences of all other organisms deposited by other authors. As can be seen by comparing the current tree with that in the chapter An Introduction to the Family Flavobacteriaceae in this Volume, the use of the new sequences actually had only a limited effect on the structure of the tree. In particular, regardless of the sequences used, *E. meningoseptica* occupies a separate position compared to all *Chryseobacterium* species, while *Bergeyella zoohelcum*, the two *Riemerella* species and members of the two recently described genera *Kaistella* (Kim et al., 2004) and *Sejongia* (Yi et al., 2005) are situated in between. Recently, *E. miricola* has linked to *E. meningoseptica* in its separate position (Li et al., 2003). The splitting of the genus *Chryseobacterium* into two branches was a consequence of the DNA-rRNA hybridization technique that was extensively used for phylogenetic investigations of the genus *Flavobacterium* and related genera during the 1980s and 1990s (Bauwens and De Ley, 1981; Segers et al., 1993; Mudarris et al., 1994; Vandamme et al., 1994; Vandamme et al., 1994; Vancanneyt et al., 1996). The resolution of this technique being lower than that achieved later on by 16S rRNA gene sequencing, the respective branching of the different *Chryseobacterium* species, *B. zoohelcum* and *Riemerella anatipestifer* was not accurately determined (Vandamme et al., 1994). Since distinct phenotypic and chemotaxonomic characteristics were found to differentiate all members of the new genus *Chryseobacterium* from *B. zoohelcum* and *R. anatipestifer* (see the sections Taxonomy and Identification in this Chapter), the organism known at that time as [*Flavobacterium*] *meningosepticum* was included in this genus although its separate position compared to other *Chryseobacterium* species was already recognized (Vandamme et al., 1994). When high-quality 16S rRNA gene sequencing finally replaced DNA-rRNA hybridization for phylogenetic studies, the separate position of *Chryseobacterium meningosepticum* became even more obvious. When a phylogenetic tree is drawn using the few sequences of the DNA gyrase large subunit (*gyrB*) gene available in this group of organisms (i.e., *E. meningoseptica*, *C. indologenes*, *B. zoohelcum*, *E. brevis* and *W. virosa*), the overall structure of the tree is similar to that of the 16S rRNA tree, except that *E. meningoseptica* is grouped with *C. indologenes* and separate from *B. zoohelcum* (Suzuki et al., 1999). The determination of the *gyrB* sequences of the other species will be necessary to assess whether the grouping (based on the sequences of a few species only) is actually sound.

Because *Chryseobacterium*, *Elizabethkingia*, *Kaistella*, *Sejongia*, *Bergeyella* and *Riemerella* species form a distinct separate branch, comparative studies of strains belonging to this group of organisms should preferably include reference strains of all of them. The invalid organism "*Haloanella gallinarum*", of which no isolates but only the 16S rRNA gene sequence is available, is also located between *Elizabethkingia* and *Chryseobacterium* species. *Ornithobacterium rhinotracheale*, *Empedobacter brevis* and *Weeksella virosa* are the closest phylogenetic neighbors of this large cluster, and the branch grouping all these organisms occupies the lowest position in the phylogenetic tree of the family Flavobacteriaceae (see the chapters An Introduction to the

Family Flavobacteriaceae, The Genera *Empedobacter* and *Myroides*, The Genera *Bergeyella* and *Weeksella*, and Capnophilic Bird Pathogens in the Family Flavobacteriaceae: *Riemerella*, *Ornithobacterium* and *Coenonia* all in this Volume).

Taxonomy

As shown in Table 1, the genus *Chryseobacterium* currently contains ten valid species; an additional species, "*C. proteolyticum*," has been published outside the *International Journal of Systematic and Evolutionary Microbiology* and has not been included yet in a validation list; the two "*C. proteolyticum*" strains are not available. The new genus *Elizabethkingia* only contains two species.

In addition to the *Chryseobacterium*, *Elizabethkingia*, *Kaistella*, *Sejongia*, *Bergeyella* and *Riemerella* species (see the section Phylogeny in this Chapter), phylogenetic studies showed that the *Chryseobacterium* branch also comprises two *Candidatus* (a provisional category created to classify organisms for which 16S rRNA gene sequences are available but that are not yet cultivated and described; Murray and Stackebrandt, 1995) species recovered from human nasal samples (Greub et al., 2004; Drancourt et al., 2004) and "*Haloanella gallinarum*," whose 16S rRNA gene sequence is deposited in databases (Fig. 1; see the section Pathogenicity and Epidemiology in this Chapter).

The reasons for creating a new genus to accommodate most of the organisms previously attributed to the genus *Flavobacterium* have been explained elsewhere (Vandamme et al., 1994; Bernardet et al., 1996) and will only be summarized here. After successive emendations, the genus *Flavobacterium* had been restricted to nonmotile and nongliding species (Holmes et al., 1984). The genus was restricted even further when it was recognized that the type species, *F. aquatile*, did not represent the genus and was consequently set aside in Holmes' next taxonomic review, i.e., in the second edition of *The Prokaryotes* (The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in this Volume; see also Holmes, 1993). Following a decision of the Judicial Commission of the International Committee on Systematic Bacteriology, *F. aquatile* had to remain the type species of the genus *Flavobacterium* even though the genus had been thoroughly emended (Bernardet et al., 1996; see the chapter The Genus *Flavobacterium* in this Volume). Hence, the other bacterial species previously attributed to the genus *Flavobacterium* had to be relocated in other or new genera. Among the four natural groups of species recognized by Holmes in the second edition of *The Prokaryotes* on the basis of habitat, resistance to antimicrobial agents, production of yellow pigment and indole, oxidation of carbohydrates, and proteolytic activity, the groups B, C, and D rapidly became (or already were) the cores of the new genera *Myroides* (Vancanneyt et al., 1996), *Sphingobacterium* (Yabuuchi et al., 1983), and *Weeksella* and *Bergeyella* (Holmes et al., 1986a; Holmes et al., 1986b; Vandamme et al., 1994), respectively (see the chapters The Genera *Empedobacter* and *Myroides*, The Genera *Bergeyella* and *Weeksella*, and The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* all in this Volume).

Holmes' group A comprised [*Flavobacterium*] *balustinum*, [*F.*] *breve*, [*F.*] *indoltheticum*, [*F.*] *meningosepticum* (which grouped strains previously known as CDC group IIa), and the CDC group IIb defined by King (1959). The heterogeneity of the latter group had long been established, and [*F.*] *indologenes* (in spite of rather low levels of DNA relatedness between the strains; Yabuuchi et al., 1983) and [*F.*] *gleum* (Holmes et al., 1984) were among its members. Some authors also considered [*F.*] *balustinum* and [*F.*] *indoltheticum* to belong to group IIb (Hugo et al., 1999). However, many other strains in CDC group IIb could not be assigned to any of these four species; some of these strains formed small genomic groups that could be the cores of new species (Ursing and Bruun, 1991).

Phylogenetic studies by Vandamme et al. (1994) demonstrated: 1) [*F.*] *breve* occupied a separate position compared to other organisms in Holmes' group A; as a consequence, the generic epithet *Empedobacter* was revived for this species and the new combination *Empedobacter brevis* was established. 2) Other organisms in group A formed a tight cluster for which the new generic epithet *Chryseobacterium* was proposed and joined in the new combinations *C. balustinum*, *C. gleum*, *C. indologenes* and *C. indoltheticum*; [*F.*] *meningosepticum* in spite of its separate position was also proposed for inclusion in the genus *Chryseobacterium*. 3) The recently described fish pathogen [*F.*] *scophthalmum* (Mudarris et al., 1994) belonged to the same cluster and was consequently renamed *Chryseobacterium scophthalmum*. 4) *Riemerella anatipestifer* and *Weeksella zoohelcum* occupied separate positions at the base level between *E. meningoseptica* and the other *Chryseobacterium* species; however, their chemotaxonomic and other phenotypic characteristics were different enough from those of members of the genus *Chryseobacterium* to warrant their separate generic status. And 5) *W. zoohelcum* was only distantly related to the type species of the genus *Weeksella*, *W. virosa*; hence, the new generic

Table 1. Currently recognized species classified in the genera *Chryseobacterium* and *Elizabethkingia*.[a]

Species[b]	Type strain	G+C (mol%)	Source	Reference(s)	Number of strains
Chryseobacterium balustinum[AL,c]	NCTC 11212	33	Heart blood of freshwater fish (dace, *Leuciscus leuciscus*), Dordogne, France, 1959	Brisou et al., 1959 Holmes et al., 1984a	1, 3, ?

"Chryseobacterium proteolyticum"	NIBHT P17664	37	Soil, rice field, Tsukuba, Japan	Yamaguchi and Yokoe, 2000	2, 0, 2
Chryseobacterium scophthalmum[i]	CCM 4109	34	Gills of diseased turbot (*Scophthalmus maximus*), Scotland, 1987	Mudarris et al., 1994	50, 7, 50
Chryseobacterium taichungense	CIP 108519	Not determined	Tar-contaminated soil, Taichung, Taiwan	Shen et al., in press	1
Elizabethkingia miricola[j]	JCM 11413	35	Condensation water, space station Mir, 1997	Li et al., 2003 Kim et al., in press	1, 2, 2
Elizabethkingia meningoseptica[AL,k]	ATCC 13253	37	Human cerebrospinal fluid, United States, 1949	King, 1959 Holmes et al., 1984a Kim et al., in press	?, 20, 150

Abbreviations: [T], type species; [AL], the species is cited on the Approved Lists of Bacterial Names (Skerman et al., 1980; Moore et al., 1985); ATCC, American Type Culture Collection, Manassas, Va., USA; CIP, Collection de l'Institut Pasteur, Paris, France; CCM, Czech Collection of Microorganisms, Brno, Czech Republic; DSM, Deutsche Sammlung von Mikroorganismen, Braunschweig, Germany; JCM, Japanese Collection of Microorganisms, Tokyo, Japan; LMG, BCCM/LMG bacteria collection, Laboratorium voor Microbiologie, University of Gent, Gent, Belgium; NCTC, National Collection of Type Cultures, London, England; NIBHT, culture collection of the National Institute of Bioscience and Human Technology, Tsukuba, Japan.

[a]Names in quotation marks have not been validly published. Accession number is that in the recognized culture collection in which the type strain was first deposited. The origin and G+C content are those of the type strain. When more than one strain are known, three numbers are given, i.e., the number of strains on which the original description was based, the number of strains currently available in the largest recognized culture collections (i.e., ATCC, DSM, LMG, NCIMB [National Collection of Industrial, Marine and Food Bacteria, Aberdeen, Scotland] and NCTC), and the approximate number of strains which have been included in further studies and which are or may still be maintained in specialized culture collections, respectively.

[b]Previous names and corrected epithets of species (taken from Euzéby, 1997; List of Bacterial Names with Standing in Nomenclature) are as stated in footnotes c to k.

[c][*Flavobacterium*] *balustinum* Harrison 1929, "[*Empedobacter*] *balustinum*" Brisou et al. 1959.

[d]*Chryseobacterium defluvium*, name as deposited in the 16S rRNA sequence databases.

[e][*Flavobacterium*] *gleum* Holmes et al. 1984.

[f][*Flavobacterium*] *indologenes* Yabuuchi et al. 1983.

[g][*Flavobacterium*] *indoltheticum* Campbell and Williams 1951, "*Beneckea indolthetica*" (Campbell and Williams 1951) Campbell 1957.

[h]*Chryseobacterium joosteii*, name as deposited in the 16S rRNA sequence databases.

[i]"[*Cytophaga*] *scophthalmis*", name as listed in 1989 in the catalogue of strains of the Czech Collection of Microorganisms, [*Flavobacterium*] *scophthalmum* Mudarris et al. 1994.

[j][*Chryseobacterium*] *miricola*, name as deposited in the 16S rRNA sequence databases, [*Chrysebacterium*] miricola Li et al., 2003.

[k][*Flavobacterium*] *meningosepticum* King 1959, [*Chryseobacterium*] *meningosepticum* (King 1959) Vandamme et al. 1994.

epithet *Bergeyella* and the new combination *B. zoohelcum* were proposed for this species.

To minimize the inconvenience for clinical microbiologists, the etymology of the new generic epithet *Chryseobacterium* (a golden yellow rod) was chosen to be as similar as possible to that of *Flavobacterium* (a yellow rod). For the same reason, the name "[*Flavobacterium*] *aureum*" had previously been proposed, although not validly published, for CDC group IIb by Price and Pickett (1981). *Chryseobacterium balustinum* (Harrison, 1929) and *C. indoltheticum* (Campbell and Williams, 1951), the two oldest species, could not be selected as the type species of the genus *Chryseobacterium* owing to their meager characterization and to the fact that they were each represented by a single strain. *Chryseobacterium meningosepticum*, although clinically important and well characterized, was also not a good candidate since it was the most aberrant member of the genus. Both the phenotypic and genomic heterogeneity of *Chryseobacterium indologenes* (initially proposed to encompass all CDC group IIb strains) were known since its original description (Yabuuchi et al., 1983). *Chryseobacterium gleum* was chosen as the type species since its description was based on firm phenotypic and genomic grounds following an extensive comparative study of 12 strains (Holmes et al., 1984). As a matter of fact, since the identification of differentiating characteristics for *C. indologenes*, *C. gleum*, and the related strains was (and still is) problematic (see the section Identification in this Chapter) and since several genomic groups have been found within group IIb in addition to these two species (Ursing and Bruun, 1991), some authors proposed to continue referring to this taxon by the designation of "*Chryseobacterium* sp. CDC group IIb" (Ursing and Bruun, 1991; see the chapter The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in this Volume).

Several new *Chryseobacterium* species have been described since the genus was established: "*C. proteolyticum*" (Yamaguchi and Yokoe, 2000), *C. defluvii* (Kämpfer et al., 2003), *C. joostei* (Hugo et al., 2003), [C.] *miricola* (Li et al., 2003), *C. daecheongense* (Kim et al., 2005a), *C. formosense* (Young et al., 2005), and *C. taichungense* (Shen et al., 2005) (see Table 1).

Recently, Kim et al. (2005b) performed a polyphasic study of several [C.] *meningoseptica* strains and of the only [C.] *miricola* strain available. All the techniques used confirmed the separate position of these two species compared to all *Chryseobacterium* species. Hence, the new genus *Elizabethkingia* was proposed to accomodate these two species (Kim et al., 2005b). Since the more simple epithets derived from the family name of Elizabeth O. King, who first described the bacterium (King, 1959), were already attributed to other bacteria or to various eukaryotes (J. Euzéby, personal communication), the epithet was based on her two names. Admittedly, this new nomenclatural change is a kind of tongue-twister and an additional inconvenience for clinical microbiologists after the change from *Flavobacterium* to *Chryseobacterium* proposed in 1994 for this clinically important organism (Vandamme et al., 1994). However, the study by Kim et al. (2005b) only confirmed and substantiated previous reports on the phenotypic and genomic discrepancies between *E. meningoseptica*/*E. miricola* and the other *Chryseobacterium* species, and some kind of decision had to be taken. Importantly, the study by Kim et al. (2005b) also resulted in the identifion as *E. miricola* of a strain previously considered *E. meningoseptica*, thus making a second strain of the former species available.

Habitat and Ecology

The variety of ecological niches represented by members of the genera *Chryseobacterium* and *Elizabethkingia* (Table 1) reflects that found in the whole family Flavobacteriaceae (see Table 1 in the chapter An Introduction to the Family Flavobacteriaceae in this Volume): they are widely distributed in nature and consequently found in clinical specimens and various food products (Jooste and Hugo [1999] and references therein). However, most recent surveys using a variety of techniques (either culture-independent or requiring previous bacterial isolation) to unravel the phylogenetic composition of complex bacterial communities were more generally aimed at revealing members of the phylum "Bacteroidetes", or at best, members of the family Flavobacteriaceae (see the chapters An Introduction to the Family Flavobacteriaceae and The Genus *Flavobacterium* both in this Volume). Some of these studies revealed the phylogenetic diversity of bacterial populations in Antarctic sea ice, Antarctic lakes, and mangrove environments by sequencing the 16S rRNA gene of many isolates; they identified several members of the genus *Flavobacterium* in these biotopes but failed to reveal any strain affiliated to the genus *Chryseobacterium* (Bowman et al., 1997; Nakagawa et al., 2001; Van Trappen et al., 2002). Similarly, members of the family Flavobacteriaceae were found in various soil and freshwater environments following the sequencing of cloned polymerase chain reaction (PCR)-amplified 16S rRNA genes, but no strain related to *Chryseobacterium* was found (Borneman et al., 1996; Crump et al., 1999).

Other studies used oligonucleotide probes for either in situ hybridization or probing of a 16S rDNA clone library to investigate bacterial communities. The 16S rRNA gene sequence of *Chryseobacterium* strains and related organisms was specifically taken into account in designing some of these probes, and their specific hybridization to reference strains of *Chryseobacterium* spp., *Bergeyella zoohelcum* and *Riemerella anatipestifer* was controlled (Weller et al., 2000). Bacterial strains with 16S rRNA sequences highly homologous to the same sequences in these species were subsequently detected in a river (Manz et al., 1996; O'Sullivan et al., 2002).

The main environments in which *Chryseobacterium* strains are known to occur are listed below. Although recent publications usually refer to *Chryseobacterium* strains specifically, many earlier reports should be interpreted with care since they deal with poorly identified "*Flavobacterium*" strains that might actually have belonged to other taxa in the family Flavobacteriaceae.

Environmental Isolates

Some members of the CDC group IIb, later described as *C. indologenes* and *C. gleum* (see the section Taxonomy in this Chapter), were found to occur in soil and water by Tatum et al. (1974). In his extensive phenotypic study of Gram-negative yellow-pigmented rods originating from various sources, Hayes (1977) delineated nine different phena. According to Owen and Holmes (1981), members of Hayes' phenon 1 could be attributed to the CDC group IIb and, although most members of this phenon were isolated from meat (see below), some originated from river water and soil samples (Hayes, 1977). *Chryseobacterium indologenes* strains recently recognized from their 16S rRNA gene sequence in soil samples in Indonesia and Spain have been shown to degrade various toxic compounds (Radianingtyas et al., 2003; Lopez et al., 2004; see the section Applications in this Chapter). The only bona fide *C. indoltheticum* strain available in culture collections was isolated from marine mud, but the exact location is unknown. Although most strains of the human pathogen *E. meningoseptica* were isolated from clinical specimens, strains isolated from soil or river water were also included in some studies (Owen and Holmes [1981] and references therein; Bruun, 1982; Bruun and Ursing, 1987). A *E. meningoseptica* strain (16S rRNA gene sequence no. AJ616734) was isolated from a eutrophic shallow lake in Eastern Asia (G. Wu et al., unpublished data). The description of "*Chryseobacterium proteolyticum*" was based on two strains retrieved from the soil of a rice field and from the bank of a brook in Japan (Yamaguchi and Yokoe, 2000) and *C. daecheongense* was isolated from the sediment of a shallow, freshwater lake in Korea (Kim et al., 2005). The recently described species *C. formosense* and *C. taichungense* were isolated from the rhizosphere of garden lettuce and from a sample of tar-contaminated soil, respectively, both in Taiwan (Young et al., 2005; Shen et al., 2005). In a recent survey of carbohydrate-degrading bacteria in various biotopes of subtropical islands, strains identified as *Chryseobacterium* spp. from their 16S rRNA gene sequences were found to predominate in terrestrial environments (Rosado and Govind, 2003). Among the very diverse bacterial community recovered from samples of penguin guano collected in Antarctica, several strains were related to *C. indologenes* according to the results of phenotypic tests and comparison of 16S rRNA gene sequences (Zdanowski et al., 2004). Interestingly, the same kind of habitat also harbored members of the recently described genus *Sejongia*, one of the close phylogenetic neighbors of the genera *Chryseobacterium* and *Elizabethkingia* (Yi et al., 2005). A *Chryseobacterium* sp. belonging to CDC group IIb was part of the normal microbiota associated with marigold flowers (Luis et al., 2004). Four *Chryseobacterium* sp. and "*Haloanella gallinarum*" strains were recovered among the biofilm microflora of a domestic sink drain (McBain et al., 2003), and *E. meningoseptica* strains were also isolated from the slimy brown deposit swabbed inside the spout of sink taps in a hospital during an outbreak (Hoque et al., 2001). Several *Chryseobacterium* strains were identified among the culturable bacterial population in the groundwater of a municipal water supply in Germany (Ultee et al., 2004). According to the results of several commercial identification galleries, *Chryseobacterium* spp. were also among the most common potentially pathogenic bacteria isolated from samples of treated and untreated drinking water in South Africa (Pavlov et al., 2004).

Since members of most *Chryseobacterium* and *Elizabethkingia* species exhibit varying degrees of tolerance to NaCl, as shown by their ability to grow on Difco Marine agar 2216 (1.95% NaCl; Bernardet et al., 2002; see the sections Isolation and Cultivation and Physiology in this Chapter), the environmental strains may occur both in freshwater and seawater, as well as in freshwater and marine fish (see below). In contrast with many *Flavobacterium* species recently recovered from cold environments (see the chapter The Genus *Flavobacterium* in this Volume), most *Chryseobacterium* species were not considered psychrophilic, except those associated with food and dairy products (see below). Also in contrast

to *Flavobacterium* strains, the role played in the degradation of biomacromolecules by the *Chryseobacterium* strains that occur in soil and water is not known.

Fish-associated members of the genera *Chryseobacterium* and *Elizabethkingia* have been repeatedly reported. They may represent pathogenic (see the section Pathogenicity and Epidemiology in this Chapter) or spoilage (see below in this section) organisms. They may also belong to the normal bacterial flora that colonize the mucus at the surface of the skin and gills and the intestine of healthy fish. Moreno et al. (1999) investigated the microflora in the mucus of farmed eels (*Anguilla anguilla*) using fluorescent in situ hybridization; however, among the range of oligonucleotide probes they used, the one targeting the "*Cytophaga-Flavobacterium* cluster" was not specific enough to distinguish the *Chryseobacterium* strains from related organisms. The identification techniques, namely fatty acid analysis and carbohydrate utilization profiles, used by Nedoluha and Westhoff (Nedoluha and Westhoff, 1997a; Nedoluha and Westhoff, 1997b) also proved inadequate to specifically detect *Chryseobacterium* strains in the skin, gills and intestine of farmed striped bass (*Morone saxatilis*) reared in three different aquaculture systems, although members of the phylum "Bacteroidetes" were indeed detected. The eel harboring the *Chryseobacterium* strain studied by Lijnen et al. (2000) was apparently healthy (I. Roelents, personal communication); hence, the strain was presumably a part of its normal microflora or a transient colonizer. Similarly, there was no mention of any disease in the salmon (*Oncorhynchus keta*) harboring the intestinal *C. balustinum* strain investigated by Morita et al. (1997). During a survey of bacteria associated with the skin mucus of farmed fish in Brittany (France), 10 *Chryseobacterium* sp. strains were identified from their phenotypic characteristics among 49 bacterial isolates (C. Michel and J.-F. Bernardet, unpublished data).

Recently, *Chryseobacterium* strains were also recognized from the gut of insects. After sequencing of 16S rDNA cloned directly from the gut content of an American cockroach (*Periplaneta americana*) revealed an organism affiliated to the family Flavobacteriaceae, a number of strains phenotypically resembling *C. indologenes* were isolated and characterized; the 16S rRNA gene sequence of one isolate proved highly related to those of the *C. indologenes* and *C. gleum* reference strains (Dugas et al., 2001). This organism, which was not found in the food supply, was considered an abundant and permanent symbiont of the cockroach. Investigating the influence of food-derived tannins on the gut microbiota of the larvae of the lepidopteran *Acentria ephemerella*, Walenciak et al. (2002) characterized a number of bacterial isolates from their 16S rRNA gene sequences; one of these gut isolates belonged to the genus *Chryseobacterium*. *Chryseobacterium* spp. were the most frequent organisms among the 36 bacterial genera identified from their 16S rRNA gene sequences in the midgut bacterial community of the biting mosquito *Culicoides variipennis* (Campbell et al., 2004). Members of the *Chryseobacterium*/*Elizabethkingia* group may also be associated with amoebae: approximately 50% of the free-living but potentially pathogenic amoebae in a Polish lake harbored endosymbiotic bacteria, including *E. meningoseptica* (Hadas et al., 2004).

Some *Chryseobacterium* strains were also recovered from particular industrial environments. For instance, *C. defluvii* was described from the bacterial flora in activated sludge (Kämpfer et al., 2003) and two *Chryseobacterium* sp. strains were detected among the complex filamentous microflora that occurs in paper mill slimes and frequently affects machine efficiency and paper quality (Oppong et al., 2003). A *E. meningoseptica* strain (16S rRNA gene sequence no. AY509953, E. Chicote et al., unpublished data) was isolated from spent nuclear fuel pools. The original strain of the recently described species *E. miricola* originated from the condensation water in a very special closed environment, the space station Mir (Li et al., 2003). Recently, the misidentified *E. meningoseptica* strain ATCC 33958 was attributed to *E. miricola* (Kim et al., 2005b); it was one of the bacterial species contaminating a commercial preparation of carboxypeptidase A (Elder and Alexander, 1982).

Food Isolates

Early studies indicated that isolates closely related to the CDC group IIb (see the section Taxonomy in this Chapter) had been isolated from a variety of food products such as milk and dairy products, canned products, poultry and poultry plants, meat and meat products, and vegetables during commercial processing (McMeekin et al., 1971; Hayes, 1977; McMeekin and Shewan, 1978; Holmes et al., 1984). Because the taxonomy of the flavobacteria has changed so drastically over the past few years, however, it is difficult to determine whether these isolates belong to the genera *Chryseobacterium* and *Elizabethkingia* or to another genus in the family Flavobacteriaceae (see the chapter An Introduction to the Family Flavobacteriaceae in this Volume). This is still true for some of the studies published nowadays in which the identification of the isolates is based on meager data. The

discussion that follows will focus on food products in which known and suspected *Chryseobacterium*/*Elizabethkingia* isolates played a role.

FISH *Chryseobacterium balustinum* has been isolated first from the scales of freshly caught halibut (*Hippoglossus hippoglossus*) in the Pacific Ocean (Harrison, 1929; Brisou et al., 1959); since this organism produced a yellowish slime on the skin, it was considered a fish spoilage agent rather than a pathogen (Austin and Austin, 1999). The only strain currently available in culture collections, however, may actually be pathogenic (see the section Pathogenicity and Epidemiology in this Chapter). Although recently isolated again from the skin and muscle of wild and farmed freshwater fish, *C. balustinum* was not regarded as an important contributor of the spoilage of the fish because of its low incidence (<1% of all isolates; González et al., 2000). The five *C. balustinum* strains, identified following a rather extensive phenotypic characterization, were not found in freshly caught fish but in fish stored more than three days in melting ice.

Gennari and Cozzolino (1989) isolated 39 strains of flavobacteria from the skin and gills of fresh and ice-stored Mediterranean sardines (*Sardina pilchardus*). Analysis of their phenotypic traits, however, could not place the isolates in any known species of the flavobacteria, but the authors found that four strains had characteristics resembling those of Holmes' group A; most of the species in this group nowadays are known as *Chryseobacterium* (see the section Taxonomy in this Chapter). The other 35 strains resembled members of the genus *Myroides* (see the chapter The Genera Empedobacter and Myroides in this Volume). In contrast to the finding of González et al., most of the flavobacteria isolates were from fresh sardines and their number decreased with time of storage in ice. Since proteolytic activity was found, the authors speculated that flavobacteria were involved in proteolytic spoilage of fresh fish early during chill storage, especially when chilling was slow or the temperature not sufficiently low. The contribution of flavobacteria to fish spoilage, however, was regarded as low compared to that of the other pigmented bacteria retrieved from the same fish (Gennari and Cozzolino, 1989).

Various proteolytic activities (i.e., degradation of skim milk, casein, and gelatin on agar media) and H_2S production were also found in *Chryseobacterium balustinum*, *C. gleum* and *C. indologenes* strains isolated from Cape marine fish in South Africa (*Empedobacter*, *Myroides* and *Weeksella* strains were also retrieved from the same fish; Engelbrecht et al., 1996). When off-odor production of the *Chryseobacterium* strains was evaluated on fish muscle extract, four of the eight *C. balustinum* strains were found to produce a pungent odor, two, a stale odor, and two, no odor. Four among the five *C. gleum* strains produced a stale odor, and one *C. indologenes* strain produced a fruity odor (Engelbrecht et al., 1996). These isolates were thought to be contaminants introduced during processing operations.

It is not known whether members of the genera *Chryseobacterium* and *Elizabethkingia* may occur in biofilms growing on the surface of seafood processing equipment as was shown for their close relative *Myroides odoratus* (Tide et al., 1999; Bremer et al., 2001).

MEAT PRODUCTS Flavobacteria have been frequently isolated from meat and poultry products (García-López et al., 1998), although they have seldom been accurately identified. When Hayes (1977) divided a large collection of flavobacteria and related Gram-negative yellow-pigmented rods into nine phena, the first five phena were found to belong to the genus *Flavobacterium*. In a study by Owen and Holmes (1981), the conclusion was drawn that Hayes' phenon 1 corresponded closely to CDC group IIb; some members of this taxon were later attributed to *C. indologenes* and *C. gleum* (see the section Taxonomy in this Chapter). The 53 strains in this phenon were isolated from the following sources: raw beef carcasses (6 isolates), raw lamb carcasses (7 isolates), raw pig carcasses (8 isolates), raw eviscerated chicken carcasses (13 isolates), raw milk (13 isolates), water from rivers or streams (2 isolates), and soil (3 isolates). Thus, *Chryseobacterium* strains clearly are found in a variety of meat products, but no mention was made about their role in these products.

POULTRY Recent studies, performed on poultry and on the air of poultry processing establishments, indicated the presence of *Flavobacterium* species (Geornaras et al., 1996; Ellerbroek, 1997). The identification procedures of these two studies were, however, insufficient to conclude whether these organisms belonged to the genus *Chryseobacterium* or to one of the other genera in the family Flavobacteriaceae.

DAIRY PRODUCTS The flavobacteria have long been known for their psychrotrophic growth and their potential to spoil milk and dairy products through proteolytic and lipolytic activities (Gilmour and Rowe, 1981; Cousin, 1982). They may also be associated with the presence of off-flavors in milk products, changes in the manufacturing characteristics of milk as a substrate for starter cultures, and even reduced

cheese yield (Cousin, 1982; Ellis and Marth, 1984; Jooste et al., 1986a).

In the review by Cousin (1982), *Flavobacterium* was listed as one of the psychrotrophic genera whose members were frequently isolated from raw and pasteurized milk as well as butter. Many studies were listed in this review (see Table 3 of Cousin, 1982) but, again, attribution of the flavobacteria reported in these studies to the genus *Chryseobacterium* or to other members of the family Flavobacteriaceae could not be determined.

Research in the Department of Food Science at the University of the Free State in South Africa has for a long time been focused on flavobacteria isolated from milk and dairy products. Jooste et al. (1985) were the first to isolate *Flavobacterium* CDC group IIb strains from milk and butter. In a subsequent study (Jooste et al., 1986a), it was suggested that these *Flavobacterium* species cause putrefaction in salted butter by growing in cream prior to churning. In another study in which *Flavobacterium* CDC group IIb and *C. balustinum* strains were isolated, Jooste et al. (1986b) found that the practical importance of dairy flavobacteria lies as much in their psychrotrophic growth and consequent proteinase production in refrigerated milk as in their contamination of milk via poorly sanitized pipelines and equipment. The numbers of flavobacteria isolated from raw milk were fairly constant during winter and summer (Fischer et al., 1987). A study by Welthagen and Jooste (1992) indicated that CDC group IIb isolates comprised the largest part of pigmented bacteria from raw milk. In subsequent investigations (Hugo and Jooste, 1997; Hugo et al., 1999), a large group of the CDC group IIb milk isolates evaluated in the abovementioned studies were identified as *C. indologenes* and one isolate as *C. gleum*. Among the remaining milk isolates, two new genomic groups (including the new species *C. joostei*; Hugo et al., 2003) were identified. A considerable number of the milk isolates could not be allocated to known or new species, however, and consequently remained classified as *Chryseobacterium* species CDC group IIb (Hugo et al., 1999). In a study by Venter et al. (1999), a metalloprotease from a strain of *C. indologenes* was purified and characterized; this protease was very heat-stable and its affinity for casein may play a role in the spoilage of milk and milk products.

OTHER PRODUCTS A *Chryseobacterium* sp. strain sharing a high degree of 16S rRNA gene sequence similarity with *C. indoltheticum* was identified in maple sap (Lagacé et al., 2004). The role of this organism in the contamination and quality of maple products has not been investigated.

Veterinary and Human Clinical Isolates

Chryseobacterium and *Elizabethkingia* strains have been isolated from a number of diseased animal species. Briefly, *E. meningoseptica* strains have been recovered from frogs (Chung, 1990; Green et al. [1999] and references therein; Mauel et al., 2002), turtles (Jacobson et al., 1989), birds (Vancanneyt et al., 1994), cats (Sims, 1974), and a dog (Bruun and Ursing, 1987). *Chryseobacterium indologenes* has also been reported from diseased frogs (Olson et al., 1992). *Chryseobacterium balustinum* and *C. scophthalmum* (Harrison, 1929; Brisou et al., 1959; Mudarris and Austin, 1989; Mudarris et al., 1994) and many strains affiliated to the CDC group IIb (J.-F. Bernardet et al., unpublished data) were isolated from diseased fish.

In humans, the most significant species is *E. meningoseptica*. Although historically associated with meningitis in premature neonates, it is now known to occur in several other types of infections. Members of the CDC group IIb have also been retrieved from a number of human cases; they were considered to be the most frequently isolated clinical flavobacteria (Holmes and Owen, 1981; Shewan and McMeekin, 1983). Even though there is usually no clear evidence of the pathogenic role of the *Chryseobacterium* and *Elizabethkingia* species other than *E. meningoseptica*, they do raise some concern since *Chryseobacterium*/*Elizabethkingia*-related infections frequently occur in immunocompromised patients and are resistant to a wide range of commonly used antimicrobial agents. Because their natural habitat is water, they may also be retrieved from hospital environments.

Extensive information on animal and human pathogenicity of members of the genera *Chryseobacterium* and *Elizabethkingia* is given in the section Pathogenicity and Epidemiology.

Isolation and Cultivation

Members of the genera *Chryseobacterium* and *Elizabethkingia* are generally not difficult to isolate and cultivate, since they are classic aerobic chemoorganotrophs. Hence, most of them grow readily on commercially available organic media, usually making unecessary the use of selective media and the addition of growth factors. The procedures used to isolate and cultivate the bacterial species now classified in the genera *Chryseobacterium* and *Elizabethkingia* were described in the previous editions of *Bergey's Manual* (Holmes et al., 1984) and *The Prokaryotes* (the chapter on The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in this Volume). More recently, the general isolation and

maintenance procedures for members of the family Flavobacteriaceae were reviewed by Jooste and Hugo (1999). The same authors more specifically reviewed these procedures for the *Chryseobacterium* species that are usually associated with food (i.e., *C. balustinum*, *C. gleum*, *C. indologenes* and *C. joostei*; Hugo and Jooste, 2003; see the section Habitat and Ecology in this Chapter). Such classic media as brain heart infusion, nutrient, Mueller Hinton, and trypticase soy were all found suitable. Interestingly, although only two *Chryseobacterium* species originated from marine environments, most species exhibit a rather high degree of halotolerance and are consequently also able to grow on Difco marine 2216 agar (1.95% NaCl among several other salts; Bernardet et al., 2002); *C. balustinum* is the only known exception, but the growth of *C. defluvii*, "*C. proteolyticum*," *C. daecheongense*, *C. formosense* and *C. taichungense* on this medium has not been tested (Table 2). Conversely, the *Chryseobacterium* strains from marine origin grow as well on the above-mentioned non-marine media as on marine 2216 agar (J.-F. Bernardet, unpublished data). Strains of *E. meningoseptica* are also able to grow on marine 2216 agar but the growth of *E. miricola* on this medium has not been tested. *Chryseobacterium indoltheticum* was originally isolated on a chitin-containing media in the course of a study aimed at retrieving chitin-degrading bacteria from marine environments (Campbell and Williams, 1951), but it was later shown to grow well on other media. Similarly, "*C. proteolyticum*" was isolated on a medium that favored the growth of protein-deaminating enzyme producers from soil, but the strains were later maintained on nutrient agar (Yamaguchi and Yokoe, 2000). The isolation of *C. defluvii* was performed on R2A agar (Oxoid); the same medium, as well as nutrient and trypticase soy agars was used for further studies (Kämpfer et al., 2003). After an isolation step on several different media, *E. miricola* was cultivated on brain heart infusion agar (Li et al., 2003). *Chryseobacterium daecheongense*, *C. formosense* and *C. taichungense* were originally isolated on nutrient agar (Kim et al., 2005; Young et al., 2005; Shen et al., 2005). Most *Chryseobacterium* and *Elizabethkingia* species tested do not grow or grow poorly on cetrimide agar while the ability to grow on MacConkey agar varies among species (Table 2); most species, except *C. scophthalmum*, also grow on β-hydroxybutyrate (without producing β-hydroxybutyrate inclusion granules); *C. defluvii*, "*C. proteolyticum*," *C. daecheongense*, *C. formosense*, *C. taichungense* and *E. miricola* have not been tested for this characteristic.

The most often used temperature range for incubation is 20–30°C (Hugo and Jooste, 2003). Very poor growth or no growth at all occurs at 5°C, while members of four among the eleven *Chryseobacterium* species and of the two *Elizabethkingia* species are able to grow at 37°C (Table 2). At 42°C, most strains will not grow, except some *C. gleum* and some *E. meningoseptica* strains (J.-F. Bernardet, unpublished data). *Chryseobacterium gleum* strains were reported to grow at 41°C in contrast with *C. indologenes* strains (Yabuuchi et al., 1983). Approximately half of the *E. meningoseptica* strains studied by Bruun and Ursing (1987) were able to grow at 40°C; this trait was characteristic for strains derived from invasive neonatal infections. Good growth was reported for *C. daecheongense*, *C. formosense* and *C. taichungense* at 28–37°C, 25–32°C and 11–36°C, respectively (Kim et al., 2005; Young et al., 2005; Shen et al., 2005).

Fish-pathogenic members of the genera *Chryseobacterium* and *Elizabethkingia* (see the chapter Pathogenicity and Epidemiology) may be isolated from samples of external lesions or internal organs inoculated on one or several of the above-mentioned media and incubated at 20–25°C. A casein-containing medium (medium K) was first used to isolate and cultivate *C. scophthalmum* (Mudarris and Austin, 1989), but later studies demonstrated that this species grows equally well and even better on marine 2216, nutrient, and trypticase soy agars (Mudarris et al., 1994; J.-F. Bernardet, unpublished data).

The distinctive bright yellow to orange pigmentation and the shiny appearance of the colonies of members of the genus *Chryseobacterium* allow the selection of putative *Chryseobacterium* strains from agar plates with mixed bacterial growth, e.g., from external lesions of fish or from soil or water samples. Enhanced production of yellow pigment by strains of *C. daecheongense*, *C. formosense* and *C. taichungense* occurs on nutrient agar (Kim et al., 2005a; Young et al., 2005; Shen et al., 2005). The yellow pigmentation of the colonies of *C. defluvii* is weaker than that of the other *Chryseobacterium* species. This is also true for *Elizabethkingia miricola*, while the colonies of *E. meningoseptica* may be weakly pigmented or non-pigmented depending on the strains (see the section Identification in this Chapter).

Specific information on the isolation and cultivation of clinical *Chryseobacterium* and *Elizabethkingia* isolates is given in the section Pathogenicity and Epidemiology.

Identification

Characteristics which differentiate members of the genera *Chryseobacterium* and *Elizabethkingia* from members of other genera in the family Flavobacteriaceae are listed in Table 2 of the

Table 2. Differentiating characteristics of *Chryseobacterium* and *Elizabethkingia* species and closely related taxa.

Symbols and abbreviations: +, positive reaction; –, netagive reaction; (+) weak or delayed reaction; v, varies within species; v, varies between references; and ND, not determined.

Since some of the characteristics listed were tested by several authors using different methods, the original publications should be consulted for direct comparison.

[a]The type of yellow pigment in *C. defluvii* and *K. koreensis* has not been determined (Kämpfer et al., 2003; Kim et al., 2004); the yellow pigment produced by *Sejongia* strains is not of the flexirubin type (Yi et al., 2005).

[b]*Elizabethkingia meningoseptica* strains either are not pigmented or produce a weak yellow nondiffusible pigment (e.g., the type strain; Bruun and Ursing, 1987). Members of all *Chryseobacterium* species produce a yellow to orange nondiffusible flexirubin type pigment.

[c]Strains of *Riemerella anatipestifer* and *R. columbina* grown on trypticase soy agar produce a light yellow-brown non-flexirubin pigment which diffuses in the agar and gives a beige color to the colonies (J.-F. Bernardet, unpublished data). On Columbia blood agar, colonies of *R. columbina* are grayish-white to beige, whereas those of *R. anatipestifer* are nonpigmented (Vancanneyt et al., 1999).

[d]*Chryseobacterium indologenes* strains can grow under anaerobic conditions in the presence of fumarate (Yabuuchi et al., 1983). This trait has not been tested in other *Chryseobacterium* species.

[e]The type strain of *Elizabethkingia miricola* can grow in the presence of 5% (v/v) carbon dioxide, although it has a strictly respiratory type of metabolism (Li et al., 2003). This trait has not been tested in *Elizabethkingia meningoseptica* and in *Chryseobacterium* species.

[f]Although its growth on marine agar has not been tested, the *Elizabethkingia miricola* type strain has been shown to tolerate seawater (Li et al., 2003).

[g]According to Yabuuchi et al. (1990), the strains of *Chryseobacterium gleum* and *C. indologenes* may be distinguished by their positive and negative reaction, respectively, for the following tests: growth at 41°C, production of phenylalanine deaminase, acid production from L-arabinose, ethanol, salicin, and D-xylose, hydrolysis of esculin after 4 h (strains of both species hydrolyze esculin after 24 h), and production of urease on Christensen's urea agar slant after 40 h. According to Ursing and Bruun (1991), members of *C. gleum* and of one allied genomic group could be differentiated from other CDC group IIb strains by their ability to grow at 40°C and to produce acid from arabinose, xylose and salicin.

[h]Most strains are negative for this characteristic.

[i]Most strains are positive for this characteristic.

[j]The two *Sejongia* species also differ by their ability to grow at 30°C (positive for *S. jeonii*, negative for *S. antarctica*).

Data taken from Bruun (1982); Yabuuchi et al. (1983); Yabuuchi et al. (1990); Holmes et al. (1984); Holmes et al. (1986b); Bruun and Ursing (1987); Ursing and Bruun (1991); Segers et al. (1993); Mudarris et al. (1994); Vandamme et al. (1994); Vancanneyt et al. (1999); Yamaguchi and Yokoe (2000); Hugo et al. (2003); Kämpfer et al. (2003); Li et al. (2003); Kim et al. (2004, 2005a,b); Yi et al. (2005); Young et al. (2005), J.-F. Bernardet (unpublished data); and Shen et al. (2005).

Abbreviations: tr, trace (less than 1%); and ND, not detected.

[a]The fatty acid composition of "*Chryseobacterium proteolyticum*" has not been determined (Yamaguchi and Yokoe, 2000). Fatty acid percentages amounting to less than 1% of the total fatty acids in all species were not included; therefore, the percentages do not total 100%. When several strains were analyzed, rounded up means are given but standard deviations are not given; the number of strains analyzed is given in parentheses after the name of each species. Data taken from studies using different growth times, media and temperatures.

[b]Unknown fatty acid; numbers indicate equivalent chain length.

[c]Fatty acids that could not be separated by gas chromatography using the Microbial Identification System (Microbial ID) software were considered summed features. Summed feature 4 contains 15:0 *iso* 2-OH and/or 16:1ω7*c* and/or 16:1ω7*t*. Summed feature 5 contains 17:1 *iso* I and/or 17:1 *anteiso* B.

Modified from Hugo et al. (2003) and taken from Segers et al. (1993), Vancanneyt et al. (1999), Kämpfer et al. (2003), Li et al. (2003), Kim et al. (2004), Kim et al. (2005a,b), Yi et al. (2005), Young et al. (2005), Kim et al. (in press), and Shen et al. (2005).

chapter An Introduction to the Family Flavobacteriaceae in this Volume (see also Bernardet et al., 2002). Those characteristics that differ among species in the genus *Chryseobacterium* are listed in Table 2 (physiological and biochemical traits) and Table 3 (fatty acid composition) in the present chapter. Since *Bergeyella zoohelcum*, *Kaistella koreensis*, the two *Sejongia* species, the two *Riemerella* species and all members of the genera *Chryseobacterium* and *Elizabethkingia* form a distinct separate branch in phylogenetic trees (see the sections Phylogeny and Taxonomy in this Chapter), all these taxa have been included in Tables 2 and 3 for convenience.

The following description of the genus *Chryseobacterium*, based on the six species known at that time (i.e., including [*C.*] *meningosepticum* and [*C.*] *miricola*), is cited from Vandamme et al. (1994):

Description of *Chryseobacterium* gen. nov. *Chryseobacterium* (Chry.se.o.bac.te'ri.um. Gr. adj. *chryseos*, golden; Gr. neut. n. *bakterion*, a small rod; N. L. neut. n. *Chryseobacterium*, a yellow rod) cells are gram-negative, nonmotile, non-

spore-forming rods with parallel sides and rounded ends; typically the cells are 0.5 μm wide and 1 to 3 μm long. Intracellular granules of poly-β-hydroxybutyrate are absent. Aerobic. Chemoorganotrophic. All strains grow at 30°C; most strains grow at 37°C. Growth on solid media is typically pigmented (yellow to orange), but nonpigmented strains occur. Colonies are translucent (occasionally opaque), circular, convex to low convex, smooth, and shiny, with entire edges. Positive for catalase, oxidase, and phosphatase activities. Several carbohydrates, including glycerol and trehalose, are oxidized. Strong proteolytic activity occurs. Esculin is hydrolyzed. Agar is not digested. Resistant to a wide range of antimicrobial agents. Branched-chain fatty acids (i.e., 15:0 *iso*, *iso* 17:1ω9*c*, 17:0 *iso* 3-OH, and summed feature 4 [15:0 *iso* 2-OH or 16:1ω7*t* or both] are predominant (Segers et al., 1993). Sphingophospholipids are absent. Menaquinone 6 is the only respiratory quinone. Homospermidine and 2-hydroxyputrescine are the major polyamines in *Chryseobacterium indologenes*, whereas putrescine and agmatine are minor components (Hamana and Matsuzaki, 1991).

The type species is *Chryseobacterium gleum* comb. nov. The DNA base composition ranges from 33 to 38 mol% guanine plus cytosine. *Chryseobacterium* species are widely distributed in soil, water, and clinical sources.

The description of *Chryseobacterium balustinum* comb. nov. (basonym, *Flavobacterium balustinum* Harrison 1929), *Chryseobacterium gleum* comb. nov. (basonym, *Flavobacterium gleum* Holmes, Owen, Steigerwalt, and Brenner 1984), *Chryseobacterium indologenes* comb. nov. (basonym, *Flavobacterium indologenes* Yabuuchi, Kaneko, Yano, Moss, and Miyoshi 1983), *Chryseobacterium indoltheticum* comb. nov. (basonym, *Flavobacterium indoltheticum* Campbell and Williams 1951), *Chryseobacterium meningosepticum* comb. nov. (basonym, *Flavobacterium meningosepticum* King 1959), and *Chryseobacterium scophthalmum* comb. nov. (basonym, *Flavobacterium scophthalmum* Mudarris, Austin, Segers, Vancanneyt, Hoste, and Bernardet 1994) are the same as the original descriptions given in Harrison (1929), Holmes et al. (1984), Yabuuchi et al. (1983), Campbell and Williams (1951), King (1959), and Mudarris et al. (1994), respectively, as well as in Holmes et al. (1984).

Since 1994, seven additional species have been described, i.e., "*Chryseobacterium proteolyticum*" (Yamaguchi and Yokoe, 2000), *C. defluvii* (Kämpfer et al., 2003), *C. joostei* (Hugo et al., 2003), [C.] *miricola* (Li et al., 2003), *C. daecheongense* (Kim et al., 2005a), *C. formosense* (Young et al., 2005), and *C. taichungense* (Shen et al., 2005). The new genus *Elizabethkingia* was recently proposed to accomodate one of these new species (*E. miricola*) and one of the *Chryseobacterium* species included in the original description of the genus, [C.] *meningosepticum* (now the type species of the genus *Elizabethkingia*). Since most of the characteristics of the newly described *Chryseobacterium* species fitted the description of the genus, they did not make an emendation of its original description necessary. However, some additional information and slight discrepancies with the description are given below in the order of the above description. The formal description of the genus *Elizabethkingia* was given by Kim et al. (2005b). Since most phenotypic characteristics of members of the genera *Chryseobacterium* and *Elizabethkingia* are very similar, and since they were previously grouped in the genus *Chryseobacterium*, they will be dealt with together below. Those few characteristics which differentiate members of the two genera are listed in Table 2 in this chapter and in Kim et al. (2005b).

Concerning first the morphological characteristics, some *Chryseobacterium* strains may also produce filaments in addition to rods in liquid culture (e.g., *C. scophthalmum*, Mudarris et al., 1994). Electron microscopy studies have seldom been performed on *Chryseobacterium* strains; the presence of a thick cell wall (i.e., about 50 nm) was reported in *C. joostei* (Hugo et al., 2003) and *C. scophthalmum* (Mudarris et al., 1994). Cells of "*C. proteolyticum*" were studied using scanning electron microscopy, but no particular structure was evidenced (Yamaguchi and Yokoe, 2000). The production of extracellular slimy substances after prolonged incubation has been reported in *C. defluvii* (Kämpfer et al., 2003) and *C. formosense* (Young et al., 2005); it is likely responsible for the mucoid consistency of colonies after three days incubation reported in *C. daecheongense* (Kim et al., 2005a) and *C. formosense* (Young et al., 2005a) and in *Elizabethkingia* species (Kim et al., 2005). Colonies of *E. miricola* are very sticky on solid media (Kim et al., 2005). Some *E. meningoseptica* strains are encapsulated, especially following passage in mice (Holmes et al., 1984). A strong odor, reminiscent of that given off by some *Empedobacter*, *Myroides* and *Sphingobacterium* strains, is produced by most *Chryseobacterium* strains in liquid and solid culture; it has been described as "fruity" (Yabuuchi et al., 1983; Yabuuchi et al., 1990) or "cheesy" (Brisou et al., 1959). Other types of odor were reported when food products were spoiled by *Chryseobacterium* strains (Engelbrecht et al., 1996; see the section Habitat and Ecology in this Chapter).

As shown in Table 2, strains of *C. balustinum*, *C. indoltheticum*, *C. joostei*, *C. scopthalmum* and *C. formosense* do not grow at 37°C. The nondiffusible, nonfluorescent bright yellow to orange pigments produced by all *Chryseobacterium* strains belong to the flexirubin type (Reichenbach et al., 1981; Yabuuchi et al., 1983; Holmes et al., 1984; Mudarris et al., 1994; Yamaguchi and Yokoe, 2000; Hugo et al., 2003; Kim et al., 2005; Young et al., 2005; Shen et al., 2005; J.-F. Bernardet, unpublished data; see below). The sentence in the original description mentioning that nonpigmented *Chryseobacterium* strains occur was actually referring to *Elizabethkingia meningoseptica* strains and should be deleted. The type of yellow pigment in

C. defluvii has not been determined; contrary to the colonies of members of other *Chryseobacterium* species, those of *C. defluvii* were described as yellowish, not bright yellow (Kämpfer et al., 2003). The production of pigment may depend on the culture medium (Hugo and Jooste, 2003); it may also increase at low temperatures, in the presence of daylight, and by such compounds as casein, milk and starch (Holmes et al., 1984). While the original *E. miricola* strain was described as white-yellow (Li et al., 2003), the production of yellow pigment is strain-dependent in *E. meningoseptica*: 20 among the 52 strains studied by Bruun and Ursing (1987) were completely colorless while the other strains (including the type strain) produced a weak yellow pigment. Flexirubin type pigments were not detected in *E. meningoseptica* and *E. miricola* strains using the KOH technique (Kim et al., 2005b). However, these authors flooded the colonies with the KOH solution directly on agar, a procedure which makes weak color shifts difficult to detect. The procedure recommended in the minimal standards for describing new taxa in the family Flavobacteriaceae (Bernardet et al., 2002) was used on *E. meningoseptica* strains grown for several days at 37°C on trypticase soy agar. Three strains, including the type strain, produced pale cream-beige colonies that turned to a brownish color when flooded with 20% KOH, contrary to nine other strains whose colonies exhibited a weaker pigmentation; the pigmentation of the colonies and the color shift in the presence of KOH were stronger when the strains were grown in an illuminated incubator (J.-F. Bernardet, unpublished data). Hence, it seems some *Elizabethkingia* strains may indeed produce small amounts of flexirubin type pigment in the presence of light. Strains of *C. balustinum*, *C. gleum*, *C. indoltheticum*, *C. joostei* and *E. meningoseptica* also produce a pinkish-brown, diffusible pigment when grown on tyrosine agar (Hugo et al., 2003; J.-F. Bernardet, unpublished data); this characteristic is strain-dependent in *C. scophthalmum* (Mudarris et al., 1994). *Chryseobacterium daecheongense*, *C. formosense* and *C. taichungense* have not been tested for this characteristic. The production of catalase has not been tested in *C. defluvii*, *C. formosense* and *C. taichungense*, but *C. daecheongense* was shown to produce catalase (Kim et al., 2005). The phosphatase activity has not been searched for in *C. defluvii*, *E. miricola* (Li et al., 2003), and "*C. proteolyticum*" (Yamaguchi and Yokoe, 2000); this activity has been detected in *C. joostei* (Hugo et al., 2003). Although all *Chryseobacterium* species are able to oxidize some carbohydrates, several of them are actually unable to oxidize glycerol and/or trehalose, contrary to the statement in the description (Table 2). *Chryseobacterium indoltheticum* is the only *Chryseobacterium* species tested which is able to degrade chitin (Campbell and Williams, 1951; J.-F. Bernardet, unpublished data). The resistance to many antimicrobial agents of members of most *Chryseobacterium* and *Elizabethkingia* species has been repeatedly reported; however, data are unfortunately lacking for the recently described species "*C. proteolyticum*," *C. defluvii*, *C. daecheongense*, *C. formosense*, *C. taichungense* and *E. miricola* (Yamaguchi and Yokoe, 2000; Kämpfer et al., 2003; Li et al., 2003; Kim et al., 2005a; Young et al., 2005; Shen et al., 2005). This characteristic is discussed in the section Pathogenicity and Epidemiology. The list of predominant fatty acids given in the genus description is also valid for the new species (see below and Table 3). Homospermidine is the major polyamine in all *Chryseobacterium* species tested, but other polyamines may occur as minor components (see below). The range of DNA G+C content for the genus should be extended to 39 mol%, a value reached by some *C. gleum* and *C. indologenes* strains (Hugo et al., 1999). The base composition of *C. formosense* and *C. taichungense* has not been determined. Food products, particularly dairy products, should be added to the list of sources of members of the genus *Chryseobacterium* (Hugo et al., 1999; see the section Habitat and Ecology in this Chapter).

The meager original descriptions of *C. balustinum* (Harrison, 1929) and *C. indoltheticum* (Campbell and Williams, 1951) have actually not been taken into consideration in the formal genus description quoted above. There exists no *C. balustinum* strain dating back to the original isolation and description. The only bona fide strain currently available in culture collections, isolated much later from a freshwater fish in France, was attributed to this bacterial species because of an overall phenotypic similarity with Harrison's description; however, even the description of this isolate is imperfect (Brisou et al., 1959). The original description of *C. indoltheticum* was based on two isolates, one of which is the type and only bona fide strain currently available. Surprisingly, the original strains were described as "motile by means of peritrichous flagella" (Campbell and Williams, 1951); the type strain is nonmotile, however (Holmes et al., 1984). Hence, the characteristics currently taken into consideration for these two species actually result from later studies (Yabuuchi et al., 1983; Holmes et al., 1984; Holmes et al., 1984; J.-F. Bernardet, unpublished data; and the chapter The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in this Volume).

In the minimal standards proposed for describing new genera and species in the family Flavobacteriaceae (Bernardet et al., 2002), par-

ticular methods were suggested to determine some of the phenotypic properties which can be used to differentiate members of the genera *Chryseobacterium* and *Elizabethkingia* from members of the other genera in the family and to differentiate among *Chryseobacterium* and *Elizabethkingia* species. These methods should preferably be used since the test conditions are critical. Some additional practical information is given below for the most problematic or delicate among those tests.

Detection of the Gliding Motility and Determination of the Pigment

The absence of gliding motility and the presence of flexirubin type pigments in members of the genus *Chryseobacterium* are two of the key characteristics which differentiate them from members of several other genera in the family Flavobacteriaceae. Information on the appropriate methods to detect gliding motility in liquid and solid cultures and to determine the type of yellow pigments was given in Bernardet et al. (2002) and in the chapters An Introduction to the Family Flavobacteriaceae and The Genus *Flavobacterium* in this Volume.

The pigments of *Chryseobacterium* strains have been identified as belonging to the flexirubin type (Reichenbach et al., 1981; see above) usually using the simple KOH test; the pigments in *C. indologenes* strains, however, have also been identified using a more sophisticated spectrophotometric method following extraction by different organic solvants (Yabuuchi et al., 1983).

The case of *C. scophthalmum* clearly illustrates the difficulty in detecting gliding motility, as well as the taxonomical and nomenclatural consequences a mistaken detection may have had before the advent of molecular methods. In the course of the original study, the fresh isolates were judged to exhibit gliding motility (Mudarris and Austin, 1989), and the new bacterial species was consequently deposited under the name "[*Cytophaga*] *scophthalmis*" in a culture collection. Gliding motility could not be confirmed, however, during a subsequent examination. The cultures were consequently considered nonmotile, and hence the new species was formally described as [*Flavobacterium*] *scophthalmum* (Mudarris et al., 1994). It was finally attributed to the genus *Chryseobacterium* after the extensive emendation of the genus *Flavobacterium* (Vandamme et al., 1994; Bernardet et al., 1996).

Production of β-D-Galactosidase

Precautions should be taken when detecting the presence of β-D-galactosidase, as it has been shown that results may differ depending on the type of test used. Nine *C. gleum* strains gave a positive result when tested using the conventional ONPG test (i.e., *o*-nitrophenyl-β-D-galactopyranoside on filter paper discs), whereas the production of enzyme was not detected on the substrate 2-naphthyl-β-D-galactopyranoside in API ZYM galleries (Holmes et al., 1984). Bruun and Ursing (1987) reported similar discrepancies between the two tests in a study of 52 *E. meningoseptica* isolates; similar to the ONPG test (Bülow, 1964), the Rosco enzyme assay system yielded positive results for all strains. The type strains of all *Chryseobacterium* and *Elizabethkingia* species and all milk isolates tested by Hugo et al. (2003) were also found negative for the production of β-D-galactosidase in API ZYM galleries and positive in the ONPG test. In an ongoing study of 70 *Chryseobacterium* fish isolates and reference strains, discrepancies in the detection of β-D-galactosidase were also noticed between the different tests used: the test included in API 20NE galleries (using *p*-nitrophenyl-β-D-galactopyranoside [PNPG] as the substrate) detected 14 positive strains. The ONPG disc test and the corresponding cupule in API 20E galleries (both using ONPG as the substrate) detected 10 positive strains; only 6 positive strains were detected using the test in API ZYM galleries (J.-F. Bernardet, unpublished data).

Acid Production from Carbohydrates

Those carbohydrates from which acid is produced are considered differentiating characteristics between *Chryseobacterium* and *Elizabethkingia* species (Table 2). The production of acid from carbohydrates should preferably be tested in ammonium salt medium (Bernardet et al., 2002). The discrepancies between the results obtained in different studies are probably at least partly due to the use of different media and incubation conditions. For instance, all three *C. gleum* strains studied by Yabuuchi et al. (1990) were able to produce acid from L-arabinose, ethanol, salicin and D-xylose. Ursing and Bruun (1991) also found all or most of their 9 strains positive or at least weakly positive for these tests, whereas all or most of the 12 *C. gleum* strains studied by Holmes et al. (1984) were considered negative for these characteristics.

Production of L-Phenylalanine Deaminase

The technique of Richard and Kiredjian (1995) has been recommended to detect the production of phenylpyruvic acid from L-phenylalanine (Bernardet et al., 2002). Briefly, 1 ml of very dense bacterial suspension is mixed with an equal volume of an aqueous, filter-sterilized solution of L-phenylalanine (0.5 g per 100 ml). After

stirring, the suspension is distributed in three tubes (0.5 ml per tube) and continuously stirred and maintained at room temperature. After 30 min, 4 h, and 18 h, 1 drop of $FeCl_3$ (2 volumes of distilled water and 1 volume of $FeCl_3$ solution, d = 1.26; the $FeCl_3$ solution included in the API galleries kit is convenient) is added to one of the tubes; a dark green color (which decreases after a few minutes) reveals the production of L-phenylalanine deaminase (Richard and Kiredjian, 1995). The intensity of the green color allows for a rough evaluation of the amount of L-phenylalanine deaminase produced, but weak reactions may be difficult to detect. Moreover, the reaction may be positive and subsequently negative; when this occurs, the strain should be considered positive (M. Kiredjian, personal communication). Using this technique, reference strains of all *Chryseobacterium* species were negative for this characteristic except the *C. scophthalmum* type strain, which was strongly positive; strains of *E. meningoseptica* were weakly positive (J.-F. Bernardet, unpublished data). Strains of "*C. proteolyticum*," *C. defluvii*, *C. daecheongense*, *C. formosense* and *C. taichungense* were not tested. Most *C. scophthalmum* strains had been found to produce L-phenylalanine deaminase on phenylalanine agar (Difco; Mudarris and Austin, 1989), while the type strain was the only positive among the six strains tested using the method of Richard and Kiredjian (J.-F. Bernardet, unpublished data). This method did not detect the production of L-phenylalanine deaminase in two *C. gleum* reference strains, whereas the three strains studied by Yabuuchi et al. (1990) were positive for this characteristic using an unspecified method. The diagnostic value of this test will only be established when several strains of each *Chryseobacterium* species become available and are tested.

Commercial Identification Galleries

Commercially available kits, strips and galleries have been extensively used over the last decade to identify bacterial strains in addition to or as a substitute for conventional biochemical tests, particularly in the clinical microbiology laboratory (see the section Pathogenicity and Epidemiology in this Chapter). Since these systems are primarily aimed at the identification of human pathogens, the temperature and time of incubation need to be adapted to the requirements of *Chryseobacterium* strains that do not grow at 37°C (Table 2). API galleries (bioMérieux) have frequently been used; API 20E, API 20NE, API ZYM, and API 50CH galleries have yielded interesting results when incubated at temperatures close to the optimum of the strains tested. Only *C. indologenes* and *E. meningoseptica* are included in the analytical profile index of API 20E and 20NE galleries. In API 20NE galleries, reference strains of *C. balustinum*, *C. gleum*, *C. indoltheticum*, *C. joostei* and *C. scophthalmum* all produced similar profiles, leading to their identification as *C. indologenes* with varying degrees of similarity; the identification of *Chryseobacterium* strains using API 20NE is usually not valid before 48 h of incubation at 30°C (J.-F. Bernardet, unpublished data). API ZYM galleries have been used following the manufacturer's instructions (i.e., 4 h of incubation at 37°C) for the *Elizabethkingia* isolates and the clinical *Chryseobacterium* isolates (e.g., *C. indologenes*; Yabuuchi et al., 1983) or at lower temperature (22–25°C) and for prolonged time of incubation (12–18 h) for environmental, fish and food isolates (Mudarris et al., 1994; Hugo et al., 2003; J.-F. Bernardet, unpublished data). Results yielded by API ZYM galleries may be interpreted either using the 0–5 color intensity scale suggested by the manufacturer or simply considering all grades from 1 to 5 as positive (Bruun and Ursing, 1987). Other commercial strips such as the Rosco system (Bruun and Ursing, 1987) and the Micronaut-E gallery (Merlin; Kämpfer et al., 2003; Shen et al., 2005) were also tested with *Chryseobacterium* strains. The *E. miricola* type strain was tested using the GN2 MicroPlate (Biolog), the Nonfergram S-1 kit (Wako Chemical), and the API 20NE and API 50CH galleries, but the authors did not discuss the respective practical value and advantage of these kits (Li et al., 2003). The descriptions of *C. daecheongense*, *C. formosense* and *C. taichungense* all included data from API galleries (Kim et al., 2005a; Young et al., 2005; Shen et al., 2005). Biotype 100 galleries (bioMérieux) have been tested on a collection of *Chryseobacterium* and *Elizabethkingia* reference strains and fish isolates; all strains were able to assimilate 4–22 substrates, and 38 substrates out of 99 were assimilated by at least one strain (J.-F. Bernardet and C. Bizet, unpublished data). Many strains of each species, however, should be tested on the Biotype 100 gallery to assess its value for the identification of new isolates.

Some *Chryseobacterium* species are differentiated with difficulty using the above-mentioned phenotypic tests. For instance, although members of the CDC group IIb (see the section Taxonomy in this Chapter) are relatively easily distinguished from other *Chryseobacterium* species and from members of the genera *Elizabethkingia*, *Bergeyella*, *Riemerella*, *Empedobacter*, *Myroides* and *Weeksella* (see above), the differentiation between members of the group, particularly between *C. indologenes* and *C. gleum*, is problematic. A list of phenotypic traits distinguishing *C. indologenes* and *C. gleum* from related taxa was proposed by Yabuuchi et al. (1983) and Holmes et al. (1984), respectively.

While the latter species was comprised of strains with very similar characteristics, there were many variable characteristics among the 13 original *C. indologenes* strains. According to Yabuuchi et al. (1990), *C. gleum* could be distinguished from *C. indologenes* on the basis of growth at 41°C, production of phenylalanine deaminase, acid production from L-arabinose, ethanol, salicin, and D-xylose, hydrolysis of esculin after 4 h (strains of both species hydrolyze esculin after 24 h), and production of urease on Christensen's urea agar slant after 40 h (Table 2). As reported above, the tests for the production of phenylalanine deaminase and for the production of acid from carbohydrates are not very easy to read and may yield different results depending on the procedure used. Moreover, the study by Yabuuchi et al. (1990) was based on only three *C. gleum* strains. Studying a larger number of strains (which had previously been identified by DNA-DNA hybridization experiments), Ursing and Bruun (1991) found that *C. gleum* formed a homogeneous group, but that it was very difficult or impossible to differentiate *C. gleum* and *C. indologenes* with certainty from other CDC group IIb strains using the characteristics proposed by Holmes et al. (1984), Yabuuchi et al. (1983), and Yabuuchi et al. (1990). The results of Ursing and Bruun (1991) agreed with those of Yabuuchi et al. with regard to the acid production from xylose and salicin, but agreed more with Holmes et al. with regard to urease production and esculin hydrolysis. As a consequence, they recommended that the name *Flavobacterium* (now *Chryseobacterium*) group IIb be used pending further investigation (Ursing and Bruun, 1991). Indeed, recent studies of collections of *Chryseobacterium* group IIb isolates from dairy products (Hugo, 1997; Hugo et al., 1999) and fish (J.-F. Bernardet et al., unpublished data) faced the same problem, even when polyphasic taxonomy was used: Only some of the strains could be grouped in delineated clusters, while the others remained isolated and classified as *Chryseobacterium* sp. CDC group IIb. Discrepancies between the results of different studies may also result from the use of different techniques or conditions; for instance, the critical growth temperature proposed for differentiating between *Chryseobacterium* species was 40°C (Ursing and Bruun, 1991), 41°C (Yabuuchi et al., 1990), or 42°C (Holmes et al., 1984; Holmes et al., 1984; Vandamme et al., 1994).

The use of other, usually more sophisticated, techniques to help identify members of the family Flavobacteriaceae was discussed by Bernardet et al. (2002) and in the chapter An Introduction to the Family Flavobacteriaceae in this Volume. Additional information on the application of these techniques to the genera *Chryseobacterium* and *Elizabethkingia* is provided below.

Fatty Acid Composition

The kind of taxonomic information resulting from the analysis of whole-cell fatty acid methyl esters (FAMEs) was discussed in the chapter An Introduction to the Family Flavobacteriaceae in this Volume. Table 3 lists the fatty acids that occur in *Chryseobacterium* and *Elizabethkingia* species and in related taxa. Hugo et al. (1999) considered that the *Chryseobacterium* species could not be differentiated from each other on the basis of fatty acid profiles, while the profiles of the related species *Elizabethkingia meningoseptica*, *Bergeyella zoohelcum* and *Empedobacter brevis* are distinct. The two *Riemerella* species differ from all other species by lacking two of their major fatty acids (i.e., 17:1 *iso* ω9*c* and summed feature 4) and by the highest proportion of 13:0 *iso*. The fatty acid composition of "*Chryseobacterium proteolyticum*" has not been determined (Yamaguchi and Yokoe, 2000), but the overall fatty acid composition of the recently described *Chryseobacterium* species (i.e., *C. defluvii*, *C. joostei*, *C. daecheongense*, *C. formosense*, and *C. taichungense*) is similar to that cited in the original genus description (see above). However, *C. defluvii*, *C. daecheongense* and *C. formosense* are characterized by a low proportion of 17:1 *iso* ω9*c* and a high proportion of 15:0 *iso* (Kämpfer et al., 2003; Kim et al., 2005a; Young et al., 2005). *Elizabethkingia meningoseptica* and *E. miricola* exhibit a low 17:1 *iso* ω9*c* content but contain the highest proportion of summed feature 4 (Kim et al., 2005b). Interestingly, the results of the new fatty acid analysis performed by Kim et al. (2005b) on the two *E. miricola* strains are quite different from those of the original analysis of the type strain (Li et al., 2003). The two *Sejongia* strains differ from all other species by distinct proportions of several fatty acids and by the presence of six additional fatty acids (Yi et al., 2005). Branched-chain fatty acids account for 80% of all fatty acids in *C. indologenes* and *E. meningoseptica* (Yabuuchi et al., 1983) and for 88% in *E. miricola* (Li et al., 2003). Therefore, although fatty acid profiles for most members of the genera *Chryseobacterium* and *Elizabethkingia* are not species specific, the determination of the fatty acid profile will help assign new isolates to the genera.

Whole-cell Protein Analysis

A good correlation between high DNA relatedness and high similarity of whole-cell protein patterns was shown for several members of the family Flavobacteriaceae (Vandamme et al.,

1996; Bernardet et al., 2002; see also the chapter An Introduction to the Family Flavobacteriaceae in this Volume). Therefore, the determination of whole-cell protein profiles may help the assignment of new isolates of *Chryseobacterium* and *Elizabethkingia* spp. or delineation of new species (Vandamme et al., 1994; Bernardet et al., 2002). However, whole-cell protein profiling requires the skill and equipment for highly standardized sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE), numerical analysis of the resulting electrophoregrams, and database comparison. Hugo et al. (1999) reported that, unlike fatty acid analysis, SDS-PAGE analysis yielded a clear differentiation between the investigated *Chryseobacterium* and *Elizabethkingia* species; about half of the more than 100 dairy isolates studied could be clustered into nine major groups while the other half occupied separate positions. Similar results were obtained when the whole-cell protein profiles of a collection of *Chryseobacterium* strains isolated from diseased fish were analyzed (J.-F. Bernardet et al., unpublished data). *Bergeyella zoohelcum* and the two *Riemerella* species, which are phylogenetically related to the genera *Chryseobacterium* and *Elizabethkingia* (see the section Phylogeny in this Chapter), were also clearly differentiated using this technique (Segers et al., 1993; Vancanneyt et al., 1999). The whole-cell protein profiles of "*C. proteolyticum*" (Yamaguchi and Yokoe, 2000), *C. defluvii* (Kämpfer et al., 2003), *C. daecheongense* (Kim et al., 2005a), *C. formosense* (Young et al., 2005), *C. taichungense* (Shen et al., 2005), *Kaistella koreensis* (Kim et al., 2004), *Sejongia jeonii* and *S. antarctica* (Yi et al., 2005), and *E. miricola* (Li et al., 2003) have not been determined.

Other Chemotaxonomic Markers

Like other members of the family Flavobacteriaceae, those *Chryseobacterium* and *Elizabethkingia* species investigated for these characteristics contain menaquinone 6 as their only respiratory quinone and no sphingophospholipids (Vandamme et al., 1994; Bernardet et al., 2002; Kämpfer et al., 2003; Li et al., 2003; Kim et al., 2005a,b).

Homospermidine is the major polyamine in *C. balustinum*, *C. gleum*, *C. indologenes* and *E. meningoseptica*; trace amounts of putrescine and agmatine are also detected in the three former species (Hamana and Mastuzaki, 1990), whereas diaminopropane and 2-hydroxyputrescine are minor components in *C. indologenes* (Hamana and Matsuzaki, 1991). Recently described *Chryseobacterium* species have not been investigated for their polyamine composition, except *C. defluvii* and *C. daecheongense*, which contain *sym*-homospermidine as the major component and spermine and spermidine as minor components (Kämpfer et al., 2003; Kim et al., 2005a). Contrary to the statement by Kämpfer et al. (2003), previous publications have shown that no polyamine pattern can be considered characteristic of all members of the genus *Chryseobacterium*. Homospermidine is the only polyamine in *Bergeyella zoohelcum*, *Ornithobacterium rhinotracheale*, *Riemeralla anatipestifer* and *Weeksella virosa* (Hamana and Nakagawa, 2001).

The only *Chryseobacterium* species in which the polar lipid content was determined are *C. defluvii* and *C. daecheongense*; the major lipid was phosphatidylethanolamine, but several other, unknown polar lipids were also detected (Kämpfer et al., 2003; Kim et al., 2005a).

Multilocus Enzyme Electrophoresis

Multilocus enzyme electrophoresis (MEE) was used in an attempt to classify 103 *Chryseobacterium*, *Elizabethkingia* and *Empedobacter* dairy isolates and 27 reference strains (Hugo and Jooste, 1997). The isolates were placed in seven clusters; although the technique was successful in distinguishing the *E. meningoseptica* and *Empedobacter brevis* strains, it was not able to differentiate such closely related species as *C. indologenes*, *C. gleum* and *C. balustinum* and scattered the eleven isolates that would later be attributed to the new species *C. joostei* (Hugo et al., 2003) among several different MEE clusters (Hugo and Jooste, 1997).

DNA-DNA Hybridization

DNA-DNA relatedness, determined using quantitative DNA-DNA hybridization techniques, is still the acknowledged standard for the delineation of bacterial species. When the technique used allows the thermal stability of the DNA hybrids (D*Tm*) to be determined, this value should also be taken into consideration (Wayne et al., 1987; Stackebrandt et al., 2002). The different techniques available and a review of their application to members of the family Flavobacteriaceae were discussed extensively by Bernardet et al. (2002), and only additional information (especially focused on the genera *Chryseobacterium*- and *Elizabethkingia*) will be given here. Table 4 is an attempt to compile most of the published *Chryseobacterium*- and *Elizabethkingia*-related DNA-DNA hybridization results and to compare the relatedness values yielded by different techniques.

On the whole, Table 4 shows that the 70% DNA relatedness threshold value proposed by Wayne et al. (1987) does apply to *Chryseobacterium* and *Elizabethkingia* species. Strains

Table 4. Published DNA-DNA relatedness values within the genera *Chryseobacterium* and *Elizabethkingia* and between members of the genera *Chryseobacterium* and *Elizabethkingia* and members of related genera.

Species	Reference(s) and DNA-DNA hybridization technique(s) used	Intra-specific DNA relatedness (%)	Inter-specific DNA relatedness (%)	DNA relatedness with other genera (%)
Chryseobacterium balustinum	**A**: Non-labeled DNA on filters, ^{3}H-labeled DNA probe in solution **E**: Initial renaturation rate spectrophotometric method **G**: Quantitative microplate method	NA (one strain only)	**A**: *C. balustinum /C. indologenes*: 26 **E**: *C. balustinum /C. indoltheticum*: 35 **G**: *C. balustinum /C. indologenes*: 14	**A**: *C. balustinum /Sphingobacterium* spp.: 5–7; *C. balustinum /Empedobacter brevis*: 10 **G**: *C. balustinum /Empedobacter brevis* and *Myroides odoratus*: 4–8
Chryseobacterium daecheongense	**K**: Initial renaturation rate spectrophotometric method	NA (one strain only)	**K**: *C. daecheongense /C. defluvii*: 34	ND

Abbreviations: NA, not applicable (only one strain available); ND, not determined.

Data from Yabuuchi et al., 1983 (A); Holmes et al., 1984 (B); Ursing and Bruun, 1987 (C); Ursing and Bruun, 1991 (D); Mudarris et al., 1994 (E-1 and E-2: two different hybridization techniques were used in this study); Hugo et al., 1999 (F); Yamaguchi and Yokoe, 2000 (G); Li et al., 2003 (H); J.-F. Bernardet, unpublished data (I); Young et al., 2005 (J); Kim et al., 2004, 2005a,b (K); and Shen et al., 2005 (M). DNA-DNA hybridization data are not available for *C. defluvii* (Kämpfer et al., 2003); the one available strain of *C. indoltheticum* has not been specifically tested for its DNA relatedness to other taxa.

belonging to the same species usually share DNA relatedness well above 70% (i.e., 75–100%), whereas DNA relatedness is distinctly below this value (5–50%) when the DNAs of strains belonging to different species are hybridized. In this latter case, the level of DNA relatedness usually reflects the phylogenetic distance between the species: strains of closely related species share about 50% DNA relatedness whereas they share 10–20% relatedness with strains of other, more distant species as reported for *C. gleum-C. indologenes* (Yabuuchi et al., 1983; Hugo et al., 1999) and for *C. scopthalmum-C. balustinum-C. indoltheticum* versus the other *Chryseobacterium* species (J.-F. Bernardet, unpublished data). However, significant discrepancies may occur when different hybridization techniques and temperatures (i.e., optimal or stringent) are used (Table 4). The only study comparing two different techniques on the same group of strains was performed on seven *C. scophthalmum* strains, and nearly identical DNA relatedness values (91–100% and 85–100%, respectively) were obtained using the initial renaturation rate spectrophotometric method (Mudarris et al., 1994) and the S1 nuclease method (J.-F. Bernardet, unpublished data). Unfortunately, such comparative data are lacking between the increasingly used quantitative microplate technique and the other techniques.

The most extensive DNA-DNA hybridization study published so far concerned a collection of 52 *E. meningoseptica* strains of varied pathological and geographic origin, including the type strain and five other reference strains (Ursing and Bruun, 1987). In a previous study of the six reference strains by Owen and Snell (1976), the type strain had already been shown to share only 29–65% DNA relatedness with the others. The study by Ursing and Bruun, using the hydroxyapatite method, confirmed that the type strain is indeed only distantly related to most other *E. meningoseptica* strains. When the optimal temperature for hybridization (60°C) was used, the 52 strains could be divided into two main hybridization groups I and II, with the former only comprising the type strain and three clinical isolates. The DNA relatedness values were 71–94% within each group, about 40–55% between members of the two groups, and <25% between members of the two groups and the type strains of *C. balustinum*, *C. gleum* and *C. indologenes*. The use of a more stringent hybridization temperature (75°C) and of additional labelled DNAs and the determination of ΔTm values resulted in the further delineation of four subgroups within the largest hybridization group II (Ursing and Bruun, 1987). When DNA-DNA experiments were performed within each of the subgroups, DNA relatedness values were very high at 60°C and still well above 75% at 75°C. On the other hand, DNA relatedness values between members of the subgroups were considerably lower at 75°C than at 60°C. These data are at variance with those of a study of *C. gleum* strains in which DNA relatedness values at 75°C could be higher than those at 60°C (Holmes et al., 1984); yet, the hydroxyapatite method was used in these two studies. Although intermediate DNA relatedness and high ΔTm values were found between members of the two major *E. meningoseptica* hybridization groups, these groups were still significantly more related to each other than to *Chryseobacterium* species. Moreover, differences between members of the two groups could not be found in phenotypic characteristics (Bruun and Ursing, 1987), antimicrobial susceptibility patterns (Bruun, 1987), and crossed immunoelectrophoresis results (Bruun and Høiby, 1987). Hence, the authors found no reason to propose a new bacterial species for members of the group that did not contain the type strain (Bruun and Ursing, 1987). As mentioned above, differentiating characteristics for some members of the genus *Chryseobacterium* (e.g., the CDC group IIb) are also difficult to find, making DNA relatedness studies even more necessary. Recently, new DNA-DNA hybridization experiments have been performed on seven *Elizabethkingia* strains using a quantitative microplate method (Kim et al., 2005b). One of the *E. meningoseptica* strains was actually shown to belong to *E. miricola* owing to its high DNA relatedness with the type strain of this species. Moreover, the *E. meningoseptica* type strain only shared 31–35% DNA relatedness with the five other strains. This result confirmed the distance between the type strain and the other strains studied, but again the authors found no phenotypic or ecological clue for splitting *E. meningoseptica* into two species (Kim et al., 2005b).

Sequence Analysis of Small Subunit rRNA and *gyrB* Genes

Sequences of the 16S rRNA of all valid *Chryseobacterium* and *Elizabethkingia* species are now available; their comparison, combined with earlier data from DNA-rRNA hybridization experiments (Bauwens and De Ley, 1981; Mudarris et al., 1994; Vandamme et al., 1994; Bernardet et al., 1996), provides a distinct view of the phylogenetic relationships within the genera *Chryseobacterium* and *Elizabethkingia* (Fig. 1) and between these genera and other members of the family Flavobacteriaceae and of the phylum "Bacteroidetes" (see Figs. 1 and 2 of the chapter An Introduction to the Family Flavobacteriaceae in this Volume). Stackebrandt and Goebel (1994) considered the 97% 16S rRNA sequence similarity value as a threshold below which two bacterial strains usually

share less than 60–70% DNA similarity and consequently belong to different species. Although these authors also clearly stated that DNA pairing studies need to be performed when strains share more that 97% 16S rRNA sequence similarity, this value has frequently been interpreted as a threshold above which no DNA reassociation study was necessary since the strains most probably belonged to the same species. However, several studies dealing with members of the family Flavobacteriaceae showed that the value of 97% 16S rRNA sequence similarity is frequently not correlated with DNA-DNA relatedness (see Bernardet et al. [2002], the references therein, and the chapter The Genus Flavobacterium in this Volume). As for members of the genera *Chryseobacterium* and *Elizabethkingia*, several examples of 16S rRNA gene sequence similarity values well above 97% between members of different species may be found in Table 3 in Li et al. (2003). For instance, the two *E. miricola* strains shared 97.8–98.4% sequence similarity with five *E. meningoseptica* strains (Kim et al., 2005b), and sequence similarities between *C. balustinum* and *C. scophthalmum* and between *C. gleum* and *C. indologenes* were as high as 98.9% and 99.0%, respectively (Li et al., 2003). The type strain of *C. joostei* also exhibited 97.7% and 97.6% 16S rRNA gene sequence similarity with those of *C. gleum* and *C. indologenes*, respectively, although DNA relatedness between the three strains was as low as 19–25% (Hugo et al., 2003). Similar values were reported in the descriptions of *C. daecheongense* and *C. formosense* (Kim et al., 2005a; Young et al., 2005). Hence, the fact that two *Chryseobacterium* strains share more than 97% 16S rRNA sequence similarity does not mean that they belong to the same species and should not be used as a reason not to perform DNA-DNA hybridization experiments. Conversely, no *Chryseobacterium* strains have been reported that simultaneously share DNA relatedness higher than 70% and 16S rRNA sequence similarity below 97%. In their description of *C. defluvii*, Kämpfer et al. (2003) decided that no DNA-DNA relatedness experiment was necessary since their isolate only shared <95.9% 16S rRNA sequence similarity with all other *Chryseobacterium* species and since the description of "*C. proteolyticum*" had previously demonstrated that low DNA relatedness was indeed correlated with 16S rRNA sequence similarity lower than 97% in the genus *Chryseobacterium* (although some species were not included in the study; Yamaguchi and Yokoe, 2000).

Sequences of *gyrB* genes, encoding the subunit B protein of DNA gyrase, are only available for a few *Chryseobacterium* species (Suzuki et al., 1999; see the section Phylogeny in this Chapter); hence, the correlation between *gyrB* sequence similarity and DNA relatedness or 16S rRNA sequencing cannot be evaluated yet.

Any combination of two or more of the above techniques constitutes a polyphasic taxonomic approach that could be used to characterize new *Chryseobacterium* and *Elizabethkingia* isolates (Vandamme et al., 1996). This approach has allowed the successful identification and description of all recently published *Chryseobacterium* species and the delineation of the new genus *Elizabethkingia*. To our knowledge, no PCR technique is available that would allow the detection of *Chryseobacterium* or *Elizabethkingia* strains in the environment and clinical samples, as well as the identification of cultured strains. The few methods currently available for typing *Chryseobacterium* and *Elizabethkingia* strain collections are discussed below.

Serotyping

Six serovars of *C. meningosepticum* A to F were initially described as being involved in human infections, mainly neonatal meningitis (King, 1959; Owen and Lapage, 1974; see the section Pathogenicity and Epidemiology in this Chapter), and serotyping has been used as an epidemiological marker in outbreaks of *E. meningoseptica* infections in neonatal intensive care units. Additional serovars G to N, not involving neonatal meningitis, have subsequently been described by Richard et al. (Richard et al. 1979, 1981), but representative strains of the serotypes I, J and L could actually belong to *Empedobacter brevis* (Owen and Holmes, 1981; Holmes et al., 1984). A serotype O was also reported (see the chapter The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in this Volume). Serotype C, seen in about two-thirds of typed isolates from neonates, is the one most commonly found and associated with high mortality and serious neurological sequelae (Bloch et al., 1997). Typing sera are not commercially available. The serology of *Chryseobacterium* species has not been developed, but serological crossreactions between some members of CDC group IIb and *E. meningoseptica* have been reported (Price and Pickett, 1981).

Molecular Typing

Few molecular methods are currently available for typing *Elizabethkingia* strains. Although rare, infections caused by *E. meningoseptica* in newborn infants are severe (see the section Pathogenicity and Epidemiology in this Chapter), and ribotyping was used to type clinical isolates for epidemiological studies. The collection of 52 *E. meningoseptica* strains (previously studied using DNA-DNA hybridization; Ursing and Bruun, 1987; [see above] and phenotypic characteriza-

tion; Bruun and Ursing, 1987) was subjected to ribotyping using two different restriction enzymes to examine the taxonomic relevance of this technique; ribotyping patterns that could identify strains within a given DNA relatedness group (see above) were indeed found (Colding et al., 1994). Using four different enzymes, these authors also assessed the epidemiological value of ribotyping; three *E. meningoseptica* strains isolated from an outbreak in a neonatal intensive care unit (Bruun et al., 1989) had the same ribotype pattern, indicating a common source of infection, as expected. The banding patterns resulting from three different restriction enzyme digestions were combined and used in another study of 92 *E. meningoseptica* clinical isolates to search for possible correlation between ribotyping and serotyping (Quilici and Bizet, 1996). Ribotyping allowing differentiation between isolates belonging to the same serotype, as well as between isolates of different serotypes, provided a useful epidemiological tool. Six different patterns were found for 21 strains isolated during the same outbreak, suggesting unrelated sources of infection.

Recently, pulsed-field gel electrophoresis of bacterial DNAs digested by the restriction enzyme *Apa*I was used to demonstrate that patient strains and environmental strains of *E. meningoseptica* isolated during an outbreak in a neonatal intensive care unit were the same strain (Hoque et al., 2001; see the section Pathogenicity and Epidemiology in this Chapter). DNA macrorestriction analysis was also used to demonstrate relapse of a catheter-related *E. meningoseptica* bacteremia (Sader et al., 1995).

Preservation

Short term (i.e., several weeks or months) preservation of *Chryseobacterium* and *Elizabethkingia* clinical strains was successfully achieved using cystine-trypticase agar (BBL; see the chapter The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in the second edition) or Dorset egg medium (Holmes et al., 1984) slants kept at 4°C. Strains of "*Chryseobacterium proteolyticum*" were maintained on nutrient agar at 4°C (Yamaguchi and Yokoe, 2000). In our experience, commercially available agar deeps (e.g., bacterial strain storage medium, Bio-Rad) are most convenient for short term storage of members of all *Chryseobacterium* and *Elizabethkingia* species and related taxa (J.-F. Bernardet, unpublished data).

Chryseobacterium and *Elizabethkingia* strains can be preserved for many years by simple cryopreservation at –70°C or less, using 10–30% (v/v) glycerol as a cryoprotectant within a routine growth medium. We have successfully cryopreserved all *Chryseobacterium* and *Elizabethkingia* species in CAS broth (i.e., 1% casitone [Difco], 0.1% $MgSO_4 \cdot 7H_2O$, pH 6.8 unadjusted) recommended by Reichenbach (1989) with 10% sterile glycerol (J.-F. Bernardet, unpublished data). Also advocated was deep freezing of *Chryseobacterium* and *Elizabethkingia* strains in defibrinated rabbit blood (Holmes et al., 1984) or in *Brucella* broth (BBL) containing 10% glycerol (see the chapter The Genera *Flavobacterium*, *Sphingobacterium*, and *Weeksella* in this Volume).

Lyophilization (freeze-drying) is also convenient for long-term preservation of *Chryseobacterium* and *Elizabethkingia* strains. We found this technique effective using a suspension medium consisting of two-thirds Bacto Brucella broth (Difco) and one-third filtered and heat-inactivated (1 h at 56°C) horse serum (C. Bizet, Collection de l'Institut Pasteur, personal communication). Lyophilization and deep freezing at –80°C were convenient for the long-term preservation of *C. joostei* strains; for shorter preservation, the strains were maintained in a freeze-dried state on filter-paper discs and stored in screw-capped tubes at –20°C (Hugo et al., 2003).

Physiology

Little is known about the biochemical physiology of *Chryseobacterium* and *Elizabethkingia*; most of the current knowledge appears in the formal description of the genus (Table 2) and in the other paragraphs of the section Identification. All *Chryseobacterium* and *Elizabethkingia* species are aerobic chemoorganotrophs; their metabolism is strictly respiratory, not fermentative, except for *C. scophthalmum*, which also exhibits a fermentative metabolism (Mudarris et al., 1994). However, some *C. gleum*, *C. indologenes* and other CDC group IIb strains can grow anaerobically in the presence of nitrate by using nitrate as a terminal electron acceptor and reducing it to N_2 (Holmes et al., 1984). *Chryseobacterium daecheongense* has been described as nitrate-reducing (Kim et al., 2005a) while the ability of *C. balustinum* to reduce nitrate has been variously assessed by different authors (Table 2). *Chryseobacterium indologenes* strains can also grow under anaerobic conditions in the presence of fumarate (Yabuuchi et al., 1983). The *Chryseobacterium* and *Elizabethkingia* strain retrieved from the gut of a cockroach by Dugas et al. (2001) is also able to use molecular oxygen and fumarate, but not nitrate. *Elizabethkingia miricola* is also aerobic with a strictly respiratory type of metabolism, although it can grow in the

presence of 5% (v/v) CO_2 (Li et al., 2003). Interesting physiological comparisons may be made with the capnophilic members of the family Flavobacteriaceae, i.e., the genera *Capnocytophaga* (see the chapter The Genus Capnocytophaga in this Volume), *Riemerella*, *Ornithobacterium* and *Coenonia* (see the chapter Capnophilic Bird Pathogens in the Family Flavobacteriaceae: Riemerella, Ornithobacterium and Coenonia in this Volume).

Most *Chryseobacterium* species exhibit a rather high tolerance to NaCl: Except *C. balustinum*, all *Chryseobacterium* species are able to grow on marine agar (e.g., Difco marine agar 2216 [1.95% NaCl in addition to several other salts]), although only members of two species were actually isolated from marine environments (Bernardet et al., 2002; Table 2). The most recently described species (i.e., "*C. proteolyticum*," *C. defluvii*, *C. daecheongense*, *C. formosense*, and *C. taichungense*) have not been tested for this characteristic. *Elizabethkingia meningoseptica* is able to grow on marine agar (J.-F. Bernardet, unpublished data) and *E. miricola* has been reported to tolerate seawater (Li et al., 2003).

Genetics

Excluding investigations targeting the whole genome (DNA-DNA hybridization and determination of the G+C content) or particular genes (sequencing of 16S rRNA and *gyrB* genes) for taxonomic and phylogenetic purposes or for the molecular typing of bacterial strains (see the section Identification in this Chapter), the genetics of *Chryseobacterium* and *Elizabethkingia* spp. has been poorly investigated. However, the gene transfer system, selectable marker system, suicide vector system, and transposon developed to genetically manipulate *Flavobacterium johnsoniae* were also used successfully on *E. meningoseptica* (McBride and Baker, 1996; McBride and Kempf, 1996). No plasmid has been reported in members of the genera *Chryseobacterium* and *Elizabethkingia* (Owen and Holmes, 1981); therefore, their widespread resistance to antimicrobial agents (see the section Pathogenicity and Epidemiology in this Chapter) is likely associated with chromosomal genes.

Pathogenicity and Epidemiology

Veterinary Medicine

Besides the *Chryseobacterium* strains that may be normal bacterial flora of various aquatic animals and those that may spoil fish products (see the section Habitat and Ecology in this Chapter), other strains have been isolated from a number of diseased animal species.

Since *Chryseobacterium balustinum* was originally isolated from the surface of dead marine fish, the current opinion is that this organism was a fish spoilage agent rather than a pathogen (Harrison, 1929; Austin and Austin, 1999); indeed, strains phenotypically similar to *C. balustinum* have recently been isolated again from the skin, muscle and intestine of apparently healthy freshwater fish (Morita et al., 1997; González et al., 2000; see the section Habitat and Ecology in this Chapter). However, the type and only bona fide strain currently available in culture collections, originally described under the name "[*Empedobacter*] *balustinum*," was isolated from the heart blood of a freshwater fish (dace, *Leuciscus leuciscus*) exhibiting signs of hemorrhagic septicemia; this strain (which cannot grow on marine agar) proved able to kill when injected into several other fish species (Brisou et al., 1959). Hence, *C. balustinum* probably occurs in freshwater as well as seawater and at the surface of fish; depending on circumstances, it may be saprophytic, become an opportunistic pathogen, or merely spoil the fish. It is also possible the neotype strain is actually different from the lost original strain.

The first strains of *C. scophthalmum* were recovered in Scotland from wild, healthy turbot (*Scophthalmus maximus*) and coastal water samples; similar organisms were subsequently isolated in 1987 from diseased turbot from the wild and during an outbreak in a local farm (Mudarris, 1989; Mudarris and Austin, 1989). The bacterium caused gill hyperplasia and hemorrhagic septicemia; diseased turbot exhibited hemorrhages in the eyes, skin and jaw, as well as several internal organs. Extensive phenotypic investigations were conducted on a large group of strains isolated in pure culture from the gills and internal organs (Mudarris and Austin, 1989). The organism was first considered a *Cytophaga* sp. after gliding motility was suspected on fresh isolates, but this character was not confirmed during later investigations. Growth occurred on marine media and also on media devoid of NaCl or seawater, demonstrating that the bacterium was halotolerant and not obligately marine. This trait, together with all other phenotypic and genomic characteristics, led to the description of the new species as [*Flavobacterium*] *scophthalmum* (Mudarris et al., 1994); it was subsequently transferred to the new genus *Chryseobacterium* (Vandamme et al., 1994). Histopathology of the disease was studied (Mudarris and Austin, 1992) and experimental infection was performed in juvenile turbot; immersion and intraperitoneal injection both resulted in high mortalities with

typical lesions (Mudarris and Austin, 1989). Interestingly, young rainbow trout kept in fresh water were also successfully infected by the same method. Control of the disease was possible by injection of or immersion in furazolidone solution, but sulfafurazole proved much less efficacious. As *C. scophthalmum* was also consistently recovered from the gills of healthy turbot, it was considered that it could actually belong to its normal microflora and that unknown factors could weaken the host and/or enhance the virulence of the bacterium (Mudarris and Austin, 1989). Immunization of turbot with the lipopolysaccharide (LPS) from *C. scophthalmum* was shown to induce high hemagglutination activities in the serum as well as in skin and gut mucus when fish were intraperitoneally injected, whereas administration of LPS by the oral route or by immersion was generally unsuccessful (Al-Harbi and Austin, 1992c). Skin and gut mucus of LPS-immunized turbot inhibited the growth of *C. scophthalmum* (Al-Harbi and Austin, 1992b). Immunohistochemical techniques were used to study the distribution of the bacterium and LPS following different routes of inoculation (Al-Harbi and Austin, 1992a). *Chryseobacterium scophthalmum* has never been isolated again since its original description. However, strains whose 16S rRNA gene sequences shared significant similarities with that of *C. scophthalmum* were found among the bacterial community in amoebae-infected gills of salmon (Bowman and Nowak, 2004).

Bacterial strains phenotypically similar to *C. indologenes* were isolated from leopard frogs (*Rana pipiens*) reared in laboratory facilities in the United States and suffering "red leg disease," a condition usually associated with *Aeromonas hydrophila* (Olson et al., 1992). In an ongoing study of CDC group IIb strains isolated from diseased fish reared under various conditions and in various geographic areas, many strains resembling *C. indologenes* were identified (J.-F. Bernardet et al., unpublished data). However, representative strains only exhibited <25% DNA relatedness with the type strain of *C. indologenes*. The degree of virulence of these isolates has not been evaluated yet by experimental infection of fish, but their susceptibility to a variety of antimicrobial agents has been tested using diffusion tests and the dilution method to assess minimal inhibitory concentrations (MICs). The results confirmed the frequency and unusual level of constitutive resistance to ampicillin, polymyxin B, chloramphenicol and oxytetracycline in fish-associated members of the genus *Chryseobacterium*; only oxolinic acid and associated sulfonamides seemed to allow the success of antibiotic therapy (Michel et al., 2005).

Strains of *E. meningoseptica* have apparently been retrieved from various animal species. This organism was the probable cause of a case of meningitis in a cat (Sims, 1974), and one of the strains studied by Bruun and Ursing (1987) was reportedly isolated from the blood of a dog. Cases were also reported from turtles (Jacobson et al., 1989) and snakes (Miller et al., 2004), and several strains were isolated in pure or nearly pure culture from internal organs of diseased birds belonging to different species (Vancanneyt et al., 1994). Several cases of *E. meningoseptica* infections were also reported in different frog species reared for food or laboratory purposes, such as leopard frog (*Rana pipiens*; Taylor et al., 1993), clawed frog (*Xenopus laevis*; Green et al., 1999), and bullfrog (*Rana catesbeiana*; Mauel et al., 2002). A bacterium responsible for hemorrhagic septicemia in farmed bullfrog in Taiwan was characterized and provisionally named "[*Flavobacterium*] *ranacida*" (Faung et al. [1996] and references therein); recently, this organism, as well as a similar isolate from clawed frogs (also with hemorrhagic septicemia) captured in South Africa and reared in a French laboratory, was also identified as *E. meningoseptica* (J.-F. Bernardet, unpublished data). The first *E. meningoseptica* infection in fish was diagnosed in June 2004 in France from farmed koi carps imported from China, and a second, similar case in carps imported from Africa was reported at the time of writing (February 2005); diseased carps displayed skin lesions and hemorrhagic septicemia (N. Keck, personal communication). "*Aegyptianella ranarum*" replicates in the red blood cells of various frog species and is transmitted by amphibian-feeding leeches; comparison of the sequence of its 16S rRNA gene showed a 91% similarity with the sequence of *E. meningoseptica* and the uncultured organism was renamed "*Candidatus* Hemobacterium ranarum" (Zhang and Rikihisa, 2004). In view of the presence of *E. meningoseptica* in different animal species reared for food or laboratory experiments or as pets, the possibility that infected animals might serve as reservoirs for human infection should be evaluated. However, since person-to-person infection has never been reported in *E. meningoseptica*, animal-to-person infection is very unlikely.

Human Medicine

Several members of the family Flavobacteriaceae (see the chapter An Introduction to the Family Flavobacteriaceae in this Volume) are known participants in human infections, although their pathogenic role is sometimes uncertain. Besides *Bergeyella zoohelcum* and to a lesser extent *Weeksella virosa*, *Empedobacter brevis*, and the three *Myroides* species (see the chapters The Genera *Bergeyella* and *Weeksella* and The Genera *Empedobacter* and *Myroides* in

this Volume), two *Chryseobacterium* species and *Elizabethkingia meningoseptica* may also be isolated from clinical specimens (Schreckenberger, 1998).

Isolation and Identification of *Chryseobacterium* and *Elizabethkingia* Strains in Clinical Microbiology Laboratories *Elizabethkingia meningoseptica* and bacteria originally designated *Flavobacterium* group IIb (*C. indologenes*, *C. gleum* and allied bacteria) by E. O. King (1959) are isolated from clinical specimens such as cerebrospinal fluids, blood, tracheal suctions, urine and wounds. They are rare isolates, occurring in less than 0.1–1.0% of positive cultures (Pickett and Pedersen, 1970; Matsen, 1975; Kirby et al., 2004). Organisms of group IIb are the most commonly isolated flavobacteria in the clinical microbiology laboratory, while *E. meningoseptica* is seen only occasionally (e.g., Holmes and Owen, 1981). *Elizabethkingia meningoseptica* is associated with often fatal neonatal meningitis, while the pathogenicity of group IIb is more doubtful.

Primary culture of *Chryseobacterium* and *Elizabethkingia* species can be done on blood, chocolate, McConkey and nutrient agar. Incubation is done at 35–37°C, but the organisms also grow well at room temperature. Assignment of a culture to the genus *Chryseobacterium* rests upon characteristics shared with *E. brevis*, *Myroides* spp., and *Sphingobacterium* spp.: strictly aerobic, nonmotile, oxidase positive, yellow pigmented, Gram-negative bacilli, highly resistant to a wide range of antimicrobial agents. Differentiation of the *Chryseobacterium* isolates from the above-mentioned taxa can be done on the basis of results for indole and urease production, gelatin hydrolysis, and acid production or assimilation of carbohydrates (see the section Identification and the chapters "The Genera *Empedobacter* and *Myroides*", "The Genera *Bergeyella* and *Weeksella*" and "The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella*" in this Volume). Differentiation of *E. meningoseptica*, members of group IIb, and *E. brevis* strains by conventional laboratory methods is difficult in the clinical microbiology laboratory. It rests mainly on the ability of *E. meningoseptica* strains to produce a weak yellow pigment or no pigment, acid from trehalose, and β-galactosidase (ONPG test) within 2 h (Bülow, 1964); members of group IIb produce a bright yellow pigment, also produce acid from trehalose, but are negative in the ONPG test after 2 h, and *E. brevis* strains produce a weak yellow pigment and are trehalose- and ONPG-negative (Bruun and Ursing, 1987; Ursing and Bruun, 1991). The use of automated identification systems, such as API and Vitek (bioMérieux), for identification has been steadily increasing for the last 15–20 years (see the section Identification in this Chapter). To the best of our knowledge, there have been no reports in the literature on the performance of automated systems to identify these organisms in large collections of clinical strains. As of May 2004, API 20E, 20NE, ID 32E and ID 32GN databases contain *E. meningoseptica* and *C. indologenes*, as does Vitek GNI+ and Vitek2 ID-GNB. Vitek GNI+ can also identify *C. gleum*, while *E. brevis* can be identified by API ID 32 GN and Vitek2 ID-GNB.

Elizabethkingia meningoseptica is the only species for which a serotyping scheme has been proposed, but it is of limited use for the identification of clinical isolates (see the section Identification in this Chapter).

Pathogenicity of *Elizabethkingia meningoseptica* in Neonates and Infants Neonatal disease, notably meningitis, caused by *E. meningoseptica*, is by far the best known example of pathogenicity in the *Chryseobacterium*/*Elizabethkingia* complex and has been reported from all over the world (Vandepitte et al., 1958; Solé-Vernin, 1960; Eeckels et al., 1965; Vaillant et al., 1974; Leitz et al., 1977; Samb et al., 1977; Torronteras-Santiago et al., 1978; Zappulla et al., 1979; Bø et al., 1986; Bloch et al., 1997 and references therein; Chiu et al., 2000; Hoque et al., 2001). Since the infection was first reported in 1944 by Shulman and Johnson (1944) and retrospectively identified by King (1959), Von Graevenitz (1985) estimated that about 120 cases had been reported in the literature. Bloch et al. (1997), in their comprehensive review of the English language literature up to 1994, found 308 reports of cultures positive for *E. meningoseptica*, of which 60% were judged to represent true infections. Neonatal infections, defined as occurring in infants 3 months of age, accounted for 115 cases, of which 97 (84%) were meningitis, sometimes with concomitant bacteremia or pneumonia (e.g., George et al., 1961; Madruga et al., 1970; Thong et al., 1981; Abrahamsen et al., 1989; Bruun et al., 1989; Heeg et al., 1994; Chiu et al., 2000). Prematurity occurred in more than half of the cases and accounted for two-thirds of the mortality of 57%. The majority of survivors suffered from post-meningitis sequelae, especially hydrocephalus. Serotype C was the predominant serotype, found in about two-thirds of the typed isolates. Since 1994, three more cases of neonatal meningitis have been reported in the literature (Chiu et al., 2000; Hoque et al., 2001).

In addition to the meningitis cases in infants <3 months of age reported by Bloch et al. (1997), there have been anecdotal reports of spontaneous meningitis cases in infants up to one and a half years of age (Samb et al., 1977; Zappulla et al., 1979; Johny et al., 1983; Sarvamangala et al.,

1983). These cases have been classified as community-acquired and presumably belong to the same disease entity as the community-acquired cases in infants <3 months of age (e.g., Sundin et al., 1991; Di Pentima et al., 1998). The outcome in these older infants appeared to be better, with survival without sequelae in most cases.

Neonatal disease also encompasses bacteremia and pneumonia, constituting 13% and 3% of cases in the review of Bloch et al. (1997). Meningitis had, however, not been excluded by lumbar puncture in all cases of bacteremia. Since 1994, at least nine cases of bacteremia have been reported in three outbreaks in neonatal wards (Hoque et al., 2001; Güngör et al., 2003; Tekerekoglu et al., 2003). Mortality in cases of bacteremia and pneumonia has been much lower than in cases of meningitis and in some instances difficult to relate to the *E. meningoseptica* infection. In a retrospective analysis of cases of nosocomial pneumonia in infants following cardiac surgery, *E. meningoseptica* strains were shown to represent 8.9% of all microbial isolates (Tan et al., 2004).

A characteristic for *E. meningoseptica* infections is that they often occur as small epidemics in neonatal wards, including intensive care units (e.g., Brody et al., 1958; Vandepitte et al., 1958; Cabrera et al., 1961; Madruga et al., 1970; Hazuka et al., 1977; Abrahamsen et al., 1989; Bruun et al., 1989; Heeg et al., 1994; Hoque et al., 2001; Güngör et al., 2003). Surveillance cultures of clinically uninfected infants hospitalized with infected infants often reveal extensive colonization with *E. meningoseptica*, sometimes accompanied by transient bacteremia.

The presence of *E. meningoseptica* in various hospital environments was reviewed by Bloch et al. (1997). Optimal growth conditions include moist, cool environments or standing water at approximately 21°C (see Green et al. [1999] and references therein). In some cases, the bacterium was isolated from such medical devices as the respirator, vaporizer and artificial ventilation tubing (e.g., Heeg et al., 1994). In other investigations, environmental cultures have demonstrated other reservoirs for the epidemic strain (e.g., Cabrera et al., 1961; Hazuka et al., 1977; Abrahamsen et al., 1989; Hoque et al., 2001; Güngör et al., 2003). Caution must, however, be exercised in the interpretation of these findings as closely related *Chryseobacterium* strains are often found in the hospital environment (Bruun et al., 1989). Hence, extensive characterization, including typing, is necessary to determine a certain source of infection. For instance, extensive screenings were performed in various hospital environments following the repeated isolation of multiresistant *E. meningoseptica* strains from neonates in an intensive care unit (Hoque et al., 2001). Using pulsed-field gel electrophoresis of DNA macrorestriction digests, several isolates recovered from sink taps and patient isolates were shown to be representatives of a single strain.

ADULTS Disease after the age of one year (here termed "adult form") is rare, with less than 100 cases reported in the literature (Bloch et al. [1997] and references therein; Chiu et al., 2000; Gunnarsson et al., 2002). It occurs either as outbreaks in hospitals after administration of contaminated medicine or use of devices contaminated via water or as more sporadic infections in immunocompromised patients or post-trauma and -surgery patients.

A number of outbreaks involving both colonized (i.e., asymptomatic carriers) and infected patients in intensive care units have been described (Olsen et al., 1965; Olsen, 1967a; du Moulin, 1979; Brown et al., 1989; Pokrywka et al., 1993). The involved patients were either colonized or infected in the lungs or suffered from transient bacteremia. The outbreaks were traced to parenteral anesthetics, aerosolized polymyxin B, respiratory tubes, or water and ice contaminated by *E. meningoseptica*. Mortality in these patients was low and could not be ascribed to *E. meningoseptica*.

More sporadic cases occurred in severely immunocompromised patients suffering from malignancy, end-stage hepatic and renal disease, extensive burns, AIDS, etc. (Sheridan et al., 1993; Sader et al., 1995; Bloch et al., 1997; Manfredi et al., 1999; Chiu et al., 2000). Again, by far the most common manifestations were pneumonia and bacteremia.

A few cases of infections in immunocompromised patients have been reported to be community-acquired (Chiu et al., 2000), but information about possible carriage of intravascular devices while at home was not given. Also, a close contact between these patients and hospitals must be presumed due to their debilitating underlying diseases. The exact role of *E. meningoseptica* infections in the mortality of immunocompromised patients is difficult to ascertain, as there are many cofactors for mortality involved. There are nine case reports of *E. meningoseptica* meningitis in adults in the literature (Madruga et al., 1970; Lapage and Owen, 1973; Mani et al., 1978; Rios et al., 1978; Harrington and Perlino, 1981; Kelsey et al., 1982; Chan et al., 1983; Sharma et al., 1984; Uchihara et al., 1988). All but one (Uchihara et al., 1988) involved known immunocompromised or neurosurgical patients. As bacterial identification pointed to CDC group IIb and not to *E. meningoseptica* in at least one of these reports, it can be concluded that meningitis in adults is extremely rare. Other rare manifes-

tations of adult *E. meningoseptica* infection include endocarditis (Werthamer et al., 1972; Sexton et al., 1985), cellulitis (Abter et al., 1993), abdominal infection (Pokrywka et al., 1993), septic arthritis (Gunnarsson et al., 2002), and eye infections (Bucci and Holland, 1991; Bloom et al., 2003).

Pathogenicity of *Chryseobacterium indologenes* and Allied Strains Included in CDC Group IIb

Strains belonging to CDC group IIb, i.e., *Chryseobacterium indologenes*, *C. gleum* and closely related strains, are the most commonly isolated flavobacteria (i.e., *Chryseobacterium*, *Elizabethkingia*, *Empedobacter*, *Myroides* and *Sphingobacterium*) in the clinical microbiology laboratory (e.g., Holmes and Owen, 1981; Yabuuchi et al., 1983; Holmes et al., 1984). Their pathogenicity for man is, however, less well documented.

There are about 35 cases of *C. indologenes*/group IIb bacteremias in the literature that, with the exception of sporadic case reports (Siegman-Igra et al., 1987; Nulens et al., 2001), have been published in three series, involving 14, 12 and 6 patients, respectively (Stamm et al., 1975; Hsueh et al., 1996b; Hsueh et al., 1996c). The first series of group IIb bacteremia cases occurred in an American intensive care unit over five months and was associated with indwelling arterial catheters (Stamm et al., 1975). Mortality between infected patients and control patients was not found to differ. The two other series of *C. indologenes* bacteremia cases (Hsueh et al., 1996b; Hsueh et al., 1996c) occurred in the National University Hospital in Taiwan and were associated with indwelling devices, such as central venous catheters, Port-a-Caths, endotracheal tubes, and drains. In six of these 18 cases, the bacteria were also isolated from tracheal aspirates or sputum, and the clinical diagnosis was pneumonia. Owing to the serious underlying conditions of these patients and the often polymicrobial nature of their infections, the pathogenic role of *C. indologenes* was difficult to determine. In two more recent cases of *C. indologenes* infection, bacteremia was associated with cellulitis in the absence of any form of immune compromise (Green and Nolan, 2001) and with chronic graft-versus-host disease in a leukemia patient after bone marrow transplantation (Lin et al., 2003).

A case of group IIb meningitis was reported in a patient after irrigation with tap water following exenteration of a paranasal sinus (Bagley et al., 1976). Susceptibility to and successful treatment with ampicillin, together with a negative indole test, do, however, throw some doubt on the identity of the causative organism.

Urinary tract infections with *C. indologenes* in connection with nephrostomy drainage and a urinary catheter, respectively, have also been reported from the National University Hospital in Taiwan (Hsueh et al., 1996b; Hsueh et al., 1996c). From the same hospital there have also been cases of ventilator-associated pneumonia, pyomyositis, and infected burn wounds (Hsueh et al., 1996a; Hsueh et al., 1997).

Antimicrobial Susceptibility of Clinical *Chryseobacterium* and *Elizabethkingia* Isolates and Treatment of *Chryseobacterium*/*Elizabethkingia* Infections

Members of *Chryseobacterium* and *Elizabethkingia* species are naturally resistant to polymyxins, aminoglycosides, chloramphenicol, and most β-lactams (Olsen, 1967b; Aber et al., 1978; Bruun, 1987; Chang et al., 1997; Fraser and Jorgensen, 1997; Kirby et al., 2004). *Elizabethkingia meningoseptica* produces at least two β-lactamases, a noninducible extended-spectrum β-lactamase and a carbapenem-hydrolyzing β-lactamase (Bellais et al., 2000). The latter enzyme, which is also produced by *C. indologenes* strains, has recently been identified in *Flavobacterium johnsoniae* (Naas et al., 2003). This means that *E. meningoseptica* is resistant to extended spectrum cephalosporins and carbapenems, but that some isolates are susceptible to ureidopenicillins. Data regarding susceptibility to piperacillin, with and without tazobactam, vary somewhat. In two recent investigations, both using the National Committee for Clinical Laboratory Standards (NCCLS) microdilution method, susceptibility to piperacillin-tazobactam was 29% and 71% of isolates, respectively (Fraser and Jorgensen, 1997; Kirby et al., 2004). Members of *Chryseobacterium* and *Elizabethkingia* species are mostly resistant to tetracyclines, erythromycin, and linezolid, while they display either an intermediate level of susceptibility or resistance to vancomycin and clindamycin (Bruun, 1987; Fraser and Jorgensen, 1997; Kirby et al., 2004). Susceptibility to trimethoprim-sulfamethoxazole also varies; in two studies (Fraser and Jorgensen, 1997; Kirby et al., 2004), 33% and 80% of susceptible isolates were found, respectively. The most active agents are minocycline, rifampicin and the newer quinolones (levofloxacin, gatifloxacin and sparfloxacin), while susceptibility to ciprofloxacin varies (Spangler et al., 1996; Fraser and Jorgensen, 1997; Kirby et al., 2004).

The high resistance of *Chryseobacterium* and *Elizabethkingia* species (and most other flavobacteria) to many antimicrobial agents and a susceptibility pattern unusual for Gram-negative bacteria have always attracted attention and been useful for their preliminary identification in

the clinical microbiology laboratory. Various studies have shown discrepancies between results of disk diffusion tests and MIC determinations, the former in general giving more sensitive results for erythromycin, clindamycin, vancomycin, tetracycline, chloramphenicol, and fusidic acid (Von Graevenitz and Grehn, 1977; Aber et al., 1978; Bruun, 1987; Fraser and Jorgensen, 1997). This has probably given rise to previous observations that *E. meningoseptica* is susceptible to antimicrobial agents traditionally used for treatment of infections caused by Gram-positive bacteria.

Elizabethkingia meningoseptica neonatal meningitis represents the greatest challenge in relation to treatment of infections caused by flavobacteria. Since cases of meningitis are rare, there are few reports of treatment experiences, and presumably the conduct of controlled trials to evaluate antimicrobial regimens will never be possible. Treatment will, therefore, depend on susceptibilities of individual strains and will probably include combinations of antimicrobials, and possibly intrathecal, as well as intravenous administration. Clinical microbiologists need to be aware of the fact that false sensitivities may be shown by disk diffusion (vide supra) and that resistance may rapidly develop during antimicrobial treatment (Hazuka et al., 1977; Ferlauto and Wells, 1981). Survival of neonatal meningitis without development of hydrocephalus is associated with time to sterilization of cerebrospinal fluid and presumably to age at presentation of meningitis and length of gestation.

A summary of antimicrobial treatment and outcomes of neonatal *E. meningoseptica* meningitis for the years 1973–1995 has been published by Di Pentima et al. (1998). At present (May 2004), there seems to be two schools of thought regarding the best choice of antimicrobial regimens for treatment, exemplified by the *Sandford Guide to Antimicrobial Therapy* (Gilbert et al. 2003) and *Antibiotic Essentials* (Cunha, 2003). *The Sandford Guide*s recommendation of vancomycin rests on the report of Di Petima et al. (1998) of two cases and on one case cited by them (Tizer et al., 1995). These three cases were successfully treated with vancomycin and rifampicin without development of hydrocephalus. The combination of vancomycin and rifampicin was shown to act synergistically in vitro by Di Petima et al. (1998). However, note that the three cases involved full-term infants 3–4 weeks of age at the time of presentation of meningitis. Other anecdotal reports have shown the successful use of rifampicin in conjunction with other antimicrobials in the treatment of meningitis (Bruun et al., 1989; Hoque et al., 2001). In *Antibiotic Essentials* (Cunha, 2003), trimethoprim-sulfamethoxazole is recommended for meningitis, while vancomycin and rifampicin is advocated for non-central nervous system infections. Again, the evidence for successful treatment is anecdotal (Ferlauto and Wells, 1981; Johny et al., 1983; Di Petima, 1995). The newer quinolones are, as mentioned above, promising agents for the treatment of meningitis. There is, however, at present no clinical experience with their use in neonatal meningitis, as they have not been approved for use in children, let alone neonates.

A recent case of *C. indologenes* bacteremia was successfully treated with piperacillin and tazobactam and the infection did not recur (Lin et al., 2003).

The resistance of *E. meningoseptica* strains to chlorine and other disinfectants has also been reported (see Green et al. [1999] and references therein). For instance, during the above-mentioned outbreak in a neonate intensive care unit, screening cultures remained positive following chlorination of the water tanks and sink taps; only after the replacement of the taps did the cultures become negative (Hoque et al., 2001).

Besides the above-mentioned, well-characterized bacterial species, other organisms belonging to the *Chryseobacterium* phylogenetic branch (Fig. 1; see the sections Phylogeny and Taxonomy in this Chapter) may prove pathogenic to humans. For instance, three potentially pathogenic organisms, "*Candidatus* Chryseobacterium timonae," "*Chryseobacterium massiliae*" and "*Candidatus* Amoebinatus massiliae," were recently recovered from human nasal samples using amoebal coculture (Drancourt et al., 2004; Greub et al., 2004). Similarly, two of the "*Haloanella gallinarum*" strains listed in databases were labelled as "undescribed bacterial pathogens isolated from human tissue" and "new pathogenic bacterium" (sequence nos. [AY244776] [Drancourt et al., 2004] and [AB035150] [H.-S. Pham et al., unpublished data], respectively).

Applications

Some *Chryseobacterium* strains have potential applications in the cleanup of various environmental contaminants. For instance, the cleanup of pentachlorophenol (PCP), a pesticide that has been associated with wood preservation and a disinfectant in the food industry, is essential since PCP poses significant health hazards. Yu and Ward (1996) used *C. gleum*, *Agrobacterium radiobacter* and *Pseudomonas* sp. as a mixed culture to degrade PCP. Although rates of PCP degradation by individual isolates were lower than

that observed for the mixed culture, *C. gleum* manifested the highest PCP degradative ability. Another bacterial consortium including *C. indologenes* and three other bacterial species was found to degrade aniline and 4-chloroaniline in a contaminated agricultural soil in Indonesia (Radianingtyas et al, 2003). A *C. indologenes* strain was also identified among the soil bacteria that were able to degrade the toxic furan and phenolic compounds resulting from the acid treatment of lignocellulose (Lopez et al., 2004). Another *C. indologenes* strain (16S rRNA sequence no. [AJ288294]; D. G. Karpouzas, unpublished data) was able to degrade the insecticide and nematocide carbofuran, a member of the carbamate group.

Other potential applications of *Chryseobacterium* strains may result from the presence of particular enzymes. For instance, Yamaguchi et al. (2001) recently described a novel enzyme from "*C. proteolyticum*" that deamidates glutaminyl residues in proteins. Protein deamidation is regarded as a promising method to improve protein functionality (e.g., emulsifiers or foaming agents) in food systems (Hamada, 1994). A *Chryseobacterium* strain isolated from an apparently healthy eel (*Anguilla anguilla*) and exhibiting a high 16S rRNA sequence similarity with *C. gleum* and *C. indologenes* was shown to secrete a novel endopeptidase that specifically cleaves the human plasminogen and could consequently reduce bacterial invasion (Lijnen et al., 2000). Cold-active proteases were characterized from a *Chryseobacterium* isolate from salmon (*Oncorhynchus keta*) intestine; analysis of its 16S rRNA sequence revealed a high similarity with that of *C. balustinum* (Morita et al., 1997). Activity of the proteases was highest at 10°C although the optimal growth temperature of the strain was 20°C. In the course of a screening of various subtropical environments for bacteria exhibiting novel carbohydrate-degrading activities, *Chryseobacterium* strains were shown to predominate in the terrestrial environments (Rosado and Govind, 2003).

Acknowledgments. The authors are indebted to Y. Nakagawa (National Institute of Technology and Evaluation, Biological Resource Center, Kisarazu, Japan), who kindly provided the phylogenetic tree (Fig. 1).

CHAPTER 6.13

The Marine Clade of the Family Flavobacteriaceae: The Genera Aequorivita, Arenibacter, Cellulophaga, Croceibacter, Formosa, Gelidibacter, Gillisia, Maribacter, Mesonia, Muricauda, Polaribacter, Psychroflexus, Psychroserpens, Robiginitalea, Salegentibacter, Tenacibaculum, Ulvibacter, Vitellibacter and Zobellia

JOHN P. BOWMAN

Introduction

The family Flavobacteriaceae represents a major branch of the Gram-negative phylum *Bacteroidetes* that is also popularly referred to as the "*Cytophaga-Flavobacterium-Bacteroides* group or phylum" (see The List of Bacterial Names with Standing in Nomenclature website for official taxonomic names). In the last decade the Flavobacteriaceae has undergone rapid expansion incorporating many new species and genera, mostly from marine and polar ecosystems. A standardized minimal set of criteria has been recently established for the description of new members of this taxonomic group (Bernardet et al., 2002). Several genera within the family, most obviously *Flavobacterium* (Bernardet et al., 1996), have undergone substantial taxonomic revision. This heightened activity has at least partially come in response to the increasing evidence that this homogenously chemoheterotrophic group has environmental significance in aquatic ecosystems. Recent research indicates the marine genera of the family are a major component of the ocean pelagic zone microbial biomass, strongly coupled to phytoplanktonic primary production (photosynthesis), and, on the basis of at least anecdotal research, responsible for a major fraction of organic matter remineralization in the oceans (reviewed by Kirchman, 2002). The marine clade of genera in the Flavobacteriaceae is phylogenetically distinct, notable for containing a large number of cold adapted (psychrophilic and psychrotolerant) species, and in this respect, it parallels marine genus clusters in phylum *Proteobacteria*, which are the only other consistently major component of surface ocean bacterioplankton. As of early 2004, 19 validly described genera, listed in the title of the chapter, belong to the marine clade of the family Flavobacteriaceae. A general coverage of the biology of these genera is the focus of this chapter.

Evolution of the Marine Clade

Currently, analysis of 16S rRNA gene sequence is used as the major criterion in establishing new taxa amongst the existing hierarchy of bacteria. This has been the case for the marine clade of the Flavobacteriaceae in which all the official names have been either created or revised only since 1997, with phylogeny used initially to designate new taxa. A large number of validly described genera and species reside within the marine clade (Table 1), which collectively forms a distinct phylogenetic branch as shown in Fig. 1. The next closest related bacterial taxon to this clade is the genus *Flavobacterium* which inhabits a wide range of aquatic ecosystems and, though found in marine ecosystems, is not halophilic. *Flavobacterium* seems to represent an ecological transition between the marine clade and a distinct cluster of soil, freshwater and warm-blooded parasitic species represented by genus *Chryseobacterium* (Fig. 1) that also belong to the family Flavobacteriaceae. This phylogenetic arrangement of genera provides a hypothesis for reconstructing the evolutionary history of the Flavobacteriaceae marine clade. Ancestral species appear to have undergone an evolutionary expansion, moving into many non-marine environments, including the human intestinal tract, which is dominated by the Bacteroidaceae (a family of anaerobic bacteria just adjacent to family Flavobacteriaceae). It can be hypothesized that the Flavobacteriaceae marine clade itself is comprised of lineages descended from ancestral species that remained within marine ecosystems. This possible long occupation of marine habitats

Table 1. Known habitats, isolation media, and incubation temperatures for Flavobacteriaceae marine clade species.

Genus	Known habitat(s)	Isolation medium	Incubation temperature (°C)	Reference(s)
Aequorivita				
A. antarctica, A. lipolytica	Seawater, sea-ice, and quartz stone subliths	MA or SW	20	Bowman and Nichols, 2002
A. crocea	Seawater, and sea-ice	MA or SW	20	Bowman and Nichols, 2002
A. sublithincola	Quartz stone subliths	R2A + sea salts, MA	20	Bowman and Nichols, 2002
Arenibacter				
A. latericius	Marine sediment, seaweed, and holothurians	Medium B or MA	25	Ivanova et al., 2001
A. troitsensis	Marine sediment	MA	25	Nedashkovskaya et al., 2003b
Cellulophaga				
C. algicola	Sea-ice algal assemblage, and seaweed	MA	10–15	Bowman, 2000
C. baltica, C. fucicola	Seaweed, and adjacent seawater (Baltic Sea)	CYT	20	Johansen et al., 1999
C. lytica	Marine sediment, seawater, and seaweed	MA	20–25	Lewin, 1969
Croceibacter atlanticus	Seawater	LMHN (HTC tech.)	20–25	Cho and Giovannoni, 2003
[C.] latercula	Seawater (aquarium)	MA	20	Lewin, 1969
[C.] marinoflava	Seawater	MA	20–25	Reichenbach, 1989
Formosa algae	Seaweed	MA	20–25	Ivanova et al., 2004
Gelidibacter				
G. algens	Sea-ice, and quartz stone subliths	MA	15–20	Bowman et al., 1997b
G. mesophilus	Seawater (Mediterranean Sea)	MA	25	Maciá et al., 2002
Gillisia limnaea	Microbial mats, and low salinity polar lakes	R2A or MA	20–25	Van Trappen et al., 2002; Van Trappen et al., 2003
Maribacter spp.				
M. orientalis, M. aquivivus	Seawater	MA	25–30	Nedashkovskaya et al., 2004a

M. sedimenticola	Marine sediment	MA	25–30	Nedashkovskaya et al., 2004a
M. ulvicola	Seaweed	MA	25–30	Nedashkovskaya et al., 2004a
Mesonia algae	Seaweed	MA	25–30	Nedashkovskaya et al., 2003a
Muricauda ruestringensis	Hexadecane enriched marine sediment	Modified MA + hexadecane	25	Bruns et al., 2001
Psychroflexus				
P. gondwanensis	Hypersaline lakes, and Antarctic	MA	20–25	Dobson et al., 1991; Dobson et al., 1993
P. torquis	Sea-ice algal assemblage	MA	4–10	Bowman et al., 1997a; Bowman et al., 1997c; Bowman et al., 1998
P. tropicus	Hypersaline lakes, and Hawaii	MA	30–37	Donachie et al., 2004
Psychroserpens burtonensis	Seawater (pycnocline of fjord)	MA (+Tween 80)	4–10	Bowman et al., 1997b
Polaribacter				
P. filamentus, P. irgensii, P. franzmannii	Seawater, and sea-ice	MA	4–10	Gosink et al., 1998
P. glomeratus	Seawater	MA	10–15	McGuire et al., 1987
Robiginitalea biformata	Seawater	LNHM (HTC tech.)	20–25	Cho and Giovannoni, 2004
Salegentibacter salegens	Hypersaline lakes, and Antarctic	MA	20–25	Dobson et al., 1991; Dobson et al., 1993
Tenacibaculum				
T. amylolyticum, T. mesophilum	Sponge tissue, seaweed	1/5 LMB	25	Suzuki et al., 2001
T. ovolyticum	Fish (Halibut) eggs	MA	20–25	Hansen et al., 1992
T. skaggerakense	Seawater	1/10 MA	20	Frette et al., 2004
T. maritimum	Fish (lesions, tissue)			Hikida et al., 1979
Ulvibacter litoralis	Seaweed	MA	25–30	Nedashkovskaya et al., 2004b
Vitellibacter vladivostokensis	Holothurian	MA	25–30	Nedashkovskaya et al., 2003c
Zobellia				
Z. galactanivorans	Seaweed	Mineral salts + carrageenan	20	Barbeyron et al., 2001
Z. uliginosa	Marine sediment	MA	25	ZoBell and Upham, 1944

Growth Media Abbreviations: MA, marine agar; SW, seawater medium; CYT, casein yeast medium; 1/5 LMB, high salt Luria marine broth; and LNHM, low nutrient heterotrophic m.

may explain why they make up such a large proportion of the marine microbial biomass (see the Ecology and Habitats section in this Chapter) and have adapted to practically all oxygenated marine econiches.

Taxonomy

Apart from 16S rRNA gene sequences, polyphasic criteria detailed in Bernardet et al. (2002) define the taxonomy of the marine clade. Characteristics that differentiate the various genera in the marine clade are shown in Tables 2–6. Almost all taxa in the marine clade are quite new and only six nomenclaturally valid species have existed for any significant length of time, and of these, four have been reclassified. Two species, *Cytophaga marinoflava* (Reichenbach, 1989) and *Cytophaga latercula* (Lewin, 1969), are misclassified at the genus-level by 16S rRNA analysis and quite distinct from the other genera within

the marine clade (Fig. 1). The genus *Cytophaga*, represented by type species *C. hutchinsonii* (a nonmarine soil species), is unrelated as it belongs to a completely different family of the phylum *Bacteroidetes*. The four other "old" species are *Tenacibaculum maritimum*, *Tenacibaculum ovolyticum*, *Cellulophaga lytica* and *Zobellia uliginosa*.

Tenacibaculum maritimum strains were originally isolated from diseased fish by Hikida et al. (1979), but the official description was not made until later by Wakabayashi et al. (1986), who called the fish strains "*Flexibacter maritimus*." The species description was then later emended by Bernardet and Grimont (1989). In *Bergey's Manual* (Volume 3, 1st edition), Reichenbach (1989) renamed *F. marinus Cytophaga marina*. Along with this species, Hansen et al. (1992) described a phenotypically similar species from diseased Atlantic halibut eggs, called "*Flexibacter ovolyticus*." Subsequent 16S rRNA gene data clearly indicated these species belonged to neither *Flexibacter* or *Cytophaga* and thus the confusion of names was finally resolved when Suzuki et al. (2001) created the genus *Tenacibaculum*. *Tenacibaculum* now contains five species (Table 1).

Cytophaga lytica, originally isolated by Lewin (1969) from a marine aquarium outflow and from the surface of marine algal species, was designated the type species of the genus *Cellulophaga* (Johansen et al., 1999). The name is a misnomer as none of the species in *Cellulophaga* actually degrade or utilize cellulose (in the form of filter paper or crystalline powdered cellulose), though they can degrade the derivative carboxymethylcellulose.

Cytophaga uliginosa (originally *Flavobacterium uliginosum*) was renamed by Reichenbach (1989) and only one strain is known. ZoBell and Upham isolated this strain, described it in a seminal paper on marine bacteria (ZoBell and Upham, 1944), and called it "*Agarbacterium uliginosa*" as it rapidly decomposes agar. Subsequently Barbeyron et al. (2001) created a new genus called appropriately "*Zobellia*," which included *Zobellia uliginosa* as the type species renamed from *Cytophaga uliginosa*.

All the remaining named species belonging to the marine clade are relatively new, have not undergone any taxonomic revision, and should remain stable nomenclatural entities. A strong and reliable taxonomic framework has thus been fortunately developed for this environmentally abundant group, unlike the case for other marine and nonmarine groups within the *Bacteroidetes* (e.g., *Flexibacter* and *Microscilla*), which still require heavy taxonomic revision.

Morphological Characteristics

Phenotypically, the marine clade has several common phenotypic properties (many listed in Tables 2–6) which can aid in initial identification.

Marine clade species are generally characterized (with some exceptions) as strictly aerobic chemoheterotrophic, halophilic, Gram-negative, rod-shaped cells, which are either nonmotile or able to glide and produce colonies pigmented yellow to a deep orange. Some species may form filaments though very long filament formation (>100 μm) is rare. The filaments of some species may be coiled or helical when cells are from log phase cultures. In older cultures, the rods and filaments of some species (such as *Gelidibacter algens* and *Croceibacter atlanticus*) may degenerate into still viable coccoidal cells, possibly spheroplasts, which are usually 1–2 μm in diameter. Some *Polaribacter* species form gas vesicles, though this trait has not been observed in any other species of the clade and thus could be idiosyncratic for the genus. *Muricauda ruestringensis* is unusual in forming long thin appendages which have at the tip a bulbous vesicle-like structure. The appendages are a continuum of the outer membrane (Bruns et al., 2001). The species also undergoes an asymmetrical life cycle in which cells contain different chromosomal DNA contents (Muller et al., 2001).

Gliding motility can sometimes be discerned directly from colonial morphology; however, in the marine clade, gliding is generally not very noticeable and often requires very close microscopic examination in wet preparations. Gliding motility is fairly obvious in some species belonging to the genera *Gelidibacter*, *Cellulophaga* and *Zobellia* but is much less obvious in the other species, especially *Cytophaga marinoflava* and *Psychroflexus torquis*, which only glide under certain conditions. See Reichenbach (1989) and individual description papers for detailed assessments of gliding motility in particular species.

Cell biomass is pigmented either yellow or orange (sometimes almost red) owing to carotenoid and/or flexirubin pigments. Flexirubin pigments produced by three species of the marine clade (Table 2) can be detected easily by addition of a strong base (e.g., 20% [w/v] KOH) to cell masses which as a result turn instantly red-brown if flexirubins are present (Reichenbach, 1989). Carotenoids can be assessed in a general way by examining the absorbance spectra of hexane or chloroform cell extracts by spectrophotometry and thin layer chromatography against known standards such as zeaxanthin and saproxanthin. Accurate molecular identification of carotenoids requires more advanced organic chemical analysis against standards,

Table 2. Morphological characteristics of Flavobacteriaceae marine clade species.

Genus	Cell mass color	Flexirubins	Cell shape(s)	Cell size range (width × length μm)	Gliding motility
Aequorivita	Y or O	–	Rods, filaments	0.2–0.5 × 0.5–20.0	–
Arenibacter	O	–	Rods	0.4–0.7 × 0.3–5.0	–
Cellulophaga	Y-O	–	Rods	0.4–0.8 × 1.5–4.7	+
Croceibacter	Y	–	Rods	0.3–0.6 × 1.5–5.0	–
[C.] latercula	O-R	–	Rods, filaments	0.3–0.4 × 1.0–40	+
[C.] marinoflava	O-Y	–	Rods	0.5–0.6 × 1.0–3.0	+
Formosa	Y	–	Rods	0.4–0.9 × 0.8–1.8	+
Gelidibacter	Y	–	Rods, filaments[a]	0.4–0.5 × 0.5–4.0	V
Gillisia	Y	–	Rods	0.7 × 3.0	–
Maribacter	Y	–	Rods	0.3–0.7 × 1.2–10	–
Mesonia	Y	–	Rods	0.4–0.5 × 1.6–2.3	–
Muricauda	Y	–	Rods (appendages)[b]	0.3–0.6 × 1.1–2.7	+
Polaribacter[c]	O	–	Rods, coils, filaments	0.3–0.8 × 0.8–48.0	–
Psychroflexus	O	–	Rods, coils, filaments[a]	0.2–2 × 2–>100.0	V
Psychroserpens	Y	–	Rods, vibrioids, coils, helices	0.5–0.6 × 2.0–20.0	–
Robiginitalea	O	–	Rods[a]	0.3–0.7 × 1.6–5.6	–
Salegentibacter	Y	–	Rods, filaments	0.5–0.8 × 1.2–12	–
Tenacibaculum	Y	–	Rods, filaments	0.4–0.5 × 1.5–30	+
Ulvibacter	O	+	Rods	0.4–0.5 × 2.5–7.3	–
Vitellibacter	Y-O	+	Rods	0.3–0.5 × 3–10	–
Zobellia	Y-O	+	Rods	0.3–0.4 × 3.0–8.0	+

Symbols and abbreviations: Y, yellow; O, orange: R, red; +, present; –, absent; and V, varies between species.
[a]Some genera convert to almost entirely coccoid bodies in stationary growth phase.
[b]*Muricouda ruestringensis* strains form appendages which only emerge from the cell outer membrane and thus are quite unlike prostheca, which are contiguous with the cell membrane and cell wall.
[c]Some but not all species can form gas vesicles (Gosink et al., 1998).

and this has been rarely done for species in the marine clade.

Physiology

Overall, marine clade species are mostly adapted to cold or cool saline, typically oceanic ecosystems. None have been found to grow in excess of 45°C, and tolerance to elevated temperatures (>50°C) is very limited. Some species, including *Polaribacter* spp., *Psychroserpens burtonensis* and *Psychroflexus torquis*, are highly cold adapted, can only grow below room temperature, and will rapidly lose viability at temperatures over 20–25°C. Marine clade species are otherwise psychrotolerant or mesophilic (Table 3), growing well at 20–25°C. The temperature requirements clearly relate to the environment from which the species were isolated. Thus tropical environments will usually yield mesophilic species while species from polar environments do not in general grow at 30°C.

Sodium is generally required by the marine clade. Certain species (Table 3) that inhabit transitional marine ecosystems with variable or low salt levels, e.g., estuarine waters or the Baltic Sea, can grow with without sodium. Some species are quite demanding and also require divalent cations for growth (Table 3). These species only grow in a narrow range of salinity concentrations and thus are classic stenohaline species. A few species, such as *Salegentibacter salegens*, *Psychroflexus gondwanensis* and *Psychroflexus tropicus*, are very broadly salt tolerant and are found in hypersaline lakes. These are unusual phylum *Bacteroidetes* species in requiring high Na ion concentrations (50–100 practical salinity units [psu]) for optimal growth. The only other known example in the *Bacteroidetes* is the species *Salinibacter ruber* (Anton et al., 2002); however, this species is only distantly related to the Flavobacteriaceae marine clade. *Psychroflexus* is also unusual in that the species have widely variant ecophysiology even though they form a distinct and coherent genus (Table 3).

All marine clade species grow aerobically and are homogenously chemoheterotrophic in nature. Facultative phototrophic, lithotrophic or autotrophic growth of any sort does not occur. In general, little specific information is available on catabolic pathways in the group, though it is suspected that most use the Embden-Parnas-Meyerhof pathway for D-glucose catabolism. A few species can grow anaerobically (Table 4) though the mechanisms and extent of this are mostly unknown. *Muricauda ruestringensis* can grow under anoxic conditions in complex media, but neither ferments carbohydrates nor uses nitrate as an alternative electron acceptor. On the other hand, *Formosa algae* and *Polaribacter* species can grow fermentatively on various

Table 3. Basic ecophysiological traits of the marine clade of the family Flavobacteriaceae.

sugars such as D-glucose and D-mannose. Denitrification is rare in the clade, and where it occurs, none of the denitrifying species appear capable of coupling nitrate to anaerobic respiration. Further analysis is required to confirm denitrification in these strains, including detection of nitrite reductase genes and gas chromatography. A small proportion of species do not form catalase (e.g., *M. ruestringensis*) or form cytochrome *c* oxidase; otherwise most are positive (Table 5), reflecting their strictly aerobic nature. All species which have been tested use menaquinone-6 as the primary isoprenoid quinone in respiratory electron transport chains.

Nutritional Characteristics

Several species require organic sources of nitrogen and in many cases other unknown growth factors found in yeast extract (Table 4). *Psychroserpens burtonensis* also requires vitamins for growth in defined media and is stimulated by the addition of Tweens. Thus generalized defined mineral salts media (see example below) are supplemented with 0.05% (w/v) yeast extract. Optionally vitamin solution such as the one formulated by Balch and Wolfe (1976) can be added as well as Tween 80 (~0.025% [v/v]). The medium may not be effective for absolutely every strain, owing to lack of knowledge in specific growth requirements. Single amino acids (such as L-glutamate or L-asparagine) may serve as sole nitrogen sources, though data on these requirements are lacking. Overall, marine clade species do not have unusual or idiosyncratic substrate utilization patterns to obtain energy and carbon. Most species can use an array of carbohydrates, including D-glucose, a few organic acids (typically tricarboxylic acid intermediates), and some amino acids. Sugar alcohols, hydrocarbons, aromatic compounds, and nitrogenous compounds (such as polyamines) are rarely used for growth. *Muricauda ruestringensis* is an interesting case in point since it was isolated from a continuous hexadecane-fed chemostat but is unable to utilize hexadecane or other hydrocarbons. Several species are asaccharolytic, preferring amino acids as sole carbon and energy sources (Table 4). Many species can use complex macromolecular substrates as carbon and/or nitrogen sources for growth. The extent of this ability varies widely between the genera (Table 4). Cellulose may even be degraded by some strains, such as *Tenacibaculum skaggerakense*, even though this polymer is not normally found in abundance in marine ecosystems. By comparison several species (especially *Cellulophaga* and *Zobellia* spp.)

Table 4. Nutritional and metabolic aspects of members of the Flavobacteriaceae marine clade.

Genus	Growth factor requirements	Anaerobic growth	Utilization of carbohydrates (D-glucose)	Polysaccharide hydrolysis (substrate)	Protein hydrolysis (substrate)

Ulvibacter	nd	–	–	–	+ (gelatin)
Vitellibacter	–	–	–	–	+ (gelatin, casein, elastin)
Zobellia	nd	–	+ (+)	+ (agar, starch, carrageenan, CMC, chitin)	+ (gelatin, casein)

Symbols and abbreviations: YE, yeast extract; IN, inorganic nitrogen (nitrate or ammonium salts) needed; AA, amino acids; +, test positive; V, test varies between species; w, weakly positive; V/w, test results are variable and weak; –, test negative; nd, no data available; and CMC, carboxymethylcellulose.

[a]Yeast extract (YE) requirement indicates at least one amino acid and other unknown factors are required for growth in a defined mineral salts medium. If only amino acids (AA) are listed, the genus needs an organic nitrogen source (such as a single amino acid like L-glutamate) but does not have any other special nutritional requirements. Vitamins may also be required when grown on a semi-defined mineral salts medium containing 0.05% (w/v) yeast extract.

[b]Substrate indicated is hydrolyzed by most strains of the respective genus.

[c]*Tenacibaculum skaggerakense* also degrades collagen, hydroxyethylcellulose, barley β-glucans and pullulan.

Table 5. Biochemical characteristics and DNA base composition of genera belonging to the Flavobacteriaceae marine clade.

can degrade agar and carrageenan, polymers produced by many marine macrophytes. Some species produce an array of strong proteases (which can be demonstrated by the degradation of insoluble proteins like elastin), a feature of various *Aequorivita* and *Vitellibacter* strains (Table 4). *Aequorivita lipolytica* also has the ability to digest a wide array of lipids and lipid-esters including tributyrin, Tweens and olive oil (Bowman and Nichols, 2002). The above metabolic tendencies indicate that marine clade members collectively can decompose and utilize a large fraction of organic substances produced in ocean surface waters and coastal environments (Cottrell and Kirchman, 2000; Kirchman, 2002).

Defined Medium for Carbon Source Testing (Nedashkovskaya et al., 2003a)

$NaNO_3$	0.02 g
NH_4Cl	0.02 g
Yeast extract	0.005 g
Carbon source	0.4% (w/v)
Artificial sea salts	100 ml

The carbon source may include carbohydrates, amino acids, and sodium salts of organic acids. Autoclave 121°C, 15 min. Filter sterilize some substrates (especially carbohydrates) because of their heat lability.

Marine Agar (MA)

Bacteriological peptone	5 g
Yeast extract	2 g
Ferric pyrophosphate	10 mg
Sea salts	35 g
Agar (optional)	15 g
Distilled water	1000 ml

Alternatively, replace sea salts and distilled water with natural seawater. Adjust pH to 7.3–7.5. Autoclave 121°C, 15 min.

Marine 2216 agar or broth can also be purchased dehydrated from Difco Laboratories.

Chemotaxonomic and Genotypic Properties

All species of the marine clade contain a high proportion of branched chain fatty acids (Table 6). The distribution of other types of fatty acids is much more genus or species specific, especially monounsaturated fatty acids and hydroxy fatty acids (Table 6), while psychrophilic species produce a greater proportion of *anteiso*-branched chain fatty acids components. *Anteiso*-branched fatty acids produce more fluid membranes at low temperature (Kaneda, 1991) and thus help maintain a constant equilibrium in membrane viscosity. Only *Psychroflexus torquis* forms polyunsaturated fatty acids (PUFA), including eicosapentaenoic acid (20:5ω3) and arachidonic acid (20:4ω6), an exceptionally rare ability amongst the Bacteria (Russell and Nichols, 1999). PUFA-synthesis ability has only been documented for various marine, cold-adapted members of order *Alteromonadales* (Gammaproteobacteria). Eicosapentaenoic acid is also produced by the species *Flexibacter polymorphus* (Johns and Perry, 1977), which is only distantly related to the

Table 6. Whole fatty acid profiles of the genera of the Flavobacteriaceae marine clade.

Flavobacteriaceae marine clade. Overall, fatty acid profiles are very useful for identifying genera within the marine clade and are important criteria for the description of new taxa. The wide range of profiles clearly reflects the evolutionary and ecological diversification of the marine clade members.

Polyamines are another useful chemotaxonomic marker which can be applied to characterize bacterial strains at approximately the family or genus level. In the marine clade, the only major polyamine present was homospermidine (Hamana and Nakagawa, 2001a). *Psychroflexus torquis* was also found to produce a large amount of the aromatic amine 2-phenylethylamine (Hamana and Niitsu, 2001b).

Almost all marine clade members have genomic DNA G+C contents falling into a relatively narrow range of 27–43 mol% (Table 5). A significant exception is the species *Robiginitalea biformata*, which has 55–56 mol% (Table 5), among the highest for the *Bacteroidetes phylum*. Further genomic analysis will be required to ascertain the genetic and evolutionary significance of this difference, which is probably linked to codon usage.

Pathogenicity

The only species within the Flavobacteriaceae marine clade known to have demonstrable pathogenicity impacting on commercial fishing are *Tenacibaculum maritimum* and *Tenacibaculum ovolyticum* (reviewed by Bernardet [1998] and Kusuda and Kawai [1998]). *Tenacibaculum maritimum* causes flexibacteriosis of several commercial fish species, resulting in serious erosion of the mouth, tail and fins from expanding lesions. Juvenile fish are especially susceptible and the disease results in high levels of mortality; 30% population losses are not unusual. *Tenacibaculum maritimum* was first isolated from Japanese sea bream (Hikida et al., 1979); however, most commercial fish species are affected, including Atlantic salmon. *Tenacibaculum ovolyticum* appears much less of a problem though it has been implicated in the disease and loss of viability of fish eggs, including those of Atlantic halibut (Hansen et al., 1992) and sardines (Miguez and Combarro, 2003). Polymerase chain reaction (PCR) techniques are available that detect as little as a single cell of *Tenacibaculum maritimum* and other bacterial fish pathogens in fish tissue samples (Wilson et al., 2002), thus enabling detection of "covert infections" in aquaculture farms.

Preservation

Almost all marine clade members form stable cultures and so can be maintained on agar plates or slants at normal growth temperature for 1–3 weeks, or when kept at 2°C, for 3–12 months. A temperature of 2°C is more ideal than 4–5°C as fungal contamination is reduced and survival for cold-adapted species is enhanced. Mesophilic species usually display better survival at slightly higher temperatures (typically 5–12°C) and thus may be contaminated by fungi. Antifungal compounds, such as nystatin, should be added to media to prevent this. Marine 2216 agar is an excellent media for agar storage. Low nutrient media or media containing a large amount of carbohydrates should not be used. The most notable exception to agar storage is the storage of *Cytophaga latercula*, which undergoes rapid autolysis and death on agar and so needs to be transferred every 1–3 days. Higher incubation temperatures require more frequent transfers. This species can be conveniently maintained as a barely visible suspension in seawater or artificial sea salts (30–35 $g \cdot liter^{-1}$) at 10–15°C for several months or even years. This method can be applied theoretically for other marine clade species though alternative storage preservation procedures should be employed as a general precaution. All marine clade species can be preserved by cryopreservation in marine 2216 broth mixed with 10–30% (v/v) glycerol. This involves creating heavy cell suspensions of strains mixed in the cryopreserving medium, which has been pre-chilled on ice, and then direct transfer to a –70°C or colder freezer. The suspensions can also be frozen directly in liquid nitrogen at –196°C. The cultures should be replaced on an annual basis if possible. Multiple vials of cryopreserved cells should be stored in one freezer in addition to a back-up set stored in a separate freezer. Lyophilization can also be employed using a variety of desiccants. Desholme and Bernardet (1998) found fetal bovine serum was an excellent desiccant for storing *Tenacibaculum maritimum*. Horse serum and skim milk can also be used, though results may be variable for some species, and lyophilized strains should have a cryopreserved back-up. Marine 2216 broth and agar (equivalent formula given below) as well as general routine growth media can be used as resuscitation media for either cryopreserved or lyophilized cultures.

Artificial Seawater Formula (ZoBell, 1946)

NH_4NO_3	2 mg
H_3BO_3	27 mg
$CaCl_2$	1.14 g
$FePO_4$	1 mg

$MgCl_2$	5.14 g
KBr	0.1 g
KCl	0.7 g
$NaHCO_3$	0.2 g
NaCl	24.3 g
NaF	3 mg
Na_2SiO_3	2 mg
Na_2SO_4	4.1 g
SrCl	26 mg
Distilled water	1000 ml

Sea salts can also be purchased from chemical companies such as Sigma-Aldrich or from aquarium suppliers (the latter source is far cheaper and has a similar level of quality).

Isolation and Cultivation

The media useful for isolation of Flavobacteriaceae marine species are shown in Table 1. In most cases, strains are obtained by directly plating samples onto agar. Seaweed and marine faunal samples (e.g., holothurians) are usually first homogenized in a solution of sea salts or natural seawater before plating. Some species, such as *Mesonia algae*, can be obtained easily by first allowing the source material to decay in natural seawater, e.g., seaweed thallus samples, thus elevating the populations of heterotrophic decomposers dramatically. Psychrophilic strains have enhanced isolation after first pre-enriching samples, such as thawed sea-ice, in a suitable medium (e.g., marine 2216 broth) at a low temperature (0–4 °C) for 24–48 h before plating. The low temperature encourages the multiplication of psychrophilic species responding to the media nutrients. Some species (including *Croceibacter atlanticus* and *Robiginitalea biformata*) have been isolated with the High Throughput Cultivation (HTC) technique (Connon and Giovannoni, 2002; Table 1). The HTC method has been used successfully for isolating strains adapted to highly oligotrophic (low nutrient) ecosystems such as open ocean seawater (e.g., Rappé et al., 2002). In this procedure the sample, usually seawater, is diluted in 96- or 384-well trays to <10 cells per well. Cultures grown from each well are then screened using fluorescent in situ hybridization (FISH) and 16S rRNA gene sequencing. In the case of *C. atlanticus* and *R. biformata*, the strains were isolated initially using low nutrient heterotrophic medium (LNHM) with the HTC technique but subsequently grown on marine 2216 agar. Not all strains obtained by HTC will grow on agar; so far it is unknown if this feature extends to the Flavobacteriaceae marine clade.

Zobellia galactanivorans was isolated using carrageenan as the sole carbon source (Table 1) and thus complex substrates may be ideal for the isolation of many species. Suitable substrates are listed in Table 4. As most species have been obtained on standard complex growth media such as marine 2216 agar or dilutions of this media, it is possible novel species may be isolated using more selective substrates as has been done successfully for isolating novel soil bacteria (Joseph et al., 2003). The incubation temperature for primary isolation plates and media usually matches the habitat temperature which for most marine ecosystems can range from sub-zero temperatures up to 30°C.

All strains grow well on marine 2216 agar at the incubation temperatures listed in Table 1.

High Salt Luria Marine Broth (1/5 LMB) (Suzuki et al., 2001)

Tryptone	2 g
Yeast extract	1 g
Artificial seawater	1000 ml

Adjust pH to 7.2. Autoclave 121°C, 15 min.

Medium B (Ivanova et al., 1996)

Bacteriological peptone	2 g
Casein hydrolysate	2 g
Yeast extract	2 g
D-Glucose	1 g
KH_2PO_4 (anhyd.)	20 mg
$MgSO_4 \cdot 7H_2O$	50 mg
Natural seawater	500 ml
Distilled water	500 ml

Adjust pH to 7.5–7.8. Autoclave 121°C, 15 min.

Low Nutrient Heterotrophic Medium (LNHM) (Rappé et al., 2002)

NH_4Cl	1.0 mg
KH_2PO_4	0.1 mg
D-Glucose	10 mg
D-Ribose	10 mg
Sodium succinate	10 mg
Sodium pyruvate	10 mg
Glycerol	10 mg
N-Acetylglucosamine	10 mg
Ethanol	0.002% (v/v)
Natural seawater	1000 ml

Filter sterilize (0.2 mm) and autoclave the natural seawater. Do not add agar to this medium.

CYT Medium (Johansen et al., 1999)

Casein	1 g
Yeast extract	0.5 g
$CaCl_2 \cdot H_2O$	0.5 g
$MgSO_4 \cdot 7H_2O$	0.5 g
Agar (optional)	15 g
Sea salts	20 g
Distilled water	1000 ml

Adjust pH to 7.3. Autoclave 121°C, 15 min.

Modified (Hexadecane) Marine Agar (adapted from Bruns et al., 2001)

Bacteriological peptone	2.5 g
Yeast extract	1.5 g
Hexadecane (optional)	0.2% (v/v)
Agar	15 g
Sea salts	22.5 g
Distilled water	1000 ml

Adjust pH to 7.2. Autoclave 121°C, 15 min.Used for isolation of *Muricauda ruestringensis*, which does not actually utilize or benefit from hexadecane.

Ecology and Habitats

Studies using 16S rRNA-based clone libraries, denaturing gradient gel electrophoresis, and FISH indicate most *Bacteroidetes* in sea-ice and seawater belong to the Flavobacteriaceae marine clade (Brown and Bowman, 2001; Bano and Hollibaugh, 2002; Junge et al., 2002; Brinkmeyer et al., 2003; Kirchman et al., 2003). Other lineages from different families of the *Bacteroidetes* also occur though often at smaller and more variable levels.

From various culture-independent studies, marine clade members occur in all marine ecosystems which have at least some access to oxygen. They also are common in some marine-derived environments including saline lakes (formed by uplifting of the seabed above sea level, e.g., Vestfold Hills, Antarctica) and lithic habitats, which act as protective environments from harsh climatic conditions including desiccation and freezing (Smith et al., 2000). This is especially the case for genus *Gelidibacter*, which appears broadly distributed, detected in sea-ice at both poles (Bowman et al., 1997c; Staley and Gosink, 1999; Brown and Bowman, 2001), in cyanobacterial communities living under semi-translucent quartz stones in Antarctic deserts (Smith et al., 2000), widely in seawater (Kelly and Chistoserdov, 2001; Macián et al., 2002), and in the surface of tropical marine sediments (Madrid et al., 2001). By comparison, *Polaribacter* has only been isolated and detected in sea-ice and seawater of polar oceans, where it is one of the dominant taxa present (Staley and Gosink, 1999; Brown and Bowman, 2001; Bano and Hollibaugh, 2002; Junge et al., 2002; Brinkmeyer et al., 2003). In regards to the benthos, the marine clade only concentrates in sediment surface mixed layers in which faunal bioturbation and oceanic currents provide sufficient oxygenation. The surface mixed layer of continental shelf sediments and marine clade members appears to be relatively common, making up about 10% of the bacterial population (Bowman and McCuaig, 2003a). Further down in marine sediment layers, which are fully anoxic, different mostly uncultured Bacteroidetes lineages lying outside of the Flavobacteriaceae predominate instead. Marine clade members (especially *Cellulophaga* species) may be encountered in some transitional marine ecosystems such as estuaries or brackish water (e.g., that of the Baltic Sea). Marine clade species (described or undescribed) have never been isolated from freshwater ecosystems. Related genera such as *Flavobacterium*, *Myroides* and *Chryseobacterium* are abundant in there instead, suggesting these genera may play an analogous role in freshwater aquatic ecosystems.

Since they are nonmotile or move by gliding, marine clade members benefit most when given access to surfaces for colonization. Surfaces in turn maximize access to nutrients through adsorption of nutrients and formation of biofilms. Nutrients are the most important factor driving life in the oceans, and marine clade organisms have characteristics which are well adapted to growth with marine biota, especially algae, living on exudates and detritus (including both simple compounds and complex macromolecules). The primarily epiphytic nature of the Flavobacteriaceae marine clade and efficient colonization of marine living surfaces have been shown by various FISH analyses. For example, marine clade members may make up as much as 70% of bacterioplankton associated with algal blooms and algal surface biofilms (e.g., Glöckner et al., 1999). Various other studies also indicate that members of the *Bacteroidetes* can proliferate on or in most marine macrobiota (Table 1) and in marine aggregates (Grossart and Ploug, 2001; Ploug et al., 2002). Psychrophilic species have been detected in or isolated from sea-ice algal assemblages, with the incidence for isolation much lower in sea-ice lacking algae (Bowman et al., 1997c; Brown and Bowman, 2001). The most likely reason for this is that algae simply provide surfaces and nutrients for bacterial proliferation. Recent studies by Junge et al. (2004) indicate that particle-associated Flavobacteriaceae marine clade species make up the bulk of bacterial populations within the brine channels of winter sea-ice. The brine channels are an unusual extreme environment combining intense cold (–1°C to <–20°C) and high salinity (up to 150 psu). Thus marine clade species in brine channels represent a special variety of extremophiles not found anywhere else. Data from such ecosystems may have significance for astrobiological research in which studies are directed toward possible extraterrestrial life in our solar system, which may well be mostly extremophilic in nature. Many of these extremophilic species remain to be cultured, and the biochemical adaptations required to survive in such environments are also only just now being investigated (Junge et al., 2004). It has been suggested that the algal phycosphere, the region around algal cells enriched with photosynthetically derived exudates, perhaps held in partially by algal exopolysaccharide gel envelopes (Krembs et al., 2003),

is a substrate concentration zone supporting enhanced growth at sub-zero temperatures. A major hurdle for cold-adapted bacteria is lack of cytoplasmic membrane permeability resulting in less efficient and slower transport of nutrients; enzyme catalysis is also impeded owing to cold denaturation. Though the permeability of cytoplasmic membranes is improved by modulation of fatty acid components (Kaneda, 1991; Russell and Nichols, 1999) and cell membrane proteins (e.g., cold-shock-like proteins), high substrate and ionic concentration in the external medium provide a favorable gradient for nutrient transport (Tokai et al., 2000) and particularly for Na^+-substrate coupled co-transport (Wilson and Ding, 2001). Sea-ice bacteria are also adept at making cold-active enzymes (Nichols et al., 1999; Deming, 2003).

The marine clade appears to have ecological impacts beyond simple mineralization-based commensalism (secondary production); some evidence suggests that algal associated species may enhance algal growth (Grossart, 1999). This could be considered a mutualistic relationship. By colonizing the surfaces of some algae or even metazoans, some bacterial species can also produce compounds which inhibit the settlement and colonization of other organisms (e.g., Egan et al., 2000). In this respect, toxic secondary metabolites allow bacteria to play an aggressive, predatory role in food webs. For example several strains (mostly related to *Cellulophaga*, *Psychroserpens* and *Formosa*) can actively attack and kill various algal species (Doucette et al., 1999; Kondo et al., 1999; Nagasaki et al., 2000; Skerratt et al., 2000; Adachi et al., 2002), in particular dinoflagellates, by producing extracellular enzymes and toxic compounds. The lysis of algal cells in blooms causes a rapid local increase in dissolved and particulate organic matter which supports bacterial growth and thus marine clade species are probably important in the instigation of algal bloom crashes and subsequent decomposition. This extends to marine aggregates (when large enough to see they are referred to as "marine snow"), which are exopolysaccharide conglomerated clumps of organic detritus generated from algal blooms and metazoan activity (e.g., zooplankton sloppy feeding and fecal pellets). As the aggregates sink to the nepheloid layer (a layer of suspended particles above the ocean bottom) and benthos (biota that live at or near the bottom), marine clade members and other bacteria actively degrade organic matter, thus making the aggregates hot spots of biological activity in an otherwise apparently quiescent pelagic zone. The break up of aggregates owing to ocean currents and upwelling would help distribute cells throughout the ocean to repeat the cycle.

Applications

Marine clade members have a substantial biotechnological potential which so far is virtually untapped. Cold-adapted species produce cold-active enzymes which have substantial industrial utility. The applications in industry are manifold and have been extensively reviewed (see, e.g., Bull et al. [2000] and Rothschild and Mancinelli [2001]); important focus areas for cold active enzymes include janitorial processes, modification of heat labile substances (such as various foods) and in energy conservation. For example, *Cellulophaga algicola* isolated from Antarctic algae produces a wide range of active extracellular enzymes capable of breaking down proteins and polysaccharides with temperature optima of only 20–30°C and remaining active at subzero temperatures (Nichols et al., 1999). Interesting uses for these enzymes are beginning to emerge. For example, *Arenibacter latericius* produces an enzyme (α-*N*-acetylgalactosaminidase IV), which can specifically modify human erythrocytes (Bakunina et al., 2002). Various marine clade species produce specialist fucoidan and agarase enzymes (Sakai et al., 2002; Allouch et al., 2003) that cleave specific polysaccharide chemical bonds and so may have utility in creating tailored oligosaccharides for the food and pharmaceutical industries.

The psychrophile, *Psychroflexus torquis*, as previously mentioned produces PUFA, which has direct applicability to the nutriceutical industry. Omega-3 PUFA (including eicosapentaenoic acid) is essential for the development of healthy infants, provides significant health benefits for cardiovascular systems and nervous systems (Li and Sinclair, 2002), and may reduce cancer and arthritis (Shahidi and Kim, 2002; Tavani et al., 2003). Arachidonic acid, an omega-6 PUFA, also produced by *P. torquis*, also has value as a fine chemical and applications as a pharmaceutical.

Several species of the marine clade, mostly undescribed, have been shown to produce bioactive compounds of pharmaceutical potential (e.g., tumor formation inhibitors, neuroactive agents; Umezawa et al., 1983; Perovic et al., 1998; Yan et al., 2002). Algicidal strains (indicated previously) have also been touted as a biocontrol for toxic algal blooms, such as the infamous "red tide," which plagues various coastlines and can lead to fish kills, damage to the aquaculture industry, human health problems, and overall degradation of the coastal marine environment.

Capnophilic Bird Pathogens in the Family Flavobacteriaceae: Riemerella, Ornithobacterium and Coenonia

P. VANDAMME, H. M. HAFEZ AND K. H. HINZ

Introduction

Riemerella columbina, *Ornithobacterium rhinotracheale* and *Coenonia anatina* were initially recognized in the course of long-term studies on the etiology of respiratory tract infections in birds as phenotypically unusual isolates. The reclassification of the organism known as *Pasteurella anatipestifer* and *Moraxella anatipestifer* (Segers et al., 1993) triggered a series of taxonomic studies leading to the stepwise characterization and description of *O. rhinotracheale* (Vandamme et al., 1994), *C. anatina* (Vandamme et al., 1999) and *R. columbina* (Vancanneyt et al., 1999). There have been no additional studies since the original description of the latter two organisms. However, the formal description of *O. rhinotracheale* led to a wealth of studies on this bacterium because of its recognition as an economically important pathogen in turkey and chicken husbandry. Rather unexpectedly, although not closely related, *Riemerella*, *Ornithobacterium* and *Coenonia* turned out to belong to the same major phylogenetic lineage, now known as the family Flavobacteriaceae (Bernardet et al., 1996).

Taxonomy

Overview

This group of capnophilic bird pathogens comprises four species. Within the genus *Riemerella*, *R. anatipestifer* is the type species with *R. columbina* as a second species. *Ornithobacterium rhinotracheale* and *C. anatina* are the type and only species of their respective genera.

Riemerella anatipestifer has been isolated worldwide from domestic and wild birds. The organism causes a disease named "exudative septicemia" (Riemer, 1904), which particularly affects ducks, less frequently geese and turkeys, and sporadically chickens and wild birds (Brogden, 1989; Hinz et al., 1998b). This pathogen has been classified in the genera *Moraxella* and *Pasteurella* but was considered species incertae sedis in *Bergey's Manual of Systematic Bacteriology* (Bøvre, 1984; Mannheim, 1984). Its affiliation with the *Flavobacterium-Cytophaga* lineage was suggested by the presence of menaquinones as sole respiratory quinones and of branched-chain fatty acids in high percentages, the absence of carbohydrate fermentation, a similar pattern of hydrolytic enzymes, the low DNA base ratio, and the lack of flagellation (Piechulla et al., 1986; Rossau et al., 1991). In 1993, DNA-rDNA hybridization experiments unequivocally demonstrated that this bacterium indeed belonged to the *Flavobacterium-Cytophaga* lineage (Segers et al., 1993). A novel genus, *Riemerella*, was proposed to accommodate this bacterium because of its genomic divergence from allied taxa and because of its unique chemotaxonomic and phenotypic properties, which included a capnophilic metabolism (Segers et al., 1993). Subsequent 16S rRNA gene sequence analysis confirmed these initial rRNA hybridization-based findings (Subramaniam et al., 1997; Ryll et al., 2001).

A group of thirteen *R. anatipestifer*-like isolates from diseased pigeons was included in a polyphasic taxonomic study which demonstrated that they represented a distinct *Riemerella* species for which the name *R. columbina* sp. nov. was proposed (Vancanneyt et al., 1999). Shortly thereafter, a second group of *R. anatipestifer*-like bacteria, known as "taxon 1502" (Hinz et al., 1998b), was described using a similar polyphasic approach (Vandamme et al., 1999). This study entailed the proposal of *C. anatina* to accommodate taxon 1502 isolates, which originated from pekin ducks, muscovy ducks, geese and pigs.

In the late 1980s the isolation of a pleomorphic Gram-negative rod-shaped bacterium from turkey and chicken samples in Belgium by Jef

Hommez (Provinciaal Verbond voor Dierenziektenbestrijding, Torhout, Belgium) triggered another polyphasic taxonomic study. Similar bacteria had been isolated in Germany, the United Kingdom, France, the Republic of South Africa and the United States (Charlton et al., 1993; Vandamme et al., 1994) and were first reported in 1993 (Charlton et al., 1993; Hafez et al., 1993). The study collection included 21 isolates from the respiratory tract of turkeys, chickens, rooks, and a partridge, and most isolates were associated with various respiratory tract infections including tracheitis, pericarditis, sinusitis, airsacculitis, and pneumonia. The taxonomic study revealed that they represented a novel bacterium for which the name *O. rhinotracheale* was proposed. Subsequent studies identified *O. rhinotracheale* as a respiratory pathogen in birds worldwide.

Phylogeny

Together with about 20 validly named genera, several generically misclassified organisms, and a number of invalid taxa, the genera *Riemerella*, *Ornithobacterium* and *Coenonia* form the family Flavobacteriaceae (Bernardet et al., 1996; Fig. 1). *Riemerella anatipestifer* and *R. columbina* isolates share a 16S rDNA sequence similarity level of about 95% and are closely related to *Bergeyella zoohelcum*, a bacterium isolated from cats, dogs and various human clinical specimens (Holmes et al., 1986). The average 16S rDNA sequence similarity level between *Riemerella* and *Bergeyella* strains is about 93.5%. *Ornithobacterium rhinotracheale* represents a rather distinct line of descent within this family, with only about 87.5% 16S rDNA sequence similarity towards its closest neighbors (the genera *Empedobacter* and *Weeksella*). *Coenonia anatina* is closely related to members of the genus *Capnocytophaga* (about 89.5% 16S rDNA sequence similarity), which are capnophilic bacteria occurring in the oral cavity of man and animals.

Identification

One-dimensional Whole-cell Protein Electrophoresis

In bacterial taxonomy, one-dimensional whole-cell protein electrophoresis has been used as a most useful primary screening tool for the rapid delineation of closely related bacteria (Vandamme et al., 1996). The technique is primarily a research tool but has been used to recognize members of the genera *Riemerella*, *Ornithobacterium* and *Coenonia* and was used as the key instrument to delineate the four species (Segers et al., 1993; Vandamme et al., 1994; Vandamme et al., 1999; Vancanneyt et al., 1999). Figure 2 shows the dendrogram derived from the numerical analysis of the unweighted pair group average linkage of correlation coefficients between whole-organism protein patterns of strains representing the four taxa and illustrates that they are readily distinguishable.

Whole-cell Fatty Acid Methyl Ester Analysis

The average cellular fatty acid methyl ester composition of *Riemerella*, *Ornithobacterium* and *Coenonia* species after cultivation for 48 h on tryptic soy agar and preparation and analysis of the profiles using the Microbial Identification System (Microbial ID, Inc., Newark, DE, USA) is given in Table 1.

The branched chain fatty acids 13:0 *iso*, 15:0 *iso*, 15:0 *anteiso*, 15:0 *iso* 3OH, and 17:0 *iso* 3OH are predominant in all species. Overall, the four average fatty acid profiles are clearly different and allow a straightforward differentiation of the four taxa, including both *Riemerella* species. The fatty acid profiles and in particular the high percentage of 15:0 *iso* 3OH and 17:0 *iso* 3OH and an unidentified fatty acid with equivalent chain length value of 13.566 also differentiate *O. rhinotracheale* from *Capnocytophaga* spp. (Vandamme et al., 1994).

DNA Base Compositions

The DNA base ratio of *R. anatipestifer*, *R. columbina*, *O. rhinotracheale* and *C. anatina* is similar: 33–35, 36–37, 37–39, and 35–36 mol%, respectively (Segers et al., 1993; Vandamme et al., 1994; Vandamme et al., 1999; Vancanneyt et al., 1999).

Isolation and Growth Conditions

Riemerella anatipestifer and *R. columbina*

During acute septicemic stage of the disease, *R. anatipestifer* can be grown from heart blood, brain, airsacs, bone marrow, liver, pneumonic lung and fibrinous exudate. *Riemerella columbina* has been isolated mostly from samples of the respiratory tract. In more chronic cases it is often difficult to isolate the agent from the lesions. Swabs from the nasal cavity, pharynx and upper part of the trachea should be taken from birds with clinically inapparent infections.

Riemerella anatipestifer and *R. columbina* are chemoorganotrophic, mesothermophilic and microaerophilic to aerophilic. Trypticase soy agar and Columbia agar base with 5–10% defi-

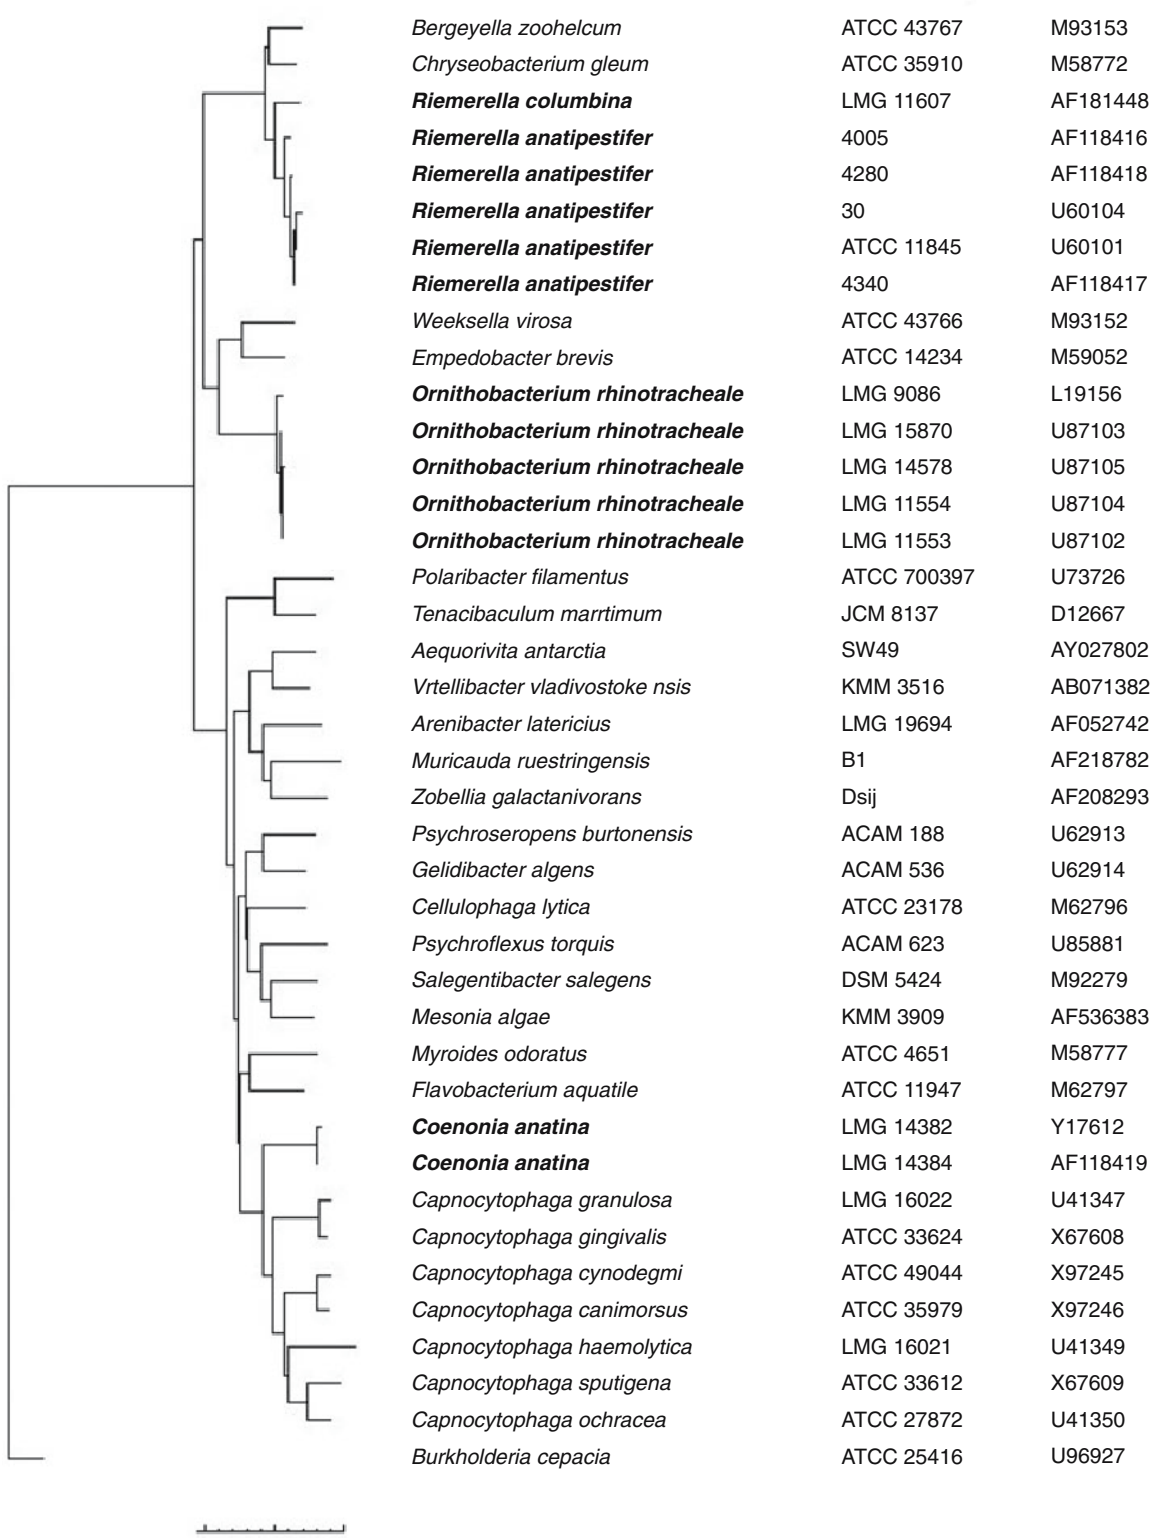

Fig. 1. Phylogenetic tree based on 16S rRNA gene sequences of *Riemerella*, *Ornithobacterium* and *Coenonia* strains and the type species of the other genera belonging to the family Flavobacteriaceae. The scale bar represents 10% difference in nucleotide sequence as determined by measuring the lengths of the horizontal lines connecting any two species. *Burkholderia cepacia*, a beta-proteobacterium, was used as an outgroup species.

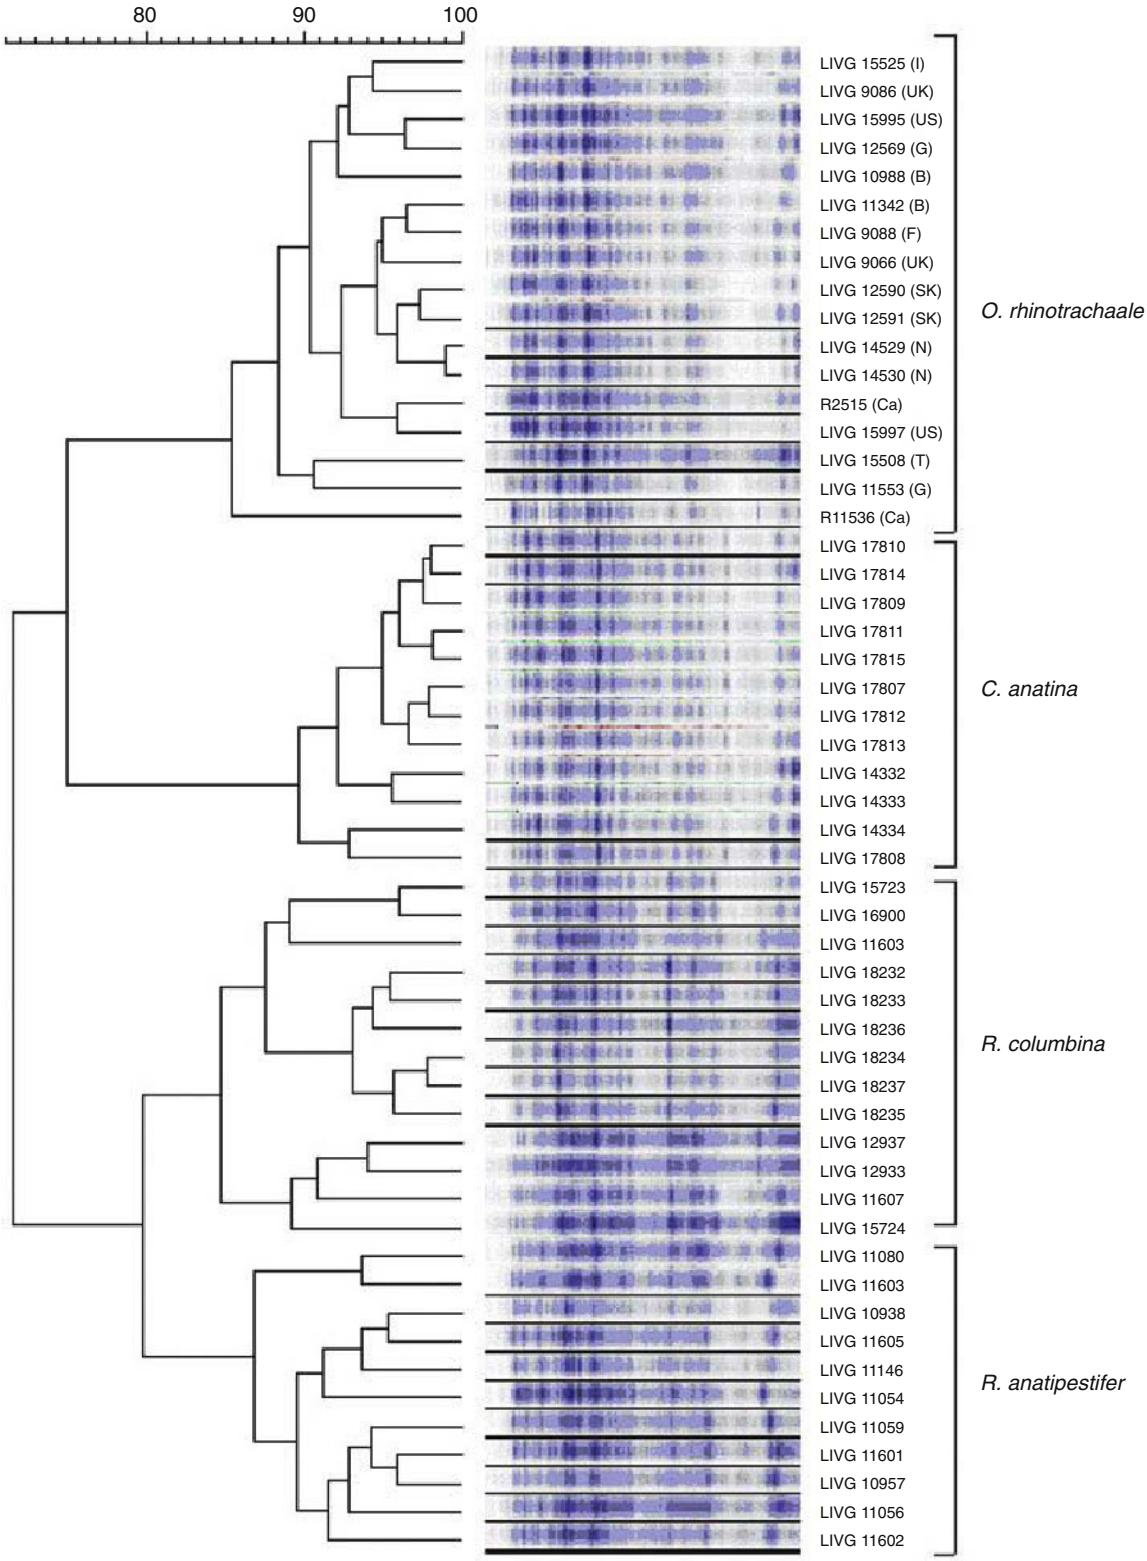

Fig. 2. Computer-reproduced images and dendrogram derived from the unweighted pair group average linkage of correlation coefficients between whole-organism protein patterns (fingerprints) of representative *Riemerella*, *Ornithobacterium* and *Coenonia* strains. For *O. rhinotracheale*, the geographic origin of the isolates is given: B (Belgium), Ca (Canada), F (France), G (Germany), I (Israel), N (the Netherlands), SA (Republic of South Africa), UK (United Kingdom), and US (United States). The numerical analysis was performed using the GelCompar 4.0 software package (Applied Maths, Kortrijk, Belgium). The profiles were recorded and stored on a PC computer. The similarity between all pairs of traces was expressed by the Pearson product moment correlation coefficient converted for convenience to a percent value.

Table 1. Whole-cell fatty acid composition of *Riemerella*, *Ornithobacterium* and *Coenonia* species.[a]

Species	13:0 *iso*	ECL[b] 13.566	15:0 *iso*	15:0 *anteiso*	15:0 *iso*3OH	16:0 3OH	17:0 *iso*3OH
R. anatipestifer[c]	15.1 ± 3.8	1.4 ± 0.5	52.4 ± 4.6	5.4 ± 1.1	8.2 ± 2.4	?	13.6 ± 3.4
R. columbina[c]	10.1 ± 1.8	Tr	45.3 ± 3.3	22.1 ± 3.3	3.9 ± 0.9	?	7.0 ± 1.5
C. anatina[d]	33.9 ± 4.6	Tr	40.8 ± 4.7	3.2 ± 0.7	6.4 ± 1.3	4.1 ± 0.9	6.3 ± 2.3
O. rhinotracheale[e]	Tr	4.2 ± 1.5	57.4 ± 6.1	Tr	8.1 ± 1.9	2.8 ± 1.8	20.2 ± 5.0

Abbreviations: ECL, equivalent chain length; and Tr, trace amount (less than 1%).

[a]Those fatty acids for which the average amount for all taxa was less than 1% are not given. Therefore, the percentages for each group do not total 100%. Mean percentages and standard deviations are given.

[b]The identity of the fatty acid is not known.

[c]Data from Vancanneyt et al. (1999). *Riemerella columbina* strains also contain 2.0 ± 0.7% of 13:0 *anteiso*, 1.0 ± 0.2% of 14:0 *iso*, 1.0 ± 0.4% of 15:0 2OH, 1.0 ± 0.1% of 17:0 2OH, and 2.9 ± 1.3% of summed feature 4, which consists of one or more of the following fatty acids that cannot be separated by the Microbial Identification System: 15:0 *iso* 2OH, 16:1 ω7c, and 16:1 ω7t.

[d]Data from Vandamme et al. (1999). *Coenonia anatina* strains also contain 2.8 ± 2.4% of 14:0.

[e]Data from Vandamme et al. (1994). *Ornithbacterium rhinotracheale* strains also contain 1.5 ± 1.0% of 17:0 *iso*, 2.9 ± 1.3% of 16:0, and 1.1 ± 0.5% of ECL 16.580.

brinated sheep blood are the only media by which riemerellae have been successfully isolated. At present, a selective medium (containing 10% defibrinated sheep blood, trypticase soy agar, or Columbia agar as the agar base and gentamycin [80-200 µg/ml] and neomycin [25-40 µg/ml]) is the medium of choice for the primary isolation because other bacterial agents, contaminants or secondary invaders may inhibit or overgrow the fragile organisms of riemerellae (Köhler et al., 1995). A comparative study revealed significantly higher isolation rates with the selective medium (Köhler et al., 1995).

Furthermore, a microaerobic atmosphere comprising 5–10% CO_2 and high humidity greatly increases the recovery of the riemerellae during primary isolation (e.g., candle jar conditions). After subculturing, some isolates can be adapted to grow on conventional media with or without additional CO_2 and with or without serum. Under strict anaerobic conditions, no growth has been observed.

Although some *R. anatipestifer* strains grew at an incubation temperature of 45°C, no growth was obtained at 4 or 55°C; maximum growth usually occurs after 48–72 h when incubated at 37°C on blood agar in a candle jar. The colonies are 2–3 mm in diameter, circular, convex, entire, transparent to grayish, glistening and butyrous.

Colonies on transparent medium (e.g., blood agar base + 5% serum) show iridescence when observed with obliquely transmitted light.

Coenonia anatina

This species can be grown from heart blood, fibrinous exudate from the surface of the heart, brain, and parenchymatous organs of birds with symptoms of a septicemic running disease. If the respiratory tract is the only affected organ system, swabs from the nasal cavity, infraorbital sinus, or trachea and/or samples of pneumonic lungs and fibrinous exudate of the air sacs should be cultured.

Coenonia anatina is a chemoorganotrophic, mesothermophilic and capnophilic microorganism. Similar to *R. anatipestifer*, the routine medium for the isolation is trypticase soy agar or Columbia agar base containing 7–10% defibrinated sheep blood. Selective medium supplemented with gentamycin (80 µg/ml) and neomycin (40 µg/ml) should be used for the primary isolation because fast growing bacteria like *Escherichia coli* or *Pseudomonas aeruginosa* may overgrow or inhibit *Canatina* (Köhler et al., 1995).

Growth is optimal at 37°C in a microaerobic and CO_2-enriched atmosphere with high humidity. *Coenonia anatina* does not grow under aerobic conditions and yields weak growth under strict anaerobic conditions. Colonies are convex, circular, opaque and glistening with entire edges and smooth surface on the 24-h blood agar culture. After 48–72 h incubation, colonies on selective medium may appear more whitish and mottled.

Ornithobacterium rhinotracheale

Samples for bacterial culture should be collected at an early stage of the disease. Trachea, lungs, and air sacs are the best tissues from which to isolate *O. rhinotracheale*. Infraorbital sinus and nasal cavity are also suitable for culture, but *O. rhinotracheale* can easily be masked by overgrowth of other bacteria.

Blood agar with 5–10% sheep blood is commonly used for primary isolation. *Ornithobacterium rhinotracheale* also grows readily on tryptose soy agar as well as in peptone water and

Pasteurella broth, both aerobically and anaerobically. There is no growth on MacConkey agar. In samples with fast growing bacteria such as *E. coli*, *Proteus* or *Pseudomonas*, *O. rhinotracheale* may be overgrown and therefore cannot be detected in routine investigation. Most *O. rhinotracheale* isolates are resistant to gentamycin (Hafez et al., 1993). Back et al. (1998) recommended the use of 10 µg of gentamycin per ml of blood agar medium to isolate *O. rhinotracheale* from contaminated samples. Blood agar containing 5 µg of gentamycin and 5 µg of polymyxin per ml of medium can also be used as selective medium.

Incubation of primary plates for 48 hours under anaerobic or, preferentially, microaerobic (5–10% CO_2) conditions is recommended. The optimal growth temperature is 37°C. On blood agar, the colonies are small, gray-white, opaque, nonhemolytic and differ in diameter (1–3 mm).

Detection and Identification

Riemerella anatipestifer and *R. columbina*

The history of the disease and its clinical signs and gross lesions may allow a presumptive diagnosis which has to be confirmed by the detection of the causal agent. After isolation, riemerellae can be detected and identified using direct and indirect methods.

Among the direct detection methods, immunofluorescent procedures can be used to identify riemerellae in tissues and exudate from infected birds (Marshall et al., 1961). More traditionally, isolated colonies should be selected and subcultured for further identification procedures. Riemerellae are usually identified by their cultural and physiological characteristics.

Riemerellae cells are Gram-negative capsulated, nonmotile, nonsporeforming rods occurring singly, in pairs, or as filamentous forms. In 16–24-h old cultures on blood agar, the rods vary from 0.2–0.4 µm in width and 1–5 µm in length.

The absence of species-specific characteristics in conventional macrotests makes reliable identification difficult. *Riemerella anatipestifer* has been described as an organism that does not produce indole and does not ferment carbohydrates (Bangun et al., 1981). However, there is no doubt that indole-producing strains exist (Pathanasophon et al., 1994; Hinz et al., 1998b). Using the buffered single substrate test (BSS-test), *R. anatipestifer* and *R. columbina* oxidatively catabolize several carbohydrates to acid (Table 2). Weak acid production by *R. anatipestifer* from carbohydrates may be masked by alkaline breakdown products from peptone when peptone-containing media are used (Hinz et al., 1998a).

Commercially available micro-test strips, especially those by which the enzyme activity of resting cells can be examined, are useful identification procedures for *R. anatipestifer* and *R. columbina* (e.g., API galleries such as 20NE, ID 32 E, and ZYM). However, it should be considered that the detection sensitivity of these commercial systems are different (Hinz et al., 1998b).

Table 3 lists differential diagnostic characteristics that can be used to distinguish *R. anatipestifer* and *R. columbina* from other bacterial species that may be encountered in specimens from birds: *C anatina*, *O. rhinotracheale*, *Chryseobacterium meningosepticum* and *Pasteurella* species. Only two characteristics clearly differentiate *R. columbina* from *R. anatipestifer*: pigment formation and esculin hydrolysis (β-glucosidase). Esculin hydrolysis, gelatinase, hyaluronidase (chondroitin sulfatase), and β-galactosidase activities are of high differential diagnostic value.

Indirect detection of riemerellae in ducks can be achieved through several enzyme-linked immunosorbent assays (ELISAs). Hatfield et al. (1987) reported on an ELISA that was more sensitive than agglutination tests to detect infection with *R. anatipestifer* by specific serum antibodies. Huang et al. (2002) developed an ELISA using a recombinant 41-kDa partial protein (P45N′) for the detection of *R. anatipestifer* infections in ducks. More recently, Lobbedey and Schlatterer (2003) reported on a direct and an indirect ELISA, which were applied for the detection of duck antibodies against *R. anatipestifer* antigens in egg yolk of vaccinees and in serum of their offspring.

In epidemiological studies, *R. anatipestifer* isolates have been serotyped using agglutination and agar-gel precipitation reactions. Both of these procedures involve surface antigens

that are presumed to be polysaccharides. To date, 21 serovars have been reported (Pathanasophon et al., 2002). DNA based fingerprinting has been performed using restriction endonucleases analysis (Rimler and Nordholm, 1998), repetitive sequence PCR (Huang et al., 1999), and restriction fragment length polymorphism analysis (Subramaniam et al., 1997). Weng et al. (1999) reported that a preliminary analysis of hybridization patterns of genomic DNA with an insertion element-based probe indicated that it might also be a useful tool for epidemiological studies.

Coenonia anatina

Isolated colonies should be selected and subcultured for further identification procedures. *Coenonia anatina* is identified by morphological, cultural and physiological characteristics. *Coenonia anatina* cells are Gram-negative, nonsporeforming, nonmotile rod-shaped bacteria. In 16-h-old blood agar cultures the mean cell size is 0.2–0.4 μm in width and 1.25–2.5 μm in length. Some cells are spherically swollen, spindle-lemon-shaped and arranged in short chains.

The main differential diagnostic characteristics distinguishing *C. anatina* from *O. rhinotracheale*, *C. meningosepticum*, *R. anatipestifer* and *R. columbina* as well as *Pasteurella* species are given in Table 3. Differential features towards *Capnocytophaga* species, the close phylogenetic neighbors of *C. anatina*, have been reported (Vandamme et al., 1999) but are not presented here because *Capnocytophaga* has not been detected in birds up to now.

The enzyme-based activity profile of *C. anatina* has a higher degree of similarity to *O. rhinotracheale* than to the riemerellae. The main features that allow the differentiation of *C. anatina* from *O. rhinotracheale* are the presence of catalase and α-L-fucosidase activity, esculin hydrolysis, and the absence of urease activity. However, it should be considered that 1–4% of the *O. rhinotracheale* field strains give a positive catalase reaction.

In contrast to *R. anatipestifer* and *R. columbina*, *C. anatina* strains display nearly identical carbohydrate acidification patterns when the test results in conventional biochemical and buffered single substrate test systems are compared. *Coenonia anatina* can be distinguished from riemerellae in being gelatinase negative and hyaluronidase, chondroitin sulfatase, *N*-acetyl-β-glucosaminidase and α-L-fucosidase positive.

Ornithobacterium rhinotracheale

Clinical signs and lesions are of little value for diagnosis since many other infectious agents can produce similar clinical signs and post-mortem lesions. Accurate diagnosis must be substantiated by direct detection or cultural isolation of the causative bacteria and/or indirectly through

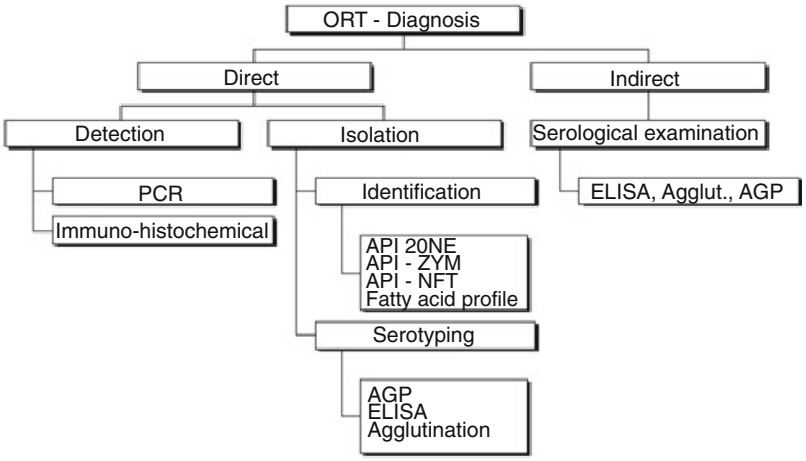

Fig. 3. Algorithm for specific laboratory diagnosis of *O. rhinotracheale* (Hafez, 2002). PCR, polymerase chain reaction; ELISA, enzyme-linked immunosorbent assay; ORT, *Ornithobacter rhinotrachaele*; and AGP, agar gel precipitation.

detection of antibodies using serological examination (Fig. 3).

Ornithobacterium rhinotracheale cells are Gram-negative pleomorphic rods. They produce oxidase but not indole. Nearly all isolates are β-galactosidase (ortho-nitrophenyl-β-D-galactoside; ONPG) positive and catalase negative, and most of them reacted positively in the urease test. However, Ryll et al. (2002) were able to isolate and identify a cytochrome-oxidase negative strain of *O. rhinotracheale* from turkeys.

Biochemical examination using commercial biochemical API 20 NE test-kit (Bio-Mérieux, France, or API 20 NFT, United States) revealed for 99.5% of *O. rhinotracheale* strains a reaction code of 022 000 4 (61%) or 002 000 4 (38.5%). Further identification could be carried out using API ZYM test system or fatty acid profile. Another commercial identification system, the RapID NF Plus system (Innovative Diagnostics, United States), gave high identification scores (Biocodes 4-7-2-2-6-4, 4-7-6-2-6-4, 6-7-6-2-6-4 or 7-2-2-6-4) when 110 strains were tested.

A specific polymerase chain reaction (PCR) test can be performed for the direct detection of *O. rhinotracheale* using the primer combination OR16S-F1 (5′-GAG AAT TAA TTT ACG GAT TAA G) and OR16S-R1 (5′-TTC GCT TGG TCT CCG AAG AT). This combination amplifies a 784-bp fragment of the 16S rRNA gene of *O. rhinotracheale,* but not of other closely related bacteria with which *O. rhinotracheale* could be confused (Van Empel, 1998a; Hung and Alvarado, 2001). This PCR assay needs optimization for the direct demonstration of *O. rhinotracheale* in diagnostic material. A sensitive immunohistochemical staining procedure was described by Van Empel et al. (1999b). Using this procedure, it was found that *O. rhinotracheale* was the cause of 70% of the cases with respiratory symptoms in broiler chickens, while by cultural and/or serological examination only 30% of the cases could be associated to *O. rhinotracheale* (Van Empel et al., 1999b).

Serological examination for indirect detection of *O. rhinotracheale* through the presence of antibodies in blood serum of birds can be carried out using a slide agglutination test prepared from different serovars, ELISA-tests, or dot-immunobinding assay (Erganis et al., 2002). The serotype specificity of the ELISA depends on the method of antigen extraction used for coating the ELISA plates. Boiled extract antigens are serotype-specific (Van Empel et al., 1997), while antigen extraction with sodium dodecyl sulfate (SDS-antigen) results in more cross-reactions (Hafez and Sting, 1999a). Self made ELISA (SDS-extraction) as well as two commercially available ELISA-kits (Biocheck and IDEXX) allowed detection of antibodies against all tested *O. rhinotracheale* serovars (Hafez et al., 2000). Generally, using ELISA, antibodies against *O. rhinotracheale* can be detected in serum and egg yolk shortly after infection, and titers will peak between 1 and 4 weeks postinfection (Van Empel et al., 1996). Because titers decline rapidly after peaking, serum samples for flock screening should be taken frequently.

Ornithobacterium rhinotracheale isolates have been subtyped through serology and DNA fingerprinting (Hafez and Beyer, 1997). Serotyping approaches included specific antisera in agar gel precipitation, ELISA, and rapid slide agglutination (Back et al., 1998; Bock et al., 1997; Van Empel et al., 1997; Van Empel, 1998a; Hafez and Sting, 1999a). Currently 18 serovars designated "A" to "R" have been reported. Most chicken isolates belong to serovar A, whereas turkey isolates are more heterogeneous and belong to serovars A, B and D (Van Empel and Hafez, 1999a). *Ornithobacterium rhinotracheale* isolates have also been typed by using several DNA fingerprinting methods including multilocus enzyme electrophoresis, ribotyping, random-

amplified-polymorphic-DNA (RAPD) and rep-PCR (Amonsin et al., 1997; Hafez and Beyer, 1997; Leroy-Sétrin et al., 1998; Hung and Alvarado, 2001).

Habitat, Epidemiology and Disease

Riemerella anatipestifer and *R. columbina*

NATURAL HABITAT. *Riemerella anatipestifer* is distributed worldwide in a wide spectrum of hosts. It has been isolated from domesticated ducks, geese, turkeys, chickens and budgerigars as well as from wild Anatidae but also from pheasants, guinea fowl, quail, partridges, guillemots, gulls and the lungs of domesticated pigs with severe pneumonia. *Riemerella anatipestifer* may persist on the mucosa of the upper respiratory tract and pharynx of clinically healthy birds (Ryll et al., 2001).

There are no indications that this organism can multiply outside the host in the environment.

EPIDEMIOLOGY. Riemerellosis is primarily a disease of young domestic ducks and geese, but affects also turkeys and sporadically chickens and pheasants. It is unknown how *R. anatipestifer* is introduced into the flock. The microorganism is probably egg-transmitted, with lateral spread most commonly via the respiratory route. Adverse environmental conditions and concomitant infections often predispose birds to outbreaks of the disease. At present, there is no information on the epidemiology of *R. columbina*.

DISEASE. The clinical signs reflect the involvement of *R. anatipestifer* with both the respiratory tract and the nervous system. In duckling flocks, outbreaks of the disease appear mostly between the second and eighth, seldom up to tenth, week of age. Signs most observed in an acute case are ocular and nasal discharge and greenish diarrhea. As the disease progresses, leg weakness, ataxia, tremor of the head and neck, loss of equilibrium, and torticollis become the prominent signs.

The mortality ranges between 1 and 10%. Surviving birds may be stunted.

The most obvious gross lesion is fibrinous exudate, which covers serosal surfaces in general, but is most evident in pericardial cavity and over the surface of liver and airsac. The fibrin contains a few inflammatory cells, primarily mononuclear cells and heterophils. The spleen may be enlarged and mottled. Fibrinous meningitis in both acute and subacute phase may be found. Localized inflammations usually occur in the skin and joints.

The present knowledge on the significance of *R. columbina* as a pathogen is limited. The clinical signs and gross lesions indicate the involvement of *R. columbina* as a pathogenic agent in the genesis of severe respiratory disease of pigeons.

Coenonia anatina

NATURAL HABITAT. *Coenonia anatina* has been found in anatine birds from Germany, England and Thailand. It has been grown from samples of commercial ducks, muscovy ducks, geese, and in one case, also from a single pigeon (B. Köhler, personal communication). *Coenonia anatina* may persist on the mucosa of the upper respiratory tract. There are no indications for its multiplication outside the host in the environment.

The isolation of *C. anatina* as pure culture, or together with *R. anatipestifer*, *Salmonella enteritidis* or *E. coli*, from samples of the respiratory tract (pneumonic lungs, air sac fibrin and pericardium) and brain of ducks and geese was always associated with signs similar to those of the *R. anatipestifer*-associated exudative septicemia.

Coenonia anatina was recovered from over 30% of the cases of septicemia-related losses in commercial duck flocks of the northern part of Germany in the period 1994–1995. Vaccination with inactivated whole-cells induced specific protection in ducklings. All these data and observations support its etiological involvement in the pathological process of diseases, which have been seen under field conditions (Vandamme et al., 1999).

With regard to the epidemiology, pathogenicity, disease and treatment, no further scientific findings are available at present.

Ornithobacterium rhinotracheale

NATURAL HABITAT. *Ornithobacterium rhinotracheale* has been isolated from chickens, chukar partridges, ducks, geese, guinea fowl, gulls, ostriches, partridges, pheasants, pigeons, quail, rooks and turkeys. Results of molecular epidemiological investigation indicate that the majority of *O. rhinotracheale* isolates recovered from domesticated poultry worldwide are represented by a small group of closely related clones and suggest that it was recently introduced to domesticated poultry from wild bird population (Amonsin et al., 1997).

EPIDEMIOLOGY. The disease is spread horizontally by direct and indirect contact through aerosols or drinking water. Vertical transmission is suspected, since some workers have isolated *O. rhinotracheale* in isolated cases from reproductive organs and hatching eggs, infertile eggs, and dead embryos after experimental infection.

DISEASE. The severity of clinical signs, duration of the disease and mortality are extremely variable and are influenced by many environ-

mental factors such as poor management, inadequate ventilation, high stocking density, poor litter conditions, poor hygiene, high ammonia level, concurrent diseases, and the type of secondary infection. Outbreaks in turkey flocks have been observed mostly in male birds over 14 weeks of age. However, in many cases, the disease also affected young poults (2–8 weeks old). The mortality ranges between 1–15% during the acute phase (8 days). Initial symptoms are coughing, sneezing and nasal discharge followed in some cases by severe respiratory distress, dyspnea, prostration and sinusitis. The symptoms are accompanied with a reduction in feed consumption and water intake. In turkey breeder flocks, clinical signs are accompanied mostly with drops in egg production and increases in the number of unsettable hatching eggs. Clinical signs in broilers generally appear between the third and fourth week of age with a mortality rate of 2–10%. The clinical signs are depression, decrease in food intake, reduced weight gains, transit nasal discharge, and sneezing, followed by facial edema. In broiler breeders and layers, the disease primarily affects the birds at the peak of production, mostly between age 24 and 52 weeks. The first signs are mild respiratory symptoms. The mortality is variable and relatively low in uncomplicated cases. Gross lesions are similar to those seen in fowl cholera in turkeys but to lesser extent. They are characterized by uni- or bilateral fibrinopurulent pneumonia and airsacculitis. Mild tracheitis, pericarditis and enteritis may also be detected.

Pathogenicity

Riemerella anatipestifer is a bacterial pathogen that causes a fatal septicemic disease primarily in ducklings and less frequently in goslings and turkey poults and only sporadically in chicks. Possibly it is also pathogenic for domesticated pigs.

The disease can experimentally be reproduced in healthy ducks by exposure to *R. anatipestifer*. The age of the bird, its genetically determined susceptibility and immune status, as well as the potential virulence of *R. anatipestifer* play an important role in the severity of the disease, which can be established most consistently by parenteral (e.g., intravenous, subcutaneous, or airsac) injection of the microorganism. On the basis of the difference in incidence, severity and extent of the disease, strains can be classified into four categories: highly virulent, virulent, slightly virulent, and avirulent.

To date, little is known on the possible virulence factors of *R. anatipestifer* involved in the pathogenesis of the disease. Obviously, factors exist that correlate with virulence as not all strains have the capacity to induce a disease. The production of a fibrinolytic enzyme (Bangun et al., 1981) and hemolysin by some strains may increase their invasiveness. Chang et al. (1998) described five different plasmid DNA profiles among *R. anatipestifer* strains. A 3.9-kb plasmid, designated "pCFC 1," seemed to be a virulence factor. This plasmid contained at least four open reading frames (ORFs) designated "*vap*D," two of which (*vap*D1 and *vap*D2) encoded proteins homologous to virulence-associated proteins of chromosomal origin that have been found in other pathogens such as *Dichelobacter nodosus*, *Haemophilus influenzae*, *Actinobacillus actinomycetemcomitans* and *Neisseria gonorrhoeae*. Weng et al. (1999) subsequently identified a virulence-associated protein homolog gene and a novel insertion sequence element, designated "ISRa1," in a second plasmid of 5.6 kb, pCFC2. The complete sequence of pCFC2 had a 28% G+C content and three large ORFs. ISRa1 was flanked by 15-bp imperfect inverted repeats and contained an ORF encoding a putative transposase of 292 amino acids. Southern blot analysis indicated that in *R. anatipestifer* strains examined, ISRa1 was present with at least 2–20 copies. Crasta et al. (2002) identified and characterized the genetic determinant (*cam*) of the cyclic AMP (CAMP) cohemolysin as a potential virulence factor.

Ornithobacterium rhinotracheale is a severe respiratory pathogen. Strains isolated from turkeys, chickens or partridges were used for aerosol challenges of both turkeys and broilers of various ages (Van Empel et al., 1996). Under experimental conditions, the most severe symptoms and pneumonic lesions were produced in turkeys when *O. rhinotracheale* was inoculated following exposure to *Bordetella avium*, *E. coli* O78:H9, turkey rhinotracheitis virus, Newcastle disease virus, infectious bronchitis virus as well as *Chlamydophila psittaci*. Neither the origin nor the serovar of the *O. rhinotracheale* strains had an effect on the pathogenicity (Van Empel and Hafez, 1999a). In other studies, airsacculitis, pneumonia, and increased mortality were observed after aerosol, intratracheal, intravenous and/or intrathoracal inoculation without a primer (Ryll et al., 1997; Sprenger et al., 1998).

Treatment

Riemerella anatipestifer and *R. columbina*

ANTIMICROBIAL SUSCEPTIBILITY. Most strains of *R. anatipestifer* are susceptible to enrofloxacin, amoxicillin, chloramphenicol, novobiocin, spiramycin, lincomycin and tetracyclines. Strains were often resistant to penicillin G, streptomycin and sulfonamides. Recently, an increase

in multiresistant strains has been observed (Köhler et al., 1995). More than 90% of the strains are resistant to kanamycin, colistin, gentamycin, neomycin and polymyxin B.

There are indications that the susceptibility of *R. columbina* is similar to that of *R. anatipestifer*.

ANTIMICROBIAL TREATMENT. The bacterial agent responds to drugs added to drinking water or parenterally injected. However, the degree of success varies among antibacterial drugs. Satisfactory treatment of acute riemerellosis is achieved if medication is started immediately after onset of clinical signs. Treatment is of considerable value in preventing disastrous losses when other control measures fail.

VACCINATION. Formalin-inactivated bacterin has been found effective for immunization of ducklings. Since immunity induced by bacterin is serovar-specific, bacterin should contain cells of predominant serovars (i.e., serovar 1) to provide an effective protection. Ducklings are vaccinated at 2–3 weeks of age.

The best results in ducklings are obtained by vaccination of the female breeder duck flocks. This induces maternally derived antibody levels in their progeny, resulting in significant protection for 2–3 weeks.

A live vaccine has been reported to provide significant protection against riemerellosis when administered to 1-day-old ducklings by aerosol or drinking water. A single vaccination provided protection for at least 42 days (Sandhu, 1991). The generation of protective immunity against *R. anatipestifer* infection in ducks has been investigated by immunizations with recombinant glutathione sulfatransferase (GST) fusion proteins consisting of OmpA (a 42-kDa major outer membrane protein) and P45N′ (a 41-kDa N-terminal fragment of a newly identified 45-kDa potential surface protein from *R. anatipestifer*; Huang et al., 2002). The DNAs encoding OmpA and P45N′ were isolated from *R. anatipestifer* serotype 15 (field strain 110/89) and serotype 19 (reference strain 30/90), respectively. Immunoblotting and ELISA results showed that the purified recombinant proteins induced the production of antibodies in immunized ducks. However, neither was protective against subsequent challenge with the virulent serotype 15 strain 34/90. All the five ducks immunized with formalinized *R. anatipestifer* strain 34/90 survived the challenge with the homologous strain, whereas six out of seven ducks in the nonimmunized control group died within a week following the challenge.

Ornithobacterium rhinotracheale

ANTIMICROBIAL SUSCEPTIBILITY. Several studies on antimicrobial resistance profiles of *O. rhinotracheale* have been published (Hafez et al., 1993; Devriese et al., 1995; Malik et al., 2003; Soriano et al., 2003).

In 1995, Devriese et al. reported on exceptionally high levels of acquired resistance to various groups of antibiotics including penicillin-cephalosporin, lincosamide and macrolide, and fluoroquinolone antibiotics in Belgium. Malik et al. (2003) examined in vitro antibiotic resistance profiles of 125 isolates of *O. rhinotracheale* isolated from turkeys in Minnesota during 1996–2002. A majority of isolates was sensitive to clindamycin, erythromycin, spectinomycin and ampicillin. Resistance against sulfachloropyridazine decreased from 1996 to 2002, but an increase in resistance was seen against gentamycin, ampicillin, trimethoprim sulfa, and tetracycline. The resistance against penicillin remained constant from year to year. Soriano et al. (2003) determined the minimal inhibitory concentrations of 10 antimicrobial drugs for Mexican isolates and found a marked resistance trend. The susceptibility of *O. rhinotracheale* to amoxicillin, enrofloxacin, and oxytetracycline was variable. However, consistent higher minimal inhibitory concentration values were obtained for gentamycin, fosfomycin, trimethoprim, sulfamethazine, sulfamerazine, sulfaquinoxaline, and sulfachloropyridazine.

In Germany (own results), all tested *O. rhinotracheale* isolates (100%) showed high sensitivity to amoxicillin, chloramphenicol and chlortetracycline. About 90 and 36% of the isolates were found to be sensitive to erythromycin and furazolidone, respectively. In addition, only 6% of tested isolates were found to be sensitive to enrofloxacin. None of isolates were susceptible to apramycin, neomycin, gentamycin and sulfonamide/trimethoprine (Hafez, et al., 1993). The sensitivity to enrofloxacin seems to be origin-related, since most of turkey isolates from Germany and the Netherlands are resistant, while 98% of strains from France and 71% of isolates from Belgium are sensitive to enrofloxacin.

ANTIMICROBIAL TREATMENT. The treatment of infections with antibiotics is very difficult because of the inconsistent sensitivity of the strains and regional variation in the sensitivity of *O. rhinotracheale* to antibiotics. It is advisable in all cases to estimate the sensitivity of strain involved. Under field conditions, however, water medication using amoxicillin at a dose level of 250 ppm for 3–7 days gives satisfactory results.

CONTROL. *Ornithobacterium rhinotracheale* is highly sensitive to different chemical disinfectants. Preparations of VENNO-VET 1 super (based on different organic acids [formic and glyoxyl acids]) and VENNO-FF super (containing different aldehydes) allowed in vitro inactivation

of *O. rhinotracheale* at concentrations of 0.5% within 15 minutes (Hafez and Schulze, 2003). However, currently, *O. rhinotracheale* infection appears to have become endemic and can affect every new restocking even in previously cleaned and disinfected houses, especially in areas with intensive poultry production as well as on multiple age farms. Failure to clean and disinfect properly after an infected flock has left can cause infection of neighboring flocks and the continuous cycling of the causative agent from house to house.

VACCINATION. Several attempts to combat the disease using vaccines were carried out with different results. Vaccination trials using autogenous bacterins successfully reduced the number of outbreaks of *O. rhinotracheale* infections in turkey flocks in the field (Bock et al., 1997). Vaccination trials using inactivated vaccine in mineral oil adjuvant in broiler, in broiler breeders as well as in turkey flocks were carried out. The early results are promising, and the vaccine gives good protection (Van Empel and Van den Bosch, 1998b; Hafez et al., 1999b). Live vaccination is also feasible, but up to now, no nonvirulent strains of *O. rhinotracheale* have been found. A temperature sensitive mutant of *O. rhinotracheale* has some protective properties, but more tests are needed to evaluate the efficacy and safety of this strain (Lopes et al., 2002). Currently, inactivated vaccine in mineral oil adjuvant for broiler breeders (Intervet) is commercially available.

CHAPTER 6.15

The Genus *Capnocytophaga*

E. R. LEADBETTER

Introduction/Habitat

Bacteria included in the genus *Capnocytophaga* typically are aerotolerant anaerobes with a requirement for significant quantities of carbon dioxide (CO_2) for initiation of growth—aerobic as well as anaerobic—and with the ability to form thin, spreading colonies (i.e., exhibit surface translocation) on solid media. They are common inhabitants of dental plaque in the oral cavities of mammals, from which they can be isolated in instances of periodontal diseases as well as from healthy individuals (Paster et al., 2001); they are less frequently isolated from lesions resulting from dog and cat bites and from inadvertant oral microbial contamination of open wounds (e.g., Chadha and Brady, 1999; Alexandrakis et al., 2000; Phibbs et al., 2002).

Seven species of the genus are presently recognized (*C. ochracea*, *gingivalis*, *sputigena*, *canimorsus*, *cynodegmi*, *hemolytica* and *granulosa*) on the basis of several polyphasic analyses including phenotypic trait analysis, 16S rRNA analysis, DNA-DNA hybridization, fatty acyl composition of cell lipids and cellular protein profiles (Williams and Hammond, 1979a; Vandamme et al., 1996).

Shortly after the initial characterization of isolates and grouping into three species (*C. ochracea*—the type strain, *C. gingivalis* and *C. sputigena*; Leadbetter et al., 1979), it was noted that strains otherwise uncategorized (known as "dysgonic fermenters," e.g., group DF-1 of the United States Centers for Disease Control and Prevention [CDC]) should properly be considered *Capnocytophaga* (Williams et al., 1979b).

Several DF-2 and DF-2-like isolates came to be considered identical to strains isolated from the mouths of dogs and were termed "*C. canimorsus*" and "*C. cynodegmi*" (Brenner et al. 1989), even though these latter species (unlike the type strain and other species) possessed catalase and oxidase activities. The properties of the Gram-negative fusiform cells in CDC group DF-3 resemble but are not identical to those of DF-1 and DF-2; these strains are not presently considered capnocytophagas (Vandamme et al., 1996).

Human oral cavity isolates labeled originally *Sphaerocytophaga* (Graf, 1961; Graf, 1962) and *Bacteroides oralis* var. *elongatus* (Loesche et al., 1964) were so regarded probably because their traits were incompletely described, unrecognized, or of mistaken significance; such strains are now regarded as *Capnocytophaga*. Their DNA G+C content is 36–44 mol%.

As revealed by phylogenetic analyses of 16S rRNA, the seven species are quite closely related (see Bernadet et al., 2002) and constitute a cohesive subgroup of the proposed family Flavobacteriaceae.

As originally noted (Holt et al., 1979b), *Capnocytophaga* cells are judged Gram-negative both from actual staining results and from transmission electron microscopic analysis of the cell envelope. Surface appendages such as flagella or pili have not been observed, nor have significant intracellular inclusions regularly been reported.

The slender rods (ca. 0.6 μm × 4–7 μm) appear to have smooth, blunt, rounded poles when unstained preparations are viewed by phase-contrast optics, but cells stained for light microscopic examination appear with pointed ends and irregular surface "blebs" apparently resulting from cell distortion during the drying and staining procedures (Holt et al., 1979b).

Physiological, Biochemical and Chemotaxonomic Properties

As noted, these bacteria are able to initiate colonial growth in air, or in its absence, provided elevated concentrations (5–10%, v/v) of CO_2 are available. Samples streaked from dental plaques form thin "lens-paper" gray colonial growth (best observed with oblique illumination) that spreads beyond the streak-lines as a result of gliding motility. Such growth is usually seen best on trypticase soy, brain heart infusion, or Todd-Hewitt agar supplemented with sheep or other blood (Leadbetter et al., 1979; Vandamme et al.,

1996). Upon transfer of such growth, more luxuriant growth occurs, and growth on the streaklines appears as gray, pink or iridescent, but cell masses removed by scraping are yellow. The different colonial hues are considered to result from the arrangement of cells of different sizes and this arrangement is characteristic for each of the species (Holt et al., 1979a). Cell masses collected from liquid cultures are likewise yellow; the pigment is considered to be of flexirubin-type although detailed chemical analysis of the capnocytophaga pigment has not been reported, and not all species have been shown to become red or pink when treated with 10% (w/v) KOH; this latter color change is considered indicative of flexirubins.

The growth requirement for CO_2, added as bicarbonate to liquid media, is not readily apparent when inocula are large masses of cells from colonies or from another liquid culture. This seemingly occurs because the inoculated population is sufficiently large and metabolically active to generate enough CO_2 to enable growth.

Acetate and succinate are the other major metabolic end products. The relationship between the need for larger-than-normal amounts of CO_2 and a role for CO_2 in a truncated propionic-type fermentation (accumulation of succinate) was at first inferred (Leadbetter et al., 1979) and later experimentally established (Calmes et al., 1980). In addition, the decarboxylation of pyruvate was experimentally established to account for acetate and CO_2 production (Kapke et al., 1980).

Although it is generally regarded that capnocytophagal growth in the presence of air is a result of fermentation rather than respiration, a single persuasive study (Spratt et al., 1996) demonstrates that the cell yield of *C. gingivalis* growth with glucose is comparable to that of other aerobic heterotrophs growing via respiration. Given this result, and the probable reduction of fumarate in accounting for succinate formation, it may be more appropriate to consider *Capnocytophaga* physiology not as fermentative but rather respiratory (either aerobic or anaerobic). The presence of benzidine-reactive components (cytochromes?) along with the assumed activities of respiratory quinone (primarily menaquinone-6) seems consistent with such an argument for respiration.

The capnocytophagas were first noted to contain unusually (at that time) large amounts of odd-number, *iso* and *anteiso*-branched, hydroxylated fatty acyl moieties. These have been shown to be characteristic components of the novel sulfonolipids ("capnoids: capnine and *N*-acyl capnine") that constitute as much as 20% of the total cell lipid (Godchaux and Leadbetter, 1980). Lipid of this type and quantity is a common feature of many cytophaga and flavobacters and may be a useful chemotaxonomic marker for certain flavobacterial subgroups although little attention has been given this possibility. In *Flavobacterium johnsoniae* the dominant *N*-acyl capnine (Godchaux and Leadbetter, 1984) is located in the cells' outer membrane (Godchaux and Leadbetter, 1988), where it may function in interacting with the solid substrata over which cells glide. The presence of *N*-acyl capnine has been shown to be a molecular correlate of gliding motility in this bacterium (Abbanat et al., 1986). The capnoids are largely localized in the cell envelope of *C. gingivalis*, where a similar role in gliding motility was postulated (Godchaux and Leadbetter, 1980).

The capnocytophagas, like so many other surface-translocating ("gliding") bacteria (Dworkin, 1969), are susceptible to growth inhibition by the antibiotic actinomycin D; this susceptibility is not common in nongliding Gram-negative bacteria.

The growth-inhibiting ability of an array of other antibiotics has been examined repeatedly (see Holt and Kinder [1989] and Roscoe et al. [1992]), reflecting the significance of capnocytophagas in various infections in the oral cavity, certain septicemal infections, and a few other uncommon disease states (Paster et al., 2002).

β-Lactam antibiotics have been considered efficacious therapeutic agents, but the emergence of novel β-lactamases frequently has rendered these drugs ineffective. Employing β-lactamase inhibitors in conjunction with β-lactam antibiotics and others (such as clindamycin, imipenem or ciprofloxin) is now considered desirable therapy.

Isolation and Maintenance

Isolation from mammalian oral cavities and infection sites (Rolph et al., 2001) such as the eye, abscesses, and bloodstream is best achieved by streak-plating samples on a medium such as trypticase soy-sheep blood agar, incubating in an anaerobic environment with an elevated CO_2 content (a classic candle-jar, for example) at 35–37°C for 3–5 days and then visually examining the agar surface for very thin (not typical, elevated) colonies that spread beyond the streakline where cells had been deposited. Such growth often is not apparent unless oblique illumination is employed. Not all blood agar media support colony spreading and instead only quite small (1 mm) colonies develop (see Holt and Kinder [1989] and Leadbetter et al. [1979]); the factors affecting colony spread have not been studied extensively, although addition of blood to media is not essential.

CHAPTER 6.16

The Genera *Rhodothermus*, *Thermonema*, *Hymenobacter* and *Salinibacter*

AHARON OREN

Introduction

The genera *Rhodothermus*, *Thermonema*, *Hymenobacter*, and *Salinibacter* all consist of Gram-negative, red- or yellow-pigmented obligatory aerobic chemoheterotrophic bacteria. The first two genera are thermophilic, with temperature optima around 60–65°C; *Hymenobacter* and related strains described in the past as "Taxeobacter" species are oligotrophic soil bacteria, some of them isolated from cold environments in the Antarctic. Finally, *Salinibacter* is a genus of extremely halophilic red bacteria that are among the most salt-tolerant and salt-requiring strains within the bacterial domain. Phylogenetically they all form deep branches affiliated with the *Cytophaga-Flavobacterium-Bacteroides* branch of the Bacteria (Fig. 1 shows *Thermonema* and *Rhodothermus*, Figs. 2 and 3 show *Hymenobacter* and *Salinibacter*).

While relatively little is known about the properties of *Thermonema* and *Hymenobacter*, extensive research has been devoted to *Rhodothermus* in view of its production of thermotolerant cellulases, xylanases, and other biotechnologically potentially valuable thermophilic enzymes. The extremely halophilic *Salinibacter* was only recently discovered, but it has become evident that *Salinibacter* makes a significant contribution to the biota of NaCl-saturated saltern crystallizer ponds. The species is of considerable interest in view of its mode of osmotic adaptation, which differs from that of the other aerobic halophiles within the domain Bacteria. Unexpectedly, it shares many properties with the extremely halophilic representatives of the archaeal order Halobacteriales.

The Genus *Rhodothermus*

Rhodothermus marinus, the type species of the genus *Rhodothermus* and presently the only recognized species of the genus, was first isolated from shallow-water submarine hot springs in Iceland (Alfredsson et al., 1988; Kristjánsson and Alfredsson, 1992). It is a thermophile that grows optimally at 65°C and tolerates up to 77°C for growth. Similar isolates have since been obtained from a variety of thermal environments on the Azores (Nunes et al., 1992a) and in Japan (Sako et al., 1996). Since it was discovered that *Rhodothermus* strains possess thermophilic cellulase and xylanase activities, as well as other thermophilic enzymatic activities of potential biotechnological interest, much study has been devoted to the genus.

Taxonomy and Phylogeny

The type strain of *Rhodothermus marinus* (Alfredsson et al., 1988) is DSM 4252, ATCC 43812 (16S rDNA accession number X80994). The G+C content of its DNA is 64.4–64.7 mol%.

A second species, *R. obamensis*, was proposed by Sako et al. (1996) to accommodate a new isolate from a shallow marine hydrothermal environment in Tachibana Bay, Nagasaki Prefecture, Japan. The proposed type strain (OKD7 = JCM 9785) was claimed to differ sufficiently from *R. marinus* to warrant its description as a new species. The G+C content of its DNA was higher (66.6 mol%), and its 16S rDNA sequence was claimed to be only 95% similar to that of *R. marinus*. In addition, many additional differences were described, including differences in optimum temperature, cell size, and substrate utilization pattern (Table 1).

Silva et al. (2000) performed a critical comparative study of the type strains of *R. marinus* and *R. obamensis*. The higher salt tolerance of *R. marinus* as compared to *R. obamensis* was confirmed. However, no significant differences in optimum growth temperature were detected. Moreover, a great degree of similarity in the DNAs was found (DNA-DNA hybridization 78%), and renewed sequencing of the 16S rDNA

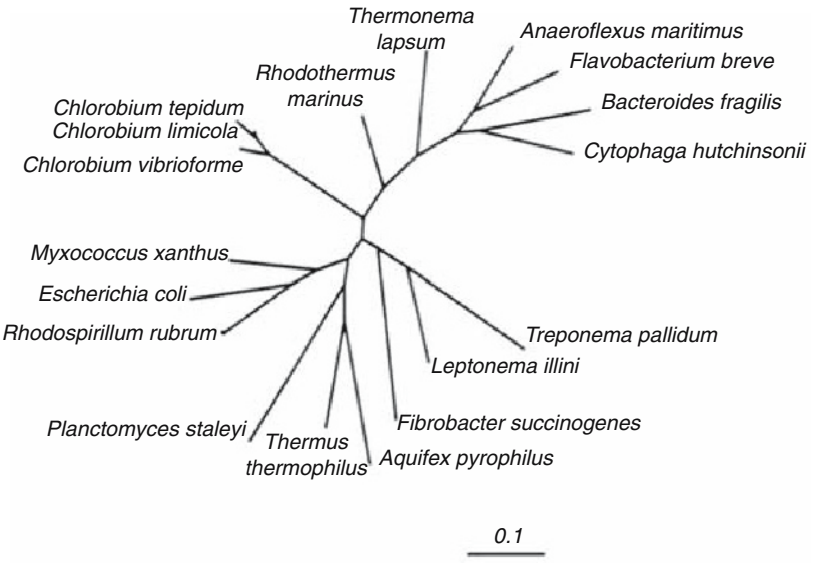

Fig. 1. Maximum-likelihood analysis of selected 16S rRNA sequences, showing the phylogenetic position of the genera *Rhodothermus* and *Thermonema* as deep branches related to the *Cytophaga-Flavobacterium-Bacteroides* branch of the domain Bacteria. The bar indicates the expected number of nucleotide substitutions per site. From Andrésson and Friðjónsson (1994); reproduced with permission.

The reconstruction is based on comparison of 16S rDNA sequences. Branching points that displayed significant bootstrap values (>75%) are indicated with asterisks. *Rhizobium radiobacter* was included as an outgroup. From Buczolits et al. (2002); reproduced with permission.

showed a much higher similarity (99.5%) than the value of 95% previously reported by Sako et al. (1996). The fatty acid profiles were also highly similar. In view of these findings, *R. obamensis* Sako et al. 1996 should be considered a junior heterotypic synonym of *Rhodothermus marinus* Alfredsson et al. 1995.

Data from Sako et al. (1996).

Ten strains very similar to the type strain of *R. marinus* were isolated from São Miguel, Azores (Nunes et al., 1992a). These isolates, together with 20 strains from shallow marine hot springs in Iceland and additional isolates obtained from Stufe di Nerone, Naples, Italy, were subjected to a comparative genomic study. Whole genome DNA-DNA hybridization confirmed that all strains investigated may be classified in a single species (77–89% similarity). Pulsed field gel electrophoresis using restriction enzymes *Ase*I and *Pme*I generated distinct electrophoretic patterns for most strains. Genome sizes of 3.3–3.6 MBp were calculated from the electrophoresis patterns. Ribotyping (restriction fragment length polymorphism of the rRNA genes) with restric-

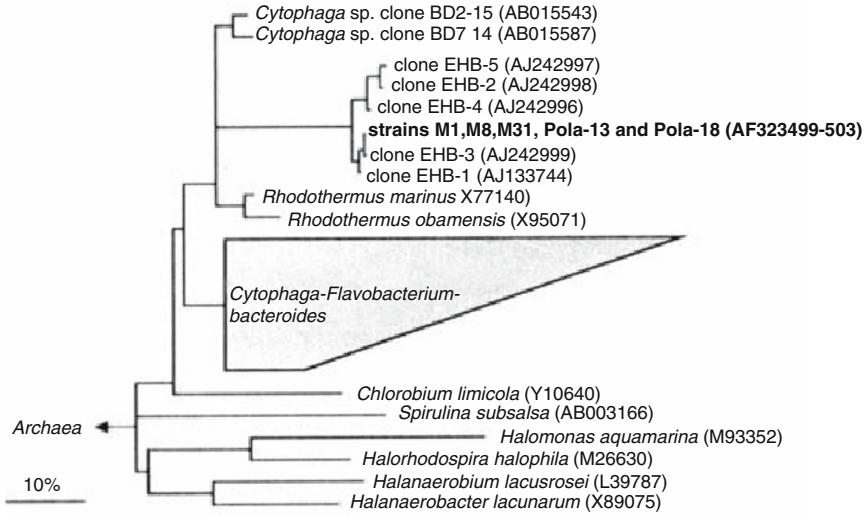

Fig. 3. Phylogenetic reconstruction based on 16S rDNA sequences from the strains and clones affiliated to *Salinibacter*. The tree is based on the results of a parsimony analysis including only complete or almost complete 16S rDNA sequences of all sequences of the *Cytophaga-Flavobacterium-Bacteroides* phylum available (over 400) and representatives of the domain Bacteria. The topology of the tree was corrected according to the results of distance matrix, maximum parsimony, and maximum likelihood analyses of various datasets. Multifurcations indicate where a topology could not be resolved unambiguously. The bar indicates 10% of estimated sequence divergence. From Antón et al. (2002); reproduced with permission.

tion enzymes *Eco*RI, *Pst*I, *Bam*HI, and *Hind*III produced several distinct ribotypes (Moreira et al., 1996).

The sequence of the single 16S rRNA gene of *R. marinus* reveals a distant relationship to the *Flexibacter-Cytophaga-Bacteroides* group (Andrésson and Friðjónsson, 1994; Fig. 1). The genome contains a single rRNA operon with an intergenic region coding for $tRNA^{Ile}$ and $tRNA^{Ala}$ between the 16S and 23S (Andrésson and Friðjónsson, 1994).

Morphological and Cultural Characteristics

Rhodothermus marinus is a Gram-negative rod-shaped bacterium (Fig. 4). Cells are generally 2–3 × 0.5 μm in size. When grown on carbohydrate-rich media, slime capsules may be formed around the cells (Alfredsson et al., 1988). Motility is rarely observed in liquid cultures, but the presence of a single polar flagellum was reported in strains isolated from São Miguel, Azores (Nunes et al., 1992a).

Rhodothermus marinus is a thermophile. The type strain grows up to 77°C, with an optimum at 65°C. No growth was observed below 54°C (Alfredsson et al., 1988). A claim for a higher temperature optimum for the strain originally designated "*R. obamensis*" (optimum 80°C, maximum 85°C; Sako et al., 1996) was not confirmed in a controlled comparative study (Silva et al., 2000). Under optimal growth conditions, growth rates of about 0.5 h^{-1} are reached (Alfredsson et al., 1988).

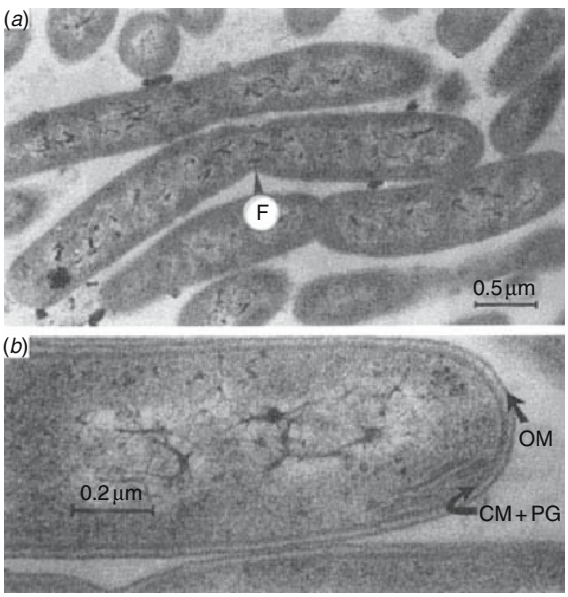

Fig. 4. Electron micrographs of *Rhodothermus marinus* strain R-18. (a) Thin longitudinal and cross-sections showing the width and length of typical cells as well as dividing cells with furrowing (F). (b) The cell envelope, consisting of a cytoplasmic membrane plus peptidoglycan layer (CM + PG) and a well-separated outer membrane (OM). From Alfredsson et al. (1988); reproduced with permission.

Rhodothermus strains require salt for growth. Optimal growth is achieved at 1–3% NaCl. Some strains, including the type strain, can grow above 6% NaCl (Alfredsson et al., 1988), while the isolate formerly designated "*R. obamensis*" toler-

ates up to 5% only (Sako et al., 1996; Silva et al., 2000). Growth is optimal in the neutral pH range.

Rhodothermus is an obligatory aerobic heterotroph that does not reduce nitrate. Substrates used for growth include common sugars, like glucose, mannose, galactose, sucrose, lactose, maltose, raffinose, cellobiose, sorbitol, mannitol and starch, and some carboxylic acids (acetate, lactate and pyruvate). Cellulose, xylans, and other complex polysaccharides can be broken down as well (see the section on biotechnological Applications in this Chapter). Proteins (casein and gelatin) and protein hydrolysates (casein, peptone, and casamino acids) can also serve as carbon and nitrogen sources, as can certain amino acids. Glutamate and aspartate are used by most strains examined, and some strains use other amino acids as well (Alfredsson et al., 1988; Nunes et al., 1992a; Sako et al., 1996).

Physiological, Biochemical and Chemotaxonomic Properties

With an optimum growth temperature of around 65°C and the ability to grow up to about 80°C, *Rhodothermus* is a true thermophile. When "*R. obamensis*" was exposed to supraoptimal temperatures (90–95°C), stress proteins were induced that improved survival. Putative heat shock proteins and high temperature growth-specific proteins have been detected. The putative heat shock proteins were similar to the ATP binding subunits of ATP-binding cassette (ABC) transporters, and the high temperature growth-specific proteins corresponded to domains II and III of elongation factor Tu (Takai et al., 1998a).

The thermal properties of many enzymes of *Rhodothermus* have been characterized, also in view of possible biotechnological applications. Tables 2 and 3 summarize some of these data.

The ability of *Rhodothermus* to produce thermophilic xylanases, cellulases, and other enzymes that hydrolyze complex polysaccharides has become the subject of in-depth studies because of their biotechnological potential. Table 3 summarizes some of the properties of the enzymes involved in polysaccharide metabolism, and further details are given below.

Rhodothermus marinus grows on xylan as carbon and energy source with a high rate (growth rate up to 0.43 h^{-1}). Under these conditions at least two thermostable xylanolytic enzymes are secreted into the medium, an endo-1,4-β-xylanase and a xylan 1,4-β-xylosidase (Dahlberg et al., 1993; Manelius et al., 1994). A multidomain endo-β-1,4-xylanase encoded by the gene *xyn1* was cloned and expressed in *Escherichia coli*. This protein contains five domains. Two carbohydrate-binding domains (CBDs) are repeated in tandem at the N-terminus. The *xyn1* gene is the first example encoding a CBD family IV in combination with a xylan hydrolyzing catalytic domain of the glycosyl hydrolase family 10. The enzyme binds specifically to xylan, to β-glucan, and to amorphous, but not to crystalline, cellulose (Nordberg Karlsson et al., 1996; Nordberg Karlsson et al., 1997; Nordberg Karlsson et al., 1998a). A truncated enzyme (411 amino acids + a 22-amino acid leader peptide) contains the catalytic domain only. The products of xylose degradation are mainly xylobiose and xylotetrose. The enzyme is optimally active at 80°C and pH 7.5. Under these conditions, its half-life is 100 min, but it can be further stabilized by 1 mM Ca^{2+}. The enzyme has no exo- or endo-cellulase activity (Nordberg Karlsson et al., 1998b). An efficient production protocol of the truncated *Rhodothermus* xylanase in *E. coli* has been designed, using fed-batch cultures (Nordberg Karlsson et al., 1999; Ramchuran et al., 2002). Optimization of the growth conditions enabled a yield of 35% of the intracellular protein being recombinant xylanase (Nordberg Karlsson et al., 1999). The two N-terminal carbohydrate-binding domains (CBM4-1 and CBM4-2) of the native xylanase have also been investigated in further depth, and they have been cloned and produced in *E. coli*. They bind to insoluble xylan and to phosphoric-acid-swollen cellulose, but not to Avicel or to crystalline cellulose (Abou Hachem et al., 2000). Binding of two ions of calcium to CBM4-2 increases its unfolding temperature by approximately 23°C (Abou Hachem et al., 2002). CBM4-2 has a β-sandwich structure formed by 11 strands and contains a prominent cleft which is the binding site for xylan (Simpson et al., 2002). High quality nuclear magnetic resonance (NMR) spectra of the domain now exist, enabling the assignment of virtually all ^{1}H, ^{13}C and ^{15}N resonances (Jamieson et al., 2002).

Rhodothermus marinus produces α-L-arabinofuranosidase when grown on yeast extract + birch wood xylan or some other polysaccharides and low-molecular-weight carbohydrates. This is the most thermostable arabinofuranosidase reported so far (Gomes et al., 2000).

Rhodothermus can also make a thermostable extracellular endocellulase. This endo-β-1,4-glucanase is active on carboxymethylcellulose but does not degrade Avicel, Sigmacell 10 cellulose, granular cellulose, *p*-nitrophenyl-β-D-cellobioside, or 4-methylumbelliferyl-β-D-cellobioside. Carboxymethylcellulose is split into glucose, cellobiose, cellotriose, and larger oligosaccharides (Hreggvidsson et al., 1996). A thermostable cellulase of glycosyl hydrolase family 12 from *R. marinus*, encoded by the gene *celA*, was cloned and overexpressed in *E. coli*. The recombinant enzyme showed activity on

Table 2. Thermal properties of selected enzymes of *Rhodothermus marinus* (including the strain formerly designated *R. obamensis*).

Enzyme	Thermal properties	Further details	References
Phosphoenol-pyruvate carboxylase	Optimum activity at 75°C; is rapidly inactivated at 100°C and gradually inactivated at 93°C; 50% of activity is left after 30 h at 80°C; the enzyme is stabilized at 93°C by the positive effector acetyl CoA and by the substrate phosphoenolpyruvate	The gene *ppc* coding for the enzyme was cloned and overexpressed in *Escherichia coli*; the native enzyme is a tetramer of 107.8-kDa subunits (each 937 amino acids); activity is optimal at pH 8.0	Takai et al., 1997a; Takai et al., 1997b; Takai et al., 1998b
Citrate synthase	Optimally active at 85°C; 20–30% of the optimal activity remains at 40°C; half life at 80°C, 2.9 and 28 min for the hexameric and the dimeric form, at 90°C, 18 and 12 min, respectively	There is a hexameric (280 kDa) and a dimeric (100 kDa) enzyme; the dimeric enzyme also has 2-methylcitrate synthase activity	Nordberg Karlsson et al., 2002
Ferredoxin	Highly stable; the midpoint for thermally induced unfolding is 102°C	A $[3Fe\text{-}4S]^{+1/0}$ ferredoxin with an apparent molecular mass of 9 kDa and an unusually low reduction potential of –650 mV; the molecule is very sensitive to oxygen; the function of this ferredoxin in *Rhodobacter* is yet unclear	Pereira et al., 2002
DNA polymerase I	Optimally active at 55°C; has a half life of 2 min at 90°C; four out of the 45 *Rhodothermus* strains tested had DNA Polymerase activity with >10% activity remaining after 30 min at 95°C	The 924-amino acid, 104.8-kDa protein has been cloned; it has DNA polymerization activity, 5′ → 3′ exonuclease activity, and 3′ → 5′ proofreading activity	Blöndal et al., 2000; Hjörleifsdóttir et al., 1997b
DNA ligase	None out of 9 strains tested had DNA ligase activity that was active after 30 min at 90°C. The purified enzyme was most active from 55 to 75°C. Its half life at 91°C was 7 min	The 712 amino acid, 79.5-kDa enzyme was cloned and overexpressed in *E. coli*; it has a higher DNA ligation efficiency than the enzyme from *Thermus scotoductus* and *Thermus thermophilus* at temperatures between 37 and 46°C	Hjörleifsdóttir et al., 1997b; Housby and Southem, 2002; Housby et al., 2000; Thorbjamardóttir et al., 1995
Type II thymidine kinase	Optimally active at 65°C; has a half life of 15 min at 90°C	The gene of this first thymidine kinase described from a thermophilic bacterium encodes a 213-amino acid, 23.6-kDa protein; the enzyme functions in the pyrimidine salvage pathway	Blöndal et al., 1999
Mannosylglycerate synthase	Optimally active at 85–90°C; upon incubation at 90°C, 50% of activity is lost in 30 min. At 65°C, the specific activity was fivefold lower than at the optimum temperature, and the half life for inactivation increased to 170 min.	The 46.1-kDa enzyme, encoded by the gene *mgs*, has been overexpressed in *E. coli*	Martins et al., 199

Table 3. Thermal properties of *Rhodothermus* enzymes involved in degradation of complex polysaccharides.

Enzyme	Thermal properties	Further details	References
Endo-1,4-β-xylanase	Half life 14h at 90°C and pH 7	None	Dahlberg et al., 1993
Xylan-1,4-β-xylosidase	Highest initial activity at 90°C; half life 45min at 90°C and pH 7, and 14h at 85°C	Apparent size 169kDa by gel filtration	Dahlberg et al., 1993; Manelius et al., 1994
Cellulase (extracellular endo-β-1,4-glucanase)	50% of activity remains after 3.5h at 100°C and 80% after 16h at 90°C	Apparent monomer of 49kDa; pH optimum 7	Hreggvidsson et al., 1996
Cellulase of glycosyl hydrolase family 12	Highest initial activity at 100°C; 75% of activity left after 8h at 90°C	A 260-amino acid, 28.8-kDa protein, encoded by the *celA* gene; pH optimum 6–7	Halldórsdóttir et al., 1988
Amylase	Optimally active at 85°C, pH 6.5–7; half life at 85°C 3h	None	Gomes et al., 2003
Pullulanase	Optimally active at 80°C, pH 6.5–7; half life at 85°C 30min	None	Gomes et al., 2003
β-Glucanase	Optimally active at 85°C, pH 7.0; fully active after 16h at 80°C, with a half life of 3h at 85°C	The mature enzyme (29.7kDa) is made with a 30-amino acid signal peptide	Spilliaert et al., 1994
Laminariase	Optimally active at 88°C and pH 5.5; stable for more than 2 days at 80°C	Encoded by the *lamR* gene	Krah et al., 1998 Petersen et al., 2000
Mannanase	Optimally active at 85°C and pH 5–6.5; half life of 45.3h at 85°C and 4.2h at 90°C	A 997-amino acid, 113-kDa protein	Gomes and Steiner, 1998; Politz et al., 2000
Branching enzyme (transglucosidase)	Optimally active at 65°C and pH 6–6.5; stable after 30 min at 80°C; 50% of activity is retained after 16 h at 80°C	The predicted protein of 621 amino acids, 72kDa, is probably an intracellular enzyme	Shinohara et al., 2001
α-Galactosidase	Optimally active at 85°C, with a broad pH range of 4–8; half life 2h at 75°C	The protein is a tetramer of 50-kDa subunits	Blücher et al., 2000
α-L-Arabinofuranosidase	Optimally active at 85°C and pH 5.5–7; half life 8.3 h at 85°C and 17 min at 90°C	None	Gomes et al., 2000

carboxymethylcellulose and lichenan, but not on birch xylan or laminarin (Halldórsdóttir et al., 1988). The catalytic module is preceded by a linker sequence and an N-terminal highly hydrophobic putative signal peptide. This signal peptide showed a marked cytotoxic activity to *E. coli*. Deletion of the part of the gene that encodes this signal peptide enabled highly increased production of recombinant cellulase, yielding a mutant protein with threefold higher specific activity than that of the full-length enzyme. The mutant protein (Cel12A) is highly thermostable, has a half life of over 2 h at 90°C, and can function to 103°C (Wicher et al., 2001). Production of this cellulase in *E. coli* was optimized in substrate limited fed-batch cultures of *E. coli* BL21(DE3) (Ramchuran et al., 2002). The structure of the protein has now been resolved to 1.8 Å (Crennell et al., 2002).

Rhodothermus produces a thermostable amylase and a pullulanase (a debranching enzyme that hydrolyzes α-1,6 linkages in dextrins; see Table 3). Growth in the presence of maltose (1.5 g/liter) + yeast extract (8.3 g/liter) resulted in optimal induction of these enzymes (Gomes et al., 2003). A thermostable β-glucanase encoded by the gene *bglA* was discovered in a gene library of *R. marinus* in *E. coli*. Two transformants produced halos on lichenan plates after Congo-red staining. The gene encodes a 29.7-kDa β-glucanase with a 30-amino acid signal peptide. An 889-bp fragment containing the catalytic domain was overexpressed in *E. coli*. The enzyme showed activity on lichenan, β-glucan and laminarin, but not on carboxymethylcellulose or xylan (Spilliaert et al., 1994).

In addition, a laminarinase (transglycosylating 1,3[4]-β-glucanase; the LamR protein) was found that cleaves the 1,3-β-linkages of 3-O-substituted β-glucose in β-glucans such as laminarin and curdlan and also the 1,4-β-linkages of 3-O-substituted β-glucose in β-glucans such as lichenin and 1,3-1,4-β-glucan from the cell walls of barley endosperm (Petersen et al., 2000). The *lamR* gene has been cloned and expressed in *E. coli*, and site-directed mutagenesis studies have been performed to identify the residues involved in the active center to elucidate the catalytic mechanism (Krah et al., 1998).

When grown in a medium containing locust bean gum + yeast extract, *R. marinus* produces a thermostable endo-(1,4)-β-mannanase (Gomes and Steiner, 1998). Screening of expression libraries for mannanase-positive clones led to the identification of the gene encoding a 997-residue, 113-kDa protein. The enzyme contains an N-terminal domain of unknown function and a C-terminal mannanase domain of 550 amino acids with homology to known mannanases of glucosidase family 26. The enzyme effectively hydrolyzes carob-galactomannan (locust bean gum) and to a smaller extent guar gum. Truncated enzymes of 45 or 50 kDa containing the catalytic domain only have been produced in *E. coli*. These were heat-stable as well and retained more than 70 and 25% of their initial activity after 1 h at 70°C and 90°C, respectively (Politz et al., 2000).

The gene encoding a novel thermostable branching enzyme (transglucosidase) was isolated from "*R. obamensis*." The predicted 621-amino acid 72-kDa protein has no signal sequence, so it probably is an intracellular enzyme. The gene has been expressed in *E. coli* and in the fungus *Aspergillus oryzae*. The enzyme produces α-1,6 branching linkages by a transglycosylation reaction of α-1,4-glucan. Activity was higher toward amylose than toward amylopectin (Shinohara et al., 2001).

On media with galactooligo- or polysaccharides as single carbon source, *R. marinus* produces a thermostable α-galactosidase that hydrolyzes both high- and low molecular weight galactosaccharides (Blücher et al., 2000).

Some other enzymes of *Rhodothermus* have been investigated at the protein and/or at the gene level: 1) DNA helicase, a protein predicted to harbor a 428-amino acid intein, is a close homologue of the DnaB intein in *Synechocystis* PCC6803 (Liu and Hu, 1997). 2) The 5-aminolevulinic acid dehydratase encoded by the *hemB* gene is a predicted 340-amino acid 37.4-kDa protein that shows homology with eubacterial and eukaryotic 5-aminolevulinic acid dehydratases (Gudmundsdóttir et al., 1999). 3) Different restriction endonucleases. The most often encountered type, named *Rma*I, is a type II restriction endonuclease that is an isoschizomer of *Mae*I and recognizes the sequence 5' C/TAG 3'(Rönkä et al., 1991). And finally, 4) other type LI restriction endonucleases detected during screening of a large number of *Rhodothermus* strains are isoschizomers of *Bst*B1 and *Eco*RV (Hjörleifsdóttir et al., 1997a).

In addition to its thermophilic properties, *Rhodothermus* is also a moderate halophile, requiring salt for growth and tolerating NaCl concentrations up to 5–6%. Its mode of osmotic adaptation has been investigated, and the organism was found to contain two novel organic osmotic solutes: 2-*O*-α-mannosylglycerate and 2-*O*-α-mannosylglyceramide (Fig. 5). α-Mannosylglycerate has also been detected in many other themophilic and hyperthermophilic Bacteria and Archaea (*Thermus*, *Rubrobacter*, *Methanothermus*, *Archaeoglobus* and *Aeropyrum*), but the amide has thus far been found only in *Rhodothermus* (Santos and da Costa, 2002). The α-mannosylglyceramide was originally incorrectly identified as 2-*O*-β-mannosylglycerate (Nunes et al., 1995), but the structure has been revised later (Silva et al., 1999). "*Rhodothermus obamensis*" was found to contain α-mannosylglycerate only and to lack the amide form (Silva et al., 1999). The intracellular K^+ concentration, as measured by ^{39}K NMR, increases with salinity and is sufficiently high to balance the negative charges of the mannosylglycerate. Glutamate, trehalose and glucose were found as minor components that may participate in osmotic stabilization of *Rhodothermus* (Nunes et al., 1995).

At relatively low growth temperatures application of water stress to *R. marinus* led to accumulation of α-mannosylglycerate and its amide, in addition to low levels of trehalose, glutamate and glucose. At the highest growth temperatures α-mannosylglycerate was the major compatible

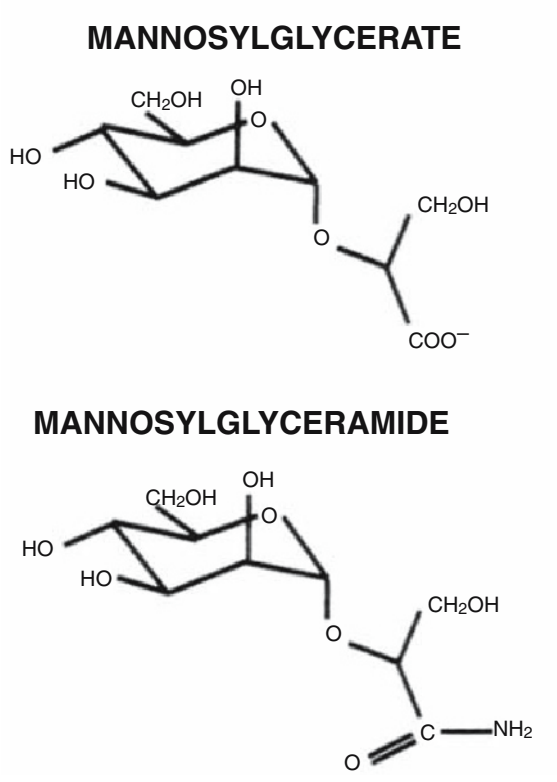

Fig. 5. Structures of mannosylglycerate and mannosylglyceramide. From Santos and da Costa (2002); reproduced with permission.

solute, and the amide was not detected (Silva et al., 1999). α-Mannosylglycerate accumulated in response to both supraoptimal temperatures and salinity, while α-mannosylglyceramide accumulated exclusively in response to salt stress (Nunes et al., 1995; Silva et al., 1999). The effectivity of α-mannosylglyceramide as a compatible solute, as judged by the stabilization of rabbit muscle lactate dehydrogenase against thermal inactivation, was less than that obtained with α-mannosylglycerate or hydroxyectoine, but similar to that of diglycerol phosphate (the compatible solute of *Archaeoglobus fulgidus*) and of trehalose (Borges et al., 2002).

On the basis of enzymatic activities detected and in vivo ^{13}C labeling experiments, the biosynthesis of α-mannosylglycerate in *Rhodothermus* was suggested to proceed via two alternative pathways (Fig. 6). In the first, guanosine-5′-diphosphate (GDP)-mannose is condensed with D-glycerate to produce α-mannosylglycerate in a single reaction catalyzed by mannosylglycerate synthase. In the other pathway, a mannosyl-3-phosphoglycerate synthase catalyzes the conversion of GDP-mannose and D-3-phosphoglycerate into a phosphorylated intermediate, which is then converted to mannosylglycerate by the action of a phosphatase. The activities of the enzymes of the pathway were not influenced by the NaCl concentration in the growth medium. However, the combined mannosyl-3-phosphoglycerate synthase/phosphatase system was optimally active only when NaCl or KCl had been added to the assay mixture (Martins et al., 1999).

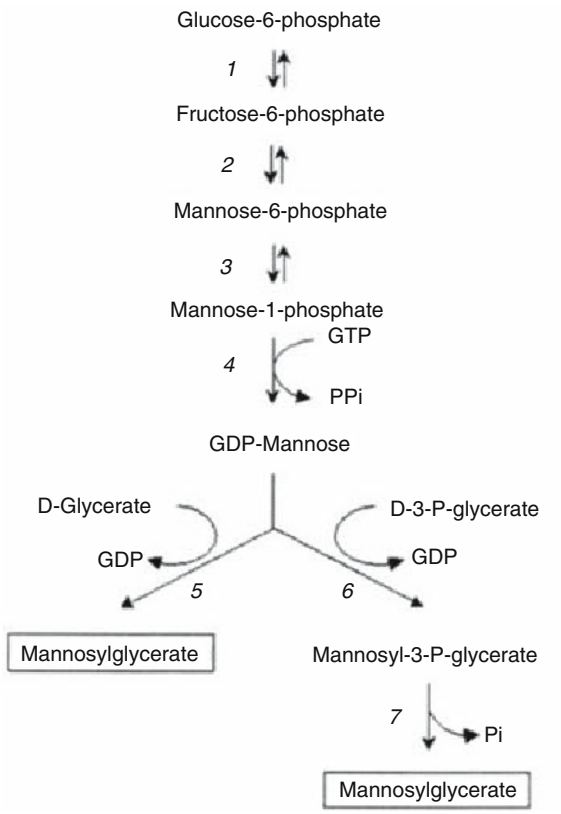

Fig. 6. Proposed pathways for the synthesis of mannosylglycerate in *Rhodothermus marinus*. 1, phosphoglucose isomerase; 2, phosphomannose isomerase; 3, phosphomannose mutase; 4, mannose-1-phosphate guanylyltransferase; 5, mannosylglycerate synthase; 6, mannosyl-3-phosphoglycerate synthase; and 7, mannosyl-3-phosphoglycerate phosphatase. From Martins et al. (1999); reproduced with permission.

The mannosylglycerate synthase of *Rhodothermus* has been purified, and the gene *mgs* that encodes it has been identified in a genome library. The gene, which codes for a 46.1-kDa protein, has been overexpressed in *E. coli*. The enzyme was optimally active at 85–90°C (see also Table 2) and has a broad pH optimum at 5.5–8.5 (Martins et al., 1999). Use of the *Rhodothermus msg* gene on a plasmid, combined with other genetic manipulations, enabled the production of high purity specifically labeled GDP-mannose and mannosylglycerate in *E. coli* (Sampaio et al., 2003).

The components of the respiratory chain of *Rhodothermus* have been investigated in-depth. Menaquinone MK-7 is the major lipoquinone. Minor amounts of MK6 (3% in the type strain of *R. marinus*, 10% in "*R. obamensis*") and MK-5 (7% in "*R. obamensis*") were also found (Tindall, 1991; Sako et al., 1996). A number of cytochrome-containing enzymes that make part of the electron transfer chain to oxygen have been characterized. Their properties are summarized in Table 4.

The respiratory chain contains a caa_3 terminal oxidase, a novel cytochrome *bc* complex, and a high potential iron sulfur protein that serves as an electron carrier between this complex and a terminal oxidase (Pereira et al., 1999a; Pereira et al., 1999b). The membrane-bound heme centers have been identified by spectroscopic methods such as electron paramagnetic resonance and by

Table 4. Cytochromes of the respiratory system of *Rhodothermus marinus*.

Activity	Cytochrome	E'_o, mV (heme center)
Electron carrier	*c*	+267 (C)
Succinate: menaquinone oxidoreductase	*b*	+75 (B), –65 (B)
Menaquinol:HiPIP oxidoreductase	*bc*	+235 (B), +235 (C), +80 (C), –45 (C+C)
Terminal oxidase	cbb_3	+195 (C), +120 (B), –50 ($C+B_3$)
Oxygen reductase, HiPIP oxidase	caa_3	+260 (C), +255 (A), +180 (A_3)

Abbreviation: HiPIP, high-potential iron-sulfur protein.
From Pereira et al. (2000a).

redox potentiometry. B- and C-type hemes are most abundant in the membrane, with small amounts of heme A being present as well. The heme centers have relatively low reduction potentials, ranging from +267 to –65 mV. No Rieske-type center could be detected, suggesting the absence of a canonical complex III (Pereira et al., 1999b; Pereira et al., 2000a).

The following components have been characterized: 1) An NADH:menaquinone oxidoreductase (Complex I), with at least four Fe-S centers (Fernandes et al., 2001a). The purified complex showed optimal activity at 50°C and pH 8.1. The purified enzyme contains 13.5 ± 3.5 iron atoms and about 3.7 menaquinone per flavin adenine mononucleotide (FMN). Electron paramagnetic resonance (EPR) spectroscopy showed the presence of at least five Fe-S centers: two $[2Fe\text{-}2S]^{2+/1+}$ and three $[4Fe\text{-}4S]^{2+/1+}$ centers (Fernandes et al., 2002).

2) A succinate:menaquinone oxidoreductase with three subunits of 70 kDa (the flavin containing subunit), 32 kDa (the iron-sulfur subunit), and 18 kDa (the anchor subunit). It is optimally active at 80°C and has a high affinity for succinate and fumarate. The complex contains two B-type hemes (Fernandes et al., 2001a; Fernandes et al., 2001b).

3) A membrane bound high potential iron sulfur protein (HiPIP) of about 10 kDa. It contains a single $[4Fe\text{-}4S]^{3+/2+}$ cluster with a high redox potential of +260 mV. It is part of the main membrane-bound electron transfer pathway. It is reduced by NADH or by succinate when further electron flow is blocked by addition of cyanide, and it serves as intermediate between the *bc* complex and the caa_3 terminal oxidase (Pereira et al., 1994; Pereira et al., 1999b).

4) Menaquinol:HiPIP oxidoreductase (complex III). This is a novel multihemic cytochrome *bc* that contains at least three subunits (43, 27 and 18 kDa) and five low-spin heme centers of the B and C types in a 1:4 ratio. All C-type hemes are found in the 27-kDa subunit. The complex shows three distinct redox transitions with midpoint potentials at +235, +80, and –45 mV. The first involves one B- and one C-type heme; the second and third transitions involve one and two C-type hemes, respectively. The complex couples the electron transfer between the quinols reduced by the dehydrogenases and a HiPIP, the final electron donor to the terminal oxidases (Pereira et al., 1999a).

5) A cbb_3-type oxidase as the major terminal oxidase. The complex was partially purified. Its five subunits have apparent molecular masses of 64 kDa, 57 kDa, 36 kDa, 26 kDa (the subunit carrying the C-type heme), and 13 kDa. There are two low-spin heme C centers and one high- and one low-spin heme B center. The reduction potentials are +195 mV (heme C), +120 mV (heme B), –50 mV (heme C), and –50 mV (heme B_3; Pereira et al., 2000a).

And lastly, 6) the caa_3 terminal oxidase, belonging to the superfamily of heme-copper oxidases, serves as an HiPIP: oxygen oxidoreductase. This complex was reconstituted in liposomes and was shown to function as a proton pump (Pereira et al., 2000b). It has three subunits with apparent molecular masses of 42 kDa, 19 kDa, and 15 kDa and a C-heme containing subunit of 35 kDa. The hemes show unusually low reduction potentials of +260 (heme C), +255 (heme A), and +180 mV (heme A_3; Pereira et al., 1999c). The complex acts as a proton pump (Pereira et al., 2000b). The kinetics of the different transformations and reactions within the complex have been characterized in-depth (Sigurdson et al., 2001). The genes for the subunits (*rcoxA – rcoxD*) are organized in an operon that contains at least five genes. These genes have been cloned and sequenced (Santana et al., 2001). It is interesting to note that the outcome of the cytochrome oxidase test has been reported differently by different authors. Alfredsson et al. (1988) and Sako et al. (1996) reported a positive oxidase reaction, but Kristjánsson and Alfredsson (1992) note a negative oxidase reaction for *R. marinus*. Nunes et al. (1992a) state that all their *Rhodothermus* isolates from the Azores were oxidase-negative.

Phospholipids are the main lipid components of *Rhodothermus*; glycolipids are absent or form minor components only. Five to seven phospholipids were detected, of which the following have been identified: phosphatidylethanolamine, diphosphatidylglycerol, and phosphatidylglycerol (Tindall, 1991; Nunes et al., 1992b).

The branched fatty acids *iso*-C15:0, *iso*-C17:0, *anteiso*-C15:0, and *anteiso*-C17:0 are the dominant fatty acids in *Rhodothermus* lipids. Straight unbranched fatty acids are present as well (Tindall, 1991; Chung et al., 1993; Moreira et al., 1996; Sako et al., 1996; Silva et al., 2000; Table 5). The relative amounts at which the different fatty acids are found in the lipids depend on the medium and the growth conditions. Thus, when grown on yeast extract + peptone or on yeast extract alone, the branched *iso*-C15:0 and *iso*-C17:0 were the major fatty acids. However, when glutamate was the sole source of carbon, *n*-C16 was the major component, and straight-chain fatty acids reached about 50% of the total fatty acids. Following growth on yeast extract + glutamate, the relative proportion of *iso*-C16:0 reached high levels (Chung et al., 1993).

Rhodothermus is colored red by carotenoids, and absorption spectra of cells in acetone show a peak at 476 nm and shoulders at 456 and 502 nm (Alfredsson et al., 1988). These carotenoids

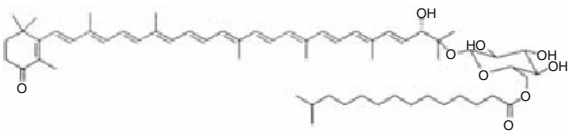

Fig. 8. The structure of salinixanthin, the major carotenoid pigment of *S. ruber*.

have recently been identified as (all-*E*, 2′*S*)-2′-hydroxy-1′-(β-D-glucopyranosyloxy)-3′,4′-didehydro-1′,2′-dihydro-β,ψ-caroten-4-one (3.3% of total carotenoid) and its C-6″ acyl derivative (55%) and (all-*E*)-1′-(β-D-glucopyranosyloxy)-3′,4′-didehydro-1′,2′-dihydro-β,ψ-caroten-4-one (2.5%) and its C-6″ acyl derivative (39%; Fig. 7). Both carotenoid acyl glucosides exhibited the same acyl profile, the major esterifying acids being the branched odd-carbon *iso*-C13:0, *anteiso*-C13:0, *iso*-C15:0 and *anteiso*-C15:0. A similar monocyclic carotenoid acyl glucoside is present in the phylogenetically related *Salinibacter ruber* (salinixanthin, Fig. 8).

The following polyamines have been detected in *Rhodothermus marinus*: spermidine [$NH_2(CH_2)_3NH(CH_2)_4NH_2$], spermine [$NH_2(CH_2)_3NH(CH_2)_4NH(CH_2)_3NH_2$], thiopentamine [$NH_2(CH_2)_3NH(CH_2)_3NH(CH_2)_4NH(CH_2)_3NH_2$], the tertiary tetra-amine N^4-aminopropylspermidine [$NH_2(CH_2)_3N((CH_2)_3NH_2)(CH_2)_4NH_2$], and the quaternary penta-amine N^4-*bis*(aminopropylspermidine) [$NH_2(CH_2)_3N^+((CH_2)_3NH_2)_2(CH_2)_4NH_2$] (Hamana et al., 1992; Hamana et al., 1998). "*Rhodothermus obamensis*" contains in addition two novel linear hexamines: $NH_2(CH_2)_3NH(CH_2)_3NH(CH_2)_3NH(CH_2)_4NH(CH_2)_3NH_2$ and $NH_2(CH_2)_3NH(CH_2)_3NH(CH_2)_4NH(CH_2)_3NH(CH_2)_3NH_2$ (Hamana et al., 1998).

Table 6. Medium for *Rhodothermus* (modified *Thermus* medium 162 of DSMZ).[a]

Yeast extract	2.5g
Tryptone	2.5g
Agar	28.0g
Nitrilotriacetic acid	100mg
$CaSO_4 \cdot 2H_2O$	40mg
$MgCl_2 \cdot 6H_2O$	200mg
0.01M Fe-citrate	0.5ml
Trace element solution[b]	0.5ml
Phosphate buffer[c]	100ml

[a]Combine all ingredients except phosphate buffer. Adjust pH to 7.2 with NaOH, autoclave, and add the sterile phosphate buffer.

[b]Trace element solution contains (per liter): nitrilotriacetic acid, 12.8g; $FeCl_2 \cdot 4H_2O$, 1.0g; $MnCl_2 \cdot 4H_2O$, 0.5g; $CoCl_2 \cdot 4H_2O$, 0.3g; $CuCl_2 \cdot 2H_2O$, 50mg; $Na_2MoO_4 \cdot 2H_2O$, 50mg; H_3BO_3, 20mg; and $NiCl_2 \cdot 6H_2O$, 20mg. Dissolve the nitrilotriacetic acid, adjust the pH to 7.0 with KOH. Dissolve the other salts separately, combine, and adjust the pH to 6.8 with NaOH or H_2SO_4.

[c]Phosphate buffer contains (per liter): 5.44g of KH_2PO_4 and 43.0g of $Na_2HPO_4 \cdot 12H_2O$, pH 7.2, and is autoclaved separately.

Isolation and Maintenance

Rhodothermus can be isolated from submarine hydrothermal environments worldwide. No selective medium for the isolation of *Rhodothermus* has been described yet. The species can be grown on a simple yeast extract-tryptone medium with the appropriate salt concentration, such as specified in Table 6. Red colonies developing on agar plates following aerobic incubation at 65°C may well be *Rhodothermus* strains. Final identification should be based on 16S rDNA sequencing and comparison with other properties described for the genus.

Rhodothermus is sensitive to penicillin, erythromycin, tetracycline, and chloramphenicol and resistant to the aminoglycoside antibiotics kanamycin, streptomycin, and gentamycin (Alfredsson et al., 1988; Nunes et al., 1992a).

Rhodothermus can be preserved by lyophilization.

Ecology

Rhodothermus lives around submarine hot springs (Alfredsson et al., 1988; Sako et al., 1996). Because of its narrow range of growth-

permissive temperature (54–77°C), it can only grow very close to the openings of these hot springs, as only a few cm from the openings the water would be too cold. Moreover, *Rhodothermus* is obligatory aerobic, and geothermic water is usually anaerobic until it emerges from the ground or the seabed and absorbs oxygen from the surroundings. *Rhodothermus* is a heterotroph, and suitable organic material must therefore be present as well in its habitat. The requirements for oxygen, salt, organic nutrients, and temperature thus define a very narrow niche for this genus in the hot spring environment (Alfredsson et al., 1988).

Material containing 16S rDNA sequences related to *Rhodothermus* (87% similarity to *R. marinus*) has been recovered from an orange-colored microbial mat in an alkaline hot spring in Nakabusa, Japan at 58–60°C (Nakagawa and Fukui, 2002).

Applications

The thermophilic nature of *Rhodothermus* makes the organism an interesting potential source for thermostable enzymes. Its ability to degrade xylans, cellulose, and other polysaccharides (see Table 3) makes the organism of special interest. As described above, the relevant enzymes have been cloned and in a number of cases optimized for biotechnological production by genetic engineering. To the knowledge of the author, *Rhodothermus* is not yet used in industrial applications, but a number of patents have been issued describing potential applications in the future (Dahlberg et al., 2002; Wicher et al., 2002).

Xylan is the most abundant hemicellulose in plant cell walls. Xylanases are therefore important in pulp and paper industry, as well as in the food industry. The thermostable *Rhodobacter* xylanase (both the native form of the enzyme and the truncated engineered form; Nordberg Karlsson et al., 1996; Nordberg Karlsson et al., 1998b; Nordberg Karlsson et al., 1999; Abou Hachem et al., 2000; Ramchuran et al., 2002) has successfully been used in small-scale experiments for the prebleaching of hardwood and softwood kraft pulps. The truncated enzyme performed very well, and the presence of the additional domains in the full-length enzyme, including carbohydrate-binding modules, did not improve the bleaching process (Pfabigan et al., 2002). The combined use of arabinofuranosidase-rich xylanase and mannanase from *R. marinus* in the prebleaching of softwood kraft pulp gave a significant increase in brightness of the pulp (Gomes et al., 2000).

No methods have yet been developed for the genetic manipulation of *Rhodothermus*. The finding of the 2935-bp cryptic plasmid pRM21 in seven out of the 41 strains investigated may open interesting possibilities regarding its genetic manipulation. The plasmid contains one major open reading frame with a deducted product similar to RepA proteins, with the highest similarity to RepA of *E. coli* plasmid pSa. The small size and the apparent stability of this first plasmid characterized from *Rhodothermus* make it an attractive candidate for future use as a cloning vector (Ernstsson et al., 2003).

The Genus *Thermonema*

In 1987, Schofield et al. described the isolation of five strains of very long, thin filamentous bacteria from hot springs in New Zealand. These isolates displayed terminal swellings (Fig. 9), showed gliding motility on agar plates, and grew optimally at 60°C. A formal description of the species as *Thermonema lapsum* followed two years later (Hudson et al., 1989). A second species of the genus, *T. rossianum*, was recovered from saline hot springs in the Bay of Naples, Italy (Tenreiro et al., 1997). The isolation of *Thermonema* strains from submarine smectite cones on the seafloor in northern Iceland (Marteinsson et al., 2001) suggests that such organisms can probably be found worldwide in hot spring areas.

Taxonomy and Phylogeny

Two species are presently recognized within the genus *Thermonema*: 1) *T. lapsum* (the type species of the genus), with type strain 23/9^T = ATCC 43542 = DSM 5718 (16S rDNA accession number: L11703). The G+C content of its DNA

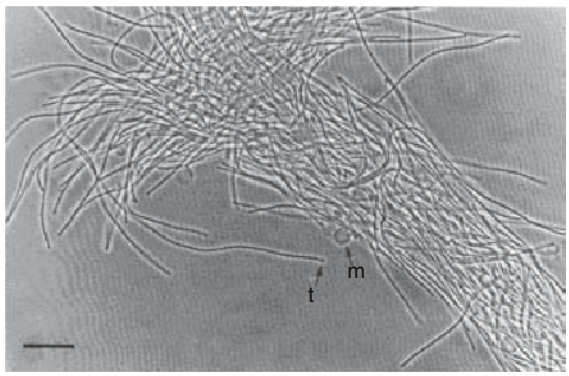

Fig. 9. Phase-contrast micrograph of *Thermonema lapsum* strain 23/9^T showing terminal (arrow t) and mid-filament (arrow m) swellings. The bar is 21 μm. From Schofield et al. (1987); reproduced with permission.

is 47 mol%. An additional strain is strain 19/15, deposited as ATCC 34543 (Hudson et al., 1989).

And 2) *T. rossianum*, with type strain NR-27^T = DSM 10300 (16S rDNA accession number: Y08956; Tenreiro et al., 1997). The G+C content of its DNA is 50.9 mol%.

Analysis of the 16S rRNA gene of *T. lapsum* showed the organism to form a deep branch affiliated with the *Cytophaga-Flavobacterium-Bacteroides* branch of the Bacteria (Andrésson and Friðjónsson, 1994; Patel et al., 1994; Fig. 1).

Morphological and Cultural Characteristics

Thermonema cells are very long slender filaments. The cell length may exceed 60 μm, but cells are only 0.25–0.3 μm (*T. lapsum*) to 0.7 μm wide (*T. rossianum*; Hudson et al., 1989; Tenreiro et al., 1997). As no septa can be seen within these thin filaments, each one probably represents a single cell. *Thermonema lapsum* is motile by gliding; no motility has been reported in *T. rossianum*.

Physiological, Biochemical and Chemotaxonomic Properties

The polar lipids of *T. rossianum* are dominated by lipids that show a positive ninhydrin reaction. Two of these are aminophospholipids. No information is available on the identity of the other three major fractions, except that they do not react with α-naphthol (detecting carbohydrates) and do not contain phosphate groups (Tenreiro et al., 1997). Dominant fatty acids in the lipids of *T. lapsum* are *iso*-C15:0, *anteiso*-C15:0, and C15:0. The lipopolysaccharide fraction of this organism is particularly rich in hydroxy fatty acids (Patel et al., 1994). The most abundant fatty acids in *T. rossianum* are *iso*-C15:0, *iso*-C17:0 3OH, *iso*-15:0 3OH and *anteiso* C15:0 (Tenreiro et al., 1997). Monounsaturated fatty acids were not detected. Table 7 presents some quantitative data on the fatty acid content of different lipid fractions of *Thermonema* isolates.

Both *T. lapsum* and *T. rossianum* form bright yellow colonies. Absorption spectra of *T. lapsum* acetone extracts show an absorbance maximum at 450 nm with a shoulder at 480 nm (Schofield et al., 1987; Hudson et al., 1989). The structure of the presumed carotenoid pigment(s) present remains to be elucidated.

Both species are catalase and oxidase-positive. The major respiratory quinone of *T. rossianum* is menaquinone-7 (Tenreiro et al., 1997).

Thermonema contains homospermidine [$NH_2(CH_2)_4NH(CH_2)_4NH_2$] as the major polyamine (also found as the major polyamine in mesophilic members of the *Flavobacterium* – *Cytophaga* – *Flexibacterium* complex), with minor amounts of homospermine [$NH_2(CH_2)_4NH(CH_2)_4NH(CH_2)_4NH_2$] (Hamana et al., 1992).

Isolation and Maintenance

No selective media have yet been described for the isolation of *Thermonema* species. The strains in culture have been obtained by spreading water samples on plates followed by incubation at 60–70°C (Schofield et al., 1987). All strains grow on media containing low concentrations of complex nutrients (tryptone and yeast extract) in the presence of 1–4% NaCl (see Table 8). *Thermonema* species give rise to the development of bright yellow colonies following incubation at 60°C. *Thermonema lapsum* grows at temperatures up to 70°C (a temperature too high for the growth of *T. rossianum*). The optimum pH is in the neutral range. *Thermonema rossianum* requires 1–3% NaCl for growth (Tenreiro et al., 1997). The minimum doubling time reported for *T. lapsum* was 11 h. In broth culture it grows in clumps and as pellicle on the surface of the medium (Schofield et al., 1987).

Table 7. The major fatty acids of *Thermonema* species.[a]

Fatty acid	*T. lapsum*		*T. rossianum*

$CoCl_2 \cdot 6H_2O$	46 µg/liter	NA
Agar	NA	28.0 g
0.01 M Fe-citrate	NA	0.5 ml/liter
Trace element solution[c]	NA	0.5 ml/liter
Phosphate buffer[d]	NA	100 ml/liter

Abbreviation: NA, not added.
[a]Adjust pH to 8.2 with NaOH.
[b]Adjust pH to 7.2 with NaOH.
[c]Trace element solution contains (per liter): H_2SO_4, 0.5 ml; $MnSO_4 \cdot H_2O$, 2.28 g; $ZnSO_4 \cdot 7H_2O$, 0.5 g; H_3BO_3, 0.5 g; $CuSO_4 \cdot 5H_2O$, 25 mg; $Na_2MoO_4 \cdot 2H_2O$, 50 mg; and $CoCl_2 \cdot 6H_2O$, 45 mg.
[d]Phosphate buffer contains (per liter): 5.44 g of KH_2PO_4 and 43.0 g of $Na_2HPO_4 \cdot 12H_2O$; adjust pH to 7.2, and autoclave this solution separately from the solution of the other media components.

Thermonema species require complex mixtures of amino acids for growth (casamino acids, peptone and tryptone), and all strains are proteolytic; casein, elastin and gelatin are degraded by *T. rossianum*. No growth is obtained on carbohydrates, organic acids, or polyols. Starch and cellulose are not hydrolyzed (Hudson et al., 1989; Tenreiro et al., 1997). *Thermonema lapsum* was reported to show DNAse activity (Schofield et al., 1987). Growth is obligatory aerobic, and nitrate is not reduced.

Thermonema lapsum is susceptible to penicillin G and erythromycin and resistant to vancomycin, kanamycin, cycloserine and nalidixic acid (Hudson et al., 1989).

Thermonema can be preserved by lyophilization.

Ecology

Thermonema species are found in hot spring environments at temperatures around 60–70°C. They have been isolated from thermal springs in New Zealand (Schofield et al., 1987) and Italy (Tenreiro et al., 1997). Recently a number of isolates have been obtained from submarine smectite cones on the seafloor in northern Iceland, rising 25–45 m from the seafloor located at a depth 65 m. Hydrothermal fluid of 60–72°C rises here from small chimneys. The outer zone of these chimneys harbors *Thermonema* cells (Marteinsson et al., 2001). Surprisingly, no *Thermonema* strains have yet been isolated from terrestrial hot springs on Iceland.

The Genus *Hymenobacter*

The genus *Hymenobacter* consists of obligatory aerobic nonthermophilic, red-pigmented Gram-negative bacteria affiliated with the *Cytophaga-Flavobacterium-Bacteroides* branch of the *Bacteria*. The three species presently recognized were isolated from highly disparate environments: from soils and sandstone of the continental Antarctic (Hirsch et al., 1998; Fig. 10), from irradiated pork (Collins et al., 2000), and from air collected in the rooms of a museum in Venice (Buczolits et al., 2002). Phylogenetically affiliated and physiologically similar strains had earlier been isolated from antelope dung in South Africa and from soil on Crete. These isolates were at the time designated as members of the newly created genus "Taxeobacter" (Reichenbach, 1991; Reichenbach, 1992), but this genus name has never been validated. Although

reports of their isolation are few, organisms of this group are probably widely distributed and may be common members of the autochthonous soil flora (Reichenbach, 1992).

Taxonomy and Phylogeny

Three species of *Hymenobacter* have thus far been validly named: *H. roseosalivarius*, of which five isolates have been characterized (Hirsch et al., 1998), *H. actinosclerus* (Collins et al., 2000), and *H. aerophilus* (Buczolits et al., 2002; Table 9). *Hymenobacter roseosalivarius*, the type species, is a red to pink bacterium that was isolated from continental Antarctic soils and sandstone collected from the Antarctic dry valleys (Fig. 10).

The identification of isolates as strains belonging to the genus *Hymenobacter* is based on the color of the colonies, the shape of the cells, the range of substrates degraded, and the 16S rDNA sequence.

Morphological and Cultural Characteristics

Hymenobacter cells are rod-shaped and measure up to 4 μm in length (Table 9). *Hymenobacter roseosalivarius* has a tendency to become shorter to almost coccoid in the stationary growth phase (Fig. 10). Cells may show a tendency to aggregate. On agar plates cells may become arranged in palisades at the edge of young spreading colonies (Hirsch et al., 1998; Fig. 10 d). The same type of cell arrangement has also been noticed for "Taxeobacter" isolates (Reichenbach, 1992). *Hymenobacter roseosalivarius* cells often contain electron-dense polyphosphate granules near the cell poles, and they excrete large amounts of extracellular polymer.

No motility has been observed in *H. roseosalivarius*, *H. actinosclerus* and *H. aerophilus*. However, gliding motility has been reported in "Taxeobacter" strains (Reichenbach, 1991).

Physiological, Biochemical and Chemotaxonomic Properties

Meso-diaminopimelic acid has been identified in the peptidoglycan on *H. actinosclerus* and *H. aerophilus* (Collins et al., 2000; Buczolits et al., 2002).

Phosphatidylethanolamine was found as the major polar lipid in *H. roseosalivarius* and in *H. aerophilus*, together with several yet unidentified lipids. Bisphosphatidylglycerol was reported to occur in *H. roseosalivarius* but was not found in *H. aerophilus* (Hirsch et al., 1998; Buczolits et al., 2002). *iso*- and *anteiso*-methyl branched fatty acids and hydroxyl *iso*-methyl branched types are the major fatty acids (Table 10).

The major polyamine of *H. aerophilus* was identified as *sym*-homospermidine (Buczolits et al., 2002).

Hymenobacter cells are colored dark red by carotenoid pigments. A pigment extract of *H. aerophilus* in acetone has an absorbance maximum at 482 nm, with two slight inflection points at 453 and 505 nm (Buczolits et al., 2002). The major carotenoid pigment of "Taxeobacter" has been identified as (all-*E*,3S,2′*R*)-2′-hydroxyflexixanthin (3,1′,2′-trihydroxy-3′,4′-didehydro-1′,2′-dihydro-β,ψ-caroten-4-one, and (all-*E*,2′*R*)-3-deoxy-2′-hydroxyflexixanthin (1′,2′-dihydroxy-3′,4′-didehydro-1′,2′-dihydro-β,ψ-caroten-4-one) is present as a minor one (Fig. 11). The identification of these carotenoids was confirmed by their de novo synthesis and comparison with the natural compounds (Bircher and Pfander, 1997).

"Taxeobacter gelupurpurascens" was reported to show a very peculiar color change when grown at 2°C (Reichenbach, 1991), but no details were published of the nature of this color change.

All *Hymenobacter* isolates are strictly aerobic and catalase-positive. Menaquinone MK-7 has been identified as the major respiratory quinone in *H. roseosalivarius* (Hirsch et al., 1998), in *H. actinosclerus* (Collins et al., 2000), and in *H. aerophilus*. The latter was found to contain minor amounts of MK-6 as well (Buczolits et al., 2002).

The cytochrome oxidase reaction varies among different isolates: *H. roseosalivarius* and *H. actinosclerus* were reported as oxidase-positive (Hirsch et al., 1998; Collins et al., 2000), while *H. aerophilus* showed a negative or weakly positive oxidase reaction, depending on the strain and the method of detection (Buczolits et al., 2002).

Isolation and Maintenance

Hymenobacter strains and related isolates have been obtained from a wide variety of environments, including from soils in the Antarctic and the Mediterranean area, from air, and from irradiated meat products (see Table 9). They thus appear to be quite abundant, but no quantitative data are available on their distribution in different habitats.

No selective media have yet been developed for the enrichment and isolation of *Hymenobacter* species. Their isolation has generally been based on the color of their colonies on agar plates. Hirsch et al. (1998) obtained *H. roseosalivarius* from Antarctic soils and sandstone samples on low nutrient media incubated with illumination to encourage growth of algae, which might provide exudates for better growth of the bacteria. *Hymenobacter actinosclerus* was first

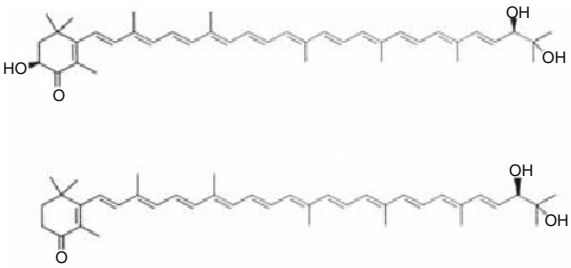

Fig. 11. 2′-Hydroxyflexixanthin and 3-deoxy-2′-hydroxyflexixanthin, the two carotenoid pigments of "Taxeobacter." After Bircher and Pfander (1997).

isolated from pork chops irradiated with 1.75 kGy. Its decimal reduction dose in buffer was found to be 3.45 kGy and in minced pork as high as 5.05 kGy (Collins et al., 2000). Whether other *Hymenobacter* species are as radiation-resistant and whether the property can be used in a positive selection procedure toward their selective isolation remain to be ascertained.

All *Hymenobacter* species grow aerobically with temperature optima of 10–30°C. The most thermotolerant species described ("Taxeobacter ocellatus") does not grow above 38°C (Reichenbach, 1992). The Antarctic isolates of *H. roseosalivarius* are adapted to relatively low temperatures, show optimal growth between 10 and 27°C, and grow within the range of minima of –0.5°C to <5°C and maxima of 25–32°C (Hirsch et al., 1998). All species can grow without salt, 0.5% NaCl is optimal for *H. roseosalivarius*, and no growth is obtained at salt concentrations exceeding 4–5%.

Hymenobacter species can be grown on aerobic agar plate media containing yeast extract and other commonly used substrates such as peptone, glucose and glutamate. Table 11 presents the composition of some media that have been recommended for the cultivation of members of the group. Anaerobic growth does not occur, and nitrate is not reduced.

Hymenobacter roseosalivarius can use glucose, sucrose, mannitol, sorbitol, aspartate, malate and acetate as growth substrates. Ribose, adonitol, alanine, glutamate, glycolate, lactate and succinate are not used. All isolates belonging to the species hydrolyze gelatin, starch, casein, xylan, Tween 80 and Tween 60, as well as dead or living yeast cells. Cellulose and pectin are not used (Hirsch et al., 1998). *Hymenobacter actinosclerus* also hydrolyzes starch (Collins et al., 2000). *Hymenobacter aerophilus* was reported to assimilate acetate, propionate, fructose, glucose, mannose and sucrose (Buczolits et al., 2002). Among the "Taxeobacter" strains are those that degrade chitin ("T. chitinovorans") or pectin.

Hymenobacter aerophilus and "Taxeobacter" have been successfully preserved by lyophilization.

Hymenobacter aerophilus is inhibited by bacitracin, chloramphenicol, colistin sulfate, erythromycin, fusidic acid, gentamycin, kanamycin, nitrofurantoin, penicillin G, polymyxin B, tetracycline and vancomycin (Buczolits et al., 2002). No information has been published on the sensitivity to antibiotics of the other species.

The Genus *Salinibacter*

The existence of extremely halophilic representatives of *Cytophaga-Flavobacterium-Bacteroides* branch was first suggested by the recovery of 16S rRNA genes affiliated with the group from NaCl-saturated saltern crystallizer ponds in Spain (Antón et al., 2000). Fluorescence in situ hybridization using probes designed to react with the novel phylotype showed that the bacteria harboring this 16S rRNA sequence have a slightly curved rod-shaped morphology and are abundant in the saltern environment: They may represent up to 5–25% of the total number of prokaryotic cells present in the Spanish crystallizer ponds (Antón et al., 1999). Enrichment of saltern brine samples with low concentrations of yeast extract led to an increase in the numbers of these rod-shaped cells, and multiplication was most rapid at salt concentrations between 20 and 25% (Antón et al., 2000). This new type of rod-

[a]Adjust to pH 7.5 and solidify with agar (15 g/liter).

[b]Adjust to pH 7.2. May solidify with agar (15 g/liter).

[c]Adjust to pH 7.2 and solidify with agar (15 g/liter).

[d]Adjust to pH 7.2 with KOH and solidify with agar (15 g/liter).

[e]Mineral solution contains (per liter): nitrilotriacetic acid, 10 g; $MgSO_4 \cdot 7H_2O$, 29.7 g; $CaCl_2 \cdot 2H_2O$, 3.34 g; $Na_2MoO_4 \cdot 2H_2O$, 12.67 mg; $FeSO_4 \cdot 7H_2O$, 99 mg; and metal salt solution 44, 50 ml. Metal salt solution 44 contains (per liter): Na-EDTA, 2.5 g; $ZnSO_4 \cdot 7H_2O$, 10.95 g; $FeSO_4 \cdot 7H_2O$, 5.0 g; $MnSO_4 \cdot H_2O$, 1.54 g; $CuSO_4 \cdot 5H_2O$, 0.392 g; Co $(NO_3)_2 \cdot 6H_2O$, 0.248 g; $Na_2B_4O_7 \cdot 10H_2O$, 0.177 g; and a few drops of H_2SO_4 added to retard reprecipitation of the metal ions.

[f]Vitamin mixture contains (per liter): biotin, 4 mg; folic acid, 4 mg; pyridoxine. HCl, 20 mg; riboflavin, 10 mg; thiamine-$HCl \cdot 2H_2O$, 10 mg; nicotinamide, 10 mg; D-Ca-pantothenate, 10 mg; vitamin B_{12}, 0.2 mg; and *p*-aminobenzoic acid, 10 mg. This solution (which is stored in the dark and cold) is added after the mixture of other medium components has been autoclaved.

[g]Sterilized by filtration.

shaped extreme halophile was then designated "*Candidatus* Salinibacter" (Antón et al., 2000).

Isolation of the organism soon followed, and a formal description of *Salinibacter ruber* was published in 2002, based on the study of a number of strains obtained from saltern crystallizer ponds in Spain and on the Balearic Islands (Antón et al., 2002). Additional isolates of *Salinibacter* have recently been obtained from a salt crust near a highly saline pool in Death Valley National Park, California (Hollen et al., 2003).

Salinibacter isolates are orange-pigmented obligate aerobes that appear to prefer relatively low nutrient concentrations (yeast extract, amino acids and some sugars) for growth. All isolates are extremely halophilic, requiring at least 150 g of salt per liter for growth. Thus, they are among the most halophilic organisms within the domain Bacteria, and their salt requirement and tolerance are similar to those of the archaeal order Halobacteriales, which contains the most halophilic microorganisms known thus far (see the chapter on The Order Halobacteriales in Volume 3).

Taxonomy and Phylogeny

The 16S rDNA sequences of the *Cytophaga-Flavobacterium* group recovered from the saltern crystallizer ponds near Alicante, Spain, cluster in two groups, represented by sequences termed "Extremely Halophilic Bacteria" EHB-1 and EHB-2 (Antón et al., 2000; Fig. 3). The 16S rDNA sequences of the *Salinibacter* isolates obtained from these ponds are nearly identical and cluster with phylotype EHB-1 (Antón et al., 2002). No cultures have yet been isolated that carry the closely related phylotype EHB-2. New related 16S rDNA sequences were recovered from solar salterns on the Balearic islands Ibiza (EHB-3) and La Palma (EHB-4 and EHB-5; Fig. 3). Additional related 16S rDNA sequences have recently been amplified from a microbial mat within a salt crust developing around hypersaline pools at the Badwater site, Death Valley National Park, California (Hollen et al., 2003).

The closest relative of *Salinibacter* on the basis of 16S rDNA sequence is *Rhodothermus*, a genus of slightly halophilic (optimal growth at 0.5–2%

NaCl), thermophilic (optimum 65–70°C, maximum around 77°C) red bacteria isolated from marine hot springs. The properties of *Rhodothermus* were discussed in an earlier section (The Genus Rhodothermus). The 16S rDNA similarity between the *Salinibacter* strains and *Rhodothermus* is about 84–86%.

As specified in the sections below, *Salinibacter* shows many properties that are characteristic of the extremely halophilic Archaea of the order Halobacteriales (see the chapter on The Order Halobacteriales in Volume 3). Many of these common properties point to the possibility of convergent evolution of *Salinibacter* and the Halobacteriales toward adaptation to life at the highest salt concentrations (Oren, 2004a). It may be expected that a comparative genomic analysis of *Salinibacter* and of the halophilic Archaea may yield much relevant information on the nature of halophilism and the way halophilic properties are shared between organisms of disparate phylogenetic affiliation.

The five isolates from Spanish crystallizer ponds studied proved sufficiently similar to be classified in a single species, which was named *Salinibacter ruber* (Antón et al., 2002). The type strain is strain M31^T (DSM 13855; CECT 5946; 16S rDNA accession number: AF322499 [www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF322499]), isolated from a saltern on Mallorca, Spain (Figs. 12 and 13). The DNA G+C content of the *S. ruber* isolates is 66.3–67.7 mol% (66.5 mol% for the type strain).

Salinibacter ruber can be identified by its cell morphology and by the color of its colonies. Sequence analysis of the 16S rDNA presents the most certain way of identification, enabling also a comparison with the 16S rDNA sequence of the type strain. A specific 16S rRNA-based phylogenetic probe ("EHB412," positions 412–429, 5′-ACACCCCUAUGGGGCGUA-3′) has been developed for fluorescent in situ hybridization and colony hybridization studies for the detection of *Salinibacter* (Antón et al., 2000; Antón et al., 2002).

Morphological and Cultural Characteristics

Salinibacter is a rod-shaped, often slightly curved bacterium measuring 2–6 × 0.4 μm (Figs. 12–14). The cells stain Gram-negative. In contrast to the non-coccoid representatives of the Halobacteriales, which lyse upon suspension in distilled water, maintenance of cell shape in *Salinibacter*

does not depend on the presence of high salt concentrations. *Salinibacter* is an obligate aerobe, shows positive oxidase and catalase reactions, and does not reduce nitrate.

Two *Salinibacter* isolates were recently obtained from the Badwater site, Death Valley National Park, California (Hollen et al., 2003). Their 16S rRNA sequence is identical and shows 95–96% similarity to that of the sequences directly amplified from that environment (F.A. Rainey, personal communication). The similarity of the 16S sequences of these isolates and the type strain of *S. ruber* is only 93–94%, suggesting that they should be classified in a separate species within the genus.

Physiological, Biochemical and Chemotaxonomic Properties

The major phospholipids detected in *S. ruber* are phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol and diphosphatidylglycerol. These phospholipids contain a mixture of monounsaturated (mainly C16:1ω7 and C18:1ω7) and methyl-branched (mainly iso-branched C15:0) fatty acids (Oren et al., 2004b).

Colonies of *Salinibacter* have a bright red-orange color. The absorption spectrum of a cell extract in methanol/acetone (1:1, v/v) shows a maximum at 478 nm and a shoulder at 506–510 nm. The principal (>96 % of total) pigment of *S. ruber* has been identified as a novel acylated glucocarotenoid [(all-*E*, 2′*S*)-2′-hydroxy-1′-[6-*O*-(13-methyltetradecanoyl)-β-D-glycopyranosyloxy-3′,4′-didehydro-1′,2′-dihydro-β,ψ-caroten-4-one], now named "salinixanthin" (Lutnæs et al., 2002; Fig. 8). The esterifying fatty acid, the branched 13-methyltetradecanoic acid, is also the major fatty acid of the membrane lipids of *S. ruber*. The structure of salinixanthin resembles that of pigments of the phylogenetically related *Rhodothermus* (Alfredsson et al., 1988; Lutnæs et al., 2004; see also Fig. 7).

Salinibacter uses KCl rather than organic solvents to osmotically balance its cytoplasm with its highly saline medium. This mode of osmotic adaptation is rarely found in the domain Bacteria. Most halophilic and halotolerant representatives of the Bacteria use organic osmotic solutes instead (see the chapter on The Order Haloanaerobiales in Volume 4). This is true also for the marine, slightly halophilic *Rhodothermus marinus* (phylogenetically the closest known relative of *Salinibacter*), which uses organic solutes (α-mannosylglycerate and α-mannosylglyceramide) as osmotic solutes (Silva et al., 1999; see also the section The Genus Rhodothermus earlier in this Chapter). The only exception known previous to the discovery of *Salinibacter* was a group of anaerobic fermentative halophilic Bacteria of the order Halanaerobiales, affiliated with the low G+C branch of the Firmicutes (see the chapter The Order Halobacteriales in Volume 3). The use of KCl as osmotic solute has been well documented in the aerobic extremely halophilic Archaea of the order Halobacteriales (see the chapter on The Order Halobacteriales in Volume 3).

Intracellular potassium concentrations as high as 11–15 μmol K^+/mg of protein have been measured in *Salinibacter* strains (Antón et al., 2002). These values are in the same range as those detected in *Halobacterium salinarum* (Archaea) and correspond to 4–5 M intracellular K^+, assuming an intracellular volume of 2.75 μl/mg of protein. The presence of high intracellular K^+ concentrations in *S. ruber* was confirmed by X-ray microanalysis of single cells in the electron microscope, a technique that also confirmed the presence of high concentrations of Cl^- as the intracellular counterion, which approximately balances the sum of K^+ and Na^+ (Oren et al., 2002b). Very low concentrations of organic osmotic solutes were found in *Salinibacter* using techniques such as ^{13}C-NMR and high pressure liquid chromatography (HPLC). Compounds detected included glutamate, glycine betaine, and *N*-α-acetyl-lysine. *N*-α-acetyl-lysine was the only compound whose concentration increased with the medium salinity (Oren et al., 2002b). These organic solutes cannot be expected to significantly contribute to the osmotic balance of the cells in view of the low concentrations in which they were found.

If indeed KCl is the main osmotic stabilizer inside the cells, the intracellular enzymatic machinery should be fully adapted to the presence of high salt concentrations. In the halophilic Archaea of the order Halobacteriales such adaptation of the proteins to high salt has led to characteristic modifications of protein structure, including a high content of acidic amino acids, a low content of basic amino acids, a low content of hydrophobic amino acids, and a relatively high content of "borderline hydrophobic" amino acids serine and threonine (see the chapter on Life at High Salt Concentrations in Volume 2). Such salt-adapted proteins generally require high salt for stability and activity, and they often denature at low salt concentrations. Examination of the amino acid composition of the bulk protein of *S. ruber* showed a similar pattern as found in the Halobacteriales. The content of Asx and Glx of the *S. ruber* proteins is almost as high as that of the halophilic Archaea *Halobacterium salinarum* and *Haloarcula marismortui* (Asx + Glx = 29.2 mol%, as compared to 31.8 and 32.3 mol%, respectively), and a high apparent excess of acidic amino acids was found as well ([Asx + Glx] – [Lys + Arg] is 21.2 mol%, as compared to

25.4 and 26.2 mol% for the two halophilic Archaea). A low content of hydrophobic amino acids and a high content of serine were also observed in the *Salinibacter* bulk protein (Oren and Mana, 2002a).

The halophilic nature of the proteins of *S. ruber* was confirmed for a number of intracellular enzymatic activities. As shown in Table 12, most enzymes studied showed a marked halophilic character, most had their optimal activity at high salt concentrations, and many proved inactive in the absence of salt. The activities tested included enzymes of the central dissimilatory metabolism (isocitrate dehydrogenase and malate dehydrogenase), a central enzyme in amino acid metabolism (glutamate dehydrogenase), enzymes involved in sugar and glycerol dissimilation (hexokinase, glucose-6-phosphate dehydrogenase, glycerol dehydrogenase, and glycerol kinase), and the fatty acid synthetase complex, essential for lipid biosynthesis. Although the general trend of salt dependence of proteins is clear, significant differences occur in the relation to salt of the individual enzymes.

Isolation and Maintenance

The strains described in the literature (Antón et al., 2002) have all been isolated by plating dilutions of saltern crystallizer brine on agar plates (media described in Table 13). They were recognized as members of the genus *Salinibacter* either by colony hybridization with a probe designed to detect the *Salinibacter* 16S rRNA phylotype or by thin layer chromatography of polar lipids extracted from subcultures of selected orange colored colonies.

Table 12. The relation of several intracellular enzymatic activities of *S. ruber* to salt.

Enzyme	Salt requirement	Comments	References
Isocitrate dehydrogenase (NAD-dependent)	Optimum at 0.5–2M KCl, with rates of 60% of the optimum value at 3.3M; 70% of the optimum rates in KCl were found at 0.2–1.2M NaCl; and low activity above 3M NaCl	None	Oren and Mana, 2002a
Isocitrate dehydrogenase (NAD-dependent)	Activity approximately constant between 0 and 3.2M NaCl and increased with increasing KCl concentration	None	Oren and Mana, 2002a
Malate dehydrogenase (NAD-dependent)	Optimal activity in the absence of salt; approximately 25% of the maximum activity remained at NaCl and KCl concentrations above 3M	None	Oren and Mana, 2002a
Glutamate dehydrogenase (NAD-dependent)	Two enzymes were found (GDHI and GDHII); GDHI depends on high salt concentrations for stability, but GDHI is optimally active in the absence of salts; GDHII depends on high salt concentrations for both activity and stability; amination of 2-oxoglutarate is optimal in 3M KCl at pH 8; no activating effect was found when NaCl was replaced by KCl	Both enzymes catalyze reductive amination of α-ketoglutarate, but only GDHII displayed activity in the deamination reaction of glutamate; both enzymes were activated by certain amino acids and nucleotides; a low-molecular-weight cytoplasmic fraction activates GDHII in the presence of high NaCl concentrations	Oren and Mana, 2002a; Bonete et al., 2003
Hexokinase	Activity is inhibited by salt, and no activity was recorded in the presence of 2.1M KCl or 2.8M NaCl	None	Oren and Mana, 2003
Glucose-6-phosphate dehydrogenase (NADP-dependent)	Activity is optimal above 1.5–2M NaCl or KCl; no activity found below 0.8M salt	Constitutive	Oren and Mana, 2003
Glycerol kinase	Activity is similar from 0.6–2.8M KCl	Inducible	Sher et al., 2004
Fatty acid synthetase	Optimal activity found at 0.5–1.5M salt; little activity in the absence of salt	None	Oren et al., 2004a

Table 13. Media for the cultivation of *Salinibacter*.

[a]The author uses a version of this medium in which the concentrations of $MgCl_2 \cdot 6H_2O$ and $MgSO_4 \cdot 7H_2O$ are reduced to 25.0 and 16.3 g/liter, respectively.

[b]Adjust the final pH to 7.0. Liquid media may be solidified with agar (20 g/liter).

The fact that *Salinibacter* is insensitive to the antibiotics anisomycin and bacitracin, two antibiotics that are highly inhibitory to halophilic Archaea of the order Halobacteriales (see below), can be used to design selective enrichment and isolation protocols. Inoculation of saltern crystallizer brine from Eilat, Israel, into suitable growth medium amended with anisomycin (15 mg/liter) gave rise to a culture of *Salinibacter*. Similarly, when such a brine sample was inoculated on agar plates of modified R_2A medium (see Table 13) with bacitracin (25 mg/liter), most of the colonies that developed after 2–3 weeks of incubation at 35°C were orange colored *Salinibacter*-type cells.

Salinibacter can be grown in media with relatively low concentrations of yeast extract and other nutrients such as amino acids, in the presence of salt (200–250 g/liter). High nutrient levels are inhibitory for growth. Table 13 gives the composition of two media that proved suitable for its cultivation.

Salt concentrations of at least 150 g/liter are required, and all strains grow at NaCl concentrations up to saturation. The optimal pH range for growth is 6.5–8.0, and the temperature optimum is 35–45°C. Under optimal growth conditions doubling times of around 14–18 h are obtained.

Salinibacter is an obligate aerobe that does not reduce nitrate. Amino acids appear to be the preferred nutrients for growth. Most strains hydrolyze gelatin. According to the original description of *S. ruber* (Antón et al., 2002), growth is not stimulated by sugars at a concentration of 5 g/liter. However, it was later found that glucose, maltose, starch, and glycerol significantly increase the growth yield when added at a concentration of 0.5–1 g/liter (Oren and Mana, 2003; Oren et al., 2003). Glucose degradation starts only after more easily metabolizable substrates have been depleted from the medium. As a result, diauxic growth is obtained in medium containing both yeast extract and glucose as carbon and energy sources. No acidic products are produced during sugar metabolism. Enzymological studies suggest that glucose is metabolized by the Entner-Doudoroff pathway via hexokinase and NADP-dependent glucose-6-phosphate hydrogenase (Oren and Mana, 2003). No diauxic growth was obtained in media containing glycerol and yeast extract. Metabolism of glycerol was shown to involve an inducible glycerol kinase (Sher et al., 2004).

Salinibacter ruber is sensitive to penicillin G, ampicillin, chloramphenicol, streptomycin, novobiocin, rifampicin and ciprofloxacin. No growth inhibition was found by kanamycin, bacitracin, tetracycline and colistin. The cells are resistant to anisomycin and aphidicolin, two potent growth inhibitors of halophilic Archaea of the order Halobacteriales.

In microbiological studies of salterns and salt lakes the color of colonies on agar plates has often been used to discriminate between halophilic Archaea (red colonies) and halophilic or halotolerant representatives of the Bacteria (colorless colonies). The discovery of *Salinibacter* as a quantitatively important component of the prokaryotic community in certain hypersaline ecosystems shows that this approach may lead to incorrect identifications. It is quite possible that colonies of *Salinibacter* were observed long before the species was recognized, but were erroneously considered to be halophilic Archaea. Colony color alone is therefore insufficient to allow classification of extremely halophilic prokaryotes as members of the Archaea or the Bacteria. The color of *Salinibacter* colonies is more orange and less red-pink than that of colonies of most members of the Halobacteriales on high salt agar media. The absorption spectrum of a pigment extract in methanol-acetone (1:1, v/v) may help identify a culture as a member of the genus *Salinibacter* (salinixanthin; absorbance peak at 478 nm with a broad shoulder at 506–510 nm) or the halophilic Archaea (bacteriorubberin derivatives [see the chapter on The Order Halobacteriales in Volume 3] with absorbance maxima at 496 nm and 530 nm and a shoulder at 470 nm).

Salinibacter ruber can be preserved by lyophilization.

Ecology

Until recently there was little evidence that heterotrophic representatives of the domain Bacteria played a significant role in the microbial community inhabiting salt-saturated environments. However, now it has become clear that rod-shaped prokaryotes that carry the *Salinibacter* phylotype may be abundant in saltern crystallizer ponds, where they occur together with different types of halophilic Archaea of the order Halobacteriales (Antón et al., 1999; Antón et al., 2000). Fluorescent in situ hybridization experiments have shown that *Salinibacter* may represent up to 5–25% of the total prokaryote community in such environments (Antón et al., 2000). Moreover, pigment analysis has demonstrated that the salinixanthin of *Salinibacter* may contribute up to about 5% of the total prokaryotic carotenoids that color red-pink the crystallizer brines of the salterns near Alicante, Spain, and on Mallorca (Oren and Rodríguez-Valera, 2001). *Salinibacter* has now also been isolated from saltern crystallizer ponds in Israel (A. Oren and R. Elevi, unpublished results). The genus may thus occur widespread in hypersaline environments of near-neutral pH with salt concentrations between 150 g/liter and NaCl saturation, as was shown both by the finding of characteristic 16S rDNA sequences and by the direct isolation of new strains from the salt crust around saline pools in Death Valley, California (Hollen et al., 2003).

Salinibacter has nutritional requirements similar to those of the halophilic Archaea of the order Halobacteriales. The two groups may therefore be expected to compete for substrates such as amino acids and sugars in their natural environment. Glycerol is probably a readily available carbon and energy source in hypersaline water bodies, as it is produced in high quantities as osmotic solute by unicellular green algae of the genus *Dunaliella* (see the chapter on Life at High Salt Concentrations in Volume 2). It was shown that dissimilation of glycerol is an inducible property in *S. ruber* (Sher et al., 2004). Curiously, a recent study in which microautoradiography was combined with fluorescent in situ hybridization to obtain information about the organic substrates used by the microbial community in a saltern crystallizer pond on Mallorca suggested that glycerol was incorporated neither by *Salinibacter* nor by the members of the Halobacteriales present (Rosselló-Mora et al., 2003). The elucidation of the factors determining the community dynamics of *Salinibacter* and the halophilic Archaea in their shared habitat and the interrelationships between the two physiologically similar but phylogenetically distant groups will be a challenging topic for further study.

Acknowledgments. Research on *Salinibacter* in my laboratory is supported by the Israel Science Foundation (grant no. 504/03).

CHAPTER 7.1

The Genus Chlamydia—Medical

MURAT V. KALAYOGLU AND GERALD I. BYRNE

Introduction

A great deal has been written about *Chlamydia* during the past few years. Several excellent reviews are available as are recent symposia proceedings and a new volume dedicated to descriptions of these organisms (see Literature Cited). Members of the genus *Chlamydia* are among the "high profile" human pathogens of the 21st century (Peeling and Brunham, 1996). Millions of people are infected with *Chlamydia*, and these organisms are associated with a vast array of serious diseases. *Chlamydia trachomatis* is the most common sexually transmitted bacterial pathogen in the world. It can cause acute infections in both men and women but also can be insidious and result in serious long-term complications in women who have upper genital tract involvement. *Chlamydia pneumoniae* is a more recently identified human pathogen that has been implicated in a significant portion of community acquired pneumonia outbreaks in many parts of the world. Serologic evidence suggests that most adults have been exposed to *C. pneumoniae* by the middle stages of life. This nearly universal exposure has taken on added significance with the recognition that *C. pneumoniae* also is associated with a large proportion of cardiovascular disease patients.

The chlamydiae are a group of obligate intracellular prokaryotic pathogens that are known to be involved with human populations at least as far back as the earliest times when people settled together in large communities. Many of the great cities of North Africa and the Middle East were constructed with long, high-walled avenues without curves that led to a region of the city where those afflicted with blinding chlamydial ocular disease could go to live as beggars or, more likely, to die. These streets are called "straights" and they lead to the cities of the blind. The fact that ancient urban planners designed city layouts to accommodate citizens afflicted with a single infectious disease speaks significantly about the magnitude of human misery wrought by chlamydiae. Yet this is but a single example in the repertoire of major afflictions caused by these organisms that have impacted humankind.

Descriptions of trachoma, a blinding chlamydial ocular disease, are accurately depicted in the earliest written communications. A 5,000-year-old Egyptian document called "the Ebers Papyrus" states that eyes that suffer from a flow of matter be treated with a combination of castor oil tree leaves, goose grease, and milk of a woman who had borne a son. Interestingly, breast milk is now known to have anti-chlamydial activity according to a 1997 publication. Trichiasis is the abrasion of the in-turned eyelashes on the cornea. It is virtually pathognomonic for trachoma and its cure, as stated in the Ebers Papyrus, is to treat the afflicted individual with myrrh, lizard's blood and bat's blood, after tearing out the hairs. It is further stated that treatment with bat's blood, the rim of a new vessel, presumably rubbed along the conjunctiva, and honey may prevent exacerbation of trichiasis. These trachoma restoratives are possibly the first recorded chemotherapeutic regimens for an infectious disease. The degree of efficacy was not stated in these early writings, although there is no indication that the recommended treatment was a nostrum either. The remedies presented in the Ebers Papyrus do point out the fact that chlamydial infections have been with people for at least as long as people have been recording their activities.

There is no doubt that the disease described in the Egyptian writings was caused by chlamydiae. The problem of chlamydial diseases, however, is not just one of antiquity. It remains with us today, and chlamydial infection may be more significant now than when the Ebers Papyrus was written. Chlamydiae continue to be a worldwide infectious disease health threat in a variety of settings and conditions. These bacteria are arguably the most ubiquitously distributed pathogens on the face of the globe, causing infections in organisms ranging in complexity from mollusks to human beings. Their obligate intracellular requirements restrict the chlamydiae to life not only within the host, but also within the very cells of the host.

This limitation in niche exploitation has no doubt contributed to the phylogenetic and taxonomic separation of chlamydiae from other prokaryotes. The chlamydiae occupy a unique taxonomic position and have evolved a unique lifestyle that contributes to their peculiar pathogenic potential. The chlamydiae clearly can cause acute infectious diseases, but the hallmark of chlamydial infections is their tendency toward chronicity. Disease manifestations may become evident only years after initial exposure to these organisms. It is this feature of chlamydial infections that causes them to be so difficult to identify, recognize and effectively manage.

Taxonomy

The order Chlamydiales comprises a single family, Chlamydiaceae, and the single genus *Chlamydia*. Recently, it has been proposed, based on 16S rRNA and ribosomal intergenic spacer sequence analyses, that existing chlamydiae taxonomic schemes are inadequate and that the Chlamydiaceae are more properly grouped into two genera, the *Chlamydia* and the *Chlamydophila*. This new taxonomic scheme recently was updated to include phylogenetic analysis of a small subset of well-characterized proteins (Everett, 2000).

In this revised taxonomy, organisms clearly distinct from *Chlamydia* would form two new families. The Parachlamydiaceae would be a family comprising chlamydiae-like organisms found existing in protozoans and a variety of multicellular invertebrates, and the Simkaniaceae would be a family comprising a single strain of chlamydiae-like organisms originally isolated as a tissue culture contaminant. The genus *Chlamydia*, according to new taxonomic criteria, would comprise members of the classic *C. trachomatis* group, and the genus *Chlamydophila* would comprise most veterinary chlamydial pathogens, human-specific *C. pneumoniae* and other *C. pneumoniae*-like strains isolated from a variety of animal species. It is clear that existing taxonomic criteria are inadequate. This is especially true for classification of members of chlamydiae that cause infections in livestock and other veterinary based groups. It is also clear that there is less enthusiasm among the research community working in areas related to human diseases for splitting the genus *Chlamydia* into two genera, although there is wide agreement that some modification of existing species designations might be in order.

At the present time it is not clear if the genus *Chlamydophila* will be embraced as an alternative to *Chlamydia psittaci*, *C. pecorum* and especially *C. pneumoniae*. It is likely that a sensible compromise is needed as a way out of the current taxonomic morass. A scheme that might provide utility would be to maintain a single genus (*Chlamydia*) but increase the number of species from four to nine. Most changes would reflect a reorganization of the *C. psittaci* group, a taxonomic area that is badly in need of reorganization and was the impetus for initiating the more drastic changes at the genus level noted above. This compromise would serve to provide a meaningful working framework for the classification of veterinary chlamydial organisms and allow for *Chlamydia* to be recognized as a genus of obligate intracellular pathogens causing acute and chronic infectious diseases in people. This new classification scheme is outlined in Table 1.

General Basic Biology

The fundamental principles of chlamydial growth, development, interaction with the host, and basic biology center around the developmental cycle depicted in Fig. 1. This intracellular growth stratagem is unique to chlamydiae and the essential elements hold true for all chlamydial strains and species (Scidmore-Carlson and Hackstadt, 2000). Notable differences do exist in some of the developmental cycle details between species or strains, but this will be taken up later. In its most idealized condition, it involves the orderly alternation of two distinct developmental forms (sequence A–F of Fig. 1). One developmental form is specialized for invasion into susceptible host cells (elementary body [EB]), and the other is specialized for growth, replication and division within the host cell (reticulate body [RB]). The elementary body is a small (0.2–0.3 μm) spherical particle that is metabolically inactive but capable of initiating invasion into susceptible host cells by virtue of specialized adhesins that remain incompletely defined. It is probable that chlamydial invasion is a multistep process that requires a set of surface exposed chlamydial moieties interacting with unspecified host cell ligands. It has been suggested that chlamydial-derived, surface-exposed heparin sulfate polymers facilitate entry. Various surface-exposed chlamydial proteins also have been implicated in the entry process. The best current evidence implicates the chlamydial major outer-membrane protein as an adhesin. New information (http://www.stdgen.lanl.gov/), based initially on data provided by the complete genome sequence for several strains of chlamydiae (Stephens, 2000; Stagg, 1998), demonstrates that an entire family of chlamydial surface proteins (polymorphic membrane proteins or Pmps) also warrants study as putative host cell binding adhesins. Unfortunately, definitive statements

Table 1. The Compromise Approach to Chlamydial Taxonomy.

Traditional classification scheme	Proposed classification scheme
Human strains	Human strains
Chlamydia trachomatis L1–L3	*Chlamydia trachomatis*—similar serologic (as well as genotypic) groupings as before
Chlamydia trachomatis A, B, Ba, C	
Chlamydia trachomatis D–K	
Chlamydia pneumoniae	*Chlamydia pneumoniae*
Non-human strains	Non-human strains
Chlamydia trachomatis—mouse pneumonitis	*Chlamydia muridarum* (former mouse pneumonitis strains)
Chlamydia trachomatis—pig strains	*Chlamydia suis* (former *C. trachomatis* pig strains)
Chlamydia psittaci	*Chlamydia psittaci* (mainly bird strains) can cause serious respiratory and systemic zoonotic diseases in humans
Birds and mammals, associated with arthritis or abortion in livestock, especially sheep and cattle	*Chlamydia abortus* (former *C. psittaci*) associated with cattle and sheep abortion
Chlamydia pecorum found in various species including koalas and ruminants, causing arthritis and systemic infection	*Chlamydia caviae* (former *C. psittaci* guinea pig inclusion conjunctivitis strains)
Chlamydia pneumoniae strains found in horses and koalas	*Chlamydia felis* (former *C. psittaci* feline pneumonitis strains)
	Chlamydia pecorum (same as before)
	Uncertain taxonomic status
	Chlamydia pneumoniae—non-human strains

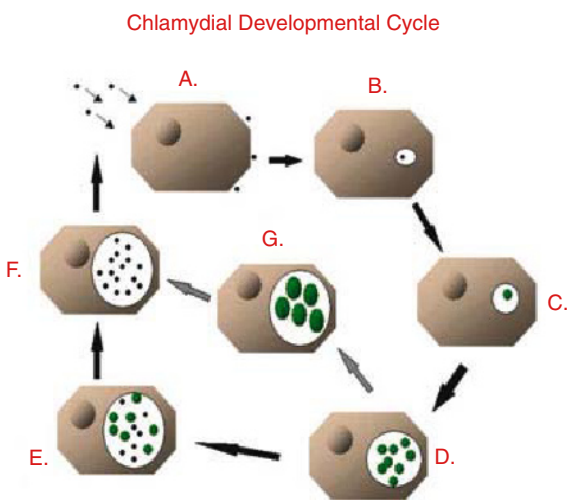

Fig. 1. Chlamydial life cycle. Chlamydiae adhere to the host cell and are endocytosed (A). The pathogen prevents phagosome-lysosome fusion (B), differentiates into the reticulate body (C) and begins replicating within the inclusion (D). Replicating reticulate bodies may re-differentiate back into elementary bodies (E, F) and lyse the host cell to begin a new round of infection. In addition, under conditions of immune-stress such as the presence of interferon-gamma, the pathogen may adopt a non-infectious, non-replicating "persistent" form (G); when the stress is removed, the pathogen can re-differentiate into infectious elementary bodies to begin a new cycle of infection.

about entry must await additional definitive studies in this area.

Chlamydial invasion resembles phagocytosis but occurs in both phagocytic (e.g., mononuclear phagocytes) and nonphagocytic (e.g., epithelial) cells and therefore has been referred to as pathogen-specified endocytosis. The internalized EB is contained within a vesicle that does not fuse with lysosomes, interrupting the normal acidification and intracellular degradation that are often the fate of less fortunate internalized organisms. It is not entirely clear how chlamydiae interfere with lysosomal fusion, but this inhibition is most likely a combination of specifying a fusion-deficient segment of the host cell membrane during entry, followed by active modification of the vesicle membrane as EB-to-RB differentiation begins. Differentiation of EB into RB occurs soon after entry. Genome sequence analysis reveals that chlamydiae have genes that code at least one and perhaps several two-component signaling systems. It is not known whether this regulatory mechanism is responsible for recognizing the new intracellular environment and initiating expression of a differentiation regulon, although a strategy such as this would be eminently reasonable.

The differentiation from EB to RB is accompanied by an entire repertoire of biochemical and morphologic changes. The RB is much larger than the EB. The small, dense EB is characterized by a rigid outer layer. The structural integrity of the EB is maintained via extensive interprotein disulfide bonds. Several chlamydial outer-membrane complex proteins are rich in cysteine, and there is evidence to suggest that cross-linking of these proteins provides EB structural integrity. The key outer-membrane complex proteins and their functions are shown in Table 2. The outer-membrane complex of RB is not extensively cross-linked, and this form of the organism is osmotically unstable once removed from the protection of the intracellular

Table 2. The chlamydial surface and outer membrane complex.

Surface structure	Properties	Function	Comments
A. Proteins			
MOMP	A 40-kDa protein, responsible for serovar specificity in *C. trachomatis*. Cysteine rich. Represents 50% of the protein in OMC of *C. trachomatis*. Some MOMP may be glycosylated.	Contributes to EB stability by disulfide cross-linkages. Has porin activity in RB. May have role in binding of EB to host cell and entry of EB. Glycosylated MOMP specifically implicated in entry process.	Surface-exposed in *C. trachomatis*. Four variable regions are surface accessible and can elicit serovar-specific antibody response and MIC test activity. Serovar specificity confirmed by genovar specificity.
OMC protein B (OmcB or Omp 2)	A 60-kDa, cysteine-rich outer membrane complex protein. May be periplasmic or surface exposed. Only present on EB. Isoelectric point varies between biovars (more disseminating strains have more basic OmcB).	Presumed to be involved in disulfide cross-linking of EB rigid OMC. Might be involved in attachment of EB to host cells.	Location (periplasm versus outer envelope) controversial as is role as heparin-sulfate-binding moiety thought to contribute to attachment and entry of EB.
OMC protein A (OmcA or Omp 3)	A 10-kDa cysteine-rich lipoprotein, periplasmic and anchored to inner leaflet of outer membrane by lipid. Only present on EB.	Presumed to be involved in disulfide cross-linking of EB rigid OMC.	Extremely cysteine-rich. Approximately 20% of the amino acids in this small (about 70 amino acids long) protein are cysteine.
POMPs	Variable in size (from 180 kDa to less than 30 kDa). Different species of chlamydiae have different numbers of *pomp* genes (from 6 in *C. psittaci* to 21 in *C. pneumoniae*) and the number of proteins expressed and surface exposed is not known and under investigation.	Not known, but could represent environment-dependent phase variation gene products. In *C. pneumoniae*, a subset of POMPs could be MIF antigen.	Regulation, expression, cellular location and function of POMPs in both *C. trachomatis* and *C. pneumoniae* is a very active area of research.
B. Other molecules			
Lipopolysaccharide	Genus specific antigen. Epitope in KDO structure. Has deep rough LPS features. Penta-acylated with fatty acids longer than C14.	Implicated as virulence factor as an inflammatory mediator with modest to low activity.	Poor activity due to penta-acylation (rather than hexa-acylation) and fatty acid composition longer than C14 (R1 = C14—C16, R2,3 = C20—O—C18–21, R4 = C14, R5 = C20—OH).
Glycosaminoglycan	Heparin-sulfate-like molecule, possibly linked to OmcB.	Suggested to be an attachment/entry ligand, at least for some strains of chlamydiae.	May be a chlamydial synthesized product or a chlamydial modified host cell product. It has certain characteristics of a capsule, which would be unusual for an intracellular organism.

Abbreviations: OMC, outer membrane complex; EB, elementary body; RB, reticulate body; MIC, micro-immunofluorescence; MOMP, major outer membrane protein; POMP, polymorphic outer membrane protein; MIF, macrophage inhibiting factor; and KDO, ketodeoxyoctonate.

vesicle. The chlamydial genome is compacted in EB. This is facilitated by the presence of histone-like proteins that bind to the DNA and cause it to form a tightly condensed, space-filling aggregate in the EB. One of the most noticeable morphologic changes that accompany EB-to-RB differentiation is the relaxation of the chlamydial DNA. This occurs in synchrony with the disappearance of the histone-like proteins, the appearance of mRNA transcripts, and a dramatic increase in the number of ribosomes present per cell. Fully differentiated RB are capable of genome replication, growth and division despite the apparent absence of at least one essential prokaryotic cell division gene (*ftsZ*) that is conserved in all other bacteria that have been examined thus far. Other oddities are associated with the basic elements of chlamydial growth, replication and metabolism. For example, peptidoglycan is not present in purified EB populations, yet genomic data indicate that the full complement of peptidoglycan biosynthetic genes are present in chlamydiae. Does this mean that a nonfunctional group of genes continues to be lugged around by these organisms? Is it possible that the peptidoglycan is present, but in such small quantities that it cannot be identified? Is peptidoglycan produced, but only during a restricted portion of intracellular development and then discarded somehow as RB mature into EB? How can all of this be explained in the context of the unusual effects that β-lactam antibiotics have on chlamydiae? It is known that sufficient penicillin penetrates into the infected host cell to affect chlamydiae in a way that interferes with cell division and results in the production of enlarged aberrant forms of the organism (Fig. 1 G). Radiolabeled penicillin, when added to chlamydial-infected host cells, binds to penicillin-binding proteins. These penicillin-binding proteins (PBP) presumably are transpeptidases, suggesting that alanyl-alanine peptide bonds are exchanged for peptide cross-linkages, but it is not clear what the putative peptides are bound to and how this relates to chlamydial cell wall structure. It is clear, however, that chlamydiae treated in this way are able to survive and resume normal growth after the penicillin is removed.

The growing population of intracellular RBs remains sequestered within the confines of a membrane-bound vesicle for their entire intracellular existence. This vesicle is termed "an inclusion," and as the number of chlamydiae within increases, a microcolony containing up to 103 organisms develops. The RBs do more than just replicate within the inclusion. There is evidence that they also influence host cell function in a variety of ways. First, fully differentiated RBs appear to line up against the luminal side of the inclusion membrane. Chlamydiae are known to have the genes responsible for the production and assembly of a type III secretion system, and it is tempting to speculate that this system may be active during this phase of intracellular development. It is clear that at least three chlamydial proteins (termed "IncA," "IncB" and "IncC") are secreted by chlamydiae and are found in the inclusion membrane. The identified Inc proteins may actually be representative of a larger family of potentially secreted/inclusion-specific proteins that share a common hydrophobic structural motif. It is not clear whether any Inc proteins are chaperoned from the chlamydial cytosol through a secretory apparatus, but it is known that when chlamydial IncA is cloned and expressed in *Shigella*, it is secreted via the *Shigella* type III secretion system in the absence of any chlamydial accessory proteins.

Chlamydia also is thought to secrete a proteosome-like apparatus that selectively degrades proteins in the host cell cytoplasm. For example, chlamydiae interfere with surface expression of both major histocompatibility complex (MHC) class I and MHC class II molecules. This inhibition is thought to be due to selective degradation of these molecules by the chlamydial proteosome. This may serve to render infected cells less visible to the immune system, although an undeniably robust immune response is generated as a result of a chlamydial infection. Details regarding the composition of the chlamydial proteosome are not known, nor is it known whether other host cell proteins are affected by the chlamydial proteosome or whether other secreted proteases are produced by chlamydiae. There is evidence that a group of unidentified host cell proteins are phosphorylated early in the course of the intracellular infectious cycle. Continued work in this area will reveal whether chlamydial gene products are involved in this interesting host cell alteration and what effect these modifications have on host cell function. Identification of a chlamydial type III secretion system has provided a stimulus for identifying and studying additional chlamydial proteins secreted directly into the host cell cytoplasm. Exploitation of this system should provide valuable new insight on subcellular interactions between chlamydiae and their host cells during the course of the intracellular growth cycle.

There are other avenues of communication between chlamydiae sequestered within the inclusion vesicle and the infected host cell. It is known that the chlamydial inclusion can fuse with secretory trafficking vesicles in ways that allow sphingomyelins to be modified to ceramides and incorporated into chlamydial membranes. There also is some evidence that chlamydial inclusions and mitochondria exhibit contact-type interactions. Ultrastructural evi-

dence suggests that this contact results in mitochondrial degradation with the suggestion that chlamydiae benefit energetically from this association.

Chlamydial Pathogenesis

In humans, three species account for the majority of chlamydial infections, and these infections lead to disease in a range of organ systems. *Chlamydia psittaci* is transmitted by contact with birds and causes psittacosis, a severe pneumonia often with systemic manifestations. *Chlamydia trachomatis* is transmitted by direct human-to-human contact to cause disease in the eye (trachoma and inclusion conjunctivitis), lung (neonatal pneumonia), or urogenital system (cervicitis, urethritis, salpingitis and pelvic inflammatory disease). *Chlamydia pneumoniae* is transmitted by airborne droplets to infect the respiratory tract (pharyngitis, bronchitis, community-acquired atypical pneumonia, and possibly adult-onset asthma); subsequently, it gains access to the vasculature and may infect the cardiovascular system, which contributes to atherosclerosis.

Many human diseases caused by bacteria result from tissue damage that occurs from replication of the organism or direct toxic effects of bacterial products. Chlamydiae also cause pathology through these means, but in addition, chlamydial pathogenesis involves tissue damage resulting from immune responses to chlamydial products (Ward, 1995). Chronic or repeated infection leads to increasingly severe chlamydial disease mediated by specific virulence determinants. In particular, the 57-kDa chlamydial heat shock protein, Hsp60, appears to be a key immunomodulator in chlamydial pathogenesis (LaVerda et al., 1999). Strong antibody responses to the protein have been associated with blinding trachoma, as well as tubal scarring and pelvic inflammatory disease, and it is possible that cross-reactivity of chlamydial Hsp60 to human heat shock proteins leads to immune-mediated pathology. In addition, chlamydial Hsp60 can induce inflammatory cascades to directly cause inflammation. For example, chlamydial Hsp60 can activate mononuclear phagocytes to secrete inflammatory cytokines, such as TNF-α, IL-1 and IL-6. Thus, Hsp60 may be involved in chlamydial pathogenesis in two ways: first by direct antigenic stimulation and second by activation of cells to induce local inflammatory reactions.

Another chlamydial virulence determinant likely involved in pathogenesis is the atypical genus-specific lipopolysaccharide (LPS). Chlamydial LPS is unique in that it has a pentaacyl lipid moiety rather than the hexaacyl moiety observed in typical lipopolysaccharides of Enterobacteriaceae (Kosma, 1999). Structure-function studies predict that this difference should cause chlamydial LPS to be only 1% as active as conventional lipopolysaccharides, although different chlamydial strains may produce distinct LPS molecules with greater or lesser amounts of activity and this is the case when TNF-α secretion is assessed from whole blood ex vivo. It has been proposed that the relatively weaker activity of chlamydial LPS results in maintenance of a low-grade, chronic inflammation characteristic of chlamydial infections. Recent work suggests that chlamydial Hsp60 and LPS share similar signaling pathways to trigger host cell activation, but further work is necessary to solidify this hypothesis.

Immunity to chlamydial infection remains incompletely understood. Natural infection confers little immunity to reinfection, and reinfection leads to increasing severity of disease. The protection that is conferred is short-lived, and vaccination studies have not shown long-lasting protection against productive infection. Both humoral and cell-mediated immune responses are elicited and likely necessary to control infection. Antibody response to the major outer-membrane protein (MOMP) can neutralize infection in animal models, but it is unclear whether humoral immunity is critical to control infection in humans. Cellular immunity is characterized by CD4 and CD8 responses. Available evidence supports an important role for CD4 cells in controlling infection, but both CD4 and CD8 T-cell restricted mechanisms likely play a role during specific stages of infection.

Chlamydiae as Human Pathogens

The following discussion focuses on the human diseases caused or associated with *C. psittaci*, *C. trachomatis* and *C. pneumoniae* (Table from Peeling et al.). The discussion is organized into organ systems to underscore the heterogeneity in chlamydial diseases. The intent of this discussion is not to replace excellent recent reviews (see Literature Cited) that detail chlamydial infections, but rather to emphasize putative pathogenic mechanisms common to all chlamydiae and outline differences between chlamydial diseases.

Chlamydia psittaci

Chlamydia psittaci is the causative agent of human psittacosis, an atypical pneumonia that leads to death in 30% of cases if left untreated and infection becomes systemic (Gregory et al.,

1997). Psittacosis is a zoonosis; 5–8% of birds are carriers and most humans are infected chiefly by respiring aerosol droplets from infected animals. *Chlamydia psittaci* has been shown to infect approximately 130 different bird species, but interestingly, psittacosis is particularly fulminant if acquired from turkeys and parrots. Accordingly, psittacosis remains a significant health threat mainly to certain professionals such as abattoir-workers and veterinarians.

The organism enters the respiratory tract within aerosol droplets and infects the respiratory epithelium, where it establishes a niche for one to three weeks before onset of symptoms. The infected individual often presents with symptoms of atypical pneumonia such as cough, fever, and chest soreness, and physical examination shows fever, rales and hepatomegaly in over 50% of patients. The latter sign highlights the capacity of *C. psittaci* to spread from the respiratory system to other organ systems. Indeed, the organism has been isolated from placentae following miscarriage, as well as detected from the liver and spleen in psittacosis models of infection. Although the exact mechanism of dissemination is not clear, mononuclear phagocytes may be the transport vehicle as evidenced by the ability of *C. psittaci* to infect and survive (but not multiply) within human, murine and pig alveolar macrophages. Also not clear is whether strains isolated from turkeys or parrots have a higher capacity to disseminate, given that psittacosis acquired from these birds tends to be more fulminant. Regardless of the involved mechanisms, disseminated psittacosis involves multiple organs, and neurological and gastrointestinal symptoms such as headache, malaise, vomiting, diarrhea or constipation, and nausea are common. If untreated, psitticosis may result in cardiac, hepatobiliary, neurologic and endocrine involvement with fatal consequences.

Diagnosis of psittacosis currently is most commonly based on clinical stigmata combined with the complement-fixation assay. However, antigen detection methods, such as enzyme immunoassay and molecular methods, such as the polymerase chain reaction (PCR), provide more sensitive and specific methods of diagnosis (Stephens et al., 1998; Shachter, 1997; Tuuminen, 2000; Mardh, 2000). Treatment with antichlamydial antibiotics, such as tetracycline or doxycycline, reduces mortality below 1%. Reinfection following recovery has been documented and there is no evidence of lasting immunity.

Chlamydia trachomatis

While *C. psittaci* establishes infection in the lung, *C. trachomatis* has the capacity to infect a range of organ systems. In the eye, *C. trachomatis* infection leads to multiple diseases including trachoma, the world's chief cause of infectious blindness (Mabey and Bailey, 1999). In the lung, the organism is responsible for pneumonia in both infants and adults. In the urogenital tract, the organism is the most common sexually transmitted bacterium that leads to salpingitis and pelvic inflammatory disease (PID), principal causes of infertility in the United States (Guaschino and De Seta, 2000; Robinson and Ridgway, 2000; Stamm, 1999). In addition, *C. trachomatis* can affect the rheumatological and lymphatic systems with diseases such as Reiter's syndrome and lymphogranuloma venereum (Inman et al., 2000; Schumacher, 2000).

Chlamydia trachomatis is grouped into three biovars, which in turn include multiple serovars based on serological reactivity to the organism's MOMP (Table). The trachoma biovar is associated with oculogenital disease and contains serovars A, B, Ba, C and D-K. Serovars A, B, Ba and C cause trachoma, and B, Ba, and D-K most often lead to sexually transmitted disease (STD) and inclusion conjunctivitis. However, serovars B and Ba have been isolated from the genital tract, suggesting that at least some serovars do not exhibit tissue specificity. The LGV biovar is composed of serovars L1, L2 and L3, which cause lymphogranuloma venereum. This sexually transmitted, lymphatic disease is very rare outside of endemic areas in Southeast Asia, South America, and Africa. The third *C. trachomatis* biovar is named "mouse pneumonitis" and is not associated with human disease.

Ocular Disease

Chlamydia trachomatis is the most common cause of chronic follicular conjunctivitis, defined as follicular conjunctival inflammation lasting for more than 16 days. *Chlamydia trachomatis* chronic follicular conjunctivitis is separated into three clinical syndromes: neonatal conjunctivitis (ophthalmia neonatorum), adult inclusion conjunctivitis (paratrachoma) and trachoma.

Neonatal Conjunctivitis. In the United States, *C. trachomatis* is the most common cause of neonatal conjunctivitis, defined as conjunctivitis that occurs within the first four weeks of life. The newborn acquires the organism from the female genital tract during delivery. It is estimated that infants born to untreated, infected mothers have a 40% chance of developing neonatal conjunctivitis and 20% chance of developing neonatal pneumonia. It therefore is imperative to screen high-risk pregnant populations for *C. trachomatis* genital tract infection and treat high-risk newborns with topical antichlamydial antibiotics shortly after delivery.

Typically, the neonate develops a watery discharge within two weeks of delivery. The dis-

charge may become mucopurulent and a pseudomembrane over the conjunctiva may form, but often the infection is mild and self-limited. However, if the infection is severe and untreated, conjunctival and corneal scarring may ensue with vision-threatening sequelae. The disease can be diagnosed with a variety of tests, the most useful being an immunofluorescent monoclonal antibody stain of conjunctival smears (100% sensitivity, 94% specificity for *Chlamydia*). Treatment often can precede diagnosis if the mother is a high-risk individual, considering topical tetracycline or erythromycin ointment applied within one hour of delivery essentially prevents chlamydial conjunctivitis. However, if the disease manifests, treatment with topical antibiotics alone may not be sufficient to eradicate the organism; furthermore, *C. trachomatis* that may have colonized the respiratory tract must be eliminated to prevent neonatal pneumonia. Therefore, in addition to topical antibiotics, a two-week course of oral erythromycin syrup is recommended in infants with chlamydial conjunctivitis, with re-treatment if symptoms and signs have not resolved.

Adult Inclusion Conjunctivitis. The route of transmission for neonatal conjunctivitis underscores the capacity of *C. trachomatis* to infect the genital tract as well as conjunctiva. Therefore, when the organism is transmitted from the adult genital tract to the adult eye, it is not surprising that a chronic follicular conjunctivitis results with similar characteristics to neonatal conjunctivitis. This form of conjunctivitis is termed "adult follicular conjunctivitis," previously known as "paratrachoma." It is estimated that half of all individuals with adult inclusion conjunctivitis also have *C. trachomatis* infection of their genital tract, but that <1% of those with genital tract infection develop conjunctivitis.

The disease manifests within two weeks of exposure. Patients often present mucopurulent discharge, hyperemia, photophobia, and foreign body sensation in one eye. If infection does not resolve, a chronic follicular conjunctivitis ensues, characterized by lymphoid follicle formation. Such follicles are rich in mononuclear phagocytes, as well as lymphocytes, and characterize initiation of chronic inflammation. If untreated, the disease progresses to resemble early trachoma, with pannus formation, papillary hypertrophy, and diffuse punctate keratitis. Corneal scarring may ensue and threaten vision; however, unlike trachoma, adult inclusion conjunctivitis often resolves without severe sequelae.

Diagnosis can be made from conjunctival swabs by a variety of methods, including Giemsa staining, immunofluorescent staining, or isolation. Direct immunofluorescent staining with monoclonal antibody has a high sensitivity and specificity for diagnosis. Treatment is with oral antibiotics, preferably with macrolides or derivatives.

Trachoma. The leading infectious blindness, this disease is also the third most common blinding disease in the world (figure from the World Health Organization). Worldwide, approximately 6 million people are blind secondary to trachoma, 150 million people exhibit active disease, and 500 million are infected. Blinding trachoma is endemic in many third world countries within Africa, the Middle East, Southeast Asia, and South America and was widely prevalent elsewhere but regressed in Europe and North America in part owing to improved living standards. The disease is well responsive to antibiotic treatment, and a World Health Organization (WHO) initiative aims to combine antibiotic treatment with surgery, hygiene education, and environmental improvements to eradicate trachoma by the year 2020.

Trachoma is a chronic, infectious, follicular keratoconjunctivitis that initially only involves the conjunctiva, but progresses to affect the eyelashes, lids and ultimately the cornea. Involvement of the latter eventually leads to corneal scarring and vision loss. Children are the primary reservoir of infection. *Chlamydia trachomatis* is transmitted chiefly by hand-to-eye contact, although vector transmission by flies also is possible. The organism establishes infection in the conjunctiva and initiates a chronic inflammation. This is characterized by lymphoid follicles, germinal centers of lymphocytes, and mononuclear phagocytes, and underscores the inflammatory nature of disease. The lymphoid follicles are surrounded by hyperemic tissue and appear grossly as papillary hypertrophy. If infection is treated at this point, the inflammation may subside with resolution of disease. However, continued conjunctival inflammation leads to conjunctival scarring with subsequent entropion (inward distortion of lids) with or without trichiasis (inwardly turned eyelashes). The latter irritates the cornea, and chronic corneal insult leads to ulceration and corneal opacity. Corneal damage leads to decrease in visual acuity, and enough damage may ensue to cause complete blindness. A simplified grading scheme has been adopted by the WHO and highlights progression of the disease. This grading scheme replaces an old classification system created by MacCallan to obtain accurate documentation during treatment trials.

Community risk factors for the development of trachoma include poverty, crowding, and unavailability of safe water for household use. Treatment for trachoma is based on the "SAFE" protocol that considers many of these important risk factors. Adopted by the WHO to eradicate trachoma by 2020, SAFE is composed of four

arms of treatment. They are: 1) Surgery to treat entropion and trichiasis; 2) Antibiotic treatment of entire communities with azithromycin or topical oxytetracycline to treat infection, as well as to lower transmission rates; 3) Face washing to improve personal hygiene; and 4) Environmental measures to improve community hygiene, such as providing safe water and adequate disposal of feces. Antibiotic treatment is perhaps the critical arm of the SAFE protocol because treatment of entire communities reduces prevalence of infection as well as re-emergent infection. However, antibiotic treatment is not sufficient for long-term control of trachomatous blindness, and surgery (where indicated), personal hygiene, and environmental improvements also must be available to eradicate the disease by 2020.

Respiratory Disease *Chlamydia trachomatis* can infect the respiratory tract and cause pneumonia in both the adult and infant. However, *C. trachomatis* adult pneumonia is exceedingly rare and documented cases only have been reported in laboratory workers inhaling large doses of the pathogen and in severely immunocompromised individuals. In contrast, *C. trachomatis* infant pneumonia is relatively common when the pathogen is transmitted from the genital tract of the infected mother to the newborn during delivery. The latter pneumonia often is mild and associated with neonatal conjunctivitis.

Chlamydia trachomatis infant pneumonia was first identified by Beem and Saxon, who detected the pathogen in approximately 90% of infants with mild pneumonia. These individuals remained afebrile but had chronic, diffuse lung involvement associated with high serum anti-*C. trachomatis* IgG and IgM. Prospective studies that followed show that 16–28% of infants born to infected mothers develop pneumonia, with a 1–5% prevalence of disease in a range of communities. The pathogen can infect a range of tissues in the neonate including the conjunctiva, respiratory tract, gastrointestinal tract, and vagina. Therefore, neonatal disease may manifest first in the conjunctiva and then in the respiratory tract because half of infants with *C. trachomatis* pneumonia also have had neonatal conjunctivitis. As with neonatal conjunctivitis, it is possible to prevent neonatal pneumonia by adequately identifying and then treating mothers with the STD prior to delivery.

Incubation time for infant pneumonia is approximately eight weeks, slightly longer than for neonatal conjunctivitis. Infants often present with a staccato cough, tachypnea and nasal discharge. However, patients usually are afebrile. Radiology is nonspecific with interstitial infiltrates and bilateral hyperexpansion; there is no pleural effusion and lobar consolidation. Most *C. trachomatis* infant pneumonia is mild and resolves even if not treated, but very young infants or immunocompromised children may develop significant disease. Complications are rare and most cases resolve spontaneously. Interestingly, an association exists between *C. trachomatis* infant pneumonia and obstructive airway disease later in life, but causality has not been determined. Disease can be diagnosed by culture, immunofluorescent staining or nucleic acid detection of sputum specimens. Macrolides are the mainstay of therapy.

Urogenital Disease The hallmark of *C. trachomatis* genital tract infections is their chronicity and persistence. These characteristics lead to human infections that often are asymptomatic or only mildly symptomatic, which may lead to severe scarring and infertility in women before the patient seeks medical attention. In addition, *Chlamydia trachomatis* is the most common sexually transmitted bacterial pathogen in the United States, with approximately 4–5 million new cases occurring annually. The combination of silent disease and frequency of infection makes chlamydial disease a serious health concern in the United States. Indeed, *C. trachomatis* genital tract disease leads to over 25,000 cases of involuntary infertility in females each year. In addition, sequelae of infection are the second most costly outcome of any STD, costing an estimated 4 billion dollars each year in health care costs.

Chlamydia trachomatis STD is transmitted from humans to humans by direct genital contact. The probability of transmission from an individual encounter is between 30 and 70%, where the higher estimates are based on sensitive nucleic acid amplification tests. Risk factors for *C. trachomatis* STD vary among study populations but often include younger age, unmarried status, low socioeconomic use, and use of oral contraceptives. Similar to other STDs, *C. trachomatis* STD is most prevalent for individuals in their late teens and early twenties.

In men, the pathogen enters the distal urogenital tract and infects urethral epithelium. A large portion of infected men remain asymptomatic, but those who do manifest disease present with symptoms within 1–2 weeks. Patients complain of dysuria and often a nonpurulent, clear-to-white penile discharge. Effective treatment for symptomatic men is available with a variety of antibiotics; however, mildly symptomatic or asymptomatic men may not seek medical attention and therefore develop epididymitis, proctitis, sexually reactive arthritis, or unknowingly transmit the organism to women.

In women, the bacterium causes a continuum of inflammatory diseases as it ascends the genital tract. *Chlamydia trachomatis* first establishes infection within the transitional epithelium of the cervix. Those individuals who become symptomatic often present with vaginal discharge and bleeding, mild abdominal pain, and dysuria. Treatment of these patients with antichlamydial antibiotics is effective and prevents sequelae. However, 70–90% of endocervical infections are asymptomatic or only mildly symptomatic, and most infected women do not present for medical treatment. The result is persistent infection that ascends by intraluminal spread up the genital tract. Thus, untreated endocervical infection leads to pelvic inflammatory disease (PID), defined as ascending infection progressing to endometritis (inflammation of the uterine endometrium), salpingitis (inflammation of the fallopian tubes), and pelvic peritonitis. *Chlamydia trachomatis* and *Neisseria gonorrhoeae* account for 65–85% of PID cases in the Unites States. In general, *N. gonorrhoeae* is recovered twice as frequently as *C. trachomatis* from PID patients, and detection of concurrent infection also is common. Furthermore, compared with *N. gonorrhoeae*, *C. trachomatis* urogenital infection generally follows a more indolent course.

Approximately half of all untreated *C. trachomatis* cervical infection leads to endometritis. Elementary bodies released from lysed cervical cells initiate infection of healthy epithelium proximal to the cervix, allowing the organisms to ascend the genital tract by repetitive cycles of epithelial cell infection and lysis. Patients with endometritis may present with abnormal menstrual bleeding and be found to have uterine tenderness and leukocytosis. Often, however, other symptoms and signs of endometritis including abdominal pain, fever and adnexal tenderness are not present, consistent with silent disease caused by *C. trachomatis*. The subclinical or minimally symptomatic disease persists, causing low-grade inflammation and tissue damage over months.

Untreated endometrial *C. trachomatis* infection ascends by intracanalicular spread up the genital tract to infect and inflame the fallopian tubes. The resulting salpingitis may manifest as bilateral lower abdominal and pelvic pain, but subclinical disease is more common with *C. trachomatis* PID. The fallopian tube infection may persist for months and cause peritubular scarring. Experimental data from lower primates suggest that women who become repeatedly infected develop more intense tubular scarring. Salpingitis, if untreated, leads to severe damage to the fallopian tubes with subsequent infertility or ectopic pregnancy.

Untreated *C. trachomatis* salpingitis may further ascend into the peritoneal cavity and cause perihepatitis and periappendicitis. The former, also known as "Fitz-Hugh-Curtis syndrome," is characterized by inflammation of the liver capsule. *Chlamydia trachomatis* perihepatitis usually is asymptomatic, but 3–10% of PID patients have cholecystitis-type symptoms such as fever and right, upper-quadrant abdominal pain. Such patients undergo laparoscopy and laparoscopic cholecystectomy, where advanced perihepatitis is seen as impressive "violin-string" adhesions between the liver capsule and visceral peritoneum. Periappendicitis, or inflammation of the appendiceal serosa and intestinal mucosa, is a less likely complication but also has been associated with chlamydial PID.

Advances in nucleic acid amplification have made available highly sensitive and specific tests for the diagnosis of chlamydial STD. The ligase chain reaction (LCR) and polymerase chain reaction (PCR) have become widely available and are more sensitive, yet still highly specific, when compared with culture. These technologies can be used to detect chlamydial nucleic acid from urine or vaginal swabs and are preferable to older methods (culture, direct fluorescent antibody, and EIA) for the diagnosis of *C. trachomatis* STD.

Treatment with a 7–14 day course of tetracyclines and macrolides is highly effective, and resistance to anti-chlamydial antibiotics has not developed in a clinical setting. It is important to treat the infection with at least 7 days of the aforementioned antibiotics to eradicate the organism. This prolonged treatment is explained in part by the biphasic life cycle of *Chlamydia*, where the extracellular EBs are metabolically inert and intracellular RBs are relatively sequestered within inclusions in host cells. Noncompliance or shorter duration of treatment may result in ineffective clearance, persistence of the organism, and development of sequelae. An alternative to tetracyclines and older macrolides is the newer azolide azithromycin, which remains within the intracellular environment considerably longer than traditional antichlamydial antibiotics. Thus, a single 1-g dose of azithromycin is equally efficacious as a 7-day course of doxycycline in the treatment of chlamydial cervicitis. Cost-effectiveness analyses demonstrate that azithromycin therapy leads to an overall reduction in morbidity and cost despite higher procurement prices for the medication.

Prevention of chlamydial STD especially is important given that most infections are asymptomatic and yet lead to silent disease and infertility. Universal screening is prohibitively costly in low-prevalence populations. Practical prevention strategies are aimed at screening of high-risk populations. Such groups often are defined as adolescent individuals with multiple, new, or

symptomatic partners that rarely or inconsistently use barrier contraception. Both universal and selective screening methods are effective in reducing the prevalence of *C. trachomatis* infection. For example, in the Pacific Northwest, prevalence of *C. trachomatis* infection declined from 10–12% to 3–5% within 8 years after screening young women attending all family planning clinics in the region. In addition, selective screening of women demonstrated a significant reduction in subsequent symptomatic PID (odds ratio 0.44, 95% confidence interval 0.2–0.9). These data clearly suggest that wide implementation of selective screening will curb chlamydial STD in the United States and reduce severe sequelae such as PID, infectious infertility, and ectopic pregnancy.

Rheumatological Disease Reactive arthritis is a systemic inflammatory condition that develops after infection of a distant site. The disease is commonly referred to as Reiter's syndrome after Hans Reiter (1881–1969), who in 1916 described a patient who presented with arthritis, urethritis and conjunctivitis. This condition is an uncommon, systemic complication of certain sexually or enterically transmitted infections, including *C. trachomatis* STD.

Approximately 1–3% of patients with urethritis develop Reiter's, and *C. trachomatis* can be isolated from the urethra of two-thirds of patients who present with Reiter's syndrome in the absence of diarrhea. The disease is much more common in men compared with women. In addition, there is a strong association between HLA-B27 and Reiter's syndrome. Four-fifths of Reiter's patients are HLA-B27 positive, suggesting that chlamydial antigens cross-react with self-antigens to induce an exaggerated immune response distant from the site of infection. It also is conceivable that such molecular mimicry prevents control of infection and leads to dissemination of the pathogen and joint seeding.

Reiter's syndrome is a spondylarthropathy characterized primarily by lower extremity oligoarthritis after urethritis or cervicitis. Patients present one to three weeks following an episode of urethritis or cervicitis. Musculoskeletal diseases include arthritis, enthesopathy (inflammation of the tendons and ligaments), and sacroiliitis. Ocular disease manifests as conjunctivitis in self-limited Reiter's or anterior uveitis in established, chronic disease. Mucocutaneous diseases are characterized by painless oral ulcers or erythematous erosion of the glans penis. Cardiovascular disease is rare and may manifest early as pericardial rubs or late as aortitis.

Diagnosis is difficult because symptoms occur serially over a long period rather than simultaneously. *Chlamydia trachomatis* most likely establishes persistent infection at the inflammatory site inasmuch as chlamydial protein and DNA can be identified at inflamed joints from Reiter's patients. In addition, chlamydial mRNA is detected in synovial biopsies, suggesting active chlamydial infection. These mRNA transcripts are specific for the inflammatory heat shock protein 60 (chsp60) but not the major outer-membrane protein (omp1), consistent with persistent chlamydial infection. Treatment is aimed at reducing inflammation with nonsteroidal anti-inflammatory drugs (NSAIDs) and eradicating infection with antibiotics. Sixty to 80% of first-time Reiter's patients develop chronic disease, and as many as a quarter of patients become functionally disabled as a result of their illness.

Lymphatic Disease The LGV biovar of *C. trachomatis* causes lymphogranuloma venerum, a sexually transmitted disease that affects the lymphatic system. The disease is endemic only in limited regions in India, Southeast Asia, and South America, occurring sporadically elsewhere. The infected individual presents with symptoms within one month of infection, and the disease progresses in three stages. In the first stage, the patient develops a painless, asymptomatic papule on the rectal or genital mucosa. If untreated, the infection gains access to the lymphatic system within weeks. Patients develop inguinal or femoral lymphadenopathy, which are distinct and painful. Infection may spread to adjacent tissue and form a bubo, which then may burst spontaneously to form an abscess or sinus tract. Spread of infection is associated with development of systemic symptoms and signs including fever and myalgias; the organism may gain access to cerebrospinal fluid and cause stigmata of meningitis. The disease then progresses to the final stage, where the granulomatous inflammation leads to ulceration of genital mucosa and obstruction of the lymphatics. The latter sequela is characterized by elephantiasis of genitalia. Diagnosis can be made clinically, serologically and by detecting the pathogen in diseased tissue. Treatment is with antichlamydial antibiotics and draining abscesses to eradicate the site of infection.

Chlamydia pneumoniae

Isolated first in 1965, *C. pneumoniae* was thought to be an unusual *C. psittaci* strain. Saikku and Grayston made the first association between the pathogen and respiratory disease in 1986, and the organism was speciated in 1989 as a leading cause of community-acquired atypical pneumonia (Saikku et al., 1988). Twelve years after speciation, *C. pneumoniae* now stands associated with a spectrum of chronic diseases ranging from atherosclerosis (Grayston, 2000) to

adult-onset asthma (Hahn et al., 1991). Its broad association with diseases in multiple organ-systems underscores the pathogen's capacity to infect a variety of host cell types. For example, whereas *C. trachomatis* is limited to productive infection within epithelial cells and fibroblasts, *C. pneumoniae* is capable of infecting and multiplying within epithelial, endothelial and smooth muscle cells in addition to fibroblasts and macrophages.

Chlamydia pneumoniae probably is a strictly human pathogen that is transmitted by respiratory droplets. It therefore initially accesses the body through the respiratory system. Upper respiratory infection leads to subclinical disease or pharyngitis, sinusitis or bronchitis. Transmission into the lower respiratory tract is followed by productive infection of alveolar macrophages and subsequent development of community-acquired atypical pneumonia. It is thought that the inflammatory response that ensues leads to microvascular damage, which enables the pathogen to escape into the vasculature. Monocytes or lymphocytes may serve as the vehicle of transport for the obligate intracellular bacterium. The pathogen thus may seed multiple sites within the vasculature, including the coronary arteries, abdominal aortic aneurysms or carotid bifurcations to induce or contribute to atherosclerotic heart and vessel disease (Muhlestein et al., 1998; Campbell et al., 2000).

Respiratory Disease The epidemiology of pneumonias is different between hospitalized patients and immunocompetent adults in the outpatient setting. While *Streptococcus pneumoniae* remains the leading cause of pneumonia in hospitals, atypical agents such as *C. pneumoniae* and *Mycoplasma pneumoniae* are very frequent causes of community-acquired pneumonias. Indeed, *C. pneumoniae* is identified in 11–36% of ambulatory patients diagnosed with pneumonia and may be the most commonly identified pathogen in community-acquired atypical pneumonias. In addition, the organism is encountered in 28% of ambulatory pediatric patients diagnosed with atypical pneumonia.

The clinical course of *C. pneumoniae* pneumonia is difficult to distinguish from other atypical pneumonias. It often follows a milder clinical course than *S. pneumoniae* pneumonia, and therefore infected patients may not seek medical attention as frequently. The organism initially is delivered into the upper respiratory tract through aerosol droplets. Upon infecting the epithelium, the pathogen incubates for up to 4 weeks and then initiates a biphasic set of symptoms. The first phase of symptoms includes stigmata of upper respiratory tract infection and includes sinusitis, pharyngitis and bronchitis. It is likely that these symptoms are the result of *C. pneumoniae*-epithelial cell interactions that trigger an inflammatory cascade, evidenced by expression of IL-8, ICAM-1 and PGE-2 by human epithelial cells and subsequent neutrophil migration following *C. pneumoniae* infection. In addition, infection of respiratory epithelium induces ciliostasis, which may aid transmission of the pathogen from the upper- to the lower-respiratory tract. The latter triggers the second phase of symptoms. These patients present with stigmata of atypical pneumonia, characterized by cough, low-grade fever and pleuritic pain. A physical examination may reveal rales and chest X-rays may show pneumonitis, but neither is specific for *C. pneumoniae* pneumonia. Onset of disease is gradual and the course chronic, with reinfection resulting in fewer cases of pneumonia. Most *C. pneumoniae* pneumonias resolve without treatment, although severe cases do occur, especially in patients with chronic obstructive pulmonary disease and in immunocompromised individuals. An important finding is the high rate of coinfection with other organisms, which suggests that the pathogen may predispose to pyogenic infections that may increase severity of disease.

Diagnosis of *C. pneumoniae* respiratory infection can be made by a variety of methods. Most diagnostic studies make use of the microimmunofluorescence (MIF) test, which has been useful in showing high prevalence of *C. pneumoniae* in community-acquired atypical pneumonia. However, cross-reactivity of *C. pneumoniae* and *C. trachomatis* by MIF makes this test suboptimal in diagnosing *C. pneumoniae* pneumonias in certain populations. In addition, different laboratories define arbitrary criteria for positive tests. Alternative diagnostic methods that detect chlamydial nucleic acid in sputum samples may be preferable but less widely available. Clinically, however, a diagnosis is not always necessary before effective treatment is begun. Patients that present with stigmata of community-acquired atypical pneumonia are treated effectively with macrolide antibiotics such as azithromycin.

Pulmonary Associations

Viral and bacterial infections, including *C. pneumoniae*, may exacerbate or trigger acute asthmatic events in patients with long-standing asthma. However, much more controversial is the hypothesis that *C. pneumoniae* may cause asthma in certain adults with no previous history of asthma. Hahn et al. proposed this hypothesis in 1991 when they reported an association between acute *C. pneumoniae* infection and adult-onset wheezing, asthmatic bronchitis and asthma (Hahn et al., 1991). Various small-scale

studies since have examined this hypothesis with equivocal results, and a large-scale prospective study will be necessary to establish a causal link between infection and adult-onset asthma.

Cardiovascular Associations

Excellent recent reviews are available on evidence linking *C. pneumoniae* infection and atherosclerotic heart and vessel disease (see Literature Cited). *Chlamydia pneumoniae*, capable of infecting all cell types within the atherosclerotic plaque, has been associated with coronary artery disease by seroepidemiological and pathological studies, experiments performed with appropriate animal models, and cell culture techniques exploring pathogenic mechanisms. Seroepidemiological evidence comes from more frequent detection of antibodies to the organism in patients with coronary artery disease compared with a control population. Pathological evidence is based on detection of *C. pneumoniae* within atherosclerotic tissue but not normal vasculature. Indeed, the organism is present within macrophage foam cells by electron microscopy and within endothelial cells, smooth muscle cells and macrophages by immunohistochemistry. In addition, *C. pneumoniae* nucleic acid is frequently recovered from atheroma, and in some instances the pathogen has been isolated from plaques. Animal model evidence is highlighted by experiments by Muhlestein et al., who showed that intranasal infection of non-hyperlipidemic rabbits with *C. pneumoniae* led to the development of atherosclerotic changes, whereas mock-infection of controls did not. Furthermore, the infected rabbits were treated with azithromycin and found to undergo regression of atherosclerosis. Cell culture studies reveal that *C. pneumoniae* is capable of altering cellular physiology in ways that may contribute to atherosclerosis. For example, infected cells release chemokines and an inflammatory cytokine cascade, induce lipoprotein oxidation, and accumulate excess levels of lipids, all events strongly linked to the pathogenesis of atherosclerosis.

It is likely that *C. pneumoniae* at least contributes to atherosclerosis and is an emerging risk factor, but does the pathogen cause the disease? The high prevalence of infection and lack of widely available, affordable and specific diagnostic methods in part make it difficult to answer this question. Well-designed experiments are necessary in seroepidemiological, pathological, animal-based, cell culture-based, and treatment-based studies. Importantly, this bacterial infection potentially is another treatable risk factor for atherosclerosis. Indeed, large scale, multicenter, randomized, placebo-controlled treatment trials of patients with coronary artery disease are currently underway to elucidate the role of antibiotics in atherosclerosis.

Neurological Associations

Chlamydia pneumoniae has been associated with diseases of the neurological system such as Alzheimer's disease and multiple sclerosis, but evidence for these associations remains highly controversial. Further work is necessary to strengthen these associations and establish *C. pneumoniae* as a risk factor, or etiologic agent, in Alzheimer's disease and multiple sclerosis.

CHAPTER 8.1

The Order Planctomycetales, Including the Genera *Planctomyces*, *Pirellula*, *Gemmata* and *Isosphaera* and the Candidatus Genera *Brocadia*, *Kuenenia* and *Scalindua*

NAOMI WARD, JAMES T. STALEY, JOHN A. FUERST, STEPHEN GIOVANNONI, HEINZ SCHLESNER AND EIKO STACKEBRANDT

Introduction

The order Planctomycetales comprises a remarkable group of budding bacteria. They and their nearest relatives, the chlamydiae (Weisburg et al., 1986; see The Genus Chlamydia–Medical in this Volume), are the only known cell-wall containing bacteria that lack peptidoglycan. Furthermore, the planctomycetes are morphologically distinctive because of their budding division, their spherical to ovoid cells with crateriform pits (Figs. 1 and 2), and the nonprosthecate appendages (stalks) produced by some members of the group (Fig. 3). Multicellular aggregates or rosettes are formed by some species that produce polar holdfasts (Fig. 3). One genus, *Isosphaera*, is a multicellular filamentous bacterium that moves by gliding. Other motile members of the group produce flagella. A relatively recent addition to the morphological oddity of the planctomycetes is the discovery of cellular compartmentalization, posing a challenge to the traditionally held view of the prokaryote:eukaryote dichotomy (Fuerst and Webb, 1991; Lindsay et al., 1997; Lindsay et al., 2001). Knowledge of the order is limited owing to the relatively few species that have been obtained in pure culture and characterized. However, through the application of molecular microbial ecology techniques over the last 10 years, it has become apparent that planctomycetes are ubiquitous in a wide range of terrestrial and aquatic environments; the physiological diversity underlying this geographic ubiquity has not yet been fully explored. The availability of genome sequence data should provide a valuable resource for the future investigation of planctomycete biology and promises to reveal previously unknown aspects of these unique organisms.

General Planctomycete Phylogeny

The planctomycetes have a typical and unique ribosomal RNA composition. Early analysis of their 16S rRNA by oligonucleotide cataloging and sequence analyses originally placed this order as a deep branch within the Bacteria (Stackebrandt et al., 1984) and/or as a group that is undergoing rapid evolution (Woese, 1987; Liesack et al., 1992b). Thus, the planctomycetes differed markedly from the heterotrophic budding and prosthecate bacteria that fall within the alpha-proteobacteria. This was supported by studies of their 5S rRNA (Bomar et al., 1988), which indicated that its length is significantly shorter than that of most bacteria, ranging from 109 to 111 nucleotides rather than the "minimal" length of 118 bases of other bacteria and archaea (Erdmann and Wolters, 1986). In addition, position 66 lacks an insertion, and numerous transversions were noted in the secondary structure, features previously unknown for other bacteria.

Since the original 16S rRNA gene sequence analyses of described planctomycete species, application of novel culturing techniques has led to the isolation of new planctomycete strains (Fuerst et al., 1991; Schlesner, 1994; Wang et al., 2002). Phylogenetic analysis of these strains using 16S rDNA sequences (Fuerst et al., 1991; Ward et al., 1995; Griepenburg et al., 1999; Wang et al., 2002) has supported the distinct phylogenetic position of the planctomycete lineage and demonstrated the great phylogenetic diversity of the group (Fig. 4). For some of these strains, analysis of sequences encoding 23S rRNA (Ward et al., 2000), the 70-kDa heat shock protein (HSP70; Ward-Rainey et al., 1997), and the β-subunit of ATP synthase (Rönner et al., 1991) supports these findings. These analyses also indicate that while the planctomycete and Verrucomicrobia lineages tend to cluster together, the grouping is not statistically significant. The relationship between the planctomycetes and the chlamydiae, first proposed as sister taxa by Weisburg et al. (1986), is better supported by bootstrapping and other resampling methods. However, an analysis of elongation factor-Tu proteins from planctomycetes suggested long-branch attraction effects as a cause for the incon-

sistent branching position of the planctomycetes and did not support a close relationship between the planctomycetes and the chlamydiae (Jenkins and Fuerst, 2001). Despite the use of alternative phylogenetic markers, the position of the planctomycetes relative to other phyla is still unclear. A recent 16S rRNA-based phylogenetic analysis of the Bacteria using the most slowly evolving sequence positions suggests that the planctomycetes may emerge at the base of the Bacterial tree—reasonable bootstrap values support early

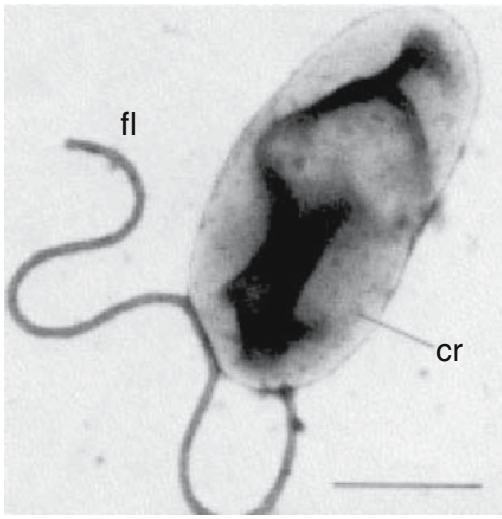

Fig. 1. An electron micrograph of a motile cell of *Pirellula marina* showing flagellum (fl) and numerous circular surface structures referred to as "crateriform structures" (cr). More distinctive crateriform structures are evidenced on some species (see Fig. 2 below). Bar = 1.0 mm. Courtesy of Heinz Schlesner.

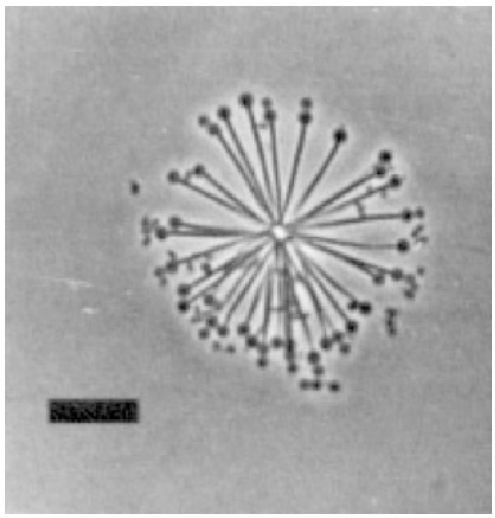

Fig. 3. A phase photomicrograph of a rosette of *Planctomyces bekefii* from University Lake, St. Lucia, Australia. The rosette consists of many spherical cells joined together at the distal tips of their stalks. Bar = 10.0 mm.

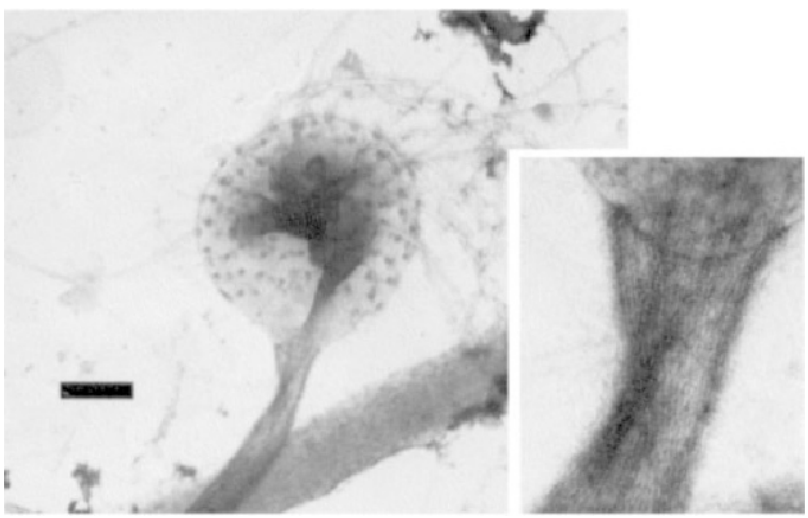

Fig. 2. An electron micrograph of a whole cell of *Planctomyces bekefii* showing many crateriform structures. The inset is an enlargement of the stalk-cell junction, showing the fibrillar nature of the stalk. Sample was collected from University Lake, St. Lucia, Australia, and stained with 1% uranyl acetate in 0.4% sucrose. Bar = 0.5 mm. Courtesy of John A. Fuerst.

Fig. 4. 16S rDNA dendrogram indicating the phylogenetic relationships between described species of the family Planctomycetaceae and isolates from various sites. Letters indicate the geographic origin of the majority of isolates (D = Denmark, G = Germany, and SH = Schleswig-Holstein). Analysis was based on 1170 unambiguous nucleotides (gaps removed). The sequence X86393 was added to the tree manually using the phylogenetic position determined on the basis of 750 nucleotides. The root was determined by using the 16S rDNA sequence of *Escherichia coli* K12 as an outgroup reference. The bar represents 10% sequence divergence, as determined by measuring the lengths of the horizontal lines connecting any two organisms. Numbers refer to bootstrap values; only values above 70% are shown.

emergence of the group, even as the first branching one in place of hyperthermophiles (Brochier and Philippe, 2002). If confirmed, such a position would place planctomycetes at the center of evolutionary microbiology and the search for the last common ancestor of the domains of life.

General Planctomycete Taxonomy

Because of their unique position within the Bacteria, a new order, Planctomycetales, was proposed to accommodate members of this group (Schlesner and Stackebrandt, 1986b). The order is named for the species *Planctomyces bekefii*, which was first described early in the century by Gimesi (1924), who observed this rosette-forming microorganism in a pond in Hungary. He regarded it as a planktonic fungus, thereby explaining the root "*myces*" in the genus name. Organisms of this group were also reported by Henrici and Johnson (1935), who observed them in lakes in the northern United States but assigned them to the bacteria as *Blastocaulis sphaerica*. Neither Gimesi nor Henrici and Johnson obtained pure cultures. The two taxonomic entities were united in 1972 when a careful comparison of both type material (archival drawings) and water samples from the original environments showed the organisms to be identical; *Pl. bekefii* was given priority (Hirsch, 1972). Subsequently several other planktonic, rosette-forming colonial species, including *Pl. crassus*, *Pl. stranskae*, *Pl. gracilis* and *Pl. guttaeformis*, were named but not isolated (see Starr and Schmidt, 1989). Some, such as *Pl. crassus*, were designated fungi, whereas others were described as bacteria. The issue was not finally resolved until 1980, when Schmidt and Starr (1980a, b) demonstrated by electron microscopy that *Pl. bekefii* from both the Hungarian and North American type localities had the cell ultrastructure of a prokaryote. Perhaps in the light of recent findings on cell compartmentalization in planctomycetes, the case from structure alone was not entirely simple and may have been due largely to the use only of chemical fixation in these early studies.

The first reports of pure cultures of this group were published in the 1970s (Staley, 1973; Bauld and Staley, 1976; Schmidt, 1978a). The organisms grew as slow-growing heterotrophs on dilute organic media. Nevertheless, many of the large rosette forms have not yet been isolated, including the type species of the genus, *Planctomyces bekefii*. All cultivated named species, and all named species described only on the basis of microscopic observation, are aquatic, occurring in freshwater lakes, marine habitats, and salt ponds. However, as described below, the presence of planctomycetes in soil and other nonaquatic habitats has been detected using culture-independent 16S rRNA-based methods. This wider habitat range is also reflected in the isolate collections obtained by Schlesner (1994) and Wang et al. (2002), who used cell wall synthesis-inhibiting antibiotics and novel carbon sources to isolate strains from soil, water, compost, manure, etc.

In addition to the unicellular and rosette-forming colonial forms, the order contains filamentous organisms. The filamentous types were initially thought to be cyanobacteria and were named "*Isocystis pallida*" (Woronichin, 1927). However, strains that have been isolated do not contain chlorophyll *a* or other photosynthetic pigments (Giovannoni et al., 1987b). Isolated strains that were obtained from neutral and alkaline hot springs at temperatures between 35 and 55°C were placed in a new genus as *Isosphaera pallida*. Table 1 can be used to distinguish the genera of the order Planctomycetales.

Chemical Properties and Chemotaxonomy

Cell Wall Structure

With the exception of the planctomycetes and *Chlamydia* spp., all other bacteria that possess a cell wall contain peptidoglycan as the main cell

Table 1. Characteristics differentiating the genera of the order Planctomycetales.

Genus	Cell arrangement	Stalk	Flagellar type	Crateriform structure	G + C content (mol%)
Pirellula	Rosettes in pure culture	–[a]	Single, polar	Reproductive pole	54–57
Gemmata	Single cells	–	Polar bundle	Over entire cell surface	64
Planctomyces	Single cells or rosettes	+	Single, polar	Over entire cell surface or reproductive pole	50–58
Isosphaera	Filamentous	–	–[b]	Over entire cell surface	62

Symbols: +, property present; and –, property absent.

[a]A rudimentary "stalk" has been reported in ATCC strain 27377 (Starr et al., 1983).

[b]Moves by gliding.

wall structural compound. The absence of peptidoglycan and the occurrence of a proteinaceous cell wall in the planctomycetes were first reported for several strains of *Planctomyces* and *Pirellula* (then *Pasteuria*; König et al., 1984). This finding explained the considerable resistance of these strains to antibiotics known to target the synthesis of peptidoglycan, including not only the ß-lactams but also non-ß-lactams such as D-cycloserine (Schmidt and Starr, 1982a; König et al., 1984); β-lactamase activity (a possible explanation for resistance) was tested in *Pi. marina* and *Pl. maris* and found to be absent (Claus et al., 2000).

The inclusion of *Gemmata obscuriglobus* and *I. pallida* in the order Planctomycetales was supported by the presence of a proteinaceous cell wall in these organisms (Liesack et al., 1986; Stackebrandt et al., 1986b; Giovannoni et al., 1987a). A more detailed analysis of the cell wall amino acid composition of members of *Planctomyces* and *Pirellula* revealed proteins rich in glutamate and cystine/cysteine, the disulfide bonds of which may contribute to the sodium dodecylsulfate (SDS)-resistance of the cell envelope (Liesack et al., 1986). The cell wall of *G. obscuriglobus*, on the other hand, is low in cystine/cysteine (Stackebrandt et al., 1986b).

Quinone Composition

Another chemotaxonomic marker that confirms the phylogenetic coherence of the order Planctomycetales is the presence of the isoprenoid quinone MK6, a menaquinone (Sittig and Schlesner, 1993) in all species investigated (a strain of *I. pallida* was not included in the study). The main isoprenoid quinone among Gram-negative bacteria is ubiquinone, but menaquinone does occur in members of lines of descent other than the planctomycetes, e.g., the *Bacteroides*, *Cytophaga*, *Flavobacterium* phylum (Collins and Jones, 1981) and certain archaeal families.

DNA Base Composition

The genomic DNA G+C content of members of the order Planctomycetales ranges between 51 and 70 mol%, with values above 60% found in strains of *G. obscuriglobus* and *I. pallida* and their relatives and in two strains that are phylogenetically related to *Pl. limnophilus* and *Pl. brasiliensis* (Griepenburg et al., 1999). The base composition of the 16S rRNA gene for most planctomycetes ranges between 53 and 57 mol%. *Isosphaera pallida* and related strains exhibit 16S rRNA values ranging between 60 and 62%; it has been suggested that these values indicate the 16S rRNA genes of these organisms have been subjected to a higher-than-normal evolutionary rate.

Lipid Composition

Members of the genera *Planctomyces* and *Pirellula* (the latter formerly called "*Pirella*") have characteristic Bacteria-type ester-linked polar lipids rather than the ether-linked lipids of the Archaea (Kerger et al., 1988). However, this may not be a universal phenomenon in planctomycetes as a whole (see below).

Early investigations of planctomycete cellular fatty acids revealed some unusual features. The presence of palmitic, palmitoleic, and oleic acids in *Pirellula* spp. and *Planctomyces* spp. was interpreted as a pattern more typical of microeukaryotes than of bacteria (Kerger et al., 1988). However, these fatty acids are not exclusive to planctomycetes but have subsequently been found widely distributed in other prokaryotic taxa. Similarly, the 18-carbon monounsaturated 18:1ω9c and 18:1ω11c fatty acids detected in members of *Planctomyces* and *Pirellula* (Kerger et al., 1988) are widely distributed among other bacteria. *Pirellula* strains possess hydroxy fatty acids of the 3-hydroxy-octadecanoic acid (3-OH-*n*-18:0) type, but lack 3-hydroxyeicosanoic acid (3-OH-*n*-20:0), whereas in *Planctomyces* strains the distribution of these compounds is reversed (Sittig and Schlesner, 1993). Evidence for the presence of 3-hydroxy acids in *I. pallida* has also been obtained (Giovannoni et al., 1987a), but attempts to obtain a more detailed composition of hydroxy fatty acids in *G. obscuriglobus* were not successful (Sittig and Schlesner, 1993). Claims of lipopolysacharide production by planctomycetes (Kerger et al., 1988) must thus await data derived by methods other than detection of hydroxy fatty acids, since lipopolysaccharide (LPS) itself has not been directly detected (Fuerst, 1995).

Data on phospholipid composition are available for only a few planctomycete strains; phospholipid pattern has been shown to be similar in phylogenetically closely related strains, but different among species (Sittig and Schlesner, 1993; Table 2).

A remarkable novel "ladderane" lipid has been found in an anaerobic chemolithotrophic ammonium-oxidizing planctomycete *Candidatus* "Brocadia anammoxidans." This lipid is a series of linearly concatenated cyclobutane rings and occurs in the membrane surrounding the internal compartment (the anammoxosome) that contains enzymes involved in ammonium oxidation. These lipids contribute to the exceptional density of this membrane and may act to limit diffusion, protecting the rest of the cell from toxic anammox intermediates (Sinninghe Damste et al.,

Table 2. Phospholipids of *Pirellula* and *Planctomyces* strains.

Strains	Phospholipids

Group 3	(+)	–	+	+	(+)	(+)	(+)	+

Symbols: +, main component; (+), present in less amounts; –, not present.
Abbreviations: PG, phosphatidylglycerol; PE, phosphatidylethanolamine; MPE, phosphatidylmono-methylethanolamine; DPE, phosphatidyldimethylethanolamine; PC, phosphatidylcholine; BPG, biphosphatidylglycerol; UP, unknown phospholipids; and Glyl, glycolipid.
[a]Groups are defined by 16S rDNA-based phylogenetic analyses as follows. *Pirellula* group 1: strain 1 (IFAM 1310), strain 140 (IFAM 1319), strain 198 (IFAM 1735); group 2: strain 143 (IFAM 1358), strain 158 (IFAM 1452); group 3: *Pi. marina* (IFAM 1313^T), strain 217 (IFAM 1945).
Planctomyces group 1: strain 203 (IFAM 1999), strain 244 (IFAM 2075), strain 237 (IFAM 2079); group 2: *Pl. limnophilus* (IFAM 1008^T), *Pl. brasiliensis* (IFAM 1448^T), strain 240 (IFAM 3001); group 3: *Pl. maris* (ATCC 29201^T), strain 130 (IFAM 1317), strain 219 (IFAM 1951).

2002). Also significant is their finding that ladderane-containing lipids included dialkyl glycerol diethers, ether-linked lipids typical of Archaea and atypical of Bacteria (i.e., found only in a few deep-branching thermophiles and some sulfate-reducing mesophiles).

Polyamine Distribution

Like phospolipid composition, polyamine distribution has been shown to be a useful chemotaxonomic marker at and below the species level (Griepenburg et al., 1999). All analyzed members of the order Planctomycetales contained significant amounts of polyamines and *sym*-homospermidine, except *Pl. limnophilus* and related strains, which had high amounts of putrescine as the dominant polyamine component. The distribution of putrescine, *sym*-homospermidine and spermidine reflects the phylogenetic diversity within the order Planctomycetales, as closely related representatives of the phylogenetic groups defined by described species and novel isolates exhibit similar polyamine patterns.

Planctomycete Ecology

Habitats and Trophic States

Planctomycetes were first observed in freshwater environments but are now known to be present in other aquatic habitats, including marine and hypersaline waters, and also in nonaquatic environments such as soil and sewage sludge. Many observations provide a record of planctomycete distribution. *Planctomyces bekefii* morphotypes have been reported in freshwater in geographically diverse locations: Hungary, Denmark, other European sites, Vietnam, Venezuela, Israel, Australia and the United States. Isolates have been obtained from environments existing in all trophic (i.e., oligotrophic to highly polluted) states. Some reports have suggested that higher numbers of planctomycetes are found in eutrophic and polluted environments than in eutrophic samples. High pH values (6.8–9.4), high conductivity, and temperate summer temperatures have also been suggested to be associated with increases in planctomycete numbers. However, in a study of Australian freshwater samples, Staley et al. (1980) suggested that planctomycetes could be found in all trophic states and that the proportion of planctomycetes to total viable heterotrophs was not dependent on trophic state. Fuerst (1995) has suggested *Pl. bekefii* as an environmental indicator for eutrophic conditions.

Mineral Encrustation

Many of the rosette-forming planctomycetes have been observed to accumulate iron and/or manganese on the surface of the stalk in their natural freshwater habitats (Schmidt et al., 1981b; Schmidt et al., 1982b). These deposits appear as phase-bright regions of the rosette structure under phase microscopy. The accumulation can be observed either at the central point where the stalks join to each other via holdfasts or all along the length of the stalks. Energy-

dispersive X-ray spectroscopy has been used to demonstrate that manganese is accumulated by members of morphotype 1a (i.e., *Pl. bekefii*), while both iron and manganese are deposited on the stalks of morphotype 1b species (*Pl. crassus*; Schmidt et al., 1981b; Schmidt et al., 1982b). Iron encrustation may be due to passive accumulation of oxidized iron, but oxidation of reduced manganese may be biologically catalyzed by the planctomycetes.

Association with Algal Blooms

A considerable amount of evidence suggests that there is an association between the occurrence of algal or cyanobacterial blooms and increases in the numbers of freshwater planctomycetes. There have been several reports that the numbers of the rosette-forming planctomycetes (*Pl. bekefii*, *Pl. guttaeformis* and *Pl. stranskae*) have been found to increase in freshwater habitats after algal or cyanobacterial blooms. Granberg (1969) observed that increases in numbers of *Pl. bekefii* and *Pl. condensatus* correlated with a seasonal increase in heterotrophic phytoplankton in a reservoir. Organisms resembling *Pl. bekefii* and *Pl. guttaeformis* have been observed in a Louisiana lake during and subsequent to a bloom of a *Pithophora* species (N. Ward, unpublished observation). Further evidence for this hypothesis is provided by the fact that laboratory enrichments of planctomycetes are favored by the presence of ambient light and consequent phototroph development (Starr and Schmidt, 1989) and that freshwater *Pirellula* occur as epiphytes of ensheathed cyanobacteria (The Order Planctomycetales and the Genera *Planctomyces*, *Pirellula*, *Gemmata*, and *Isosphaera* in the second edition). It has been suggested (Kristiansen, 1971) that decomposition of phytoplankton produces hydrogen sulfide (H_2S) and results in rising iron and manganese concentrations that may favor *Pl. bekefii* blooms.

The evidence garnered so far for the interrelationship of planctomycete and algal/cyanobacterial population dynamics in freshwater systems is mostly anecdotal, a situation that could be remedied by a systematic investigation of a freshwater body in which planctomycete numbers have been reported to fluctuate on a seasonal basis. Such a study would include detailed measurements of physicochemical parameters such as temperature, pH, dissolved oxygen, carbon and nitrogen, as well as quantification and identification of planctomycete species by microscopy and molecular (16S rDNA based) techniques. An alternative approach could involve the use of microcosms in the laboratory, if cultures of the rosette-forming species were available.

Association with Crustaceans

There have been several reports of possible association of planctomycetes with crustacea. The first of these was Metchnikoff's report of pear-shaped parasitic organisms associated with cladoceran water fleas of *Daphnia* spp. (Metchnikoff, 1888). This organism was later shown to be the non-planctomycete endospore-forming *Pasteuria ramosa* (related to *P. penetrans* and *P. thornei*, pathogens of plant-parasitic nematodes; Starr et al., 1983).

However, genuine planctomycetes have also been found in association with crustacea, including putative *Pirellula* species attached to the carapace of *Daphnia pulex* (Staley, 1973) and isolated from the hepatopancreas or whole post-larvae of the giant tiger prawn *Penaeus monodon* (Fuerst et al., 1991; Fuerst et al., 1997). The prawn isolates have been shown to be phylogenetically related to *Pirellula* or *Planctomyces* species, in the latter case very closely to *Pl. brasiliensis*, on the basis of 16S rRNA gene sequence analysis (Fuerst et al., 1997). These species may inhabit prawn hemolymph as well as the gut and may be selected for, especially in baculovirus-infected prawns. The exact nature of the association has not yet been determined.

Association with Sponges

Recently, the association of planctomycetes with sponges has been reported. Hosts were the Mediterranean sponges *Aplysina cavernicola* (Friedrich et al., 1999) and *A. aerophoba* (Friedrich et al., 2001). Also the sponge *Rhopaloeides odorabile* from the Great Barrier Reef, Australia, was found to host planctomycetes (Webster et al., 2001).

Ecology and Physiology

Despite the reported widespread distribution of planctomycete bacteria, little is known of their role in the environment. The physiology and metabolism of planctomycetes are not well understood, and most of the available physiological data were obtained to allow taxonomic description of new species and genera. All planctomycete strains currently held in pure culture are chemoheterotrophs, but representatives in mixed laboratory culture include the chemoautotrophs performing anaerobic oxidation of ammonium (see below). Carbohydrates serve as the major carbon source, but *Pl. limnophilus*, *Pl. brasiliensis* and *Pi. marina* can also utilize gelatin, while starch is used by *Pl. brasiliensis*, *Pi. marina* and *G. obscuriglobus* (Franzmann and Skerman, 1984; Hirsch and Müller, 1985; Schlesner, 1986a; Schlesner, 1989). The plancto-

mycetes are relatively slow growing; the shortest recorded generation time is 13 h for *Pl. maris* and *G. obscuriglobus* (Bauld and Staley, 1976; Franzmann and Skerman, 1984). Isolation and maintenance of many planctomycete strains require rather dilute media, and rich media have been shown to be inhibitory to growth in some cases (Schlesner, 1994).

Some species are obligate aerobes (*Pl. maris*, *G. obscuriglobus* and *I. pallida*; Bauld and Staley, 1976; Franzmann and Skerman, 1984; Giovannoni et al., 1987b), while others (*Pi. marina*, *Pl. limnophilus*; Hirsch and Müller, 1985; Schlesner, 1986a) are facultative anaerobes, in the sense that they can ferment carbohydrates. The presence of cytochrome *c* oxidase and the ability of some strains—*Pi. marina* and *Pl. brasiliensis* (Schlesner, 1986a; Schlesner, 1989)—to reduce nitrate suggest that they possess electron transport chains resembling those found in other facultative aerobes.

Isosphaera pallida exhibits a number of physiological properties not seen in other members of the order Planctomycetales. Most of these characteristics bear relation to the hot spring environments from which *I. pallida* has been isolated or in which organisms morphologically similar to *I. pallida* have been observed. The most obvious of these is the moderate thermophily (maximum temperature for growth of 55°C with an optimum of 41°C; Giovannoni et al., 1987b) of *I. pallida*, but also its phototactic ability (unique among heterotrophs) and formation of gas vesicles, which would allow vertical positioning in the water column (Giovannoni et al., 1987b). It has been suggested (Fuerst, 1995) that the phototaxis of *I. pallida* in the absence of phototrophy may make it a good model organism for studying the mechanisms of phototaxis. *Isosphaera pallida* can be grown in coculture with a hot spring phototroph (*Heliothrix oregonensis*) under aerobic conditions in the light; the phototroph cannot be grown in culture in the absence of *I. pallida* (Pierson et al., 1985). Ward et al. (1990) report detection of *I. pallida* by microscopy and 16S rRNA gene sequence-based molecular studies in the top layers of the Octopus Spring cyanobacterial mat, suggesting that this organism may be widely distributed in hot springs other than its type locality. Other physiological traits of *I. pallida* include obligate oligotrophy (growth is inhibited by glucose concentrations greater than 0.025%) and gliding motility, never previously reported in a budding bacterium.

Recent reports have identified deep-branching planctomycetes as the "missing lithotrophs" carrying out anaerobic ammonia oxidation ("anammox"; Strous et al., 1999; Schmid et al., 2000; Van Dongen et al., 2001). The anammox process removes ammonia nitrogen from wastewater, combining ammonia and nitrite into dinitrogen gas, and is important for the reduction of ammonia emissions due to agricultural use of chemical fertilizers. The planctomycetes carrying out this process have been identified by electron microscopy showing the presence of characteristic cellular compartmentalization and crateriform structures and by 16S rDNA sequencing and fluorescent in situ hybridization (FISH) with specific oligonucleotide probes directly on anammox bioreactor biomass or concentrated fractions from such biomass. This finding extends the known physiological range of the planctomycetes to include anaerobic autotrophs and has resulted in the proposition of two new *Candidatus* genera, "Brocadia" and "Kuenenia" (Strous et al., 1999; Schmid et al., 2000). Studies attempting to elucidate the mechanism of the anammox process have begun (Jetten et al., 2001).

Recent studies of sediments from the Baltic-North Sea area indicated that anaerobic ammonium oxidation is occurring (Dalsgaard and Thamdrup, 2002; Thamdrup and Dalsgaard, 2002). Ammonium-oxidizing anammox planctomycetes and their activities have also been detected in the Black Sea, the world's largest anoxic basin (Kuypers et al., 2003), and in anammox activity in an anoxic bay off the coast of Costa Rica (Dalsgaard et al., 2003), indicating a significant role for anammox planctomycetes in the global nitrogen cycle, as biological agents for molecular nitrogen regeneration in anoxic conditions.

It is worth noting that the phylogenetic diversity and depth of the planctomycete lineage suggest that physiological types other than those already reported for this group may be detected. So too, full physiological potential of existing cultured strains may not be appreciated until genome sequence annotations are interpreted and the "metabolome" deduced (see Whole-Genome Sequencing Studies).

Molecular Ecology Studies

Planctomycete sequences were detected in the very first 16S rDNA library to be constructed from a soil (Mt. Coot-tha, Australia; Liesack and Stackebrandt, 1992a; Stackebrandt et al., 1993). Since then, they have been found in multiple libraries generated from terrestrial, marine, freshwater, industrial, and organism-associated environments around the world (Table 3). This wide distribution suggests a ubiquitous distribution and diverse ecological niches for the planctomycetes. It has also stimulated renewed attempts, several of them successful, to recover some of these organisms in pure culture (see

Table 3. Selected environmental clone sequences (published) identified in public databases as members of the order Planctomycetales.

Application of New Isolation Strategies) and to detect them using specific 16S rRNA-targeted oligonucleotide probes (e.g., Neef et al., 1998). The latter study confirmed widespread distribution of planctomycetes in different ecosystems and demonstrated that the "universal" bacterial probe EUB338 does not generally hybridize to planctomycete cells. A separate study (Vergin et al., 1998) indicated a consistent mismatch between planctomycetes and another commonly used "universal" primer (27F) and, importantly, reported the first environmental, genomics data for planctomycetes; four fosmid clones containing planctomycete genomic DNA (as indicated by 16S rRNA signature) were obtained from a marine environment. In a recent study of agricultural soils, planctomycetes were found to comprise 3–12% of the ribosomal RNA abundance (Buckley and Schmidt, 2003). As the number of environmental genomics projects, both terrestrial and aquatic, continues to rapidly increase, we can look forward to a wealth of genomic sequence data from planctomycete constituents of the microbial communities that are sampled and a better understanding of their ecological roles in these communities. Comparison of these data with those obtained from ongoing genome sequence projects for cultivated planctomycete strains (see Whole-Genome Sequencing Studies) may allow us to pinpoint differences between cultivated and as-yet-uncultured strains.

Bacteriophages of Planctomycetes

The only reports of the occurrence of bacteriophages in planctomycete strains originate from the laboratory of Peter Hirsch, Kiel, Germany (Gliesche, 1980; Majewski, 1985). Phage Pl-89 was enriched by polyethylene glycol (PEG)-6000 precipitation of a mass culture of *Planctomyces limnophilus* IFAM 1008 (DSM 3776^T). This phage has been classified as a member of morphogroup B_1 (Akkerman and Eisenstark, 1974), family Styloviridae (Fig. 5). The linear double-stranded (ds)DNA has a genome size of 24.4 (±0.7) MDa (electron microscopic determination) or 28.13 MDa (*Bgl*II digest). The mol% G+C content of the DNA is 57.8%. The host strain of Phage Pi-57 is *Pirellula* sp. IFAM 1358. This phage is also a member of the Styloviridae and belongs to morphogroup B_2 (Fig. 6). The linear dsDNA has a genome size of 30.34 (± 2.19) MDa (electron microscopic determination) or 31.80 MDa (*Bgl*II digest). The mol% G+C content of the DNA is 58.7%. The DNA conformation of these tailed bacteriophages of planctomycete strains is in accordance with the description of these properties in bacteriophages of other budding bacteria such as *Hyphomicrobium*, *Caulobacter*, *Asticcacaulis* and *Ancalomicrobium* (Reanney and Akkermann, 1982).

Application of New Isolation Strategies

The most successful attempt at isolation of members of the order included the use of media containing ampicillin, cycloheximide, and a range of nutrients, including very selective carbon and nitrogen sources such as *N*-acetylglucosamine, and enrichment in dilute media (Schlesner, 1994). Many of these planctomycete isolates did not grow on nutrient-rich media; rapidly growing organisms were previously shown to overgrow planctomycetes on rich media (Hirsch and Müller, 1985). The strategy used by Schlesner (1994) resulted in the isolation of 257 putative planctomycete strains variously resembling members of the genera *Planctomyces* and *Pirellula*, but also including spherical and prosthecate cell morphologies. These strains were subsequently shown by 16S rRNA gene sequence analysis to be a set of phylogenetically novel isolates (Ward et al., 1995; Griepenburg et al., 1999). Some isolates were closely related to described planctomycete species, but the

majority of strains, isolated from a geographically rather small area (Northern Germany), were as unrelated to each other (as are the type species of the four planctomycete genera that were isolated from different continents), demonstrating that planctomycete strains were more diverse than strains held in pure culture up to that point (Ward et al., 1995; Griepenburg et al., 1999; see General Planctomycete Phylogeny). The strains were isolated from a wide range of environmental samples, extending the known habitats of the planctomycetes.

Future Directions for Isolation Strategies

Considering the enormous phylogenetic depth of the order Planctomycetales, comparable to that within the class Proteobacteria or the phylum of Gram-positive bacteria (Fig. 4), the full range of planctomycete diversity has most likely not been fully explored. The cumulative impact of recent isolation studies such as that of Schlesner (1994) and the results of 16S rRNA gene sequence based molecular ecology studies (see Molecular Ecology) suggest that the planctomycetes are a diverse and possibly ecologically very important group of bacteria. The difficulty experienced in their cultivation may be explained by the almost complete lack of knowledge of their metabolic processes. Our current attempts to isolate planctomycetes will undoubtedly be superseded by more focused and directed strategies once this physiological information becomes available and is supplemented by genomic and proteomic data.

New Approaches to Identification

Our lack of knowledge about biochemical and physiological properties that are routinely used in the identification of other prokaryotic species means that planctomycete species have often been described and identified on morphological grounds, as they were 75 years ago (Gimesi, 1924). It is only recently that comparative 16S rDNA sequence analyses and the recognition of planctomycete-specific oligonucleotides (Woese et al., 1985) and other molecular signatures (Liesack and Stackebrandt, 1992a; Liesack et al., 1992b) have provided microbiologists with a reliable and rapid tool to unambiguously affiliate strains to the order Planctomycetales and gave evidence that the genus-specific morphological properties are of phylogenetic significance (Liesack et al., 1992b). Table 4 compiles a set of 16S rDNA signatures that define the majority of strains of the four genera of the family Planctomycetaceae. This information is derived from the sequences of cultured species type strains and from the sequences of isolates found to be closely to moderately related to these type strains. Novel species can be predicted when isolates share lower than 97–98% sequence similarity with the sequence of one of the type strains.

This approach has been applied to isolates from a variety of habitats and the occurrence of many culturable potentially new species can be predicted from the molecular data. The molecular approach complements the phenotype-based classification including cell morphology and other properties such as crateriform structures and multifibrillar appendages.

Table 4. 16S rDNA signature nucleotide pairs (in bold) defining the four genera of the family Planctomycetaceae.[a]

Nucleotide position[b]	*Planctomyces* (3 species, 14 isolates)	*Pirellula* (2 species, 38 isolates)	*Gemmata* (1 species, 8 isolates)	*Isosphaera* (1 species, 13 isolates)
115–312	**U-A**	**G-C**	**C-G**	**G-C**
125–236	U-A	U-R	U-A	**A-U**
340–349	A-U	A-U	A-U	**U-A**
408–434	G-C	G-C	G-C	**A-U**
409–433	G-C	G-C	**C-G**	G-C
501–544	C-G	**G-C**	C-G	C-G
578–763	**U-A**	**U-A**	**C-G**	**C-G**
680–710	**C-G**	**A-U**	**U-A**	**C-G**
822–878	A-U	A-U	**G-C**	G-C, A-U
1028–1033	Y-R	C-G	**G-C**	C-G

1308–1329	U-A	U-A	**C-G**	U-A[d]

Abbreviations: Y, pyrimidine; and R, purine.

[a]Only organisms available in pure culture are considered. A base pair is considered a signature when present in >95% of strains of a genus.

[b]*E. coli* position (Brosius et al., 1978).

[c]*Isosphaera pallida* has A-U.

[d]*Isosphaera pallidai* has C-G.

It can be predicted that the few phenotypic and physiological differences observed in members of the Planctomycetaceae will not be sufficient to describe a significantly larger number of novel species than the ones described so far. As judged from the phylogenetic distance to the two described species of *Pirellula*, many of the strains with a *Pirellula*-type morphology represent novel species (Ward et al., 1995; Griepenburg et al., 1999). The finding of novel planctomycete organisms in different environments makes their increased isolation in the future even more likely. Certainly the spectrum of chemotaxonomic and physiological properties has not yet been fully explored in these organisms, and considering the large phylogenetic interstrain distance of many of the isolates, one would expect these phenotypic differences to be present among the planctomycete strains. However, it may not be taxonomically wise to describe these new species exclusively on the basis of 16S rDNA sequence properties, such as secondary structure idiosyncrasies or the presence of unique signature nucleotides. On the basis of the argument that each individual nucleotide position represents a genomically stable and conserved single state phenotypic character, the accumulation of discriminating molecular properties should have at least the same taxonomic weight as many of those physiological, cultural and nutritional properties traditionally used in the description of novel species. This approach has been included to describe a new species of the genus *Sulfitobacter* (*S. mediterraneus*), for which hardly any discriminating phenotypic properties have been detected when compared to the type strain of *S. pontiacus* (Pukall et al., 1999). The past 20 years have shown the potential of 16S rDNA sequence analysis to reliably indicate the presence of new species and phenotypic properties yet to be discovered; these can then be used to emend the description. However, the failure of probes and primers described as "universal" for the Bacteria to detect planctomycetes (Neef et al., 1998; Vergin et al., 1998) means that overreliance on 16S rDNA sequence analysis as a tool for systematics may pose problems. With the availability of genomic sequence from representative planctomycetes, it should be possible to target genes that are not subject to these limitations or to use a combinatorial approach that targets multiple genes.

Cell Compartmentalization in Planctomycetes

Both *Pirellula marina* and *Pirellula staleyi* possess a characteristic type of cell compartmentalization, in which a single membrane (the intracytoplasmic membrane or ICM) divides the cell into two separate regions, the pirellulosome and a polar cap region, later termed "the paryphoplasm" (Lindsay et al., 1997). The pirellulosome region contains the nucleoid and most of the RNA. A structure analogous to the pirellulosome has also been reported in *Planctomyces maris*, *Isosphaera pallida*, *Gemmata obscuriglobus* and "*Candidatus* Brocadia anammoxidans" (Lindsay et al., 2001). Additional compartments are seen within *G. obscuriglobus* (see Gemmata), i.e., a double-layered membrane encloses the nucleoid, and within "*Candidatus* Brocadia anammoxidans," i.e., a single membrane encloses each anammoxosome. This shared cellular organization has not been previously reported in other bacteria and appears to be both a taxonomically and a phylogenetically significant character common to all planctomycetes so far examined (see Figs. 7–11). The anammoxosome (Fig. 10) is correlated with production of the unique ladderane lipid discussed above; the ladderane structure is suitable for creating a membrane barrier sealing off this compartment, which is postulated to contain toxic intermediates of ammonium oxidation metabolism like hydrazine, from the remainder of the cell including the DNA and ribosomes.

Genomic Organization

Genome Size

Genome size in the planctomycetes, according to physical analysis methods, appears to be in the upper range for bacteria (i.e., 5.2 Mb in *P. limnophilus* to greater than 9 Mb in *G. obscuriglobus*; Ward-Rainey et al., 1996b). DNA-DNA reassociation techniques have also been used to investigate genome size in a number of strains (Kölbel-Boelke et al., 1985). The apparent large genome size of planctomycetes is not surprising, given that the majority of planctomycetes, both cultured and uncultured, have been found in terrestrial and aquatic samples and are therefore assumed to be free-living. Free-living organisms require greater nutritional versatility and other types of adaptability than their relatives engaged in parasitic and mutualistic relationships and therefore greater coding capacity and larger genomes (Peterson and Fraser, 2001). A relatively large genome has been suggested to benefit bacteria living in fluctuating environments, giving them the genetic flexibility to adapt to changing conditions (Roussel et al., 1994). The apparent association between the occurrence of blooms of some *Planctomyces* species and the eutrophication process raises the possibility that

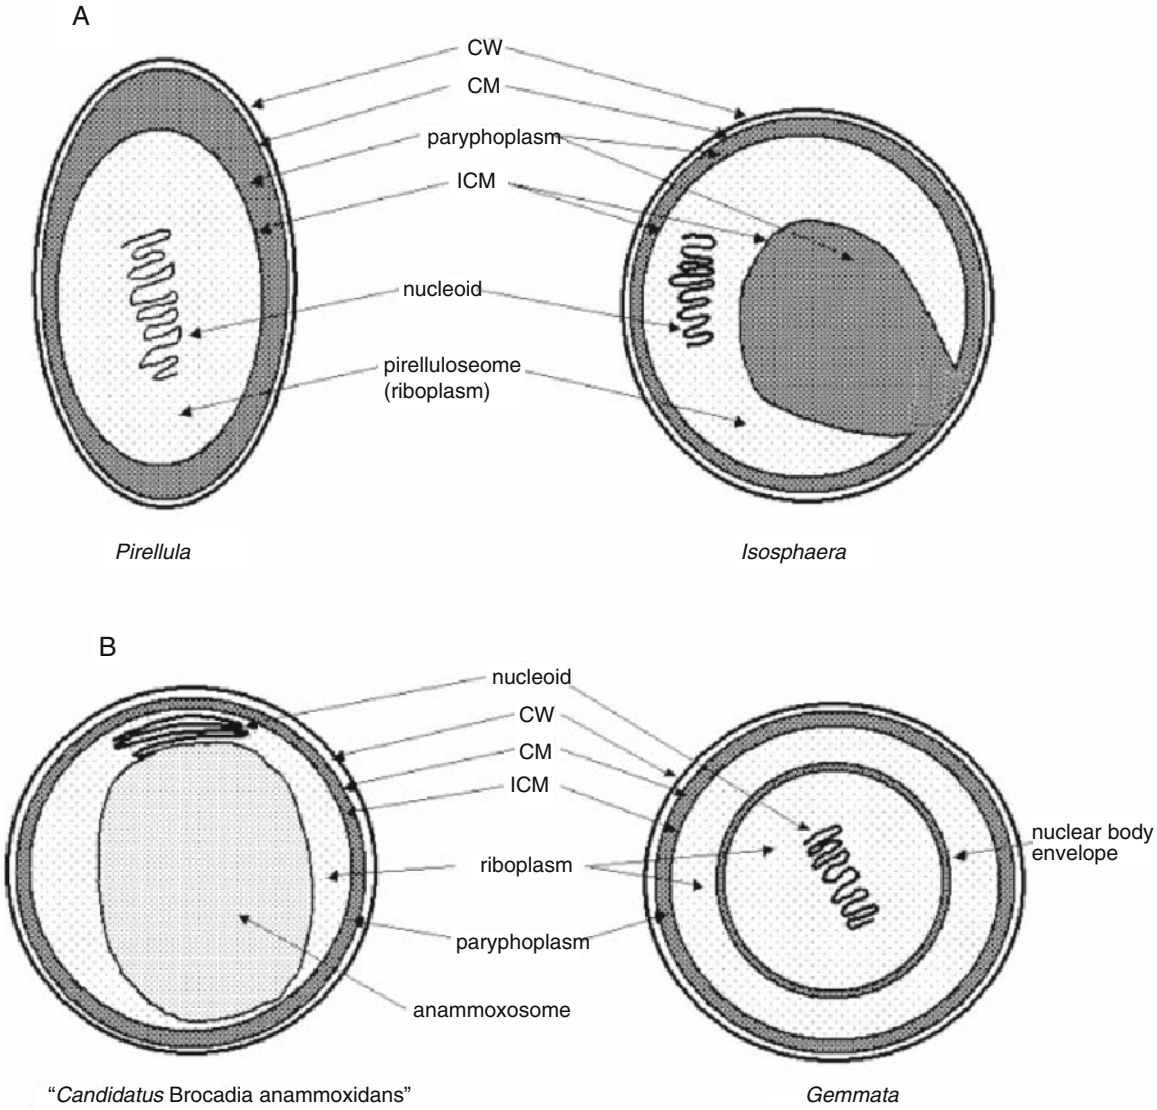

Fig. 7. Diagrams of cell organization and compartmentalization in A) *Pirellula marina* and *Isosphaera pallida* (also applies to *Planctomyces maris*) and B) "*Candidatus* Brocadia anammoxidans" and *Gemmata obscuriglobus*. The varieties of cell compartmentalization found in different planctomycetes are shown, as well as the underlying similarities in topology of their internal organization (i.e., possession of paryphoplasm compartment and ICM). ICM, intracytoplasmic membrane; CW, cell wall; and CM, cytoplasmic membrane. From Lindsay et al. (2001).

in some strains part of the genome may be devoted to the exploitation of changing nutritional conditions during eutrophication. It should be noted, however, that these species have not yet been confirmed as planctomycetes using phylogenetic/molecular approaches, although it seems likely that they will be at some point.

The morphological complexity and lifecycle of planctomycetes may also necessitate a large genome. Large genomes are associated with the ability to undergo complex differentiation, e.g., in *Streptomyces* species (8000 kb; Kieser et al., 1992; Leblond et al., 1993) and *Myxococcus xanthus* (9500 kb; Chen et al., 1991). The majority of planctomycetes possess some form of cellular appendage and have a dimorphic lifecycle. It is conceivable that a significant genetic burden would be imposed by the synthesis of stalks, holdfast material, fimbrae and flagella. An alternative explanation is that extensive genome duplication and rearrangement, such as has been found in the large genomes of members of the genus *Streptomyces* (Kieser et al., 1992; Leblond

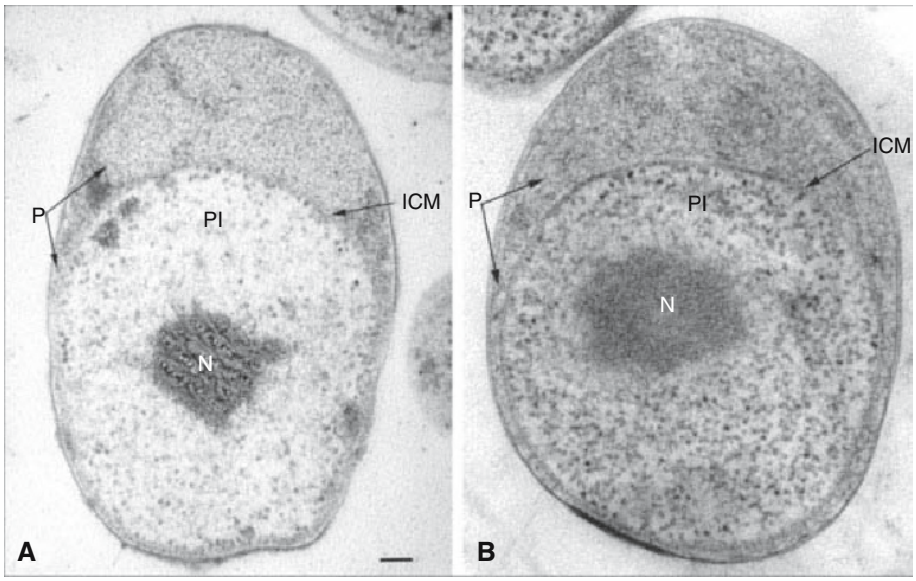

Fig. 8. Transmission electron micrograph of a thin section of a cryosubstituted cell of A) *Pirellula marina* and B) *Pirellula staleyi* displaying compartmentalization into pirellulosome (PI) and paryphoplasm (P) separated by the intracytoplasmic membrane (ICM). The nucleoid (N) is contained within the pirellulosome and thus compartmentalized and surrounded by the single ICM. Bar is 0.1 mm. From Lindsay et al. (1997).

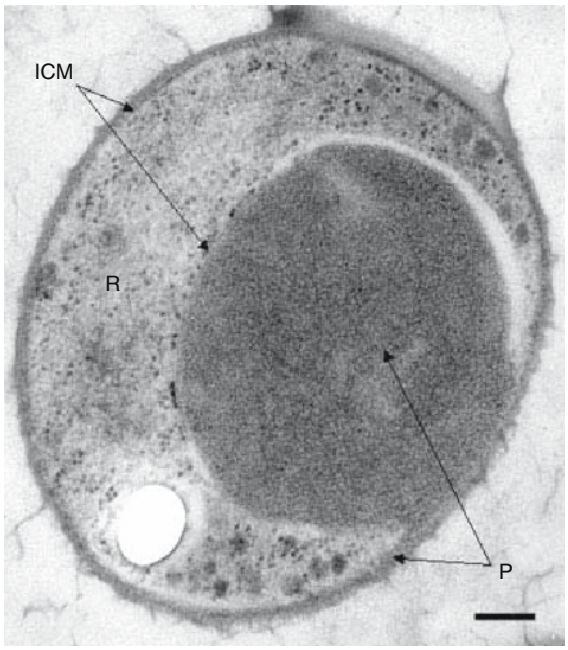

Fig. 9. Transmission electron micrograph of a thin section of a cryosubstituted cell of *Isosphaera pallida* displaying a central single intracytoplasmic membrane (ICM)-bounded invagination of the relatively electron-dense paryphoplasm (P); the other cell compartment, equivalent to a pirellulosome, contains ribosome-like particles (R). Compare with Fig. 7, diagram of planctomycete cell plans. Bar is 0.2 mm. From Lindsay et al. (2001).

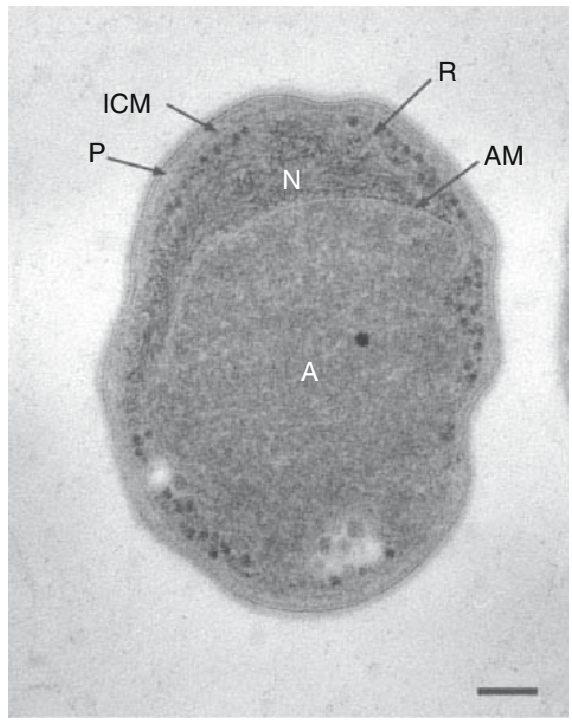

Fig. 10. Transmission electron micrograph of a thin section of a cryosubstituted cell of "*Candidatus* Brocadia anammoxidans" from a bioreactor performing anaerobic ammonium oxidation. A central anammoxosome (A) is surrounded by a single membrane (AM). The cytoplasm external to the AM contains the nucleoid (N) and ribosome-like particles and is surrounded by the intracytoplasmic membrane (ICM). A paryphoplasm (P) lies at the rim of the cell between the ICM and the cytoplasmic membrane closely apposed to the cell wall. Tubule structures are visible inside the anammoxosome. Bar is 0.1 mm. Courtesy of M. Strous, R.I. Webb, and J.A. Fuerst.

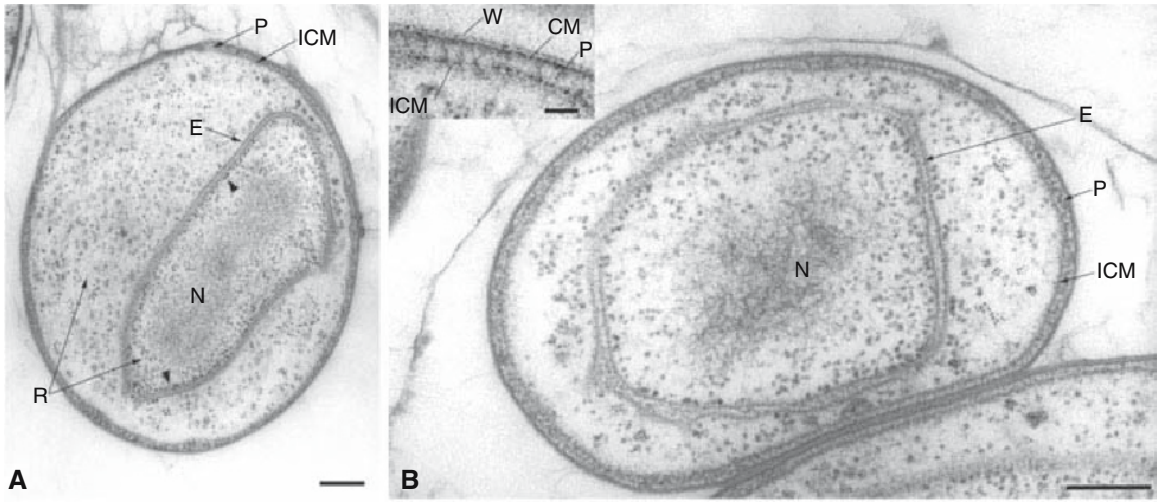

Fig. 11. A) Transmission electron micrograph of thin section of cryosubstituted *Gemmata obscuriglobus*. A nuclear body containing the fibrillar nucleoid (N) and surrounded by a nuclear envelope (E) consisting of two membranes is visible at the right side of the cell. Ribosome-like particles are visible lining the inner side of the nuclear envelope (arrowheads). Riboplasm (R) occurs in two regions, one surrounding the nucleoid within the nuclear body and the other in a larger region surrounding the nuclear body. The cell is rimmed by an electron-dense paryphoplasm (P) and the intracytoplasmic membrane (ICM). Bar is 0.2 mm. From Lindsay et al. (2001). B) Transmission electron micrograph of a thin section of a cryosubstituted *Gemmata obscuriglobus* bud cell with large nuclear body containing an extensive fibrillar nucleoid (N) bounded by nuclear envelope (E) consisting of two membranes between which is a clear electron-transparent space. The nuclear body contains ribosome-like particles as well as the nucleoid. It is surrounded by cytoplasm which contains superficially similar ribosome-like particles and is bounded by a single ICM. The cell external to this ICM is rimmed by a paryphoplasm containing relatively electron-dense cytoplasm (P). Bar is 0.2 mm. Inset: enlarged view of envelope of bud cell showing a bilayered cytoplasmic membrane (CM) underneath the cell wall (W) but closely apposed to that wall. Paryphoplasm (P) is bounded peripherally by the cytoplasmic membrane (CM) and internally by the ICM. Bar is 20 nm. From Lindsay et al. (2001). Bar is 0.5 mm. From Fuerst and Webb (1991).

et al., 1993), have also occurred in the planctomycetes. Data indicating multiple chromosomal loci for some key housekeeping genes in three planctomycete strains (see below) lend credence to this hypothesis.

It is to be expected that the ongoing planctomycete genome sequencing projects (see Whole-Genome Sequencing Studies) will allow us to better understand the relationship between the free-living lifestyle of the planctomycetes and their genome size and complexity.

Genome Topology

The chromosome of *Pl. limnophilus* was shown to be a circular molecule (Ward-Rainey et al., 1996b), as are the vast majority of bacterial strains investigated so far (Cole and Saint Girons, 1994; Fonstein and Haselkorn, 1995; see also completed genome sequencing projects). However, the phylogenetic depth within the order Planctomycetales is as great as that within the class Proteobacteria and the order Spirochetales (groups which exhibit considerable diversity in chromosomal topology); therefore, the presence of a single, circular chromosome in the planctomycete strains studied so far does not imply that all planctomycete genomes are circular.

Ward-Rainey et al. (1996b) reported the presence of an extrachromosomal element in *Pl. limnophilus* detected by pulsed field gel electrophoresis (PFGE) of undigested chromosomal DNA, and application of the same technique to *Pi. marina* also revealed a plasmid species in this strain (Ward-Rainey, 1996a). The presence of extrachromosomal DNA in some planctomycete strains suggests that plasmid transfer or plasmid-mediated conjugal transfer of chromosomal DNA may occur, but as yet there are no reports in the literature of genetic mechanisms in planctomycetes, although genomic evidence for conjugation (*tra* genes) has been reported in *G. obscuriglobus* (Jenkins et al., 2002).

Gene Distribution

Physical mapping of planctomycete genomes (*Pl. limnophilus*, *Pi. marina*, and *Pirellula* strain 140)

using probes for conserved housekeeping genes suggested that: 1) the chromosomal location of these genes varied greatly between strains, 2) the genes coding for 16S rRNA (*rrs*) and 23S rRNA (*rrl*) are separated in the genomes of all three strains investigated, and 3) more than one chromosomal locus exists for several of the genetic markers (Ward-Rainey, 1996a; Ward-Rainey et al., 1996b). Unlinked *rrn* organization had been previously reported for the planctomycete species *Pirellula marina* (Liesack and Stackebrandt, 1989) and *Planctomyces limnophilus* (Menke et al., 1991). The organization of the five sets of *rrn* genes in *Gemmata obscuriglobus* could not be unambiguously determined either by the ribotyping approach (Menke et al., 1991) or by using PFGE techniques (Ward-Rainey, 1996a). In contrast, *Isosphaera pallida* and related bacteria appear to possess the more typical rRNA gene linkage (Ward-Rainey, 1996a). The disjointed *rrn* organization has also been reported in phylogenetically unrelated lineages such as *Thermus* and *Thermotoga* (Menke et al., 1991). The lack of phylogenetic relationship between these taxa suggests that this feature has arisen independently in multiple lineages within the Bacteria and is not a phylogenetically significant marker.

Whole-genome Sequencing

Partial genome sequence data became available for *Gemmata obscuriglobus* and *Pirellula marina* (Jenkins et al., 2002), providing the first glimpse into the planctomycete genome. Many of the genes discovered by this sequence tag approach (including those for metabolism, transport, regulation, translation, and DNA replication) are consistent with the known biology of the strains. Interestingly, there were also significant matches to nuclear genes from members of the domain Eukarya that may have arisen by horizontal gene transfer events.

Whole-genome sequencing projects have been initiated for the type strain of *G. obscuriglobus* (TIGR website) and *Gemmata* sp. Strain Wa1-1. A complete genome sequence is available for *Pirellula* sp. strain 1 (Glockner et al., 2003; Real Environmental Genomics website). These studies will almost certainly shed further light on the genomic basis of planctomycete biology. Genomic and proteomic studies of *Pirellula* sp. strain 1 have already identified genes involved in *N*-acetylglucosamine metabolism (Rabus et al., 2002), which may be a key process in marine systems where *Pirellula* species are abundant (Llobet-Brossa et al., 1998; Glockner et al., 1999).

The Infancy of Planctomycete Genetics

As discussed above, the late 1990s was a period of relatively intense activity in the field of planctomycete biology. One of the welcome by-products of these research efforts is that planctomycetes are becoming more widely known amongst the general community of microbiologists, resulting in renewed interest in the organisms from various perspectives. A recent study by Leary et al. (1998) provides an example of the application of the tools of molecular biology to begin to determine mechanisms of genetic control in the planctomycetes. The *rpoN* gene, which encodes the alternative sigma factor σ^{54}, was cloned from *Pl. limnophilus* and shown to complement the Ntr^- phenotype of a *Salmonella typhimurium rpoN* mutant strain and to share significant homology with other members of the σ^{54} family. This alternate sigma factor has been found in several phylogenetic lineages within the domain Bacteria and is involved in diverse metabolic functions such as nitrogen fixation, hydrogen metabolism, and degradation of aromatic compounds (Kustu et al., 1989). Thus the detection of σ^{54} in a member of the planctomycetes suggests many further avenues to explore, including determination of the promoters in *Pl. limnophilus* with which σ^{54} participates in transcription and identification of structure-function relationships in the σ^{54} group as a whole.

An experimental system for gene transfer to model planctomycetes will be needed for substantial future progress in cell biology of planctomycetes, to take full advantage of established and emerging technologies such as fusions with green fluorescent protein (GFP) to localize proteins likely to be involved in compartmentalization. So far foreign genes or plasmids have been introduced only once into a planctomycete. The GFP-encoding plasmid with the *gfp* gene under control of a *lac* promoter was transferred via conjugation from *Pseudomonas putida* into *Planctomyces maris*, with successful expression of the fluorescent GFP protein (Dahlberg et al., 1998). Extension of such gene transfer to other planctomycetes will open new areas of planctomycete cell biology to experimental investigation.

The Described Genera

The order Planctomycetales comprises four genera, containing only 10 species. Of these species, only seven have been cultured. Three of the six species of *Planctomyces*, including the so far uncultured type species *Pl. bekefii* (Gimesi, 1924), are validly described on the basis of their morphological properties (Starr and Schmidt,

1984), a procedure allowed for by rule 18a of the International Code of Nomenclature of Bacteria (Lapage et al., 1992). Two *Candidatus* status genera, "Brocadia" and "Kuenenia," have been proposed for the anaerobic ammonium oxidizers (Strous et al., 1999; Schmid et al., 2000), and a third genus, "Scalindua," is in the process of being proposed (Schmid et al., 2003; see Ecology and Physiology).

Planctomyces

Since the first report of *Pl. bekefii* by Gimesi (1924), limnologists and bacteriologists have periodically reported similar organisms and ascribed several new species and generic names to these bacteria. Isolates of *Planctomyces* spp. were not obtained until the late 1970s (Bauld and Staley, 1976; Hirsch et al., 1977; Schmidt, 1978a). Even today, *Pl. bekefii*, *Pl. guttaeformis* and *Pl. stranskae*, as well as several other unrecognized species, remain unisolated although they are common residents of freshwater habitats. Their phylogenetic relationships to planctomycetes have also not yet been confirmed by molecular sequencing or oligonucleotide probing.

HABITAT. These bacteria have been isolated from (or observed microscopically in) freshwater, marine and saline habitats. Unicellular forms are frequently found attached to other organisms in the environment (Fig. 12). They attach by a holdfast structure located at the tip of the stalk. Species with the most striking morphology, such as *Pl. bekefii*, occur in the plankton of freshwater lakes as microcolonies of free-floating rosettes (Fig. 13). It is not known how they can specifically associate with one another to form these rosettes in the natural habitat. The colonial forms (perhaps because of their peculiar cell envelope structure) do not appear to occur in soft-water (low osmotic pressure) habitats. They are most common during the summer and early fall,

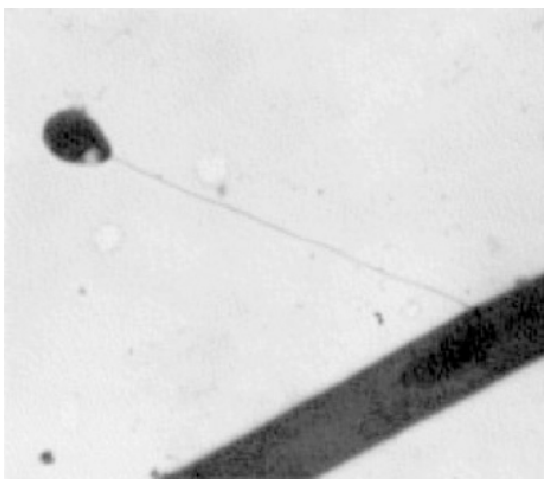

Fig. 12. A lone *Planctomyces* cell attached by its stalk to a sheathed cyanobacterial filament in a sample collected from Lake Washington. Presumably the flexible stalk acts as a tether, allowing the cell to be moved by water currents while the holdfast anchors the cell to the cyanobacterial filament. Cell diameter is about 1 mm. Electron micrograph.

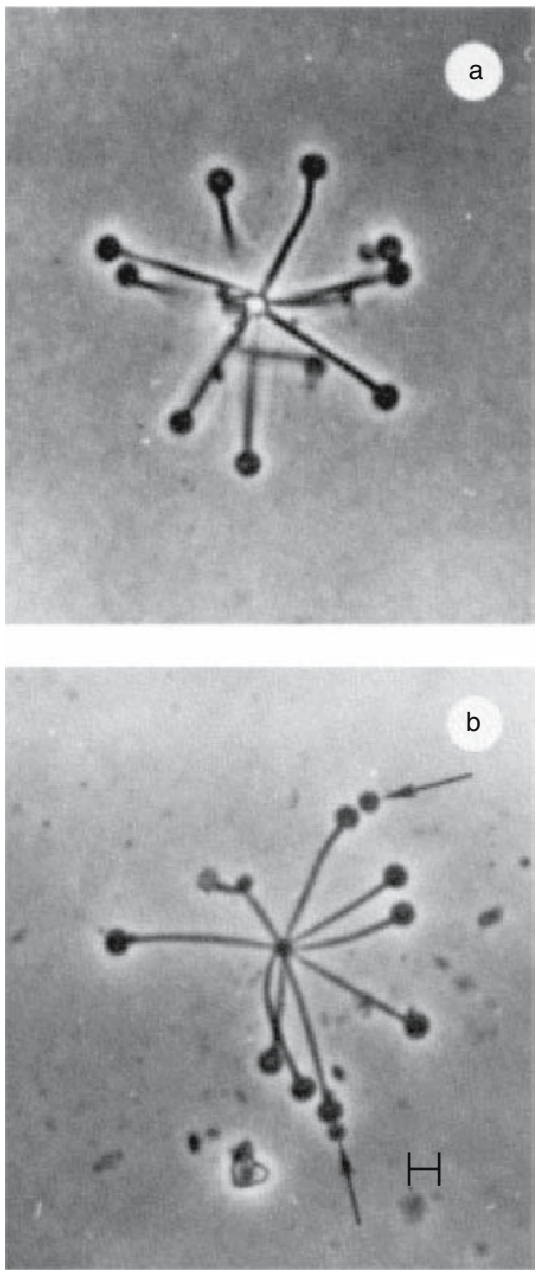

Fig. 13. Phase photomicrographs of a rosette-forming species of *Planctomyces* from University Lake, Chapel Hill, North Carolina. a) Note the encrustation in the central holdfast region of the rosette owing to deposition of iron and/or manganese oxides. b) Arrows point to buds. Bar is 2.0 mm.

particularly in eutrophic lakes. For example, in North America they are found in eutrophic lakes in the Midwest (Wintergreen Lake near Kalamazoo, Michigan) and Southeast (University Lake near Chapel Hill, North Carolina, as well as most other lakes of the Carolina and Virginia Piedmont; J. Staley, unpublished observations). These colonial forms have also been reported to occur in eutrophic ponds in Arizona (Starr and Schmidt, 1984). In contrast, rosette-forming species have not been reported in the mesotrophic to eutrophic soft-water lakes of the Pacific Northwest such as Lake Washington in Seattle, where unicellular forms are found (J. Staley, unpublished observations; see Fig. 12).

Planctomyces spp. have been enumerated in a variety of Australian freshwater habitats using Most-Probable-Number (MPN) techniques with a dilute peptone broth medium (0.01%). They were found in habitats of all trophic states and their proportion to total viable heterotrophs by this procedure (about 0.025%) was essentially the same, regardless of the trophic state of the habitat (Staley et al., 1980). Thus, higher concentrations were found in eutrophic habitats that contained correspondingly higher concentrations of heterotrophic bacteria than did the less nutrient-rich habitats.

ISOLATION: SAMPLE COLLECTION. Water samples (200 ml or more) should be collected aseptically from the environment. If enrichments are to be prepared at the day of sampling, samples can be kept at the collection temperature. For periods longer than 12–24 h, it is advisable to refrigerate. In situ temperature and salinity should be known since these parameters will determine the appropriate conditions for enrichment and isolation.

DIRECT ISOLATION AND ENRICHMENT METHODS. Because these organisms occur in low numbers in most natural environments, they usually have to be enriched. Although they are very distinctive morphologically, they have few physiological features that can be used for the development of enrichment and isolation procedures. The addition of penicillin G (1,000–2,000 U/ml) or other antibiotics that inhibit peptidoglycan synthesis may be used with some success (Schmidt and Starr, 1981a; Schlesner, 1994; Wang et al., 2002), at least at the time of plating, since all isolated strains lack peptidoglycan. Use of protein synthesis inhibitors and antifungal agents may also aid isolation of planctomycetes (Schlesner, 1994; Wang et al., 2002).

In some cases, it may be possible to isolate strains from natural samples by direct streaking of the sample onto an appropriate agar medium. For example, Hirsch et al. (1977) describe a water agar plating procedure used successfully for the isolation of *Planctomyces limnophilus*. Likewise, *P. brasiliensis* was isolated directly from a salt pit sample from Brazil (Schlesner, 1989) by streaking on a saline medium "M13" (described in Pirellula).

A variety of techniques have been applied for the enrichment of *Planctomyces* when numbers from the environment are low. A common procedure is to use the dilute peptone enrichment procedure described for *Prosthecomicrobium* and *Ancalomicrobium* (see The Genera *Prosthecomicrobium*, *Ancalomicrobium*, and *Prosthecobacter* in the second edition). Peptone (Bauld and Staley, 1976) is added to a freshly collected natural sample to a final concentration of 0.01% (or peptone and yeast extract at 0.005% each) and the enrichment incubated at room temperature (or the temperature of the environment from which it was collected). Schmidt (1978a) used somewhat lower concentrations of peptone ranging from 0.002 to 0.005% in her enrichments.

Hirsch and Müller (1985) have described other procedures that have been used successfully in the enrichment of *Planctomyces* spp. 1) In addition to using media with low nutrient concentrations, they have incubated water samples directly with no nutrient addition in either light or dark for periods of 4–16 weeks. 2) Another procedure entails hanging sterile glass slides into fresh or stored water samples and incubating in the light at 20°C. This is reminiscent of the original Henrici procedure in which submerged slides were used to detect periphytic bacteria in lakes (Henrici and Johnson, 1935). When interesting forms appear, material is scraped from the slide with a sterile scalpel and streaked onto an isolation medium. 3) In a different procedure, sterile glass coverslips, some coated with 2% water agar, were inserted vertically into a sterile water agar layer (2 cm deep) in Petri dishes to which was added sufficient sample water to cover the coverslips. Coverslips were examined periodically by phase microscopy for the attachment of budding bacteria. When coverslips contained organisms of interest, replicate ones were removed and material streaked for isolation (Hirsch et al., 1977).

ISOLATION PROCEDURES. Enrichments are examined periodically by phase microscopy to identify types characteristic of the genus: spherical to ovoid cells (oftentimes large [i.e., ≥1.0 μm in diameter]) that attach to detritus or other cells (especially sheathed organisms) and that produce polar to subpolar buds and stalks. The stalks may not be sufficiently thick to be seen by phase microscopy, so to identify these it is advisable to examine samples from prospective enrichments with the transmission electron microscope, by preparing negative stains of enrichment culture material (Fig. 14). Positive

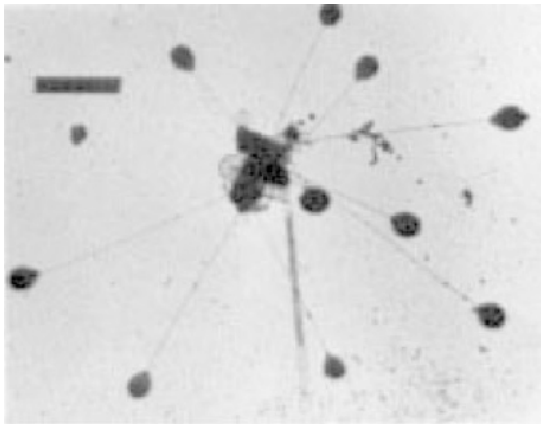

Fig. 14. An unidentified rosette-forming species of *Planctomyces* from a 0.01% peptone enrichment culture of water collected from the Mississippi River in Minneapolis. Bar is 5.0 mm.

enrichment samples are streaked or dilutions spread (spread 0.1 ml samples from 10^{-2} to 10^{-4} dilutions) on agar media. Media that have been used successfully for this purpose include PYGV medium or PYG medium (same as PYGV, but without vitamins; Staley, 1968).

PYGV Medium

Peptone	0.025%
Yeast extract	0.025%
Glucose	0.025%
Hutner's salts solution (see The Genera *Prosthecomicrobium, Ancalomicrobium*, and *Prosthecobacter* in the second edition)	20 ml/liter
Vitamin solution (see Pirellula)	10 ml/liter
Agar	1.5%

For freshwater strains, add distilled water; for marine strains, add aged seawater or artificial seawater solution at half- or full-strength (see Pirellula); for strains from other saline or brackish sources, use an appropriate salt solution mimicking that of the environment. Adjust the pH to 7.0 before autoclaving.

Schmidt and Starr (1981a) recommend using one of three other media for streaking from enrichment culture material. One medium contains 0.02% peptone, 0.01% yeast extract, 0.1% filter-sterilized glucose or galactose, 10 ml of Hutner's mineral base (Cohen-Bazire et al., 1957), 5 mM $MgSO_4 \cdot 7H_2O$, and 1.0 or 1.5% agar. Their second medium contains 0.04% peptone, 0.02% yeast extract, 5 or 10 mM magnesium sulfate, and 1.0 or 1.5% agar made up in either tap water or distilled water to which 10 ml of the Hutner's salts solution is added. The pH of this medium can be adjusted above 7.0 for alkaline samples using 0.005 M tris [hydroxymethyl] aminomethane (Trizma) buffer (Sigma Chemical Co., St. Louis, MO). Usually a pH of 7.8 or 8.0 is used. Their final medium contains 0.2% peptone, 0.1% yeast extract, Hutner's salts solution (10 ml/liter), and 5 mM magnesium sulfate, with 1.0 or 1.5% agar made up with distilled or tap water. Autolysis of osmotically unstable strains can occur in this latter medium.

Colonies of *Planctomyces* spp. develop slowly. Cultures from primary plates need to be incubated for at least one week, and often more than a month is required before they fully develop. One of the most striking characteristics of the colonies is that they continue to develop after most other colony types have stopped growing and are beginning to recede. Typical colonies of the *Planctomyces* types as well as *Pirellula* persist and form impressive mounds about a month after streaking when incubating at room temperature. Colonies may be pigmented (light rose, bright red, or yellow to ochre) or they may be unpigmented.

Repeated restreaking may be necessary to purify some strains. Indeed, some strains cannot be readily isolated even after several restreaking attempts, but some of these can be maintained in monoxenic culture with another heterotrophic bacterium (J. Staley, unpublished observations).

IDENTIFICATION. Members of the genus *Planctomyces* are budding organisms in which the daughter cells are motile by means of a subpolar flagellum. Subsequently, in their transition to the reproductive stage, these cells form noncellular, fibrillar, tubular, ribbon-like or ropelike stalks; their presence in the three cultured species (*Pl. limnophilus*, *Pl. brasiliensis* and *Pl. maris*) can only be observed by electron microscopy (Bauld and Staley, 1976). Thus, the most direct means to verify the identity of putative *Planctomyces* isolates is by transmission electron microscopy (see Figs. 10 and 12). Whole cell preparations that are negatively stained should show the typical spherical to ovoid cell types with polar stalks. Stalks are the primary characteristic used to distinguish *Planctomyces* from *Gemmata* and *Pirellula*. Although stalks have been infrequently reported from these latter two genera, they are quite rare and often nondistinctive. In contrast, stalks are very common in *Planctomyces* spp. Indeed, in a typical growing preparation of *Planctomyces* spp., all mature, budding cells would be expected to bear a stalk.

Classification of species in the genus has been based largely upon morphological attributes, especially for types that have not yet been isolated. Schmidt and Starr (Schmidt and Starr, 1978b; Schmidt and Starr, 1979) and Starr and Schmidt (1989) classified this genus into five morphotypes, I–V. Cells of morphotype I are spherical, joined together in rosettes, as represented by *Planctomyces bekefii* (Figs. 13 and 15). Cells of morphotype III are ellipsoidal and are

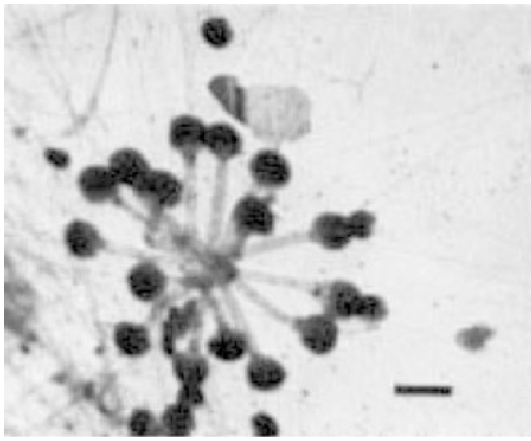

Fig. 15. An electron micrograph of an organism that resembles *Planctomyces bekefii*. Though this organism is similar to *Pl. bekefii*, note that its cells have two to four or more very long prominent filiform appendages extending outward from each cell of the rosette near the reproductive pole rather than several shorter ones characteristic of *P. bekefii* (see Fig. 2). This type of Planctomyces is common in lakes in the southeastern United States. From University Lake, Chapel Hill, North Carolina. Bar is 2.0 mm.

represented by the isolated species, *Pl. maris*, *Pl. limnophilus* and *Pl. brasiliensis*. Cells of morphotype V are bulbiform-shaped and form rosettes (Figs. 16 and 17). *Pl. guttaeformis* and *Pl. stranskae* are members of this group. No species names have been proposed for morphotypes II and IV, cells of which are ovoid. However, one member of morphotype IV is now classified as *Pirellula staleyi*. One possible future application of the morphotype scheme would be in combination with taxon-specific labeled oligonucleotide probe-based FISH. The physical distinctiveness of the individual morphotypes could thus allow determination of their phylogenetic position in relation to other planctomycete species, in the absence of cultured isolates. Fuerst (1995) suggested cloning of 16S rDNA amplified from micromanipulated cells and FISH using planctomycete-specific fluorescent oligo probes.

Ultrastructure of cultured *Planctomyces* species (e.g., *Pl. maris*) conforms to the cell plan shared by other planctomycetes (Lindsay et al., 2001).

Pure cultures are available of three described species, all of morphotype III, including *Pl. maris* (Fig. 18), *Planctomyces limnophilus* and *Pl. brasiliensis*. The stalks on these species are so fine they cannot be discerned by observation with the phase contrast microscope. When observed by the electron microscope, the stalk can be seen to contain a number of fine fibrils bundled together to form a fascicle that emanates at one pole of the ellipsoidal cells. This stalk develops at the pole near the site of the subpolar flagellum.

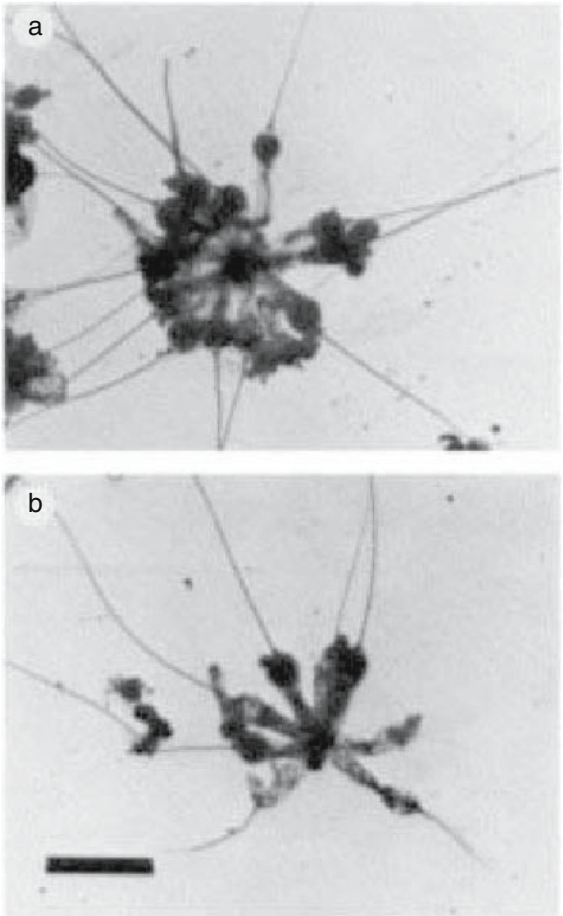

Fig. 16. Rosettes of *Planctomyces guttaeformis*. a) Note the bulbiform cells that are joined together at their narrow poles. Also note the long spike appendage extending away from the bulbous reproductive pole of mature cells in the rosette. b) Another rosette from same locale contains budding cells at different stages of development. Buds begin as spherical protuberances but then become bulbiform. Several cells in this rosette are lysed. From University Lake, Chapel Hill, North Carolina. Bar is 5.0 mm.

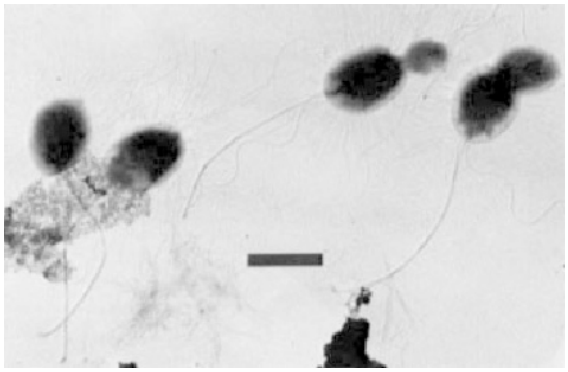

Fig. 18. Shadowed electron micrograph of cells of *Planctomyces maris*. Note the polar to subpolar buds, fibrillar stalks, subpolar flagella, and peritrichous fimbriae. Bar is 1.0 mm.

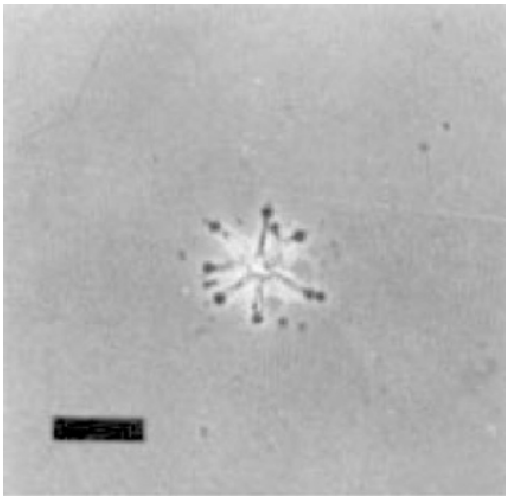

Fig. 19. A phase photomicrograph of a small rosette-forming species of *Planctomyces* from University Lake, St. Lucia, Australia, showing heavy deposition of iron and or manganese oxides on the stalks. Bar is 10 mm.

Table 5. Differentiation among isolated species of *Planctomyces*.

Character	*P. maris*	*P. limnophilus*	*P. brasiliensis*
Cell shape; maximum cell diameter	Ovoid; 1.5µm	Ovoid; 1.5µm	Spheroid; 1.8µm
Source	Marine	Fresh water	Salt pit
Colony pigmentation	Colorless to light rose	Red	Yellow
Salinity growth range (%)	1.5–4.0	<1.0	0.7–10.0
NaCl growth range (mM)	100–>300	ND	100–170
Temperature growth range (°C)	6–38	17–39	ND
G+C content (mol%)	51	53	55–58
Genome size ($\times 10^9$Da)	3.62	2.67	2.81

Abbreviation: ND, not determined.

These species are differentiated by 16S rRNA gene sequence, salt requirements for growth, and various other morphological and physiological characteristics (Table 5).

All cultured isolates have dimorphic life cycles. Reproduction occurs by budding, in which the cell envelope of the daughter bud is formed de novo (Staley, 1973; Tekniepe et al., 1981). Daughter cells are motile by a polar to subpolar flagellum. Though they lack stalks initially, these are formed as part of their maturation process in a fashion that is analogous to that of *Caulobacter* (although the stalks of *Planctomyces* spp. are not prosthecae).

All three of these species are heterotrophic organisms that grow aerobically. Various mono- and dissacharides are used, including glucose, galactose, cellobiose, maltose and *N*-acetylglucosamine. *Planctomyces maris* and *Pl. brasiliensis* also use glucuronic acid. Ammonium salts can be used as the sole nitrogen source by *Pl. maris* and *Pl. limnophilus*. Vitamins are not required by any of the isolates.

The characteristics of the other unisolated but currently recognized species are given in Table 6. All of these species produce large, conspicuous rosettes in the natural freshwater habitats in which they occur. Each cell of *Pl. bekefii* produces a distinctive thick stalk that terminates in a holdfast. The stalk is a tubular structure comprising many fibrils (Schmidt and Starr, 1980a, b). The holdfasts enable cells to join together in the natural habitat to form rosettes (Figs. 13 and 15). Some colonial forms such as *Pl. bekefii* can develop stalk encrustations (Fig. 19) containing iron and/or manganese oxides (Schmidt et al., 1981b; see Ecology and Physiology).

The most characteristic feature of *Pl. guttaeformis* and *Pl. stranskae* is their bulbiform cells (Starr and Schmidt, 1984), which are joined together at their narrow poles to form rosettes (Figs. 14 and 15). In addition, *Pl. guttaeformis* produces a long terminal spike from its large pole, a feature lacking in *Pl. stranskae*.

The use of 16S rRNA gene sequences for identification and classification of cultured isolates,

Table 6. Differentiation among recognized species of *Planctomyces* that have not yet been isolated in pure culture.[a]

Characteristic	*P. bekefii*	*P. stranskae*	*P. guttaeformis*
Cell shape	Spherical	Bulbiform	Bulbiform
Stalk	Tubular	Absent	Absent
Other appendages	Fimbriae and larger spikes[a]	Fimbriae only	Fimbriae and a single, long tapering spike

[a]At least two variants (species?) exist. One type has several shorter spikes (see Fig. 2) whereas another type has fewer, very long spikes (see Fig. 3).

now so widespread as to be almost universal, allows strains tentatively identified as *Planctomyces* spp. on the basis of light microscopy to be assigned to this genus, to other planctomycete genera, or to novel groupings (Ward et al., 1995; see also New Approaches to Identification).

Pirellula

HABITAT. *Pirellula* spp. and morphologically similar bacteria have been observed in and isolated from a variety of aquatic environments: freshwater (Staley, 1973; Tekniepe et al., 1981; Schlesner, 1994), brackish water (Gebers et al., 1985; Kölbel-Boelke et al., 1985; Schlesner, 1986a), hypersaline water of a salt pit (Gebers et al., 1985), hot springs of Tiberias in Israel (Kahan, 1961), groundwater (P. Hirsch, personal communication), alkaline water from ponds in a lime pit near Lägerdorf, Schleswig-Holstein, Germany (Schlesner, 1994), lakes rich in Na_2SO_4, Na_2CO_3 and $NaHCO_3$ ("Lacken") in Burgenland, Austria, wastewater aeration lagoons of a sugar factory, marine and brackish water basins in an aquarium (Institut für Meereskunde, Universität Kiel), water basins in a greenhouse in the botany garden of the University of Kiel, and even the pitcher trap of the insectivorous plant *Nepenthes* sp. (Schlesner, 1994).

In spite of their widespread distribution, *Pirellula*-like bacteria are only occasionally observed in water samples. After storage at room temperature (a few days to some weeks), however, such organisms are often found in high numbers, especially on the bottom or at the wall of the vessel. Obviously, the organisms live attached to surfaces and only the swarmer cells are free in the water column. When the population is very dense, however, *Pirellula*-like organisms may be found in high numbers in the free water.

ISOLATION. Various methods have been successfully applied for the enrichment of *Pirellula* spp.: 1) Storage of samples in the laboratory; 2) addition of small amounts (0.005–0.01%) of peptone, yeast extract, or glucose to the water sample; 3) addition of 0.1% chitin to the sample; and 4) addition of 0.1% KNO_3 and anaerobic incubation.

Isolation procedures take advantage of resistance to antibiotics that affect the biosynthesis of peptidoglycan and, furthermore, of the ability to utilize *N*-acetylglucosamine as sole carbon and nitrogen source (Schlesner, 1994). The salinity of the medium should not differ much from that of the natural environment, since many strains show a rather narrow salinity tolerance (H. Schlesner, unpublished observation). The following media have successfully been applied for isolation of strains of *Pirellula* spp.:

Medium M 1 + A

Solution 1

$CaCO_3$	5.0 g
$Na_2HPO_4 \cdot 2H_2O$	0.1 g
$MgSO_4 \cdot 7H_2O$	0.5 g
Hutner's basal salts (see below)	20 ml
Gellan gum (Gelrite)	9.0 g
Vitamin solution no. 6	10 ml
Distilled water	920 ml

Adjust pH to 9.0; autoclave 121°C for 20 min.

Solution 2

N-Acetylglucosamine	2.0 g
Ampicillin sodium salt	0.2 g
Distilled water	50 ml

Adjust to pH 9.0, filter sterilize, and add to solution 1.

Hutner's Basal Salts (Cohen-Bazire et al., 1957)

Nitrilotriacetate (NTA)	10.00 g
$MgSO_4 \cdot 7H_2O$	29.70 g
$CaCl_2 \cdot 2H_2O$	3.34 g
$NaMoO_4 \cdot 2H_2O$	12.67 mg
$FeSO_4 \cdot 7H_2O$	99 mg
Metal salt solution "44" (see below)	50 ml
Double-distilled water	900 ml

First dissolve the NTA by neutralization with KOH. Add the other salts. Adjust pH to 7.2 with KOH or H_2SO_4. Adjust volume to 1000 ml with double distilled water. Store cold (5°C) and clean. The solution is clear.

Metal Salts Solution "44"

Ethylene diamino tetraacetate (EDTA)	250.0 mg
$ZnSO_4 \cdot 7H_2O$	1095.0 mg
$FeSO_4 \cdot 7H_2O$	500.0 mg
$MnSO_4 \cdot H_2O$	154.0 mg
$CuSO_4 \cdot 5H_2O$	39.2 mg
$CoCl_2 \cdot 6H_2O$	20.3 mg
$Na_2B_4O_7 \cdot 10H_2O$	17.7 mg
Double-distilled water	1 liter

To retard precipitation, add a few drops of H_2SO_4 before making to volume. Store cold (5°C).

Vitamin Solution No. 6 (Staley, 1968)

Biotin	4.0 mg
Pyridoxine hydrochloride	20.0 mg
Thiamine hydrochloride	10.0 mg
Ca pantothenate	10.0 mg
p-Aminobenzoic acid	10.0 mg
Folic acid	4.0 mg
Riboflavin	10.0 mg
Nicotinamide or nicotinic acid	10.0 mg
Vitamin B_{12}	0.2 mg
Double-distilled water	1 liter

Stirring of the mixture improves dissolution. Sterilize by filtration only. Store dark and cold (5°C).

Medium M 30 + A

Solution 1	
Hutner's basal salts	20 ml
Artificial seawater	250 ml
Buffer: 0.1 M Tris/HCl, pH 7.5	50 ml
Agar	18 g
Distilled water	630 ml

Autoclave at 121°C for 20 min.

Solution 2

N-Acetylglucosamine	2.0 g
$Na_2HPO_4 \cdot H_2O$	0.1 g
Ampicillin sodium salt	0.2 g
Vitamin solution no. 6	10 ml
Distilled water	40 ml

Add filter-sterilized to solution 1.

Artificial Seawater (Lyman and Fleming, 1940)

NaCl	23.477 g
$MgCl_2$	4.981 g
Na_2SO_4	3.917 g
$CaCl_2$	1.102 g
KCl	0.664 g
$NaHCO_3$	0.192 g
KBr	0.096 g
H_3BO_3	0.026 g
$SrCl_2$	0.024 g
NaF	0.003 g

Medium 31 + A

Solution 1	
$CaCl_2 \cdot 2H_2O$	0.1 g
$MgCl_2 \cdot 6H_2O$	0.1 g
Hutner's basal salts	20 ml
Buffer: 0.1 M Tris/HCl, pH 7.5	50 ml
Agar	18.0 g
Distilled water	880 ml

Adjust pH to 7.5; autoclave at 121°C for 20 min.

Solution 2

N-acetylglucosamine	2.0 g
$Na_2HPO_4 \cdot 2H_2O$	0.1 g
Ampicillin sodium salt	0.2 g
Vitamin solution no. 6	10 ml
Distilled water	40 ml

Adjust pH to 7.5, filter-sterilize, and add to solution 1.

To minimize growth of fungi, cycloheximide (0.2 g/liter) may be added to solution 2 of each respective medium. For culturing or long-term storage of pure cultures, the above media should be enriched by adding 0.25 g of peptone and 0.25 g of yeast extract to solution 1. Good results are also obtained with medium M 13.

Medium M 13 (Schlesner, 1986a)

Peptone	0.2 g
Yeast extract	0.2 g
Glucose	0.2 g
Hutner's basal salts	20 ml
Vitamin solution no. 6	10 ml
Buffer: 0.1 M tris/HCl, pH 7.5	50 ml
Artificial seawater	250 ml
Distilled water	670 ml

IDENTIFICATION. *Pirellula* spp. are easily recognized by their morphology. The cells are ovoid, sometimes elliptical, or nearly spherical. They are polarly organized. From the smaller cell pole, holdfast substance is excreted which allows the cells to attach to surfaces or to each other and form rosettes (Fig. 20). Buds develop at the broader pole as a minor mirror image of the mother cell (Fig. 21). Immunoferritin labeling experiments have shown that at least the surface components of the new buds are synthesized de novo (Tekniepe et al., 1982). The buds are motile by means of a 20-nm thick single flagellum that is inserted polarly to subpolarly (Schlesner, 1986a) at the proximate (reproductive) pole (see Fig. 1).

Crateriform structures are scattered over the whole cell surface of the buds in the early developmental stage, while in adult cells their distribution is restricted to the reproductive pole only (Fig. 22A). Adult cells also have fimbriae, originating from the crateriform structures (Fig. 22A). Another type of surface structure,

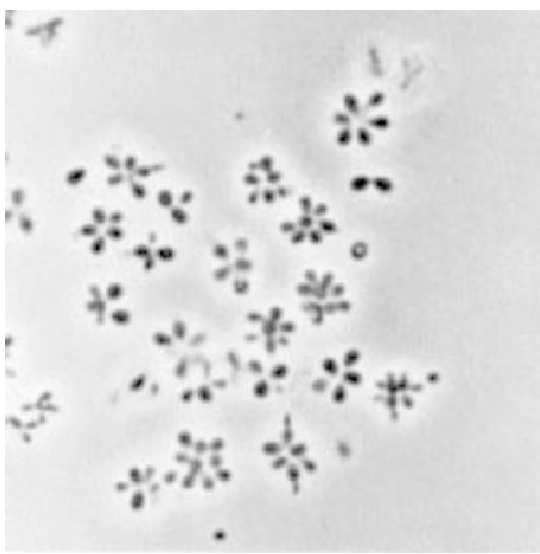

Fig. 20. Phase photomicrograph illustrating rosette formation by *Pirellula marina*.

described as "stacked disks" (Schmidt and Starr, 1979), is shown in thin sections through the reproductive cell pole (Liesack et al., 1986).

Ultrastructure of *Pirellula marina* and *Pirellula staleyi* in thin section conforms to the planctomycete cell plan, with the nucleoid enclosed within a membrane-bounded pirellulosome compartment (Fig. 8). An unusual feature found on cells of two strains of *Pirellula staleyi* are hump-like prosthecate protrusions observed on either side of the cell (Butler et al., 2002; Fig. 22B).

Colonies are red, pink or colorless. Pigmentation seems to be of taxonomic significance, as homology groups derived from DNA/DNA hybridization experiments with 54 strains contained either pigmented or unpigmented strains (Bartels and H. Schlesner, unpublished observations).

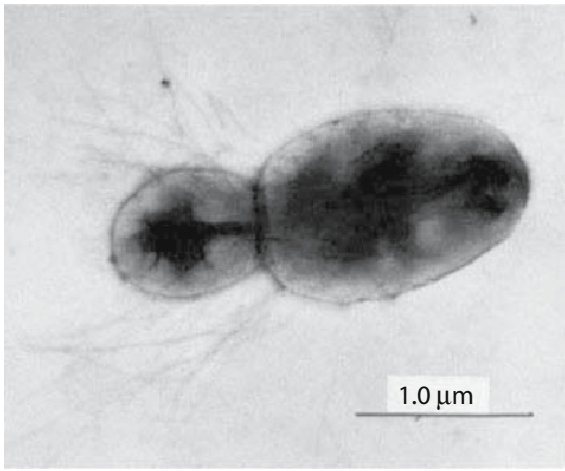

Fig. 21. An electron micrograph of *Pirellula marina* showing a single polar bud.

Phylogenetic clusters of Australian isolates from the prawn *Penaeus monodon* grouping loosely with *Pirellula marina* also were either pink-pigmented or nonpigmented (Fuerst et al., 1997), with the pink strains most closely related to pink or red strains from Europe and forming a cluster distinct from *Pi. marina*.

The phylogenetic position of seven strains of *Pirellula* spp. (including *Pi. staleyi* and *Pi. marina*), analyzed by 16S rRNA cataloging, showed a great phylogenetic diversity among these strains (Stackebrandt et al., 1986a). These findings were supported by analysis of 5S rRNA (Bomar et al., 1988) and subsequent 16S rRNA gene sequencing studies (Ward et al., 1995; Griepenburg et al., 1999). An isolate (ATCC 35122), originally identified as *Pirellula staleyi* on the basis of morphology, has been confirmed by 16S rRNA sequencing as *Pirellula staleyi* (Butler et al., 2002).

Despite their phylogenetic diversity, the strains investigated are phenotypically very similar. As carbon sources, mainly sugars and sugar derivatives are utilized; *N*-acetylglucosamine serves as both carbon and nitrogen source. Sugar alcohols may or may not be utilized. Some strains are able to reduce nitrate anaerobically. All strains tested so far hydrolyze gelatin; casein, DNA or starch is hydrolyzed by some strains, but cellulose is not hydrolyzed at all. Additional methods will have to be applied to find more discriminating taxonomic characteristics.

Two species are described. The type species is from freshwater: *Pirellula staleyi* (Schlesner and Hirsch, 1987), syn. *Pirella staleyi* (Schlesner and Hirsch, 1984), syn. *Planctomyces staleyi* (Starr et al., 1983), syn. *Pasteuria ramosa* (Staley, 1973). The other species is marine: *Pirellula marina* syn. *Pirella marina* (Schlesner, 1986a). The strain

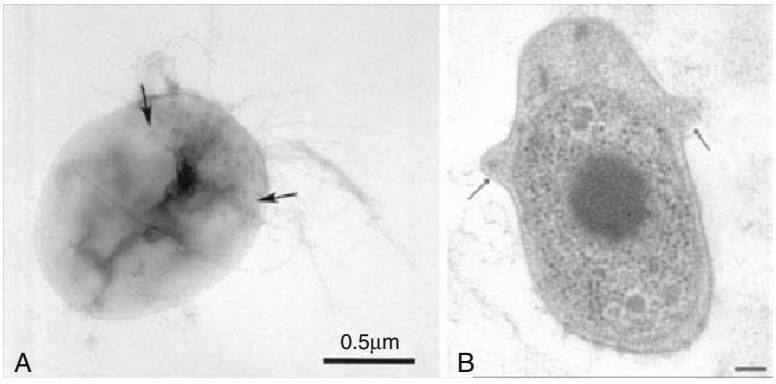

Fig. 22. A) Transmission electron micrograph of negatively stained cell of *Pirellula staleyi* (ATCC 35122) showing polar crateriform structures on cell surface (arrows) and polar flagella and fimbriae appendages. Micrograph courtesy of M. K. Butler and J. A. Fuerst. B) Transmission electron micrograph of thin section of cryosubstituted *Pirellula staleyi* ATCC 35122, showing hump-like protrusions (arrows) on either side of the cell. The typical *Pirellula* cell plan including the pirellulosome compartment is also illustrated here. Bar is 0.1 mm. From Butler et al. (2002).

ATCC 35122 was recently confirmed as a strain of *Pi. staleyi* on the basis of its molecular and ultrastructural characteristics (Butler et al., 2002).

Gemmata

HABITAT. The genus *Gemmata* is at present represented by one species, *G. obscuriglobus*. The single strain UQM 2246 representing the single species was isolated from a single source, the surface waters of Maroon Dam, during a study of the microflora of freshwaters in southeast Queensland, Australia (Franzmann and Skerman, 1984). Additional, as yet undescribed, *Gemmata*-like bacteria have been isolated from leakage water from a compost heap (Schlesner, 1994; Ward et al., 1995) and, more recently, from Australian soil (Wang et al., 2002). The latter is the first report of cultivated soil-dwelling *Gemmata* strains; previously the only evidence for soil harboring planctomycetes was from molecular ecology studies (see Molecular Ecology).

TAXONOMY. The discoverers of the strain recognized the similarities of this coccoid budding bacterium to a strain of great significance in the history of Planctomycetales systematics, strain ATCC 27377, which at one time was proposed as the neotype of *Pasteuria ramosa*, but later transferred to the genus *Planctomyces* (Starr et al., 1983) and to the genus *Pirella* (Schlesner and Hirsch, 1984), a genus name later rejected in favor of *Pirellula* (Schlesner and Hirsch, 1987; see Pirellula for a detailed account of these changes). Franzmann and Skerman (1984) distinguished *Gemmata obscuriglobus* (UQM 2246) from ATCC 27377 by DNA base content, number of flagella on swarmer cells, lack of a discrete holdfast, the possession of a phase-dark inclusion in *Gemmata* postulated to contain DNA, and several other phenotypic characters outlined in Table 7. Later molecular systematics investigation of the 16S rRNA and 5S rRNA of *G. obscuriglobus* confirmed its status as a distinct genus and as a member of the phylogenetically distinct bacterial order Planctomycetales (Stackebrandt et al., 1986a; Bomar et al., 1988). *Gemmata* occupies a distinct position within the Planctomycetales phylogenetically; both 16S rRNA and 5S rRNA sequence similarities with other Planctomycetales genera indicate that the root of the evolutionary tree derived for members of the order lies close to the point at which the ancestor of *G. obscuriglobus* branched off. Thus, this species is the deepest branching organism within the order Planctomycetales (Stackebrandt et al., 1986a; Bomar et al., 1988; see Fig. 4).

ISOLATION. The only existing strain of *G. obscuriglobus*, UQM 2246, was isolated from

Table 7. Characteristics of *Gemmata obscuriglobus* UQM 2246 and strain ATCC 27377.

Character	UQM2246[a]	ATCC 27377[b]
G+C content (mol%)	6.4 ± 1.0	5.7
Cell shape	"Puckered" spherical to ovoid	Ovoid
Cell size (μm)	(1.4–3.0) × (1.4–3.0)	(0.5–3.0) × (1.0–5.0)
Crateriform structure distribution	Uniform	Polar
Reproduction	Budding	Budding
Gram reaction	–	+
Fimbriae	+	+
Motile swarmer cells	+	+
Flagellation	Multitrichous	Monotrichous
Colony color	Rose	Yellow
Catalase	+	+
Oxidase	–	+

[b]Data from Staley (1973) and Schlesner and Hirsch (1984).

the surface waters of the littoral zone of a freshwater dam in subtropical Queensland, Australia. Micromanipulation using the equipment and methods of Skerman (1968) as applied by Franzmann (1983) was employed in the isolation. This method employs a micromanipulator consisting of a glass microtool attached to a magnet, which is in turn carried on a metal slide that is part of a lens "collar" screwed onto the microscope objective mounting. A Leitz 32× Phaco phase objective is used on a phase contrast microscope (preferably an Olympus CHA microscope equipped with a Reichert phase contrast condenser or any system compatible with a Leitz 32× Phaco objective). The microtool is focused by moving the lens collar up and down on the objective mounting; once focused, it can be used to transfer cells on an agar surface across the surface and away from other cells by trapping cells in the water film around the microtool and moving the mechanical stage controls, the agar plate being mounted on the stage. The whole assembly can be placed in a UV-sterilizable Perspex chamber or in a plastic bag with eyepiece holes to facilitate aseptic handling of plates. Nine-cm plastic Petri dishes containing 10 ml of lakewater agar (filtered lakewater solidified with 1.5% Noble agar for optical clarity; see below for formula) are inoculated by running an approximately 0.5-ml drop of sample water down the center of a plate which is surface-dried in advance. Storage of samples before inoculation should be avoided. Inoculated plates are allowed to remain horizontal until free moisture is absorbed. Plates are examined after 8 h incubation at 28°C or until microcolony formation is apparent. Cells from microcolonies displaying cell morphology and size consistent with *Gemmata* are manipulated away from the central inoculum line to a position on the surface of the same plate, well separated from the inoculation line. Position of a single cell can be marked using a microtool and an agar block circumscribing that area is excised with a sterile scalpel and transferred to a fresh lakewater agar plate or to a fresh lakewater peptone yeast extract agar plate (see formula below). Purity can be checked microscopically at each stage of the isolation. Strains can be maintained on soil extract agar supplemented with 0.1% glucose or on casitone yeast extract agar: *Gemmata obscuriglobus* and a strain closely related to *Gemmata* from soil (Wang et al., 2002) grow well on M1 agar of Schlesner based on *N*-acetylglucosamine as the carbon source (Schlesner, 1994). Strains of planctomycetes isolated more recently than *G. obscuriglobus* have been isolated using this or a similar medium combined with peptidoglycan synthesis-inhibiting ampicillin alone (Schlesner, 1994) or ampicillin combined with the protein synthesis inhibitor streptomycin (Wang et al., 2002).

Lakewater Noble Agar (Franzmann and Skerman, 1981)

Filter water from a eutrophic lake or pond through a 2-mm membrane filter and add Bacto Noble agar to 1.5%. Sterilize by autoclaving at 121°C for 20 min.

Lakewater Peptone Yeast Extract Agar (Franzmann and Skerman, 1981)

Bacto peptone	0.1 g
Bacto yeast extract	0.1 g
Bacto agar	15 g
Filtered eutrophic lakewater	1 liter

Filter the eutrophic lakewater through a 0.2-m membrane. Sterilize by autoclaving at 121˚C for 20 min.

Casitone Yeast Extract Agar

Bacto casitone	5 g
Bacto yeast extract	3 g
$MgSO_4 \cdot 7H_2O$	2 g
Bacto agar	15 g
Distilled water	1 liter

Adjust pH to 7.2, add the agar, and sterilize the medium by autoclaving at 121˚C for 20 min.

Soil Extract Agar with 0.1% Glucose

Soil	1000 g
Distilled water	1 liter

Mix soil with water and autoclave at 121°C for 20 min. Add 10 g of $CaCO_3$ and mix. Decant and filter liquid. Autoclave filtrate at 121°C for 20 min. and store as stock solution. To the stock solution, add agar to 1.5% and autoclave at 121°C for 20 min. After autoclaving, add filter-sterilized glucose aseptically to the agar medium to give a final concentration of 0.1%.

Additional *Gemmata*-like strains have been isolated from soil, freshwater, and the leakage water from a compost heap, using media formulated with antibiotics inhibiting cell-wall synthesis (combinations of ampicillin [200 μg/ml], streptomycin [1000 μg/ml] and cycloheximide [20–100 μg/ml] or penicillin G [500 μg/ml], streptomycin [1000 μg/ml] and amphotericin B [Fungizone; 0.25–0.5 μg/ml]; Wang et al., 2002). The media used were freshwater media M1 or M31 (Schlesner, 1994; see Pirellula).

IDENTIFICATION. *Gemmata obscuriglobus* is a budding, nonprosthecate aerobic organism with spherical to ovoid cells. Initial appearances from negative-stain transmission electron microscopy and phase contrast light microscopy (Fig. 23) suggest a spherical or ovoid shape.

Consistent with the position of the genus within the order Planctomycetales, cells observed by negative staining possess crateriform structures—circular areas on the cell that accumulate negative stain (Fig. 24). These are distributed all over the cell surface, similar to the

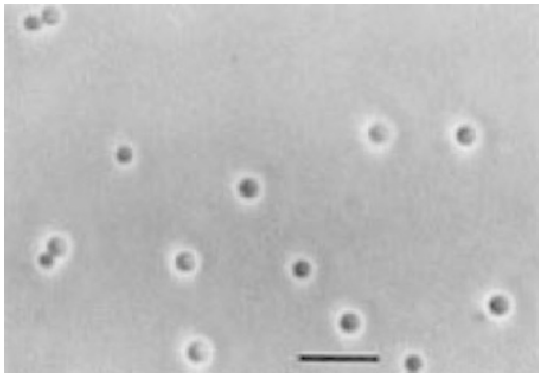

Fig. 23. Phase contrast photomicrograph of cells of *Gemmata obscuriglobus* (UQM 2246). Budding is displayed in addition to the superficially spherical cell shape. Bar is 10 mm.

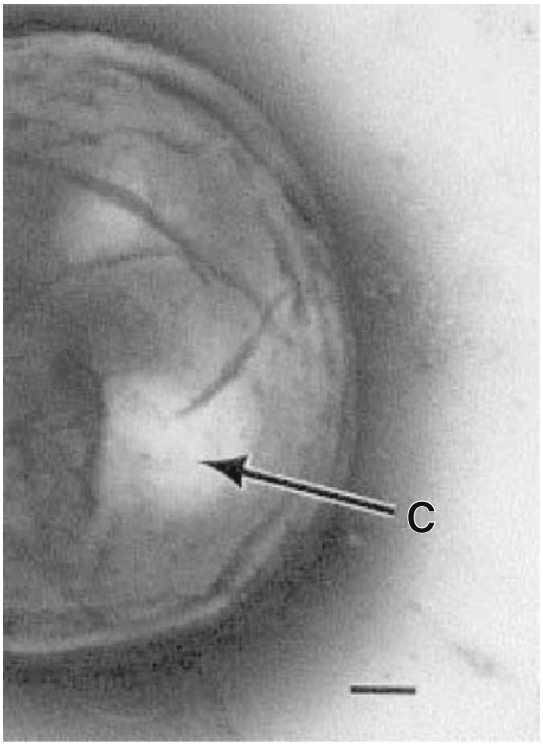

Fig. 24. Electron micrograph of a portion of a negatively stained cell of *Gemmata obscuriglobus* (UQM 2246), displaying crateriform structures (C), which are electron-dense pits distributed uniformly over the cell surface. The arrow points to one example of such a structure; many others are visible on the cell surface displayed. Fimbriae are visible outside the cell perimeter. Negatively stained with 1% uranyl acetate supplemented with 0.4% sucrose. Bar is 0.2 mm.

distribution found in the genus *Planctomyces*, but unlike that in *Pirellula* species (Schlesner and Hirsch, 1984). Such crateriform structures have also been observed in metal-shadowed cell walls of *G. obscuriglobus* (Stackebrandt et al., 1986b). The cell walls of *G. obscuriglobus*, like those of other Planctomycetales, lack peptidoglycan and diaminopimelic acid and are also similar to those of other members of the order in the predominately proteinaceous composition of the wall (Stackebrandt et al., 1986b). In thin sections, the cell wall has the typical appearance expected for the peptidoglycan-less walls of Planctomycetales (Fig. 11), with inner and outer electron-dense layers separated by an electron-transparent layer, the inner layer being more electron-dense, as found for morphotype IV planctomycete ultrastructure by Tekniepe et al. (1981). *Gemmata* thus shares budding reproduction, crateriform structures, and cell-wall composition with other genera of the Planctomycetales, and this relationship is confirmed by the high number of Planctomycetales-specific signature oligonucleotides present in the 16S rRNA oligonucleotide catalog of the genus (Stackebrandt et al., 1986a) and by the presence of the unique Planctomycetales-specific "short" 5S rRNA with lack of insertion at position 66 and numerous characteristic base-pair inversions (Bomar et al., 1988).

In the initial study of *G. obscuriglobus*, Franzmann (1983) noted that in some thin-sectioned cells nuclear material was packaged in a discrete body within the cell and that this might be correlated with the appearance of phase-dark inclusions in light microscopy preparations. Intracellular membrane material was commonly seen in thin sections, and although in some cases an appearance of membrane involvement with nuclear packages suggested that they may be membrane-bound structures, it was thought that this may be artifactual and further studies were required to resolve the nature of the nuclear packages. Such packages often consist of an appearance of fibrillar material within a shell of electron-dense amorphous material separating the material from the rest of the cell. Several such packages can occur within a single cell. A cell inclusion in *G. obscuriglobus* was indeed later confirmed as a DNA-containing body, surrounded by a double membrane, by transmission electron microscopy. This region was termed "the membrane-bounded nuclear body" (Fuerst and Webb, 1991, and Fig. 11A–C), although recent DAPI (4′,6′-diamidino-2-phenylindole hydrochloride) studies suggest that it is the phase-light rather than phase-dark interior cell region in phase contrast microscopy which contains the DNA. *Gemmata obscuriglobus* structure (Fig. 11A, B) including the membrane-bounded nuclear body is particularly well-preserved by cryosubstitution (a technique that avoids some of the artifacts of chemical fixation, which in *G. obscuriglobus* can result in crescent-shaped cells due to osmotic shrinkage effects)

and can also be demonstrated by freeze-fracture techniques (Fuerst and Webb, 1991; Fig. 11C). This was the first example of cell compartmentalization in planctomycetes, which was also later demonstrated in other planctomycete species (Lindsay et al., 1997; Lindsay et al., 2001). In addition to the membrane-bound nucleoid, the cell of *G. obscuriglobus* displays the common features of all planctomycete compartmentalization—an intracytoplasmic membrane and a paryphoplasm region, in this case at the outer rim of the cell (Fig. 11A, B). The intracytoplasmic membrane is distinct from and not connected with the cytoplasmic membrane, which is closely apposed to the cell wall. Both the membrane-bounded nucleoid and the region between the nuclear envelope and the intracytoplasmic membrane contain electron-dense ribosome-like particles. The membrane-bounded nuclear body has also been found in new isolates phylogenetically most closely related to *Gemmata* (Wang et al., 2002) so that this character appears to be an ultrastructural feature of potential taxonomic significance for delineating members of the *Gemmata* genus.

The recently isolated strains of Wang et al. (2002) conform to the general morphological properties of the genus *Gemmata* by having spherical cells bearing uniformly distributed crateriform structures, containing a membrane-bounded nuclear body and a distinct ribosome-containing compartment, and reproducing by budding. They also share most of the characteristic *Gemmata*-specific 16S rRNA signature nucleotides and, like *G. obscuriglobus*, contain a 10-base sequence insertion at *E. coli* position 998 (Fuerst et al., 1991). On the basis of their 16S rDNA sequence similarity values, these strains probably represent novel species.

All isolated *Gemmata* strains are pink or red in colony color (Franzmann and Skerman, 1984; Wang et al., 2002).

As shown in Table 7, differentiation of *Gemmata obscuriglobus* from the morphologically similar ATCC 27377 is based on the higher G+C content of *Gemmata*, occurrence of phase-dark inclusions, flagellation, oxidase test, utilization of fructose and pyruvate, temperature range for growth, and colony color. The G+C content for ATCC 27377 has been the subject of several determinations, with slightly variable results; thus, Starr et al. (1983) reported a high value of 59.00 mol% by buoyant density and Schlesner has noted a lowest value of 56.40 mol% by thermal denaturation (Schlesner and Hirsch, 1984), while for their comparison, Franzmann and Skerman (1981) used the figure of 57.1 mol% found by Staley (1973) by thermal denaturation. In all cases, however, the G+C content of *G. obscuriglobus* is significantly higher.

Isosphaera

Isosphaera pallida (an aerobic, heterotrophic budding bacterium) is unusual because it is phototactic and motile by gliding. With other members of the Planctomycetales, *Isosphaera* shares characteristics that are of potential evolutionary significance—the presence of proteinaceous cell walls and phospholipids containing β-hydroxylated fatty acids (Stackebrandt et al., 1984; Giovannoni et al., 1987a; Kerger et al., 1988). These traits, and the budding mode of reproduction, first led to the suggestion that *I. pallida* was a planctomycete (Giovannoni et al., 1987a); molecular phylogenetic comparisons of 5S rRNA supported this classification (Bomar et al., 1988) but showed that *I. pallida* was only distantly related to members of the genera *Gemmata*, *Pirellula* and *Planctomyces*. Subsequent analyses of 16S rRNA gene sequences have confirmed the results obtained with the 5S molecule.

HABITAT. *Isosphaera pallida* commonly occurs in North American and European hot springs at temperatures from 35 to 55°C. It is found either as a component of microbial mats or planktonically, in which case it may be suspended in the water column by gas vacuoles. The co-occurrence of *I. pallida* with cyanobacteria may be a coincidence. *Isosphaera pallida* is an obligate aerobe and, like cyanobacteria, requires neutral or alkaline conditions for growth.

The first axenic cultures of *Isosphaera pallida* (strain IS1B) were obtained from hot springs located on the Warm Springs Indian Reservation, Oregon, United States. Subsequently, five additional strains were isolated from hot springs in Yellowstone National Park, United States, and Big Spring, Thermopolis, Wyoming, United States. The reports of Geitler (Geitler, 1955; Geitler, 1963) had suggested that mesophilic strains of *Isosphaera* may inhabit environments other than hot springs, and these recent results confirm this. Recently isolated *Isosphaera*-like strains have been obtained from leakage water from a compost heap (Schlesner, 1994; Ward et al., 1995) and from lakewater and a laboratory ampicillin solution (Wang et al., 2002). Studies on filamentous isolates of the "Nostocoida limicola III" morphotype from activated sludge have shown them to be close relatives of *Isosphaera*. These strains are nonthermophilic and do not display gliding motility (Liu et al., 2001).

TAXONOMY. *Isosphaera pallida*, the only recognized species of the genus *Isosphaera*, inspired a debate in the taxonomic literature long before it was first isolated in pure culture in 1979 (Giovannoni et al., 1987b). The organism attracted attention because of its conspicuous habitat and morphology. The distinctive chains of spherical, budding cells formed by *Isosphaera*

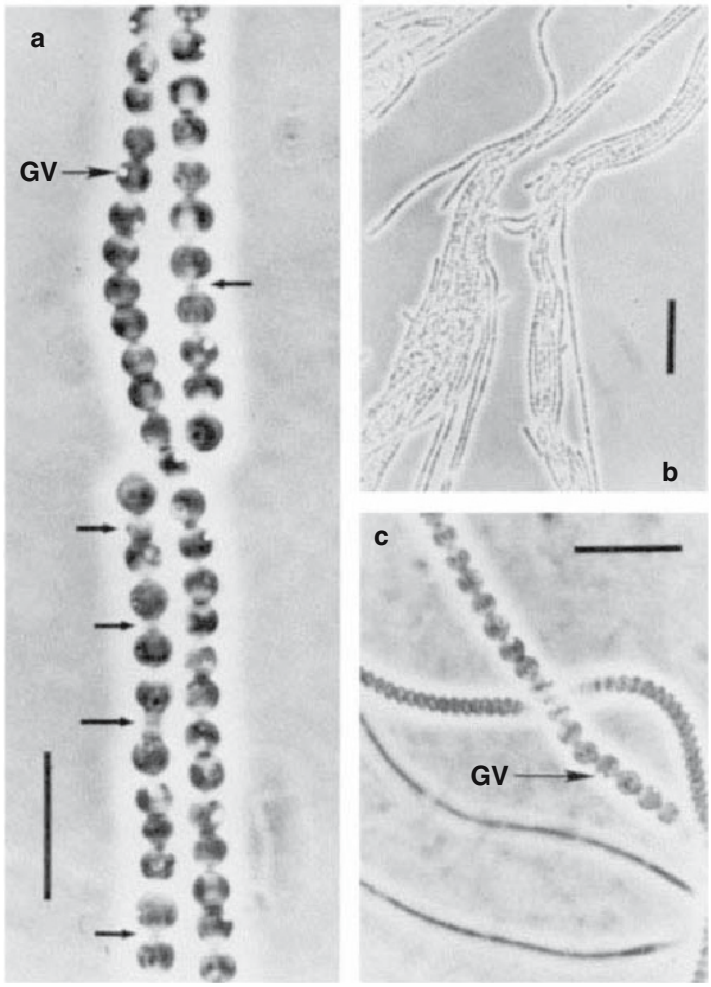

Fig. 25. Phase contrast micrographs of *Isosphaera pallida*. a) Exponential phase culture (strain IS1). Bar is 10 mm. b) Exponential phase culture (strain IS1). Bar is 50 mm. c) *Isosphaera* from a natural population, Mammoth Hot Springs, Yellowstone National Park, United States, showing *Isosphaera pallida* and *Spirulina*. Bar is 10 mm. Arrows indicate buds. GV, gas vacuoles. Note that the frequency of buds in the exponentially growing culture (b) is low, suggesting that the process of bud development is relatively short compared to the cell cycle.

(Fig. 25) are readily distinguishable from morphologically similar organisms, such as cyanobacteria of the genus *Pseudanabaena*. However, because of this similarity, *Isosphaera pallida* was originally described by Woronichin (1927) as a cyanobacterium, *Isocystis pallida*, only on the basis of observations of collected field specimens. This early case of mistaken identity was understandable, considering that *I. pallida* is invariably found in the euphotic zone of hot springs in association with cyanobacteria.

Geitler (1955) obtained the first enrichment cultures of an organism resembling *Isosphaera*. These were taken from a water-filled depression in a rotting spruce stump. He concluded that his isolate was a yeast and assigned it to a novel genus and species, *Torulopsidosira filamentosa*. After examining collected specimens of *Isocystis pallida*, he assigned it also to the genus *Torulopsidosira* (Geitler, 1963). This decision was based on two observations. The fact that the organisms divided by budding suggested that they were yeasts, since Geitler was dubious that budding occurred in bacteria. Secondly, cytological staining indicated that the nuclear material was sequestered within a small region of the cell—indicating a structure similar to a eukaryotic nucleus. Although it is now clear that *Isosphaera* is a prokaryote, modern staining techniques (e.g., 4×, 6-diamidino-2-phenylindole) confirm Geitler's early observation (Geitler, 1963) that the nuclear material is located in a distinct region of the cell.

The micrographs of *Torulopsidosira filamentosa* provided by Geitler show an organism strongly resembling *I. pallida* in size, shape, and the distinctive formation of intercalary buds within filaments. This suggests that species similar to *Isosphaera* may occur in habitats outside of hot springs. Indeed, in the original definition of the cyanobacterial genus *Isocystis* by Borzi, eight species were named, not including *I. pallida*. One of these, *I. salina* was described from saline springs and mineral waters. We obtained mixed enrichment cultures of cyanobacteria and *Isosphaera* from a saline (13% NaCl) hot spring in Utah, United States. Attempts to obtain pure cultures failed, even when the *Isos-*

phaera medium was supplemented with 0.2 M NaCl.

The conclusions of Geitler were later disputed by Rathsack-Kunzenbach, who was familiar with *Isocystis pallida* from hot spring collections in Greece. Rathsack-Kunzenbach's extensive description and discussion indicated that *Isocystis pallida* from their cultures and *I. pallida* are the same. They detected a weak red fluorescence attributed to cyanobacterial pigments in their cultures. However, we have been unable to confirm this fluorescence with North American collections or cultured material.

Following the first isolation, it immediately became apparent that *Isosphaera* was neither a yeast nor a cyanobacterium, but instead, an aerobic, heterotrophic bacterium. It is a salmon color in culture owing to the presence of carotenoids, but absorbance spectra reveal no maxima corresponding to chlorophylls or phycobiliproteins. rRNA sequence analysis and a number of phenotypic characters, including the presence of a proteinaceous cell wall and the possession of phospholipids with β-hydroxylated fatty acids, revealed the *Isosphaera* strains to be planctomycetes.

ISOLATION. *Isosphaera pallida* can be isolated on plates of medium IM incubated in an atmosphere of 5% CO_2/95% air. Medium IM is a dilute mineral medium containing no added carbon sources and containing 50 mM bicarbonate. The pH of the medium (7.9) is determined by the bicarbonate/CO_2 buffering system.

Medium IM (Pfennig and Trüper, 1981)

Solution A

$CaCl_2 \cdot 2H_2O$	0.32 g
$MgSO_4 \cdot 7H_2O$	0.4 g
KCl	0.5 g
NaCl	1.0 g
$(NH_4)_2SO_4$	0.5 g
KH_2PO_4	0.3 g
$FeCl_3$	0.292 mg
Trace element solution SL-7a	10 ml
Vitamin B_{12}	5 mg
Water	1 liter

Adjust to pH 7.6 with NaOH, remove precipitate by filtration through Whatman no. 1 filter paper, and store at 4°C.

Solution B

$NaHCO_3$	42.0 g
Water	1 liter

Autoclave, then bubble vigorously with sterile CO_2 for 1 h.

Final Medium

Solution A	250 ml
Solution B	100 ml
H_2O	650 ml

After combining solution A + H_2O and autoclaving, add sterile solution B.

In the dark, or in the light with 3-(3,4-dichlorophenyl)-1,1-dimethyl urea (an inhibitor of photosystem II) present, medium IM is selective for *Isosphaera*. Plates of medium IM streaked with microbial mat material from a hot spring and incubated in the dark at 45°C usually develop small (1–2 mm) colonies of *Isosphaera* after two weeks. The colonies are firm to the touch of an inoculating loop. In part, the basis for the selectivity of medium IM seems to be the absence of added carbon other than the contaminating organic compounds present in Bacto-agar. However, *Isosphaera* is not agarolytic.

The *Isosphaera*-like strains of Schlesner (1994) and Wang et al. (2002) were isolated using media containing the antibiotics ampicillin (inhibiting cell wall synthesis in peptidoglycan-synthesizing bacteria) and streptomycin (inhibiting protein synthesis in many bacteria; see above for concentrations used). D-Arabinose Supernatant R2A Medium employing filtered effluent from secondary clarifier of an activated sludge plate was found to be essential for isolation of *Isosphaera*-like isolates from activated sludge (Liu et al., 2001).

CULTIVATION. *Isosphaera* can be routinely cultivated in liquid batch culture on medium IMC sparged with 5% CO_2/95% air.

Medium IMC

To Medium IM, add 0.025% D-glucose, 0.025% casamino acids, and vitamin solution (0.5 ml/liter; added after autoclaving). Vitamin solution contains: nicotinic acid, 2 mg/ml; thiamine HCl, 1 mg/ml; p-aminobenzoic acid, 0.2 mg/ml; and biotin, 0.02 mg/ml.

The minimum doubling time observed (18 hours) occurs at 42°C, but substantial growth is seen at temperatures from 37 to 55°C. A high concentration of CO_2 is probably not required for growth.

Although visible growth occurs on Bacto-agar without organic supplements, the addition of carbon sources at low concentration enhances growth on plates. Only a few compounds, including glucose, ribose, and lactate, are utilized as sole sources of carbon for growth. Growth is more robust in the presence of casamino acids, suggesting that they are assimilated but not utilizable as sole carbon sources. D-Glucose concentrations of 0.025% are routinely employed because higher concentrations (0.05% D-glucose) inhibit growth. Ribose, which serves as a sole source of carbon for growth in three of four strains investigated, is also inhibitory at concentrations above 0.25%.

The optimal growth temperature of strain IS1B is 42°C. Growth of this strain occurs at temperatures up to 55°C and as low as 37°C.

IDENTIFICATION. The moderately thermophilic aerobic and heterotrophic *I. pallida* is unambiguously identifiable. *Isosphaera pallida* cells are spherical and typically vary in size from 2.0 to 2.5 μm, although some cells are larger in stationary phase cultures. In wild-type strains, the cells are arranged in unbranched filaments of indefinite length. Repeated subcloning results in selection for short chain mutants, such as the type strain, IS1B (S. Giovannoni, unpublished observations). Cells are budding, but the frequency of buds within the unbranched filaments of indefinite length is low. Ultrastructural observations have revealed that the cell surface is uniformly and densely covered with pili. However, there is no evidence for flagella. The mechanism of motility remains unknown. As with other planctomycetes, surface crateriform structures are present. In *I. pallida* they appear to be uniformly distributed over the cell. Electron-transparent "holes" of similar size and density are found in the isolated SDS-insoluble cell wall fraction.

Freshly isolated strains produce gas vacuoles containing gas vesicles with typical conical ultrastructure (Fig. 26). The gas vacuoles are small

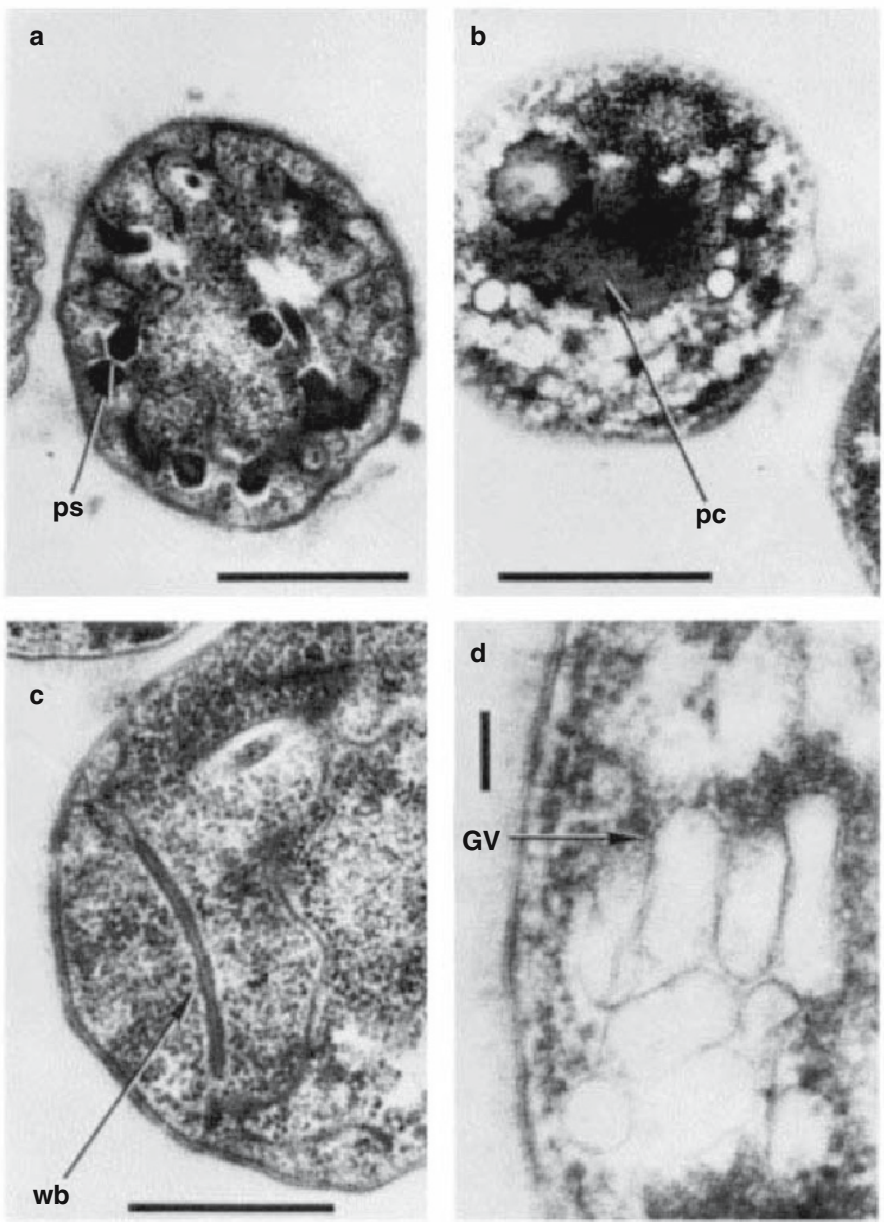

Fig. 26. Thin-sections showing cytoplasmic inclusions of *Isosphaera pallida*. a) Polyhedral structures (ps). Bar is 1 mm. b) Paracrystalline inclusion (pc). Bar is 1 mm. c) Wall body (wb). Bar is 1 mm. d) Gas vesicles (GV). Bar is 0.1 mm.

and usually occur singly in cells. Polyhedral structures, similar in appearance to carboxysomes, are often seen. However, there is no evidence for autotrophic metabolism. Also seen are paracrystalline inclusions and "wall bodies." No functions are associated with these structures. Electron microscopy of thin sections of cells prepared by cryosubstitution have confirmed that the cell plan of *Isosphaera* conforms to the general plan shared by all planctomycetes (Lindsay et al., 2001), but in *I. pallida* the paryphoplasm is invaginated to form a large central region (Fig. 9).

The salmon-colored colonies of *I. pallida* are motile. Motility occurs most readily on Gelrite surfaces, though migration is observable to a lesser degree on agar, particularly if it has excess surface moisture. When suspensions of concentrated cells are dropped on plates, they form multiple aggregates (called "comets") of variable size. These move randomly at about an equal rate in darkness or in uniform light. In the presence of a directional light source, the aggregates are phototactic.

Wang et al. (2002) isolated *Isosphaera*-like strains that conformed to the general properties of the genus *Isosphaera* as currently described (spherical cells, reproducing by budding; uniformly distributed crateriform structures; cell compartmentalization, with a single membrane containing the nucleoid; and characteristic 16S rRNA signature nucleotides). However, the filaments seen in *I. pallida* were not observed in these strains.

Preservation of Planctomycete Strains

Planctomycete strains have been successfully stored by lyophilization and under liquid nitrogen; they have been revived after liquid nitrogen storage for several years. Also, when reviving stored ampoules of *G. obscuriglobus* from liquid nitrogen, soil extract agar supplemented with 0.1% glucose is superior to lakewater agar. Planctomycetes including *G. obscuriglobus* can also be successfully stored frozen in 10% glycerol in deionized water at –70°C, with revival onto Schlesners M1 agar (J. A. Fuerst, unpublished results).

CHAPTER 9.1

The Genus *Thermus* and Relatives

MILTON S. DA COSTA, FRED A. RAINEY AND M. FERNANDA NOBRE

Introduction

In 1969, Brock and Freeze described a thermophilic organism that they named *Thermus aquaticus*. Since then the bacteria of the genus *Thermus* have become the archetypal thermophilic bacteria even though other organisms have been described that grow at much higher temperatures. Not only are these organisms easy to grow, but some strains are transformable and are rapidly becoming the mainstays of molecular biology of thermophilic bacteria. The importance of these organisms to our knowledge of thermophilic lifestyles was recently reaffirmed by the complete genome sequencing of *Thermus thermophilus* HB27 (Henne et al., 2004).

This chapter should probably be entitled the "Family Thermaceae" or the "Order Thermales" as defined by us (da Costa and Rainey, 2001a; Rainey and da Costa, 2001), but we have decided to retain the title of the original chapter in *The Prokaryotes* as an indication of continuity and because the species of the genus *Thermus* continue to be the most studied organisms of this family. Moreover, the four new genera of the family Thermaceae have only recently been proposed to accommodate thermophilic or slightly thermophilic bacteria that are distinct but closely related to the species of the genus *Thermus*. These recently proposed genera are *Meiothermus* (Nobre et al., 1996b), *Marinithermus* (Sako et al., 2003), *Oceanithermus* (Miroshnichenko et al., 2003a; Mori et al., 2004) and *Vulcanithermus* (Miroshnichenko et al., 2003b). The organisms of these genera constitute the family Thermaceae, which together with the species of the genus *Deinococcus* constitute a deep branching lineage designated the "Phylum *Deinococcus*/*Thermus*" (Rainey et al. 1997; Battista and Rainey, 2001).

The Genera *Thermus* and *Meiothermus*

Taxonomy and Phylogeny

The genus *Thermus* currently comprises eight validly described species, namely *T. aquaticus* (Brock and Freeze, 1969), *T. thermophilus* (T. Oshima and Imahori, 1974; Manaia et al., 1994), *T. filiformis* (Hudson et al., 1987b), *T. brockianus* (Williams et al., 1995), *T. oshimai* (Williams et al., 1996), *T. scotoductus* (Kristjánsson et al., 1994), *T. antranikianii* and *T. igniterrae* (Chung et al., 2000).

Comparison of the 16S rDNA sequences of the type strains of each of the eight validly described species of the genus *Thermus* shows the 16S rDNA sequence similarities to be in the range 91.2–96.4% (Fig. 1). *Thermus oshimai* is the most unrelated of the species of the genus *Thermus* as reflected by the 16S rDNA sequence similarity values. The other species of the genus *Thermus* have 16S rDNA sequence similarities in the range 94–96%. Within each species the 16S rDNA similarity values are in the range of 98.9–99.7% for *T. aquaticus*, 99.9–100% for *T. brockianus*, 99.2–99.9% for *T. filiformis*, 99.8–100% for *T. oshimai*, 98.7–99.9% for *T. scotoductus*, 99.4–100% for *T. thermophilus*, and 99.9–100% for *T. igniterrae* and *T. antranikianii* (Chung et al., 2000). These values are based on the comparison of all published strains and a large number of unpublished full 16S rDNA sequences for strains of the species of the genus *Thermus* (F. A Rainey, unpublished results). Such data are however of little use in the differentiation of strains within a species. In these organisms the phenotypic characteristics of most species overlap and it is becoming increasingly difficult to differentiate new species from those that have been described (Table 1). Diversity within groups of strains considered to belong to the same species is sometimes extreme and easily verified by the variation in the fatty acid composition (da Costa et al., 2001b). The species *T. thermophilus*, for example, has extremely variable fatty acid composition even though some strains, namely HB8, HB27 and AT-62, share extremely high DNA-DNA hybridization values and 16S rDNA sequence similarity (Manaia et al., 1994; Nobre et al., 1996a). This species has been easily distinguished from the strains of other species by the ability of the strains to grow at temperatures above 80°C and in media containing 3% NaCl. However, one unpublished strain does not grow in NaCl-

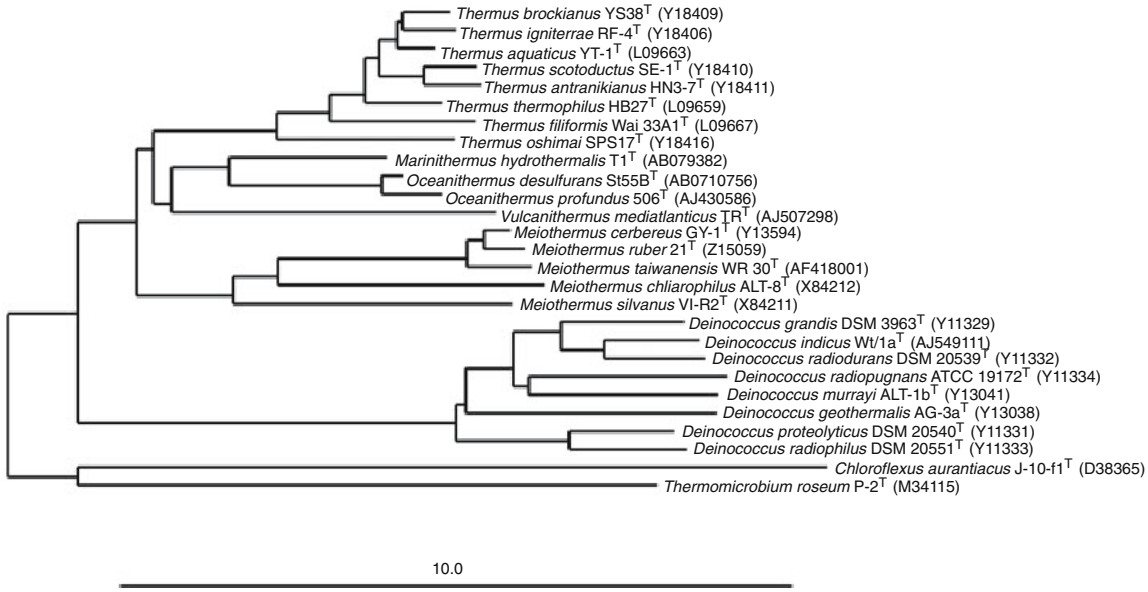

Fig. 1. Phylogenetic dendogram based on 16S rRNA gene sequence comparisons of the validly described type species of the Phylum *Deinococcus-Thermus*. *Thermomicrobium roseum* and *Chloroflexus aurantiacus* are outgroups. The dendrogram was constructed from evolutionary distances using the neighbor-joining method. The scale bar represents 10 inferred nucleotide changes per 100 nucleotides.

containing media because it lacks the genes leading to the synthesis of the compatible solute mannosylglycerate, necessary for growth in media containing more than 1% NaCl (da Costa et al., 2001b; S. A. Alarico et al., unpublished results).

In addition to the type strain of *Thermus aquaticus* (YT-1, = ATCC 25104), another of the original isolates of Brock and Freeze (1969), designated "Y-VII-51B" (=ATCC 25105), isolated from Pacheteaus Calistoga in California, has recently been found to be very closely related to the type strain of *T. antranikianii* (Chung et al., 2000). At the time, however, it was perfectly acceptable that these strains were classified in the same species for the lack of more precise methods of classification of prokaryotes. Moreover, this species is only easily distinguished from all other species on the basis of fatty acid composition (Table 2). The species *T. filiformis* was described on the basis of one strain from New Zealand with a stable filamentous morphology (Hudson et al., 1987b). Other strains from New Zealand belong to this species on the basis of DNA-DNA hybridization values but are not filamentous (Georganta et al., 1993). Moreover, the type strain of *T. filiformis* possesses very high levels of *anteiso*-fatty acids as well as 3-OH fatty acids, while the other strains have high levels of *iso*-fatty acids and lack 3-OH fatty acids (Ferraz et al., 1994; Nobre et al., 1996a). The biochemical and physiological diversity of *T. filiformis* strains that share high DNA-DNA hybridization values makes it difficult, if not impossible, to define a distinct phenotype for this species (Hudson et al., 1987b; Hudson et al., 1989; Georganta et al., 1993).

The description of the species *T. scotoductus* was based on strains isolated from hydrothermally fed hot water taps in Iceland, as well as strain X-1 isolated from a thermally polluted stream in the United States (Ramaley and Hixson, 1970; Kristjánsson et al., 1994). The lack of pigmentation was one of the characteristics used to discriminate *T. scotoductus* from other species of the genus which rarely comprise nonpigmented strains. Two other nonpigmented strains NH and DI, isolated from hot tap water in London, were later found to be practically identical to the type strain from Iceland (Pask-Hughes and Williams, 1975; Tenreiro et al., 1995b). Strains from a hot spring at the end of a nonilluminated tunnel at Vizela, Portugal, were also found to be closely related to the type strain of *Thermus scotoductus* (Tenreiro et al., 1995b) and were, not surprisingly, nonpigmented. However, yellow-pigmented strains from hot springs in the Azores exposed to sunlight were also found to be very closely related to *T. scotoductus* (Santos et al., 1989; Tenreiro et al., 1995b; Williams et al., 1996; F. A. Rainey et al., unpublished observation). Moreover, only the strains from Iceland and from London have identical fatty acid compositions (Nobre et al., 1996a).

These results also appear to leave the species *T. scotoductus* without distinct phenotypic characteristics. The species *T. aquaticus* can be easily distinguished from *T. brockianus*, but all of the extensively characterized strains of the former species originate from Yellowstone National Park (Munster et al., 1986; Williams et al., 1995). However, the strains of *T. brockianus* and *T. aquaticus* are also very difficult to distinguish from strains of other species of the genus *Thermus*.

Phylogenetic analysis based on 16S rDNA sequence analysis shows that the species of the genus *Meiothermus* form a separate line of descent from the species of the genus *Thermus* with which they share about 86% 16S rDNA sequence similarity (Nobre et al., 1996b). It was suspected for some time that the red-pigmented "low-temperature" species designated "*Thermus ruber*" formed a separate line of descent from the "high-temperature" species of the genus *Thermus* (Weisburg et al., 1989; Bateson et al., 1990; Embley et al., 1993), but aside from the different growth temperature ranges and the red pigmentation, there were no other characteristics that allowed the proposal of a new genus. The description of two new, slightly thermophilic species that, based on 16S rRNA sequence analysis and chemotaxonomic parameters, were more closely related to *Thermus ruber* than to the other species of the genus *Thermus* led to the proposal of the genus *Meiothermus* for the species with low growth temperatures (Tenreiro et al., 1995a; Nobre et al., 1996b).

The species *M. ruber*, *M. silvanus*, *M. chliarophilus*, *M. cerbereus* and *M. taiwanensis* have been validly described (Loginova et al., 1984; Tenreiro et al., 1995a; Nobre et al., 1996b; Chung et al., 1997; M. Y. Chen et al., 2002). The phylogenetic analysis of the species of the genus *Meiothermus* shows that *M. ruber*, *M. cerbereus* and *M. taiwanensis* are closely related to each other, sharing about 97–98% 16S rDNA sequence similarity (Chung et al., 1997; M. Y. Chen et al., 2002). *Meiothermus silvanus* and *M. chliarophilus* are more distantly related to the *M. ruber*/*M. cerbereus*/*M. taiwanensis* clade, sharing no more than about 90% sequence similarity with each other or with the other three species of *Meiothermus* (Tenreiro et al., 1995a; Chung et al., 1997; M. Y. Chen et al., 2002). It could be argued that *M. chliarophilus* and *M. silvanus* should be placed in two separate genera, but the lack of physiological and biochemical distinctiveness of these two species does not support such a proposal (Fig. 1).

One strain, named "*M. rosaceus*," which shares about 99% 16S rDNA sequence similarity with *M. taiwanensis*, has not been validly described (C. Chen et al., 2002b). This organism was isolated from the Tengchong hot springs in Yunnan Province, China, and may represent a new species.

The validly described species of the genus *Meiothermus* are still very easy to distinguish from each other primarily because the number of species is small and some of the species (such as the yellow-pigmented species *M. chliarophilus*) have been isolated from only one site, which limits diversity of characteristics within this species (Tables 3 and 4). All the species can at present be distinguished from other species of the genus by their distinct fatty acid compositions, namely the strains of *M. ruber*, which have been isolated from hydrothermal areas throughout the world (Nobre et. al., 2001). An additional species of this genus named "*Meiothermus timidus*" has been characterized recently. The strains of this species, isolated from hot springs in Continental Portugal and the Island of S. Miguel in the Azores, are yellow-pigmented and most closely related to *M. chliarophilus*. These organisms show that yellow-pigmentation is more common than previously recognized in this genus (A. L. Pires et al., unpublished observations).

Habitats

The strains of the genus *Thermus* are generally isolated from hydrothermal areas where the range of water temperature is 55–70°C and that of pH is 5.0–10.5 (Kristjánsson and Alfredsson, 1983; Munster et al., 1986; Hudson et al., 1989; Santos et al., 1989). The recovery of strains of the genus *Thermus* from geothermal sites with very high temperatures and low pH, as well as from cold water sources, is believed to be due to the dispersal of organisms from thermal environments that the organisms actually colonize (Williams and da Costa, 1992).

The first isolates of the genus *Thermus* were obtained from hydrothermal areas in Yellowstone National Park and Pacheteaus Calistoga in California (Brock and Freeze, 1969). Isolates were then recovered from several hydrothermal areas in Japan (Yoshida and Oshima, 1971; Saiki et al., 1972; Taguchi et al., 1982), followed by isolations from Iceland (Pask-Hughes and Williams, 1977; Kristjánsson and Alfredsson, 1983; Hudson et al., 1987a), New Zealand (Hudson et al., 1986), New Mexico (Hudson et al., 1989), continental Portugal, the Island of São Miguel in the Azores (Santos et al., 1989; Manaia and da Costa, 1991), the Australian Artesian Basin (Denman et al., 1991), and the Kamchakta Peninsula (R. Sharp, unpublished results). Strains of the genus *Thermus* have also been isolated from shallow marine hot springs in Ice-

land (Kristjánsson et al., 1986), the islands of Fiji (Hudson et al., 1989), and the island of São Miguel in the Azores (Manaia and da Costa, 1991). Recently, isolates of the genus *Thermus* have also been obtained from abyssal geothermal areas in the Mid-Atlantic Ridge and in the Guaymas Basin, Gulf of California, at depths of 3500 and 2000 m, respectively (Marteinsson et al., 1995; Marteinsson et al., 1999). Some shallow marine hydrothermal areas contain less salt than the surrounding seawater (Kristjánsson et al., 1986), but others have salt concentrations similar to those of seawater. To our knowledge, all *Thermus* isolates from these springs are halotolerant (Manaia and da Costa, 1991; Tenreiro et al., 1997). Most of these isolates have higher growth rates in media without added NaCl but grow in media containing 3–6% NaCl. All the *Thermus* strains isolated from saline thermal environments appear to belong to the species *T. thermophilus* (da Costa et al., 2001b). On the other hand the vast majority of the strains of *Thermus* isolated from inland hydrothermal areas do not grow at salinities above 1% NaCl (Kristjánsson et al., 1986; Hudson et al., 1989; Santos et al., 1989; Manaia and da Costa, 1991; Manaia et al., 1994). However, some inland geothermal areas in Japan and Iceland also vent saline water and yield halotolerant *Thermus* strains, many of which also belong to *T. thermophilus* (Waring, 1965; Yoshida and Imahori, 1971; Alfredsson and Kristjánsson, 1995).

Strains of the species of the genus *Thermus* are also commonly isolated from man-made thermal environments. The isolation of strains from man-made environments was, in fact, simultaneous with the description *Thermus aquaticus* (Brock and Freeze, 1969). Later, nonpigmented *Thermus* strains were isolated from hot water taps, thermally polluted streams (Ramaley and Hixson, 1970; Pask-Hughes and Williams, 1975; Degryse et al., 1978; Stramer and Starzik, 1981), and hot water systems (Brock and Boylen, 1973). Strains of the genus *Thermus* have also been isolated from self-heating compost piles in Switzerland and Germany (Beffa et al., 1996). One strain SA-01 and classified as *T. scotoductus* was isolated from a rock surface with a temperature of about 60°C from a gold mine, at a depth of 3200 meters, in South Africa (Kieft et al., 1999).

The strains of the genus *Meiothermus* have been isolated from a large number of geothermal areas ranging from Yellowstone National Park, the Island of São Miguel in the Azores, several hot springs in continental Portugal, the Hveragerthi and Geysir areas of Iceland, and the Kamchatka Peninsula to the North Island of New Zealand and China (Loginova et al., 1984;

[a]Undetected fatty acids or those whose values are less than 0.5% in all strains are not shown.

[b]Unknown fatty acid or alcohol with an equivalent chain length (ECL) of 16.090.

Sharp and Williams, 1988; Donato et al., 1991; Tenreiro et al., 1995a; Chung et al., 1997; M. Y. Chen et al., 2002; C. Chen et al., 2002b). Strains of the species *M. ruber* were also recovered from fermentors fed with yeast factory wastewater and maintained at 60°C (Hensel et al., 1986). In natural environments, these organisms are generally isolated from areas where the range of water temperature is 40–70°C and the pH is neutral to alkaline. Strains of *Meiothermus*, unlike strains of *T. thermophlus*, have not been isolated from marine hot springs and no halotolerant or slightly halophilic strains are known.

The strains of *M. silvanus* have been isolated from hot springs in northern Portugal and from the Geysir area of Iceland (Tenreiro et al., 1995a; Nobre and da Costa., 2001). Strains of *M. cerbereus* have been isolated from the Geysir area of Iceland, and closely related but not extensively characterized strains have also been isolated from Yellowstone National Park (Nold and Ward, 1995; Chung et al., 1997). Strains of *M. chliarophilus* have only been isolated from the hot spring at Alcafache in central Portugal with a vent temperature of 50.5°C and a pH of 8.1 (Tenreiro et al., 1995a). The strains of *M. taiwanensis* have been isolated from hot springs in Taiwan (Chen et al., 2002a). However, strains of *M. ruber* have been isolated worldwide (Nobre and da Costa, 2001). One factor leading to the frequent isolation of *M. ruber* strains from several geothermal areas around the world may be the high temperature used for enrichment of these organisms from water and sediment samples. Enrichments performed in liquid media at 60°C or higher invariably lead to the isolation of strains with optimum growth temperatures of about 60–65°C and closely related to *M. ruber*. Other species with optimum growth temperatures of about 50–55°C and maximum growth temperatures of about 60°C are not isolated under these enrichment conditions.

Genome Sequence of *T. thermophilus* HB27

Strain HB27 is not the type strain of the species *Thermus thermophilus* but is probably the most investigated strain of the genus *Thermus*. Strain HB27, like other strains of *T. thermophilus*, is amenable to genetic manipulation and is now a model organism for genetic studies in *Thermus* spp. For these reasons the genome was completely sequenced (Henne et al., 2004). The genome consists of a chromosome with 1,894,877 base pairs and a megaplasmid with 232,605 base pairs. The complete genome sequence confirms the results of several physiological, metabolic and biochemical studies. The organism, for example, possesses genes for the Emden-Meyerhof pathway, a complete tricarboxylic acid cycle, and gluconeogenesis. The respiratory chain contains reduced nicotinamide adenine dinucleotide (NADH)-dehydrogenase, a cytochrome-dependent succinate dehydrogenase, two sets of genes for terminal cytochrome *c* oxidases, and cytochromes *a*, *caa3* and *ba3* among others. ATP synthesis is accomplished via a V/A type synthase. It was known that strain HB27 did not use nitrate as an electron acceptor for anaerobic respiration, and the putative genes for dissimilatory nitrate reductase are not present in the genome (da Costa et al., 2001b). Also interesting is that a gene cluster with homology to *sox* genes of sulfur-oxidizing organisms is present in this organism. Moreover, another gene cluster has homology to the periplasmic thiosulfate/cytochrome oxidoreductase complex of *Rhodopseudomonas palutris*. The implication, of course, is that energy could be derived from oxidation of reduced sulfur compounds, but this has not been shown in strain HB27, although it has been detected in strains of *T. scotoductus* (Skirnisdottir et al., 2001). Motility has never been observed in any strain of *Thermus*; this observation was confirmed from the complete genome sequence of strain HB27, which does not possess genes for flagellum synthesis.

Isolation Procedures

A low concentration of organic constituents and an incubation temperature of 65–75°C were stressed by Brock (1984) as important factors for the isolation of *T. aquaticus*. *Therrnus* strains are easily isolated by inoculating samples of water, biofilms or mud in a medium containing Castenholz D basal salts medium (Castenholz, 1969) supplemented with yeast extract (1.0 g · liter^{-1}) and tryptone (1.0 g · liter^{-1}). This medium has been used in many studies to grow strains of the genus *Thermus* and has been called simply *Thermus* medium (Brock and Freeze, 1969; Munster et al., 1986; Williams and da Costa, 1992). Sample volumes of 0.5–1.0 ml are generally sufficient, but the medium can be made up at twice the concentration to accommodate large inocula. Turbid cultures are streaked on the same medium solidified with 2–3% agar. Plates are sealed or placed in containers to reduce evaporation and incubated aerobically for several days at the appropriate temperature. Streaking samples directly onto solidified *Thermus* medium has also been successful (Hudson et al., 1986). Large sample volumes have been filtered using membrane filtration (0.20 or 0.45 μm pore size), after which the filters have been placed on the plates (Chung et al., 2000).

Basal mineral medium 162 (Degryse et al., 1978) with 0.25% tryptone and 0.25% yeast extract, with or without solidifying agents, has also been extensively used to grow *Thermus* and *Meiothermus* strains. Many strains will grow on 0.4% yeast extract, 0.8% polypeptone, and 0.3% NaCl (T. Oshima and Imahori, 1974), but this is not true of *T. aquaticus*. The growth of the majority of the strains of *Thermus* is inhibited by levels of organic nutrients higher than about 1.0%. Hexoses are particularly inhibitory, apparently because of acidification of the medium. Some strains, particularly those closely related to *T. thermophilus* HB8, are more resistant to organic nutrients in the culture medium and are frequently grown in a medium containing (per liter of water) trypticase or polypeptone, 8.0 g; yeast extract, 4.0 g; and NaCl, 2.0 g (M. Oshima and Yamakawa, 1974). The review by Sharp et al. (1995) gives an extensive list of media, and their formulae, used to grow the strains of this genus for several purposes and should be consulted. Defined media have also been used with some success for experimental protocols but not for enrichment of samples (Silva et al., 2003).

Preservation of Strains

Most strains of *Thermus* and *Meiothermus* can be stored frozen at –80°C in *Thermus* medium containing 10–15% glycerol, or in liquid nitrogen, for years without loss of viability. Lyophilized strains have been maintained for many years. Strains grown densely on plates of *Thermus* medium survive for about 1 month at 4°C.

Morphology, Metabolism, Physiology and Biochemical Characteristics

The strains of the genus *Thermus* form rod-shaped or filamentous cells that stain Gram negative. The type strain of *Thermus filiformis* has, in contrast to other strains, a stable filamentous morphology and does not form short rod-shaped cells on solid or in liquid media. Transmission electron microscopy shows that the strains of the

genus *Thermus* have an envelope consisting of a cytoplasmic membrane with a simple outline, a cell wall with an inner, electron-dense thin layer representing the peptidoglycan connected to an outer corrugated "cobble-stone" layer by irregularly spaced invaginations (Brock and Edwards, 1970). Unusual morphological structures, called "rotund bodies," are occasionally seen in many strains by phase-contrast and transmission electron microscopy. These structures consist of several cells bound by a common external layer of the cell envelope enclosing a large space between the cells (Brock and Edwards, 1970; Becker and Starzyk, 1984). The strains of the closely related genus *Meiothermus* have cells with similar morphology. Rotund bodies have, however, not been seen in any of the strains of *Meiothermus*. The type strain of *M. taiwanensis* also forms long stable filaments (M. Y. Chen et al., 2002). A crystalline surface protein layer (S-layer) has been identified in *T. thermophilus* strains $HB8^T$ and HB-27. The S-layer of strain HB8 is composed of a major protein with a molecular weight of 100 kDa, designated P100 (Caston et al., 1988; Faraldo et al., 1992; Olabarría et al., 1996; Fernández-Herrero et al., 1997).

The growth temperature range of the species of the genus *Thermus* is between about 45°C and 82–83°C. Only a few strains, all belonging to *T. thermophilus*, are capable of growth at 80°C or above (Manaia et al., 1994). The majority of the strains of the genus *Thermus* have a maximum growth temperature slightly below 80°C (Brock and Freeze, 1969; Chung et al., 2000; da Costa et al., 2001b). The optimum growth temperature of these organisms is about 70°C, but the optimum growth temperature of some strains can be as high as 75°C. The species of the genus *Meiothermus* have lower growth temperature ranges than those of *Thermus*; *M. ruber* has an optimum growth temperature of about 60–65°C, a maximum growth temperature just below 70°C, and a minimum growth temperature of about 35–40°C. The species *M. silvanus*, *M. cerbereus* and *M. taiwanensis* have lower growth temperature ranges with an optimum of about 55°C, whereas *M. chliarophilus* is the least thermophilic of the known species of this genus, with an optimum growth temperature of about 50°C (Loginova et al., 1984; Tenreiro et al., 1995a; Chung et al., 1997; M. Y. Chen et al., 2002).

The strains of this genus use carbohydrates, organic acids, and amino acids as sources of carbon and energy. None of the strains of the genus *Thermus* appears, however, to be able to carry out fermentation. The strains of the species of the genus *Thermus* have a respiratory metabolism and many are strictly aerobic. Some strains are also capable of growth under anaerobic conditions using nitrate as electron acceptor; some strains also reduce nitrite (Hudson et al., 1989; Santos et al., 1989; Manaia et al., 1994; Chung et al., 2000). A few strains (among them SA-01 and NMX2 A1, classified as *T. scotoductus*), use NO_3^{-1}, Fe(III) and S° as terminal electron acceptors coupled to growth (Kieft et al., 1999). These strains also reduce Mn(IV), Co(III), Cr(VI) and U(VI). Another strain of *T. scotoductus*, designated IT-7254, oxidizes thiosulfate to sulfate in the presence of organic carbon sources (Skirnisdottir et al., 2001). The enhancement of growth by thiosulfate in medium containing organic carbon substrates, such as acetate, indicates that the organism is facultatively chemolithoheterotrophic. *Thermus thermophilus* HB27 may also be able to obtain energy from reduced sulfur compounds, since several gene homologues related to sulfur oxidation are present in the genome of this organism (Henne et al., 2004).

The strains of the species of the genus *Meiothermus* also have a respiratory metabolism, and most strains seem to be strictly aerobic. However, some strains are also capable of growth using nitrate as electron acceptor, but none of the strains appears to be capable of carrying out fermentation. All strains are chemoorganotrophic, growing on amino acids, peptides and proteins and simple and complex carbohydrates. The strains of *M. cerbereus* and some strains of *M. silvanus* require reduced sulfur compounds, such as thiosulfate, cysteine, or thioglycolate, for growth in liquid media but not in the corresponding medium solidified with agar. Under the conditions examined, sulfate is not produced during growth on thiosulfate, and the requirement for reduced sulfur compounds during growth in liquid medium cannot be easily explained. The type strain of *M. ruber* oxidizes thiosulfate to sulfate, although this strain shows no requirement for reduced sulfur compounds and growth is not improved by their addition to the growth medium (Chung et al., 1997). The oxidation of thiosulfate to sulfate by the type strain of *M. ruber* may be analogous to the so-called "gratuitous oxidation of sulfur compounds" found in other heterotrophic bacteria (Das et al., 1996).

The majority of the isolates of the species of the genus *Thermus* form yellow-pigmented colonies, although the color varies considerably from deep yellow to very pale yellow. Many strains, isolated primarily from man-made environments that are maintained dark, are nonpigmented, although yellow-pigmented strains can also be isolated in low numbers in these environments. Nonpigmented *Thermus* strains have been isolated from abyssal hot springs, although some isolates were also yellow-pigmented (Marteinsson et al., 1995). In some strains, pigmentation appears to be an unstable characteristic because spontaneous nonpigmented mutants are fre-

quently produced that never revert to yellow-pigmentation. Moreover, the consistent isolation of nonpigmented strains from dark environments leads to the hypothesis that the yellow pigmentation of *Thermus* is favored in natural thermal areas exposed to sunlight where carotenoids would protect the cells from sunlight, while nonpigmented strains would have a selective advantage in nonilluminated environments because the production of carotenoids is energetically expensive and serves no useful function. A gene cluster involved in latter part of the synthesis of carotenoids in strain HB27 is located in the megaplasmid designated TT27 (Henne et al., 2004). Carotenoid-overproducing mutants are more resistant to ultraviolet irradiation than the wild-type strain and carotenoid-underproducing mutants are (Hoshino et al., 1994; Tabata et al., 1994). Nevertheless, the carotenoid-overproducing mutants grow slower than the wild-type strain at supraoptimal temperatures. These results could explain why nonpigmented strains predominate in dark environments over pigmented strains. The curing of carotenogenic gene-containing plasmids from plasmid-bearing strains under laboratory conditions could also explain the high frequency of pigmentation loss by some strains in the laboratory.

The strains of four of the five species of the genus *Meiothermus* form reddish-pigmented colonies, although the color varies considerably from orange-red to deep red. The differences in pigmentation appear unrelated to the site of isolation or to the taxonomic status of these strains, because isolates recovered from the same geothermal area and belonging to the same species can have different pigmentation (Hensel et al., 1986; Sharp and Williams, 1988; Chung et al., 1997). The strains of *M. chliarophilus* form bright yellow-pigmented colonies (Tenreiro et al., 1995a). This species has been recovered only from one hot spring in central Portugal, and the isolates may belong to one clone. It is possible, therefore, that strains of *M. chliarophilus* originating from other geothermal areas could also produce red-pigmented cells. However, recent results show that isolates of "Meiothermus timidus" from the Azores and from Continental Portugal produce yellow-pigmented cells, leading us to envision that this new species has a stable yellow pigmentation.

The peptidoglycan of the strains of the genus *Thermus* contains L-ornithine as the diamino acid and glycylglycine as the interpeptide bridge (Merkel et al., 1978; Pask-Hughes and Williams, 1978), consistent with the A3β murein type of Schleifer and Kandler (1972). This peptidoglycan type is also found in species of the genera *Meiothermus* and *Deinococcus* (Hensel et al., 1986; Embley et al., 1987; Sharp and Williams, 1988). The major respiratory quinone of the strains of all the genera of the family *Thermaceae* is menaquinone 8 (MK-8; Collins and Jones, 1981; da Costa et al., 2001b; Miroshnichenko et al., 2003a; Miroshnichenko et al., 2003b; Sako et al., 2003). The presence of ornithine and MK-8 corroborates the phylogenetic interpretation that the genera of the Thermaceae and Deinococcus are related to each other, although they share few other phenotypic characteristics.

The polar lipid composition of the species of *Thermus* consists of one major phospholipid, designated phospholipid 2 (PL-2), and one major glycolipid, designated glycolipid 1 (GL-1), which comprise 80–95% of the total polar lipid phosphorus and carbohydrate. Other minor polar lipids, namely phospholipid 1 (PL-1) and glycolipid 2 (GL-2), are also detected by thin-layer chromatography in most strains of the genus *Thermus* (Prado et al., 1988; Donato et al., 1990). The major glycolipid of several strains has been identified as a diglycosyl-(*N*-acyl)glycosaminylglucosyldiacylglycerol, which contains three hexose residues and one *N*-acylated hexosamine. The polar head group of GL-1 may contain *N*-acylglucosamine or *N*-acylgalactosamine, three glucose residues, two glucose residues plus one galactose, or one glucose plus two galactose residues (M. Oshima and Yamakawa, 1974; Prado et al., 1988; Wait et al., 1997). The terminal galactose, present in GL-1 of several strains, such as *T. thermophilus* strain HB8, is in the rare furanose configuration instead of the more common pyranose configuration (Wait et al., 1997). The polar lipid composition of the species of *Meiothermus* consists of one major phospholipid that is probably very similar to PL-1 of the strains of *Thermus* spp. and two prominent glycolipids, designated "glycolipid 1a" (GL-1a) and "glycolipid 1b" (GL-1b), that migrate very close to each other (Donato et al., 1991; Tenreiro et al., 1995a; Chung et al., 1997). The formation of two separate glycolipids by *Meiothermus* spp. is due to the differential binding of fatty acids to the hexosamine of the polar head group; 2-hydroxy fatty acids are exclusively amide-linked to the hexosamine of GL-1a, whereas 3-hydroxy and saturated branched-chain fatty acids are amide-linked to the hexosamine of GL-1b (Wait et al., 1997; Ferreira et al., 1999).

Unexpectedly, terminally and subterminally branched long chain diols, identified as 16-methylheptadecane-1,2-diol and 15-methylheptadecane-1,2-diol, were detected as major components of GL-1 and GL-2 of *T. scotoductus* X-1 and *T. filiformis* Tok A4 (Wait et al., 1997). Similar diols were also recently detected as major glycolipids of other *T. scotoductus* strains (Balkwill et al., 2004). Long chain diols had only been detected in *Thermomicrobium roseum*

(which apparently lacks glycerol-based lipids), where they appeared to be the exclusive backbone structure of the polar lipids (Pond et al., 1986; Pond and Langworthy, 1987). In the species of *Thermus*, long chain diol-based lipids never completely replace the normal glycerolipids. The levels of diols vary with the strain, and some strains have only vestigial amounts. Long chain diols have also been identified in the glycolipids of *Meiothermus* spp. (Ferreira et al., 1999; M. Y. Chen et al., 2002). The presence of long chain diols in *Thermomicrobium roseum*, *Thermus* and *Meiothermus* species, in conjunction with 16S rDNA phylogenies, leads to the hypothesis that these lipid backbones reflect a distant but definite relationship between the Deinococcus–Thermus phylum and the phylum Thermomicrobi (van de Peer et al., 1994).

Iso- and *anteiso*-branched C15:0 and C17:0 fatty acids are the predominant acyl chains of the strains of the genera *Thermus* and *Meiothermus*. Straight chain saturated fatty acids and unsaturated branched chain fatty acids are minor components at the optimum growth temperature in the vast majority of the strains (Donato et al., 1990; Nobre et al., 1996a); nevertheless, straight chain C16:0 reaches levels of about 20% of the total fatty acids in *T. thermophilus* AT-62 (Nobre et al., 1996a). *Iso*-branched fatty acids predominate over *anteiso*-branched fatty acids in the vast majority of the strains at the optimum growth temperature (Nobre et al., 1996a) except in the type strain of *T. filiformis,* where *anteiso*-branched fatty acids account for 60–70% of the fatty acids (Table 3). Some strains of the genus *Thermus*, namely most strains of *T. aquaticus* and the type strain of *T. filiformis*, also contain moderate levels of branched chain 3-hydroxy fatty acids. 3-Hydroxy fatty acids are exclusively amide-linked to the galactosamine present in the glycolipids but are never present in the strains where glucosamine replaces galactosamine (Carreto et al., 1996). Branched-chain 2-hydroxy fatty acids account for 7–13% of the total fatty acids of all strains of the genus *Meiothermus* examined (Tenreiro et al., 1995a; Nobre et al., 1996a; Chung et al., 1997; M. Y. Chen et al., 2002). The strains of *M. ruber* and *M. cerbereus* also contain appreciable amounts of branched-chain 3-hydroxy fatty acids (Table 4), but these are practically absent in *M. chliarophilus* and *M. silvanus* (Nobre et al., 1996a; Chung et al., 1997).

With the exception of the strains of *T. thermophilus*, none of the organisms of the genera *Thermus* and *Meiothermus* grow in media containing over 1% NaCl. The majority of the strains of *T. thermophilus* are halotolerant and grow in yeast extract-containing media with 3–6% NaCl. Trehalose is the primary compatible solute, but lower amounts of mannosylglycerate also contribute to the osmotic balance during salt stress (Nunes et al., 1995; Empadinhas et al., 2003; Silva et al., 2003). Three structurally linked genes for the synthesis of trehalose, namely *otsA* (encoding trehalose-phosphate synthase), *otsB* (encoding trehalose-6-phosphate phosphatase), and *treS* (encoding the maltose-converting trehalose synthase), lead to the synthesis of trehalose, and structurally linked *mpgs* (encoding mannosylphosphoglycerate synthase) and *mpgp* (encoding mannosylphosphoglycerate synthase), lead to the synthesis of mannosylglycerate in strains RQ-1, Fiji3 A1, PRQ-14, B and T-2. These organisms grow in a defined medium (without yeast extract, as a source of trehalose) containing up to 6% NaCl. Strains HB8, GK24 and AT-62 that do not have a complete *otsA* gene and strain HB27 that does not possess the *otsA-otsB-treS* gene cluster do not synthesize trehalose and do not grow in media containing more than 2% NaCl. Strain CC-16, which lacks *mpgs-mpgp* but possesses *otsA*, *otsB* and *treS*, only grows in media containing up to 1% NaCl. Apparently, mannosylglycerate is important during low level osmotic adjustment, while trehalose is a compatible solute with a role in osmotic adjustment in media containing higher concentrations of salt (Silva et al., 2003; S. Alarico et al., unpublished results). The species of the genera *Marinithermus*, *Vulcanithermus* and *Oceanithermus*, in contrast to the species of *Thermus* and *Meiothermus*, inhabit marine hydrothermal vents and are all slightly halophilic.

The Genera *Marinithermus*, *Vulcanithermus* and *Oceanithermus*

Species belonging to the genera *Marinithermus*, *Vulcanithermus* and *Oceanithermus* have been recently described (Miroshnichenko et al., 2003a; Miroshnichenko et al., 2003b; Mori et al., 2004; Sako et al., 2003). Surprisingly, independent manuscripts describing two of these clearly distinct genera with the same generic epithet were submitted almost simultaneously to the *International Journal of Systematic and Evolutionary Microbiology*, leading to a change in one name while the manuscripts were being reviewed. These organisms originate from abyssal hydrothermal areas on the East Pacific Rise, the Suiyu Seamount off Japan, and the Mid-Atlantic Ridge and are thermophilic, with an optimum growth temperature range of 60–70°C. All species require at least 0.5% NaCl for growth and have an optimum NaCl concentration for growth of about 3%. The colonies are nonpigmented or cream-colored. The species

Table 5. Characteristics that distinguish the species of the genera *Marinithermus*, *Vulcanithermus* and *Oceanithermus*.

Characteristic	*Marinithermus hydrothermalis* T1^T	*Vulcanithermus mediatlanticus* TR^T	*Oceanithermus profundus* 506^T	*Oceanithermus desulfurans* St55B^T
Habitat	Deep sea hydrothermal chimney in the Izu-Bonine Arc, Japan	Deep sea hydrothermal chimney in Mid-Atlantic Ridge	A hydrothermal vent site in the Eastern Pacific	A hydrothermal vent site in the Western Pacific
Morphology	Rods or filamentous (rotund bodies not present)	Rods (rotund bodies not present)	Rods (rotund bodies present)	Rods (rotund bodies present)

Abbreviations: MK-8, 2-methyl-3-prenyl-1,4-naphthoquinone, a lipophilic nonprotein component of the electron transport chain in bacteria, with a prenyl side chain containing eight isoprene units; *iso*-$C_{15:0,}$; *iso*-$C_{17:0,}$; *iso*-$C_{16:1,}$; *anteiso*-$C_{15:0,}$; 3-OH $C_{11:0,}$; and nd, not determined.

From Miroshnichenko et al. (2003a, 2003b), Sako et al. (2003), and Mori et al. (2004).

Marinithermus hydrothermalis is strictly aerobic and heterotrophic (Sako et al., 2003), but *Oceanithermus profundus* (Miroshnichenko et al., 2003a), *O. desulfurans* (Mori et al., 2004) and *Vulcanithermus mediatlanticus* (Miroshnichenko et al., 2003b) are microaerophilic, are facultatively anaerobic, and, with the exception of *O. desulfurans*, can utilize molecular hydrogen as a source of electrons in the presence of an organic carbon source (Table 5). These organisms have optimum O_2 concentrations for growth of 2–6%; electron acceptors for anaerobic respiration depend on the organism but include nitrate, nitrite or elemental sulfur. Fermentation has not been detected.

Interestingly, the cells of these species resemble those of *Thermus* and *Meiothermus*. Some species, namely the two species of *Oceanithermus*, form "rotund bodies" similar to those seen in *Thermus* strains. The fatty acid composition of these novel organisms, composed primarily of saturated *iso-* and *anteiso*-branched chains, closely resembles that of *Thermus* spp. and *Meiothermus* spp. However, *V. mediatlanticus*, *O. profundus* and *O. desulfurans* have very high levels of unsaturated fatty acids that can reach over 30% of the total fatty acids. Moreover, branched chain cyclopropane fatty acids derived from the unsaturated fatty acids were also detected in small amounts in *V. mediatlanticus*. The polar lipids of *V. mediatlanticus* are composed of phospholipids and glycolipids that appear to be very similar if not identical to those of *Thermus* spp., but *O. profundus* has only phospholipids, which is a novel characteristic within the family Thermaceae, whose members also possess glycolipids.

Applications

The exploitation of thermostable enzymes is a major goal of biotechnology; however, the main thrust is directed to the utilization of enzymes from organisms that grow at or near the boiling point of water, leaving out organisms that grow in the temperature range of of the *Thermus*-like organisms. Despite all the interest in the biotechnological exploitation of hyperthermophilic organisms, *T. aquaticus* YT-1 produces one of the most valuable enzymes in scientific and economic terms. This enzyme is, of course, the Taq polymerase. This enzyme made the polymerase chain reaction (PCR) and thereby recombinant DNA technology possible, and even other polymerases from hyperthermophiles have not replaced the Taq polymerase.

Compatible solutes such as glycerol and trehalose have been extensively used to protect proteins, enzymes, and cells from thermal denaturation, from desiccation, and during long-term storage. Other compatible solutes, like ectoine, have also been found to be useful in cosmetics, and additional functions may be forthcoming as applied research finds new solutions for modern needs. Mannosylglycerate has been found to be more efficient than other solutes in protecting model enzymes from heat denaturation and freeze-drying and may, in the future, replace other compatible solutes for these purposes (Ramos et al, 1997; Borges et al., 2002). *Thermus thermophilus* appears to be the organism of choice for the production of this compatible solute since all other thermophilic or hyperthermophilic organisms that produce this compatible solute grow very poorly or are too fragile for industrial production. Moreover, recombinant production of the compound remains elusive in many industrial strains.

CHAPTER 10.1

The Family Chloroflexaceae

SATOSHI HANADA AND BEVERLY K. PIERSON

Introduction

The first multicellular filamentous anoxygenic phototrophic bacterium was discovered in thermal environments (Pierson and Castenholz, 1971) and was soon described as a new genus and species with the name of "*Chloroflexus aurantiacus*" (Pierson and Castenholz, 1974a). The organism showed gliding motility and contained pigment-bearing vesicles called "chlorosomes." Chlorosomes are generally observed in green sulfur bacteria that are strictly anaerobic phototrophs sensitive to oxygen. The pigment-bearing vesicles in *Chloroflexus aurantiacus* were very similar, both structurally and functionally, to those in green sulfur bacteria (Schmidt, 1980a). Aside from this pigment resemblance, however, significant differences were found between the filamentous organism and green sulfur bacteria. In addition, this new phototroph apparently differed in many phenotypic characteristics from purple bacteria, which is another type of anoxygenic photosynthetic bacteria. Therefore, the new family Chloroflexaceae was created for this filamentous phototroph containing prominent features (Trüper, 1976).

Following the description of *Chloroflexus aurantiacus*, related mesophilic filamentous phototrophs were found in freshwater habitats: Two genera, *Chloronema* (Dubinina and Gorlenko, 1975) and *Oscillochloris* (Gorlenko and Pivovarova, 1977; Keppen et al., 1994), were individually proposed for the isolates. Like *Chloroflexus aurantiacus*, these mesophiles are morphologically filamentous, show gliding motility, and contain chlorosomes as light-harvesting components. On the other hand, a chlorosome-less filamentous phototroph, *Heliothrix oregonensis*, was also found in a hot spring (Pierson et al., 1984a). The *Chloroflexus*-like bacterium is an interesting organism in that it does not contain bacteriochlorophyll (Bchl) *c* but does contain as its sole chlorophyll species Bchl *a*. Recently, another chlorosome-less filamentous phototroph was newly isolated from a hot spring and proposed as *Roseiflexus castenholzii* (Hanada et al., 2002b). Although *Roseiflexus castenholzii*, like *Heliothrix oregonensis*, lacks Bchl *c* and chlorosomes, genotypic and phenotypic comparisons showed that they were phylogenetically distant from each other.

Filamentous morphology and gliding motility are typical features of these organisms, whereas these properties are seldom observed in any other anoxygenic photosynthetic bacteria, i.e., purple bacteria, green sulfur bacteria, and the heliobacteria. The phylogenetic analysis based on 16S rRNA sequence also supported the solitary taxonomic position of this group: Oyaizu et al. revealed that *Chloroflexus aurantiacus* belonged to a deep branching lineage (phylum) of the domain Bacteria together with the genera *Herpetosiphon* and *Thermomicrobium*, which are comprised of nonphototrophic bacteria, and that *Chloroflexus aurantiacus* was phylogenetically distant from any other photosynthetic group (Oyaizu et al., 1987).

The phototrophic group (as well as the phylogenetic phylum) was at first called "green nonsulfur bacteria," because the first discovery possessed chlorosomes, a trait typical of green sulfur bacteria. However, this appears to be a misnomer for the following reasons: 1) the group is clearly distant from green sulfur bacteria and 2) two of the total of five phototrophic genera have no chlorosomes and indeed are not green but red to orange. Therefore, two new general terms representing the photosynthetic group have been proposed: "multicellular filamentous green bacteria" (Pfennig, 1989) and "filamentous anoxygenic phototrophs" (Pierson and Castenholz, 1995). Considering the common features of the members (and desiring to avoid calling them "green") in this chapter, we use the term "filamentous anoxygenic phototrophs" (FAPs) to refer to this phototrophic group composed of the family Chloroflexaceae.

FAP organisms have been observed in marine and hypersaline environments as well as in hot springs and freshwater habitats (Stolz, 1983; D'Amelio et al., 1987; D'Amelio et al., 1989; Mack and Pierson, 1988; Venetskaya and Gerasimenko, 1988; Garcia-Pichel et al., 1994; Pierson et al., 1994). These halophiles are morphologi-

cally diverse: They vary in cell diameter, and some hypersaline filaments have complex internal membranes seldom observed in *Chloroflexus aurantiacus*. Most marine and hypersaline FAPs contain chlorosomes as well as Bchl *a* and *c* as photosynthetic pigments (and sometimes Bchl *d*). The one exception to this is the marine purple filaments described by D'Amelio et al. (1987). J. A. Klappenbach and B. K. Pierson (unpublished observation) found that the FAPs previously described in enrichment cultures (Pierson et al., 1994) were phylogenetically related to other chlorosome-containing FAPs. Nübel et al. (2001) investigated, by rRNA-based comparison, the phylogeny of hypersaline *Chloroflexus*-like organisms that formed microbial mats in evaporation ponds in a saltern. They revealed that these hypersaline filaments were phylogenetically related to FAPs. As mentioned above, FAPs are distributed throughout various environments and have significant physiological, morphological and taxonomic diversity.

FAPs are important to the study of the evolution of photosynthesis. It is clear that FAPs are phylogenetically distant from purple bacteria and are phenotypically very distant from them as well. However, these two groups resemble each other structurally and functionally in their photochemical reaction centers (the reaction center is an essential protein that contains bacteriochlorophylls for the primary action in photosynthesis). On the other hand, several FAPs obviously possess chlorosomes as a light-harvesting system like that of green sulfur bacteria, in spite of the phylogenetic distance between these two photosynthetic groups. Xiong et al. (2000) reported that the gene sequences of encoded enzymes for the biosynthesis of bacteriochlorophylls were closely related between the green sulfur bacteria and the FAPs. These findings indicate that FAPs are so-called "chimeric organisms" endowed with the purple bacterial photochemical system and the green bacterial light-harvesting system. This presents a puzzle in understanding the evolution of photosynthesis, since these three photosynthetic groups are phylogenetically diverse from one another. To explain the discrepancy between the taxonomic distance and photosynthetic similarity, the possibility of horizontal transfers of photosynthetic genes between these groups was suggested (Blankenship, 1992).

A similar discrepancy between the phototrophic groups is also found in the pathways of carbon dioxide fixation. Recently, Keppen et al. (2000) separated a mesophilic species *Oscillochloris trichoides* from the family Chloroflexaceae and proposed a new family name Oscillochloridaceae for the mesophilic species. One of the notable features of this organism is the presence of a reductive pentose phosphate cycle, i.e., the Calvin-Bassham-Benson cycle (Ivanovsky et al., 1999). *Chloroflexus aurantiacus* does not use this type of pathway to fix carbon dioxide, but uses the 3-hydroxypropionate cycle (Holo, 1989; Strauss and Fuchs, 1993) or the reductive dicarbonate cycle (Ivanovsky et al., 1993) as do the early branched-off bacteria and chemoautotrophs of Archaea. It is quite interesting that *Oscillochloris trichoides* includes the reductive pentose phosphate cycle, because this carbon dioxide fixing pathway is found generally in autotrophs that belong to the Proteobacteria or Cyanobacteria.

As mentioned above, there are interesting evolutionary peculiarities in the photosynthetic group that includes the family Chloroflexaceae. Therefore, it is possible that FAPs may be key organisms in resolving the process of evolution in carbon dioxide fixation as well as in photosynthetic systems.

Phylogeny

Until the early 1990s, only one 16S rRNA sequence, that of *Chloroflexus aurantiacus*, was available for phylogenetic analysis in the family Chloroflexaceae. Over the past decade, however, sequence data have been increasing for the filamentous anoxygenic phototrophs (FAPs). Molecular techniques containing enzymatic amplification of nucleotides and cloning have made possible the determination of rRNA (or its gene sequence) of members in mixed cultures or natural microbial mats. Weller et al. (1992) determined a partial 16S rRNA sequence of *Heliothrix oregonensis* in coculture with *Isosphaera pallida* and succeeded in obtaining several *Chloroflexus*-related clone sequences from microbial mats in a hot spring. Similarly, Nübel et al. (2001) analyzed the phylogeny of filamentous anoxygenic phototrophs in hypersaline environments and gave us phylogenetic information about halophilic species. Through culture-independent rRNA sequence analysis, Boomer et al. (2002) determined the taxonomic position of filamentous phototrophs that formed the distinct red bacterial mats in hot springs. Gich et al. (2001) were successful in sequencing the 16S rRNA gene of a possible *Chloronema giganteum* in a mixed culture through molecular techniques. *Chloronema giganteum* is thought to be a freshwater species, though it remains to be isolated. Phylogenetic analyses, not only on axenic cultures but also on enriched cocultures and natural microbial communities, are key to understanding the phylogenetic diversity of FAPs and the relationships between them.

Figure 1 shows the FAP phylogenetic tree based on 16S rRNA sequences of its members,

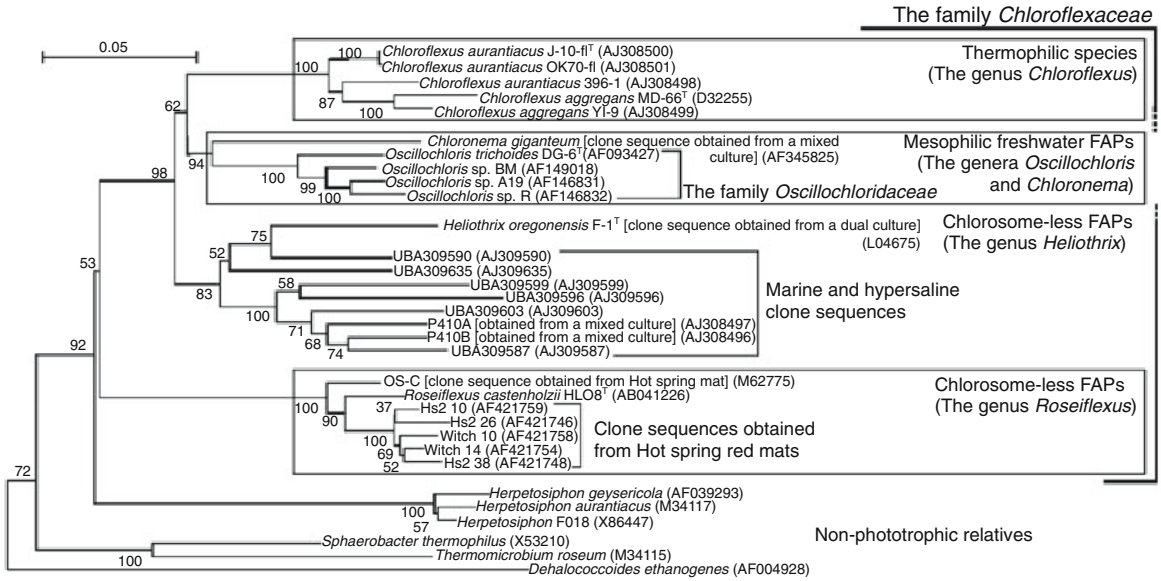

Fig. 1. A phylogenetic tree showing the relationship among the filamentous anoxygenic phototorophs (FAPs) and related non-phototrophic species based on 16S rRNA gene sequence. Bootstrap confidence values from 100 bootstrap replicates are indicated at the branching points. Bar = 5 nucleotide substitutions in 100 nucleotides in 16S rRNA sequences. The accession number of each reference species is shown in parentheses.

with clone sequence data obtained from mixed cultures and natural microbial mats. The tree indicates that each of the four phenotypes (thermophilic, mesophilic, halophilic or chlorosome-less filaments) forms an individual phylogenetic cluster or clusters and does not intermingle with the others. Two mesophilic freshwater species, *Oscillochloris trichoides* and *Chloronema giganteum* (the clone sequence was obtained from a mixed culture), are related to each other, and these are placed beside a coherent cluster composed of thermophilic *Chloroflexus aurantiacus* and *Chloroflexus aggregans*. Chlorosome-less filaments are divided into two lineages, one represented by *Heliothrix oregonensis* and the other by *Roseiflexus castenholzii*, with a great phylogenetic distance between them. The *Roseiflexus* lineage contains clone sequences obtained from microbial mats in Yellowstone National Park (United States): five clone sequence series, e.g., Hs2 and Witch, from the red-colored bacterial mats that comprised chlorosome-less filamentous phototrophs (Boomer et al., 2002) and a clone sequence, named "OS-C," from microbial mats in Octopus Spring in the Lower Geyser Basin, Yellowstone National Park (Weller et al., 1992). *Heliothrix oregonensis* is related to clone sequences retrieved from hypersaline environments by Nübel et al. (2001). This cluster is a widely diverse assemblage composed mainly of a lot of clone sequences obtained from microbial mats in evaporation ponds with various salinities (5.5–16%). It also includes two different 16S rRNA gene sequences (P4-1-0 clone A and P4-1-0 clone B) recovered from an enrichment of halophilic FAPs. Nübel et al. (2001) reported that the enriched halophilic filaments in medium containing 9% sea salt had in vivo absorption maxima at 850 and 755 nm (which were due to Bchl *a* and *c*, respectively), showed gliding motility, and had filaments resembling those of the "marine *Chloroflexus*-like organisms" (MCLOs) described by Pierson et al. (1994). The sequence similarities between *Heliothrix oregonensis* and the hypersaline clone sequences are approximately 84–86%. Although these values are very low, a high bootstrap confidence (83%) at the branching point strongly suggests that *Heliothrix oregonensis* and halophiles belong to the same assemblage, in spite of their clear phenotypic differences. One must be cautious in this interpretation, however, because the 16S rRNA data from *Heliothrix* include only a partial sequence. Because of this, it was omitted from all phylogenetic trees published in *Bergey's Manual of Systematic Bacteriology* (Pierson, 2001).

The divergence within the 16S rRNA sequence of the FAPs that comprise the family Chloroflexaceae and its relatives is very large (more than 22%). Although this group contains only five genera, phylogenetically it is as diverse as larger taxa, such as Proteobacteria and Gram-positive bacteria. Recently, and chiefly by taking account of the rRNA sequence difference, a mesophilic freshwater species, *Oscillochloris trichoides*, was separated from the family Chlo-

roflexaceae. A new family name, Oscillochloridaceae, was proposed for it. From a phylogenetic viewpoint, still more families might be separately created for a few of the five genera, e.g., *Heliothrix* and *Roseiflexus*, and also marine or hypersaline relatives, as species become isolated.

Within the Bacteria, the phylum that includes the FAPs as shown in Fig. 1 also includes filamentous chemotrophs but not the more distantly related unicellular chemotrophs included in Fig. 1. The phototrophs form a cohesive group. Species of *Herpetosiphon* are the closest chemotrophic relatives. Together these phototrophs and filamentous chemotrophs have similar morphological and gliding properties, and the species that have been analyzed (the genera *Chloroflexus* and *Herpetosiphon*) have similar wall structure.

Within the phototrophs, the "green" genera which contain chlorosomes and accessory light-harvesting Bchl *c* or *d* appear to form a branch distinct from the "red" genera which lack chlorosomes and have only Bchl *a*. The genera *Chloroflexus*, *Oscillochloris*, *Chloronema*, the hypersaline MCLO (marine and hypersaline *Chloroflexus*-like organism) and other hypersaline strains are all closely grouped. Each genus has no more than 85% similarity to the others, suggesting that they might represent four different clades at the level of family. The genus *Roseiflexus* and the red mat sequences reported by Boomer et al. (2002) appear to group together (distinct from the green line) but also do not show tremendous closeness. The one exception to this generalization is the genus *Heliothrix*, which lacks chlorosomes and falls within the "green" group in Fig. 1. Cautious interpretation is required, however, since the *Heliothrix* sequence is limited in length. The lack of sequence data for the large red filaments studied by Boomer et al. (2000) is unfortunate, and it will be interesting to see whether they are eventually placed in the "red line." The red line appears to be distant from either the chemoheterotrophic genus *Herpetosiphon* or the green line.

This chapter emphasizes the 16S rRNA phylogeny but other relevant phylogenies that include *Chloroflexus aurantiacus* and examine its relationships to other phototrophs have been constructed using Hsp60 and Hsp70 signature sequences (Gupta et al., 1999), group 1 and 2 σ factors (Gruber and Bryant, 1997; Gruber and Bryant, 1998a), and RecA sequences (Gruber et al., 1998b). The position of *Chloroflexus* in a deeper branch of the 16S rRNA tree than other phototrophs does not correlate with the suggested pattern of evolution of photosynthetic genes obtained from sequence analysis of pigment synthesis genes (Xiong et al., 2000). Since much of the photosynthetic apparatus may have been acquired in different lines of descent by lateral gene transfer, phylogeny of the organisms does not necessarily correlate with evolution of photosynthetic ability.

Taxonomy

Five genera have been described as filamentous anoxygenic phototrophs (FAPs): *Chloroflexus*, *Chloronema*, *Oscillochloris*, *Roseiflexus* and *Heliothrix*. The genus "*Chlorocrinis*" (Ward et al., 1998) does not exist. This was a tentative name originally proposed for the organism subsequently named "*Chloroflexus aggregans*." Two additional organisms have been well characterized and will certainly constitute new genera, the marine and hypersaline *Chloroflexus*-like organism (MCLO; Pierson et al., 1994) and the red hot spring mat filaments (RCR; Boomer et al., 2000). Although most of the genera are readily distinguished from each other by 16S rRNA (Fig. 1), distinguishing phenotypic features are not always very obvious and some of the differences are subtle (see Table 1). These features are discussed in more detail in the section "IDENTIFICATION." This section highlights the taxonomic difficulties posed by the relative lack of and overlap of phenotypic characters.

The genera *Chloroflexus*, *Oscillochloris*, *Chloronema* and the MCLO are readily distinguished from *Heliothrix*, *Roseiflexus* and the RCR because the first four organisms all contain Bchl *c* or *d* and chlorosomes in addition to Bchl *a*. However, distinguishing among these four green organisms by phenotypic characters is not easy. *Oscillochloris* species appear to be sulfide-dependent and to grow primarily photolithoautotrophically or photoheterotrophically. They do not grow well aerobically, although some strains may grow well under microaerobic conditions. *Chloroflexus* species, however, grow best photoheterotrophically and also grow well under aerobic conditions. Gas vesicles are frequently observed in the genus *Oscillochloris* and have not been reported in the genus *Chloroflexus*. *Oscillochoris chrysea* has incomplete septa lined with chlorosomes. The genus *Chloroflexus* has its chlorosomes confined to the cell periphery. *Oscillochloris* species have been observed in muds and in algo-bacterial mats up to 45°C. *Chloroflexus* species are found in hot spring mats in the presence or absence of sulfide at temperatures around 45°C and at much higher temperatures. However, organisms appearing identical to the genus *Chloroflexus* have been observed in mesophilic freshwater (Gorlenko, 1976) and marine habitats (Mack and Pierson, 1988). The genus *Chloronema* also has gas vesicles and is larger in diameter than *Chloroflexus* species and

Symbols; +, positive; –, negatives; ND, not determined. *Each organism would also contain another bacteriochlorophyll, possibly Bchl *a*, that is essential to its photosynthesis.

Oscillochloris trichoides, but is narrower than *Oscillochloris chrysea*. *Chloronema* species are planktonic, unlike all the other filamentous anoxygenic phototrophs. The MCLO is readily distinguished from the other three green genera on the basis of habitat (found in hypersaline microbial mats), dependence on high sulfide, and its distinctive ultrastructure with infoldings of the cell membrane forming pockets lined with chlorosomes on the cytoplasmic side (Pierson et al., 1994).

The three organisms lacking chlorosomes are more readily distinguished from each other. All contain Bchl *a* and are found in hot spring microbial mats. *Roseiflexus castenholzii* has narrow filaments (1.0 μm or less in diameter) and lacks internal membranes (Hanada et al., 2002). *Heliothrix oregonensis* is larger (1.5 μm in diameter) and also lacks internal membranes (Pierson et al., 1984a; Pierson et al., 1985b). The RCR filaments are also 1.5 μm in diameter, but the cells contain abundant internal membranes (Boomer et al., 2000).

The genus *Chloroflexus* has two species, *Chloroflexus aurantiacus* and *aggregans*. The species are readily distinguished by 16S rRNA but phenotypically are very similar except for the aggregating ability of *Chloroflexus aggregans* (Hanada et al., 1995a).

The genus *Oscillochoris* has two species, *Oscillochoris trichoides* and *chrysea*, which can be distinguished on the basis of size and ultrastructure. *Oscillochoris chrysea* is very large (4–5 μm in diameter) and has partial septa bearing chlorosomes.

The genus *Chloronema* has the species *Chloronema giganteum* and the incompletely described species *Chloronema spiroideum*.

A higher level taxonomy has recently been described in the *Bergey's Manual of Systematic Bacteriology* (Castenholz, 2001; Garrity and Holt, 2001). The phylum formerly described as the green nonsulfur bacteria has been named the "phylum Chloroflexi" after the genus *Chloroflexus*, the most thoroughly studied genus in this group. The phylum contains one class, the "Chloroflexi." All members are Gram-negative filamentous gliding bacteria lacking a lipopolysaccharide-containing outer membrane and containing L-ornithine instead of the diaminopimelic acid in the peptidoglycan. These organisms are phylogenetically related by 16S rRNA analysis and have been divided into two orders: the "Chloroflexales," which contains all the phototrophic organisms (or at least the organisms containing Bchl), and the "Herpetosiphonales," which are not photosynthetic and contain no Bchl. The "Chloroflexales" contains only one family, the "Chloroflexaceae," which includes all the filamentous anoxygenic phototrophic bacteria. The phylogenetic distances between the genera in the 16S rRNA tree, however, are great enough to warrant taxonomic distinction at the level of family. Consequently, one proposal already exists to create a new family, "Oscillochloridaceae," for the genus *Oscillochloris*. The current descriptions of these two families will need refining before any new families are created, partly because of the paucity of distinguishing phenotypic characters. It may be that new families will be appropriate for all of the genera described here. The phylogenetic position of *Heliothrix oregonensis* is more uncertain because only a partial sequence of its 16S rRNA has been determined. The RCR has yet to be sequenced. Nevertheless, on purely phenotypic characters, one could suggest the creation of two suborders, one including the "green line" of *Chloroflexus*, *Oscillochloris*, *Chloronema*, and the MCLOs, all of which contain Bchl *c* or *d* and chlorosomes. The other suborder would include the "red line" of the genera *Heliothrix*, *Roseiflexus*, and the RCR, which lack Bchl *c* and *d* and chlorosomes. The uncertain taxonomy of this group is a reflection of the limited number of species that were available for study until very recently. Our current suggestions are tentative as we gather more information about newly emerging genera, and as cultivation techniques and sequence analyses improve, for strains previously described on the basis of field observations only.

Habitat

The filamentous anoxygenic phototrophs (FAPs) belonging to the family Chloroflexaceae or the related family Oscillochloridaceae are widely distributed throughout various environments such as hot and cold springs, freshwater lakes, river water and sediments, and both marine and hypersaline environments.

The Genus *Chloroflexus*

Chloroflexus species, which are unbranched filamentous anoxygenic phototrophic bacteria with a diameter of about 1 μm, are generally found in neutral to alkaline hot springs. Both authentic species in this genus, *Chloroflexus aurantiacus* (Pierson and Castenholz, 1974a) and *Chloroflexus aggregans* (Hanada et al., 1995a), have been isolated from hot springs. Almost all strains in the genus *Chloroflexus* are thermophiles grown at around 55°C, and these organisms are distributed worldwide. In natural hot springs, the organisms formed yellow-orange-greenish mats with cyanobacteria. The mats vary in morphology and color, depending on temperature, pH,

Fig. 2. The microbial mat consists of a dark green layer (cyanobacteria) and yellow streamers (*Chloroflexus* sp.). The mat was collected from Okukinu Meotobuchi Hot Spring in Japan (57°C, pH 7.0). The length of yellow streamers is about 10–15 mm.

and sulfide concentration (Castenholz, 1984; Jørgensen and Nelson, 1988; Castenholz and Pierson, 1995). The *Chloroflexus* mats appear in hot spring effluents as thin orange films or yellow-orange streamers formed on the surface of dark green cyanobacterial mats (Fig. 2).

In North America, *Chloroflexus* populations with cyanobacteria are found up to 70–72°C, and the lower temperature limits are 30–40°C, with a pH between 5.5 and 10 (Pierson and Castenholz, 1995). These conditions are nearly the same even in hot springs in other regions, such as Japan, Italy and Iceland. In the extensive survey in Japanese hot springs, *Chloroflexus* strains were isolated from hot spring water at temperatures of 50–70°C with pH of 6.4–8.2 (Hanada et al., 1995b). Pentecost investigated a microbial community in Italian hot springs with travertine deposits (Pentecost, 1995). *Chloroflexus* spp. were predominantly observed in these hot springs at 40–60°C and were isolated from 39.5–63.4°C (most abundantly from 55–60°C). Jørgensen and Nelson studied microbial mats in Icelandic sulfide-rich hot springs with pH of 7.5 and 8.5 (Jørgensen and Nelson, 1988; Keppen et al., 1994). They reported that *Chloroflexus* species were well developed at 55–66°C. Almost all researchers also mentioned observing these *Chloroflexus*/cyanobacterial mats in hot springs with sulfide concentrations under 100 μm. In natural hot springs, *Chloroflexus* spp. appear to grow photoheterotrophically or chemoheterotrophically by using substrates derived from cyanobacteria, since all isolated strains belonging to the genus *Chloroflexus* show good growth both in photoheterotrophic conditions (anaerobically in the light) and chemoheterotrophic conditions (aerobically in the dark).

However, several researchers have reported a *Chloroflexus* strain growing independently without cyanobacteria. A dark green mat of nearly pure *Chloroflexus* strains was found in Yellowstone National Park (Castenholz, 1988b). The hot water at that site contains a large amount of sulfide (up to 1000 μm), and this high concentration prevents cyanobacteria from growing. This *Chloroflexus* strain, designated the "GCF strain," would grow photoautotrophically using sulfide as an electron donor in the hot springs. A physiological study of the GCF strain mat in the laboratory revealed that the strain showed sulfide-dependent photoautotrophic growth but no respiratory growth in the presence of oxygen. A similar case was reported in Nakabusa Hot Spring, Nagano Prefecture, Japan (Sugiura et al., 2001), in which the authors found pure *Chloroflexus* mats devoid of cyanobacteria. This type of mat was well developed at the high temperature zone (71–77°C; pH 8.5) preventing the growth of cyanobacteria (in Japan, no cyanobacteria are able to grow at a temperature of more than 70°C, although cyanobacteria commonly can be seen at up to 73–74°C in western North America). The growth of the *Chloroflexus* mats is considered to be sulfide-dependent and photoautotrophic, since the hot spring effluent includes sulfide. The high photoautotrophic activity, susceptibility to oxygen, and thermotolerance of these cyanobacteria-independent *Chloroflexus* mats make them clearly different from any known strains of *Chloroflexus aurantiacus* or *Chloroflexus aggregans*. Therefore, these autotrophic strains may be classified as a new species in the genus *Chloroflexus*, although they have yet to be axenically isolated or phylogenetically analyzed.

There is no evidence to support that *Chloroflexus* spp. grow in acidic (less than pH 6) or brackish-saline hot springs. In a survey of various hot springs over a wide area of Japan, no *Chloroflexus* mat was observed in such hot springs (Hanada et al., 1995b). In Japan, the organism also appeared to be absent in springs with high iron contents. However, Pierson and Parenteau (2000) found a *Chloroflexus* strain in an iron-depositing hot spring (Chocolate Pots, Yellowstone National Park). The hot water contained a large amount of ferrous iron (the concentration was more than 100 μm). The *Chloroflexus* strain formed a microbial mat with a cyanobacterium, *Synechococcus* sp., in the hot water stream at 49–54°C. Since the *Chloroflexus* mats contain abundant iron deposits, it is quite possible that the *Chloroflexus* strain oxidizes ferrous iron as an electron donor for photosynthesis, which is known to occur in some species of purple bacteria and green sulfur bacteria (Ehrenreich and Widdel, 1994; Heising et al., 1999).

In addition to the thermophiles, a mesophilic variety of *Chloroflexus aurantiacus*, called *Chloroflexus aurantiacus* var. "*mesophilus*," was also reported (Gorlenko, 1976; Pivovarova and Gorlenko, 1977). The variety grows in the temperature range of 10–40°C with an optimum at 20–25°C. The mesophile was isolated from mat communities in the bottom mud of freshwater lakes. Gorlenko (1976) mentioned that mesophilic *Chloroflexus* spp. are commonly observed in the anoxic zones of freshwater lakes.

Mesophilic Freshwater Forms (the Genera *Oscillochloris* and *Chloronema*)

Mesophilic freshwater species of the filamentous anoxygenic phototrophs, the genera *Oscillochloris* and *Chloronema*, have been observed mainly in anaerobic environments containing significant amounts of sulfide, such as algobacterial mats formed on mud surfaces or the anoxic zones of freshwater lakes. In their habitats, they are often associated with purple sulfur bacteria and green sulfur bacteria, *Beggiatoa* and *Oscillatoria*.

Almost no freshwater mesophiles have been isolated as pure cultures, and *Oscillochloris trichoides* is the sole species proposed and described on the basis of axenic cultures (the family Oscillochloridaceae was newly created for the organism; Keppen et al., 1994; Keppen et al., 2000). Although strains of *Oscillochloris trichoides* are basically freshwater forms, they have been observed in various fresh or brackish water environments, e.g., microbial mats in a sulfide-containing warm spring, shallow river water, a littoral estuary, and a brackish alkaline soda lake. The organism is a mesophile with optimal growth temperatures of 28–30°C, but it may occur in natural warm springs with temperatures up to 45°C. Another species, *Oscillochloris chrysea*, with wide filamentous morphology (the cell diameters are 4.5–5.5 μm) has been found on the surface of mud in freshwater streams with high organic content from domestic sewage effluents (Gorlenko and Pivovarova, 1977; Gorlenko, 1988).

Chloronema spp. have been observed below the chemoclines of freshwater lakes. One species in the genus, *Chloronema giganteum*, was found in the metalimnion and upper hypolimnion of shallow stratified freshwater lakes (Dubinina and Gorlenko, 1975; Gorlenko and Lokk, 1979b). The lake waters contained ferrous iron with high concentrations and no or low concentrations of hydrogen sulfide. Borrego et al. (1998) studied natural populations of anoxygenic phototrophs in the anoxic hypolimnion of 17 holomictic lakes in the United States and Spain and indicated that *Chloronema* spp. were predominant in 13 of those lakes during summer stratification.

Chlorosome-less Filaments (the Genera *Heliothrix* and *Roseiflexus*)

Possession of chlorosomes is one of the conspicuous features of most FAPs. However, the group also contains two photosynthetic species lacking chlorosomes, *Heliothrix oregonensis* and *Roseiflexus castenholzii*. Both species are thermophiles and have been isolated from hot springs. *Heliothrix oregonensis* is found in some hot springs in western North America at temperatures up to 55°C, at approximately pH 8.5, without hydrogen sulfide (Pierson et al., 1984a; Pierson et al., 1985b). In the natural hot springs, the organism forms bright orange masses on the layer of cyanobacteria. Puffs and tufts often form on the surface of its mat where it is exposed to oxygen (Castenholz, 1988b). *Heliothrix oregonensis* is impressively dominant in small alkaline pools at the Warm Springs Indian Reservation (Oregon), and an apparently identical organism is also common in several alkaline hot springs in Yellowstone National Park.

Another chlorosome-less filament is an organism described as *Roseiflexus castenholzii* (Hanada et al., 2002b). Phylogenetic analyses and phenotypic comparisons revealed that the organism was not closely related to *Heliothrix oregonensis*, although both lack chlorosomes and contain Bchl *a* as the sole photosynthetic pigment. *Roseiflexus castenholzii* was first found in Japan's Nakabusa Hot Spring. The organism forms a distinct, dense red layer underneath the mats of cyanobacteria and *Chloroflexus* spp. The red layer is dominated by *Roseiflexus* filaments. In Nakabusa hot spring, the *Roseiflexus* mat is observed at temperatures of 45.5–68.5°C at pH 7.8–8.2 (Sugiura et al., 2001). The red mat is also observed in other Japanese hot springs, such as Meotobuchi (Tochigi Prefecture; 57°C, pH 6.8) and Atagawa (Shidzuoka Prefecture; 44°C, pH 8.0). The morphological and spectroscopic properties of the filaments in these hot springs are completely identical. Boomer et al. (Boomer et al., 2000; Boomer et al., 2002) reported on red mats in alkaline hot springs of Yellowstone National Park. The temperature and pH ranges of hot springs containing the mats were 30–50°C and 7.5–8.7, respectively. The phylogenetic analysis based on 16S rRNA sequence revealed that the Yellowstone filaments were closely related to *Roseiflexus castenholzii*, but there were clear differences between these filaments and those of *Roseiflexus castenholzii* in morphological and spectroscopic characteristics. These differences suggest that the Yellowstone filaments belong

not to *Roseiflexus castenholzii* but to a novel species related to it.

In addition, it was reported that a FAP containing only Bchl *a* was observed in hypersaline mats (the salinity of brine is about 8%). The organism was found in close association with a cyanobacterium, *Microcoleus chthonoplastes* (D'Amelio et al., 1987). Little is known about this hypersaline organism except for its morphological properties.

FAPs in Marine and Hypersaline Environments

Chlorosome-bearing filamentous bacteria have been frequently observed in marine or hypersaline environments (Pierson et al., 1994), although no pure culture has been isolated to date. In the marine intertidal environment, these organisms were most notably observed in association with species of *Thiocapsa*, *Chloroherpeton*, *Oscillatoria* and *Beggiatoa* (Mack and Pierson, 1988). It was demonstrated that these FAPs showed diel migration in the intertidal microbial mats. During the day, these filaments were found below the layer of a purple sulfur bacterium, *Thiocapsa* sp.; at night, they migrated to the surface. The migration could be induced artificially by changing the intensity of the illumination (Mack and Pierson, 1988).

A lot of FAPs have been found globally in hypersaline environments, such as evaporation ponds of salterns. Stolz has identified the organisms involved in hypersaline microbial mats in Laguna Figueroa, Baja California, Mexico (Stolz, 1983; Stolz, 1984; Stolz, 1990) by transmission electron microscopy. Using similar methods, D'Amelio et al. (1989) confirmed their occurrence in Guerrero Negro in Baja California and in Solar Lake, on the Sinai Peninsula of Egypt. Venetskaya and Gerasimenko (1988) also detected them in the hypersaline lagoons near the Sea of Azov, Ukraine.

The FAPs formed olive-green layers within the hypersaline microbial mats. The mats were composed of cyanobacteria, *Beggiatoa*, and some purple sulfur bacteria. The mats occurred in evaporation ponds at 18–21°C and pH 7.8–8.4. Temperatures in the mats themselves often exceeded 30°C, and they reached 40°C in summer. The salinities ranged from about 7 to 14% (Pierson et al., 1994).

These filaments were identified only morphologically, but the pigment analysis on the mats in Guerrero Negro revealed the presence of γ-carotene in particular layers (Palmisano et al., 1989); this carotenoid is typical of FAPs. The molecular analysis of hypersaline mats in Guerrero Negro by Nübel et al. (2001) suggested that these filaments were obviously related to the FAPs. In addition, uptake experiments using ^{14}C-labeled bicarbonate indicated that marine filaments clearly showed the light-dependent assimilation of carbon (Pierson et al., 1994).

Isolation

Of the filamentous anoxigenic phototrophs (FAPs), the following species have been isolated as axenic monocultures or as dual-cultures with a nonphototrophic bacterium: *Chloroflexus aurantiacus* and *Chloroflexus aggregans* isolated from hot springs; *Oscillochloris trichoides*, a mesophile from freshwater environments; and *Heliothrix oregonensis* and *Roseiflexus castenholzii*, chlorosome-less thermophiles from hot springs. In this section, we show mainly the procedures of enrichment, isolation, cultivation, and maintenance of these isolated species (especially the genus *Chloroflexus*, the first discovery among the FAPs). Also, several researchers have succeeded in enriching other FAPs in fresh and saline habitats, although no axenic culture has been obtained. We therefore provide helpful information for enriching these other FAPs in freshwater, marine and hypersaline environments.

The Genus *Chloroflexus*

Facultative Thermophilic Species: Enrichment and Isolation Almost all strains that have been isolated axenically are able to grow photoheterotrophically and chemoheterotrophically and inhabit microbial mats in hot springs with cyanobacteria. Microbial mats formed in hot springs (at approximately 30–70°C) should be collected in vials along with the hot water and brought to the laboratory at normal temperature (12–25°C) in darkness. The collected *Chloroflexus* strains retain their viability under these conditions. Cooler or warmer temperatures, or light irradiation, will usually shorten the survival time. Freezing as well as extensive exposure to oxygen should be avoided. Enrichment and isolation of these *Chloroflexus* strains are generally done according to the following procedures.

Co-enrichment with cyanobacteria is a simple and usually successful method. A sample of a microbial mat is inoculated and incubated in a liquid medium for cyanobacteria, e.g., D medium. The incubation is done in a cotton-plugged flask under low-intensity light (1000–3000 lux; fluorescent or incandescent bulbs) at an appropriate temperature (e.g., 45–55°C). The one or more species of cyanobacteria grown in the medium will excrete organic compounds, which will support the heterotrophic growth of *Chloroflexus* strains. While these cultures also contain other non-phototrophic bacteria, the

coexistence of *Chloroflexus* strains with cyanobacteria is very stable.

A coculture can also be established on 1.5% agar-solidified D medium. Cyanobacteria grown on agar plates often glide out from the initial inoculum spot, sometimes forming fascicles or circling aggregates. These cyanobacteria may be transferred to fresh plates or to a similar liquid medium. The transferred cyanobacterial filaments invariably include *Chloroflexus* filaments. Occasionally, a bi-culture composed of a *Chloroflexus* strain and a cyanobacterium without other non-phototrophic contaminants may be obtained.

Using an agar medium like the one described above, the photoheterotrophic *Chloroflexus* strains may be simply isolated from these cocultures with cyanobacteria or directly from microbial mats even in hot springs. A small piece (4–16 mm^2) of the cocultured cyanobacteria or a collected mat sample is placed on 1.5% agar DG medium (D medium with 0.8 g/liter of glycylglycine as buffer; the pH is adjusted to 8.2 before autoclaving) and incubated at 45–50°C under illumination (fluorescent or incandescent bulbs; 10–100 W/m^2). After one to a few days, some of the cyanobacteria will have spread by gliding motility. *Chloroflexus* strains may be carried along with the cyanobacterial trichomes, since these trichomes generally glide more slowly than do cyanobacteria. However, wisps of gliding trichomes of *Chloroflexus* species will form frequently beyond the edge of the cyanobacteria (Fig. 3). These wisps of *Chloroflexus* strains may then be picked up with a watchmaker's forceps and streaked on a new DG plate that contains yeast extract (0.02–0.2 g/liter). An axenic culture can be obtained by repeatedly picking fine trichomes, if possible a single filament, from the tips of speading wisps and streaking them (Fig. 4).

For direct isolation of *Chloroflexus* strains, another method, using PE medium, was reported (Hanada et al., 1995b). PE medium is a newly designed medium containing acetate, glutamate, succinate, casamino acids, and yeast extract as carbon sources as well as some vitamins. As a buffering agent, phosphate is substituted for the glycylglycine used in previous methods for *Chloroflexus*, and the pH of the medium is adjusted to 7.5. Instead of the nitrate present in medium D, ammonium sulfate is added as a nitrogen source. The medium includes thiosulfate for possible utilization. The PE medium can therefore support the heterotrophic growth of *Chloroflexus* strains independent of cyanobacteria.

The collected bacterial mats may be dispersed and directly streaked on 1.5% agar plates of PE medium and then incubated at 55°C under incandescent light (30 W/m^2). Green or orange gliding trichomes will appear on the plate in a few days. The new medium, however, also will enrich aerobic or fermentative non-phototrophic bacteria. To selectively enrich *Chloroflexus* strains, agar plates should be incubated alternately under aerobic and anaerobic conditions after every transfer. *Chloroflexus* strains can sustain their growth under both conditions because they are generally facultative bacteria able to grow photoheterotrophically under anaerobic conditions and chemotrophically under aerobic conditions by respiration. An easy and convenient way to achieve anaerobic conditions is to use an oxygen absorber called "the Ageless S-100" (Mitsubishi Gas Chemical Co., Tokyo, Japan) with a sealed nylon bag. By the repetition of alternate aerobic and anaerobic culturing, bacteria other than

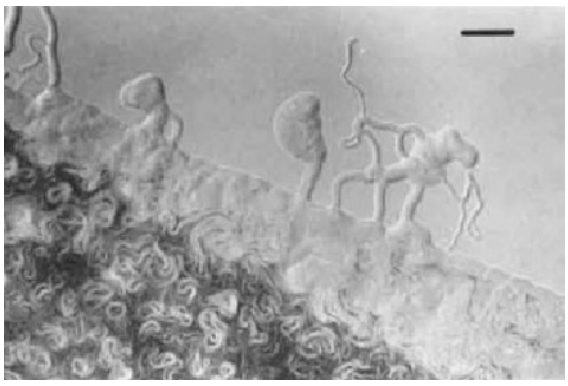

Fig. 3. Dual culture of *Chloroflexus aurantiacus* (NZ-Mar. 62-fl) and the cyanobacterium *Synechococcus lividus* (OH-53-s) on an agar surface (DG medium, 45°C). The dark area at the lower left is the population of *Synechococcus*. The lighter swirls and wisps of filaments advancing toward the upper right are *Chloroflexus*. Bar = 0.2 mm.

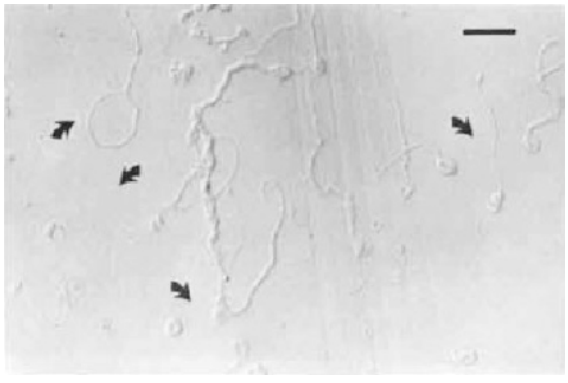

Fig. 4. Culture of *Chloroflexus aurantiacus* (OK-70-fl) on an agar surface at 45°C, 10 days after streak dilution. Single and double filaments are indicated by arrows. Bar = 0.2 mm.

Chloroflexus species will be efficiently removed. This is an efficient and reproducible method for isolating facultative *Chloroflexus* strains capable of growing both photoheterotrophically and chemoheterotrophically.

Facultative Thermophilic Species: Cultivation and Maintenance For the cultivation of *Chloroflexus* strains, variations of D medium are commonly used. D medium is prepared as a 20-fold concentrated stock (pH 3) and can be stored at 4°C without autoclaving. The culture medium (DG medium) is prepared by diluting the stock and adding glycylglycine (0.8 g/liter) as a buffer. Yeast extract (2.0 g/liter) and NH_4Cl (0.2 g/liter) are usually supplemented for liquid axenic cultures in screw-cap tubes or flasks. The pH should be adjusted to 8.0–8.2 with NaOH before autoclaving. To exclude nitrate, the base of D medium has also been modified (Castenholz, 1988a), since *Chloroflexus* strains require reduced forms of nitrogen (Brock, 1978) and the ND medium serves as an adequate substitute for D-based medium. In the DSMZ (Deutsche Sammlung von Mikroorganismen und Zellkulturen, the German Collection of Microorganisms and Cell Cultures), *Chloroflexus* strains are usually grown photoheterotrophically in D-based medium with 0.5 g of glycylglycine, 0.5 g of yeast extract, and 0.4–0.5 g of $Na_2S \cdot 9H_2O$ per liter. To eliminate oxygen, sodium sulfide is added from a separate sterile solution after autoclaving and cooling. In all cases, the *Chloroflexus* medium is adjusted to pH 8.2 with NaOH prior to autoclaving. For photoheterotrophic growth, screw-cap tubes or flasks should be filled to the top with preheated medium before incubation. All inoculated media are incubated and maintained at about 52–60°C under incandescent light (10–30 W/m^2). Cultures at 55°C should be transferred every 7–14 days. Agar-shake cultures (containing 1.0% agar) and agar plates (1.5% agar) are also used for maintaining these *Chloroflexus* species.

Facultative *Chloroflexus* strains are tolerant of oxygen and may also be grown as chemoheterotrophs by respiration. The same basic medium with yeast extract and casamino acids may be used with vigorous shaking or with an aeration system, using sterile-filtered line air. Aerobic growth has been sustained in DG medium plus 0.2 g of NH_4Cl, 0.5 g of yeast extract, 1.0 g of casamino acids, and 2.0 g of sodium acetate per liter (Sirevåg and Castenholz, 1979).

PE medium is another appropriate culture medium for all facultative *Chloroflexus* strains (Hanada et al., 1995b). The medium can be used for both photoheterotrophic and chemoheterotrophic culturing. *Chloroflexus* strains grow with a good rate and yield in the medium whether in the anaerobic condition in light or in the aerobic condition in the dark.

PE medium is also suitable for the maintenance of *Chloroflexus* cultures. The viability of most *Chloroflexus* strains can be extended to a few months by using PE medium as a maintenance medium in liquid anaerobic culture under low light intensity (less than 5 W/m^2) at 55°C. Under these conditions, *C. aurantiacus* J-10-fl survived in a screw-cap tube for 3 months with little degradation of its pigments.

Cultivation of Strictly Photoautotrophic Species For species that are strictly photoautotrophic, e.g., the GCF strain from sulfidic hot springs (Castenholz, 1973; Giovannoni et al., 1987), a sulfide-containing inorganic medium, e.g., DGN medium with $Na_2S \cdot 9H_2O$ (0.5 g/liter or about 2 mM final concentration) and $NaCO_3$ or $NaHCO_3$ (2.0 g/liter) as an inorganic carbon source (Madigan and Brock, 1977a; Brock, 1978) can be used. Since this physiological type of the genus *Chloroflexus* is very sensitive to oxygen, anaerobic procedures are necessary both for preparing media (e.g., purging with an anaerobic gas mixture) and for handling samples. Hungate tubes or other sealed anaerobic vessels with butyl rubber stoppers may be used for cultivation. Giovannoni et al. (1987) reported that the best liquid medium for photoheterotrophic growth was a DGN medium modified by adding 0.2–0.5 g of yeast extract and 1.0 g of D-glucose per liter. All strictly photoautotrophic cultures should be maintained at moderately thermophilic temperatures (45–55°C) in dim light (5–10 W/m^2).

Cultivation of a Mesophilic Variety Gorlenko (1976) succeeded in the enrichment of a freshwater, mesophilic variety of *Chloroflexus aurantiacus* found in lake-bottom water and sediment columns supplemented with Na_2SO_4 (0.6 g/liter), $Na_2S \cdot 9H_2O$ (0.1 g/liter), yeast extract (0.025 g/liter), and casein hydrolysate (0.025 g/liter) at a temperature of 25–30°C under illumination (<30 W/m^2). To isolate mesophilic strains, a technique similar to that used for thermophilic strains can be used, although Gorlenko (1976) did not explain how he isolated the mesophile from an initial enrichment. A mesophilic *Chloroflexus* strain was cultured (Pivovarova and Gorlenko, 1977) within soft agar medium (0.4%) with mineral salts and supplemented with 0.4 g of Na_2SO_4, 0.5 g of tryptone, and 0.5 g of yeast extract per liter (pH 7.0). The culture grew in the temperature range of 10–40°C. Pivovarova and Gorlenko (1977) maintained the mesophilic strain in soft-agar (0.4%) shake cultures in cotton-plugged tubes that were kept illuminated at approximately 30 W/m^2 and warmed to 28°C.

Other Information Other information useful for enrichment, isolation, and maintenance is as follows. First, the addition of 3,4-dichlorophenyl-1,1-dimethylurea (DCMU) to 5–10 μm is a good way to selectively enrich *Chloroflexus* strains without cyanobacteria or to remove cyanobacteria from mixed cultures, because the chemical compound prevents the cyanobacterial oxygenic photosynthesis. Second, manually picking an individual filament makes it possible to obtain a single clone of a strain. Finally, a dual culture with a cyanobacterium may offer the advantages of safe and stable maintenance of *Chloroflexus* strains.

The Genus *Oscillochloris* (the family Oscillochloridaceae)

Strain SR-1, the original type strain of *Oscillochloris trichoides*, was isolated from algobacterial mats by serial dilutions in test tubes (Gorlenko and Korotkov, 1979a). The isolation medium was a slightly modified version of a medium commonly used for green sulfur bacteria. The modified medium contained the following compounds: additional anhydrous Na_2SO_4, 330 mg/liter; yeast extract, 25 mg/liter; tryptone, 25 mg/liter; vitamin B_{12}, 20 μg/liter; $Na_2S \cdot 9H_2O$, 300 mg/liter; agar, 0.2–0.4%; and some trace elements (pH 7.5). The incubation was done at 25–35°C under a light intensity of 2000 lux. By serial dilutions (3–4 times), associated phototrophic bacteria, mainly purple nonsulfur bacteria, were removed and mono-phototrophic cultures were established. The cultures still contained some non-phototrophic contaminants, including facultative anaerobic fermenting bacteria and sulfur- and sulfate-reducers.

Whereas the enrichment of strain SR-1 was subsequently lost, another strain, DG-6, was isolated in pure culture and was described as the neotype strain of *Oscillochloris trichoides* (Keppen et al., 1993; Keppen et al., 1994). Following this description, further related strains have been isolated from fresh- and brackish-water environments (Keppen et al., 2000). A slightly modified DGN medium (see above) was used for the isolation of these strains: Nitrates were omitted, and KH_2PO_4 (1 g/liter), 0.2–0.25% $NaHCO_3$, 0.02–0.1% $Na_2S \cdot 9H_2O$ and a vitamin mixture (Madigan et al., 1974) were added (occasionally 0.25% Na_2CO_3 was also added). The pH was adjusted to 8.2–9.0. Cultures were inoculated with bacterial mats from warm springs, river water, or lake water and were incubated under strictly anaerobic conditions at 28°C with illumination of 1000 lux.

All strains of *Oscillochloris trichoides* are maintained in the same medium and routinely cultivated in screw-cap bottles completely filled with medium under the same conditions as those used in the isolation. These strains are basically photoautotrophic growers, but their growth is promoted by the addition of some organic compounds, i.e., acetate, pyruvate, casein hydrolysate, or yeast extract.

Another species in the genus, *Oscillochloris chrysea*, has not been grown in semisolid agar media, thus no pure culture of this species has been obtained.

The Genus *Chloronema*

Although *Chloronema* spp., which are Bchl *d*-containing mesophilic organisms, generally dominate in the hypolimnion of freshwater lakes, no pure culture has been established and knowledge about cultivation of those filaments is also very limited. Recently, Gich et al. (2001) reported on the phylogenetic analysis of an enrichment of *Chloronema* established by Rémy Guyoneaud. They have also obtained different enrichments from Little Long Lake, Wisconsin, and are studying properties of the *Chloronema* enrichments (F. Gich, personal communication).

The Genus *Heliothrix*

Heliothrix oregonensis was isolated from microbial mats at the Warm Springs Indian Reservation, Oregon (Pierson et al., 1984a; Pierson et al., 1985b). The chlorosome-less filamentous organism is closely associated with a nonphotosynthetic aerobic bacterium, *Isosphaera pallida* (belonging to the family Planctomycetaceae in the phylum Planctomycetes). The organism can, therefore, be brought into coculture with *I. pallida*. The medium used for isolation and enrichment is IMC medium (Pierson et al., 1984a) containing 0.025% glucose and 0.025% casamino acids as energy sources, along with some vitamins. *Heliothrix* filaments can be collected from the orange-red microbial mat by a syringe with a 17- or 18-gauge needle. The collected material should be washed immediately to remove unicellular cyanobacteria and other non-phototrophic cells. Since the filaments are large enough to be seen with a dissecting microscope at high resolving power, they can be picked up manually. A single, axenic filament picked up is then inoculated into a pure culture of *I. pallida* (strain IS-1B) on an agar plate and incubated aerobically at 45°C in the light.

The coculture can be maintained on slants or plates of agar-solidified IMC medium (pH 8.1) at 45°C under a moderate light intensity (3000 lux) in an atmosphere of 95% air and 5% CO_2. The culture can be maintained by monthly transfers.

The Genus *Roseiflexus*

Another chlorosome-less filamentous anoxygenic phototroph, *Roseiflexus castenholzii*, is a facultative bacterium able to grow photoheterotrophically in the light and chemoheterotrophically in the dark; it forms a distinct red layer within the microbial mats (Hanada et al., 2002b). The red layer is composed predominantly of the organism, whereas other phototrophs, i.e., cyanobacteria and *Chloroflexus* spp., are rarely found in this layer. A collected red layer is cut into a small piece (about 100 mm^3) and gently dispersed with a sterile homogenizer in buffer. The moderately dispersed filaments are then washed with sterile buffer and harvested by low-speed centrifugation. Most non-phototrophic unicellular contaminants may be removed by repeating this rinse process a few times. The rinsed *Roseiflexus* fragments are inoculated on PE medium (pH 8.0) solidified with 1.5% agar (see "The Genus *Chloroflexus*" in this section) and anaerobically incubated at 50°C in incandescent light (30 W/m^2). Red to reddish-brown colonies may be formed on the plate after a few weeks of incubation. The colonies may still contain non-phototrophic contaminants, e.g., thermophilic *Bacillus* spp. and *Thermus* spp. These contaminants can be removed by alternating incubation under aerobic and anaerobic conditions after every transfer (see "The Genus *Chloroflexus*" in this section).

Roseiflexus castenholzii is cultivated and maintained in the same PE medium in screw-cap bottles under incandescent light (30 W/m^2) or in flasks shaken vigorously (200 rpm) in the dark at 50°C. The pH of the medium should be adjusted to 7.5. Also, 02YE medium (pH 7.5) has been used to culture the strain. This medium contains 0.2% yeast extract, 0.38 g of KH_2PO_4, 0.39 g of K_2HPO_4, 0.5 g of $(NH_4)_2SO_4$, 1 ml of a vitamin mixture, and 5 ml of a basal salt solution per liter. The vitamin mixture and basal salt solution are the same as those used in PE medium. The aerobic and anaerobic cultures should be transferred every week and two weeks, respectively.

Enrichments of Marine and Hypersaline FAPs

No axenic culture of marine and hypersaline filamentous anoxygenic phototrophs (FAPs) has yet been obtained. Likewise no general, standard methods to enrich them have been established. However, several mixed cultures containing these organisms have been enriched and maintained for several years (Pierson et al., 1994). A marine FAP from an intertidal habitat on Mellum Island, Germany, was maintained in a medium of normal seawater salinity. The medium is modified from the standard medium for marine purple and green sulfur bacteria (Pfennig and Trüper, 1992). The modification includes the addition of acetate and yeast extract and the omission of sulfate. Aluminum phosphate is also added to the medium as an artificial sediment for the adhesion of gliding bacteria (Widdel and Bak, 1992). Hypersaline FAPs from evaporation ponds in salterns with various salinities have also been enriched successfully. The compositions of media used in successful enrichments vary, since they should be fitted to the chemical characteristics of their habitats. Most media, however, are based on the medium designed for the marine FAP mentioned above. The hypersaline FAP cultures obtained from microbial mats in Baja California have been enriched in a similar medium with additional NaCl (the final concentrations are approximately 13–16%). Some hypersaline FAPs can also grow photoautotrophically in the presence of sulfide. For such strains, the range of sulfide concentrations is 0.25–10 mM, and growth is optimized in 2.5 mM sulfide. The optimal temperature for growth is 35–40°C, and no growth has been observed above 42°C. The cultures grow best under dim incandescent light (10 W/m^2). More details on the cultivation of marine and hypersaline FAPs are given in Pierson et al. (1994).

Nübel et al. (2001) reported the successful enrichment of hypersaline FAPs from evaporation ponds in Guerrero Negro, Baja California, using a different medium. In that case, they used the inorganic medium for cyanobacteria (Garcia-Pichel et al., 1998) containing 9% commercial sea salts. The medium was also modified by adding NH_4Cl (200 mg/liter), yeast extract (250 mg/liter), $Na_2S_2O_4$ (70 mg/liter), $Na_2S \cdot 9H_2O$ (150 mg/liter), DCMU (1.2 mg/liter), and resazurin (0.0001%) as a redox indicator. The incubation was done anaerobically at room temperature (20–25°C) under natural daylight. They observed that Bchl *c*-containing gliding filaments with a diameter of about 1 μm were grown in the enrichments. However, no growth was seen after subsequent transfers to fresh medium, and no cultures have been maintained.

Identification

All filamentous anoxygenic phototrophs (FAPs) have the following features: 1) unbranched multicellular filamentous morphology; 2) gliding motility; and 3) anoxygenic photosynthetic activity. Currently, an organism with this combination of features would be classified as a FAP, possibly in the family Chloroflexaceae or the family Oscillochloridaceae. The differential characteris-

tics of valid genera and species belonging to the FAPs are summarized in Table 1. The five FAP genera can be differentiated from each other by their pigmentation, morphology, and growth temperatures. Of these FAP genera, the presence of chlorosomes is a notable trait in the three genera *Chloroflexus*, *Oscillochloris* and *Chloronema*. These chlorosome-containing FAPs also include a typical carotenoid, β-carotene, as well as Bchl *c* (or *d* in the genus *Chloronema*) as photopigments, while no β-carotene is detected in the chlorosome-less FAPs (the genera *Heliothrix* and *Roseiflexus*). The chlorosome-containing FAPs can be classified further into two groups, depending on their growth temperatures: the genus *Chloroflexus* on the one hand and, on the other, the mesophilic freshwater forms. *Chloroflexus* consists of thermophiles that grow well at 55°C, with the sole exception of *Chloroflexus aurantiacus* var. "*mesophilus*" (Dubinina and Gorlenko, 1975). In spite of the difference in growth temperature, the mesophilic variety of *Chloroflexus* is more similar morphologically and physiologically to the thermophilic *Chloroflexus* species than to the mesophilic freshwater genera, i.e., both mesophilic and thermophilic *Chloroflexus* species have slender filaments, respond similarly to oxygen, and lack gas vesicles. On the other hand, the mesophilic freshwater forms, which include the genera *Oscillochloris* and *Chloronema* species, have relatively thick morphologies and intracellular gas vesicles and in general are not highly tolerant to oxygen. Further information on identification and classification within these subgroups and genera is provided below.

The Genus *Chloroflexus*

The genus *Chloroflexus* contains two species, *Chloroflexus aurantiacus* and *Chloroflexus aggregans*. *Chloroflexus aurantiacus* is the type species of this genus, and almost all strains in the species are thermophilic filamentous bacteria with a diameter of about 1 μm. They are generally found in neutral to alkaline hot springs, where they form microbial mats with or without cyanobacteria. *Chloroflexus aurantiacus* contains Bchl *a* and *c* as photosynthetic pigments, and the latter is present in intracellular vesicles (i.e., chlorosomes). The organism has a conspicuous peak at 740 nm in the in vivo absorption spectrum of the near infrared (IR) region that is attributable to chlorosomes (Bchl *c*) and also shows absorption peaks at 808 and 868 nm in the near IR region that are due to Bchl *a*. It contains β- and γ-carotene and OH-γ-carotene glucoside esters as carotenoid pigments. *Chloroflexus aurantiacus* can grow photoheterotrophically in the light and chemoheterotrophically in the dark. Some strains, e.g., strain OK-70-fl, are able to grow photoautotrophically by fixing carbon dioxide as the sole carbon source in the presence of sulfide. The respiratory quinone of the species is predominantly menaquinone (MK)-10, and the major cellular fatty acids are palmitic ($C_{16:0}$), stearic ($C_{18:0}$), and oleic acids ($C_{18:1}$). The mol% G+C of the DNA is 53.1–54.9% (by buoyant density [Bd]) or 56.9–57.1% (by high pressure liquid chromatography [HPLC]).

Another species, *Chloroflexus aggregans*, is phenotypically very similar to the type species. However, there are clear differences between the two species: 1) the cells of *Chloroflexus aggregans* are wider than those of *Chloroflexus aurantiacus*; 2) *Chloroflexus aggregans* contains mainly γ-carotene and its derivatives, with only trace amounts of β-carotene, whereas β-carotene is a major component in *Chloroflexus aurantiacus*; 3) *Chloroflexus aggregans* includes a small but significant amount of MK-4 in addition to the dominant homologue MK-10. Besides these phenotypic differences, the sequence similarity of 16S rRNAs between the two species is very low (92.8%), warranting classification as different species.

The Genera *Oscillochloris* and *Chloronema*

The mesophilic freshwater forms, the genera *Oscillochloris* and *Chloronema*, are classified mainly according to their morphological and pigmentation properties. Like *Chloroflexus* species, the *Oscillochloris* species are straight flexible filaments containing Bchl *c* as the major light-harvesting pigment. The *Oscillochloris* filaments have no sheath or a thin sheath. Another genus, *Chloronema*, consists of members containing Bchl *d* as the major light-harvesting pigment. The *Chloronema* filaments are often spirally twisted and thickly sheathed.

The Genus *Oscillochloris*

Of these mesophilic freshwater forms, *Oscillochloris trichoides* is the sole species whose description is based on axenic cultures. *Oscillochloris trichoides* strains have been isolated from fresh- and brackish-water environments. The filaments are 0.8–1.4 μm wide. The filaments may or may not have a thin sheath, or they may be surrounded by a thin layer of slime. Intracellular gas vesicles are formed along the cell septa (cross-walls). The organism is a mesophile grown optimally at 28–30°C, at pH 6.8–9.0. The type strain is strictly anaerobic and obligately phototrophic. Its growth under photolithoautotrophic conditions can be detected in the presence of sulfide and/or molecular hydrogen as the electron donors. The optimal concentration of sulfide ($Na_2S \cdot 9H_2O$) is 0.5–0.7 g/liter. The in vivo absorption spectra of cell suspen-

sions have maxima at 748 and 852 nm in the IR region. The photosynthetic pigment is Bchl *c*, with a small amount of Bchl *a*. *Oscillochloris trichoides* also contains β-carotene and γ-carotene. The predominant quinone is MK-10. The mol% G+C of the DNA is 59.2% (by the melting temperature method [Tm]).

A different species, *Oscillochloris chrysea*, was also proposed within the genus. The organism has a large cell morphology (4.5–5.5 μm wide). The cell wall has no outer membrane but a thick peptidoglycan layer, and the cells are stained Gram positive. Phototrophic and probable chemotrophic growth occurs. The organism develops at 10–20°C, at pH 7.5–8.5. It contains Bchl *a* and *c*, as well as some carotenoids. Since no pure culture is available, little is known about other physiological and chemotaxonomic properties of this species.

The Genus *Chloronema* *Chloronema* species are gas-vesicle-containing straight or spiral-shaped filaments found in hypolimnion-metalimnion of freshwater stratified lakes. The notable feature of these filaments is the presence of Bchl *d*, which is not found in any other FAPs. An in vivo absorption peak of chlorosomes in this group is obviously blue shifted (720 nm). This genus contains two species, *Chloronema giganteum* and *Chloronema spiroideum*. Since neither species has been isolated or cultivated successfully, the classification is based solely on morphology. *Chloronema giganteum* has a filamentous morphology with a diameter of 2.0–2.5 μm, while the diameter of *Chloronema spiroideum* filaments is slightly smaller (1.5–2.0 μm).

The Genera *Heliothrix* and *Roseiflexus*

The chlorosome-less FAPs consist of two genera (*Heliothrix* and *Roseiflexus*) that are phylogenetically distant from each other (the sequence similarity of 16S rRNA is 78.6%). Despite this distance, the pigment profiles of these two genera resemble each other. Both contain Bchl *a* as the sole photosynthetic pigment, and both lack any other bacteriochlorophylls. They have mainly γ-carotene derivatives (precisely, keto-3,4-didehydro-OH-γ-carotene; myxocoxanthin) as major carotenoids and, unlike the chlorosome-containing filaments, contain no β-carotene. Each of these chlorosome-less filaments inhabits hot springs and forms distinct red or red-orange microbial mats in thermal environments. Other characteristics of these organisms appear below.

The Genus *Heliothrix* The organism *Heliothrix oregonensis* was isolated as a stable coculture with a non-phototrophic aerobic bacterium, *Isosphaera pallida*. The coculture could grow at 40–55°C. The growth was supported by mainly photoheterotrophic metabolism. The diameter of *Heliothrix* filaments is 1.5 μm, and the septa (cross-walls) can be seen with a phase-contrast microscope. The cells frequently contain large amounts of polyhydroxybutyrate granules. The in vivo absorption spectrum has conspicuous peaks at 795 and 865 nm (due to Bchl *a*) in the IR region.

The Genus *Roseiflexus* *Roseiflexus castenholzii* is a filament (diameter of 0.8–1.0 μm) and a thermophilic facultative phototroph that grows at 45–55°C and pH 7–9. The organism grows photoheterotrophically under anaerobic and light conditions, and aerobic growth in the dark occurs at full atmospheric oxygen tension. Neither photoautotrophic nor fermentative growth is observed. No invagination of intracytoplasmic membrane is present. The cell suspension shows absorption maxima at 801 and 878 nm in the IR region. Pigmentation occurs under both aerobic and anaerobic conditions. The cellular fatty acids consist of $C_{16:0}$, $C_{14:0}$, and $C_{15:0}$, and no unsaturated fatty acids are detected. The respiratory quinone system is occupied predominantly by MK-11. The mol% G+C of the DNA is 62.0% (HPLC).

Preservation

All strains deposited in the German culture collection (DSMZ) and belonging to *Chloroflexus aurantiacus* or *Chloroflexus aggregans* can be preserved in liquid nitrogen (–196°C) under aerobic conditions when 5% dimethylsulfoxide, 5% methanol, or 10% glycerol is used as a cryoprotectant (Malik, 1998). The cultures are also successfully freeze-dried by avoiding exposure to oxygen during the process. Cultures thus preserved show good survival rates after drying and in long-term storage.

Little information is available about the long-term preservation of other FAPs, but *Roseiflexus castenholzii* can be safely stored in 15% glycerol at –80°C for at least a year.

Physiology

Among the filamentous anoxygenic phototrophs (FAPs), physiological information centers mostly on *Chloroflexus aurantiacus*, since the organism was identified early and the first to be isolated as a pure culture. In this section, we present a number of physiological findings of the extensive range of studies on *Chloroflexus aurantiacus*. We also mention important physiological properties that have been investigated in

several species, i.e., *Chloroflexus aggregans*, *Heliothrix oregonensis*, *Oscillochloris trichoides* and *Roseiflexus castenholzii*.

Autotrophy

While *Chloroflexus aurantiacus* generally grows well under photoheterotrophic conditions, some strains in this species can grow photoautotrophically. Madigan and Brock (1975) revealed that *Chloroflexus aurantiacus* strain OK-70-fl could oxidize sulfide photoheterotrophically, with fixing of carbon dioxide. Photoautotrophic growth is also achieved with hydrogen as an electron donor instead of sulfide (Holo and Sirevåg, 1986). In the *Chloroflexus aurantiacus* strain OK-70-fl, the unique 3-hydroxypropionate cycle is operated for fixing carbon dioxide (Sirevåg and Castenholz, 1979; Holo, 1989; Strauss et al., 1992; Eisenreich et al., 1993; Strauss and Fuchs, 1993). Glyoxylate is formed from acetyl-CoA after the fixation of two molecules of CO_2 by two respective enzymes, acetyl-CoA and propionyl-CoA carboxylases, while acetyl-CoA is regenerated in this cycle (Menendez et al., 1999). Another fixing cycle, the reductive dicarboxylic acid cycle, is also proposed in a different *Chloroflexus* strain (Ivanovsky et al., 1993). Similar CO_2 fixing pathways are widely found in autotrophic *Crenarchaeota*, e.g., *Sulfolobus*, *Metallosphaera* and *Acidianus* (Menendez et al., 1999).

Although photoautotrophic growth of the *Chloroflexus* strain is a very slow process, this type of metabolism apparently occurs in some hot springs (Castenholz, 1973; Giovannoni et al., 1987). The GCF strain, a strain that grows without cyanobacteria in natural hot springs, shows a high level of sulfide-dependent phototrophic activity even in the laboratory. The GCF strain is unable to grow by respiration. The sulfide- or hydrogen-dependent photoautotrophy seen not only in GCF strain but also in *Chloroflexus aurantiacus* strain OK-70-fl is not observed in any other strains, e.g., strain J-10-fl, the type strain of *Chloroflexus aurantiacus*, or in any strains of the closely related species, *Chloroflexus aggregans*. The inability of the GCF strain to respire may be due to its adaptation to anaerobic environments without oxygenic cyanobacteria. Alternatively, the other *Chloroflexus* strains may have acquired a respiratory ability and high tolerance to oxygen after living in environments containing cyanobacteria.

The freshwater mesophile *Oscillochloris trichoides* can grow photolithoautotrophically using sulfide or hydrogen as an electron donor and carbon dioxide as a carbon source (the preferable mode is a photolithoheterotrophic growth in the presence of some organic acids). Because the type strain of this species (strain DG-6) clearly shows activities of ribulosebisphosphate carboxylase and phosphoribulokinase, it appears to fix carbon dioxide by the Calvin-Bassham-Benson cycle (Ivanovsky et al., 1999). The fixing cycle is generally found in autotrophs belonging to the Proteobacteria and cyanobacteria.

Roseiflexus castenholzii, one of the chlorosome-less FAPs, is a "true" heterotroph and requires yeast extract for good phototrophic growth. No photoautotrophic growth has been observed in any cultural conditions (Hanada et al., 2002b).

In marine and hypersaline FAPs, light-dependent uptake of bicarbonate was reproducibly demonstrated in situ and in the laboratory (Pierson et al., 1994).

Heterotrophy

Almost all strains in the genus *Chloroflexus* can grow heterotrophically using various organic compounds (a number of sugars, organic acids, and amino acids) under either aerobic (in the dark) or anaerobic (in the light) conditions in the presence of folic acid and thiamine as growth factors and in the presence of inorganic carbon (Madigan et al., 1974; Pierson and Castenholz, 1974a; Pierson and Castenholz, 1974b; Hanada et al., 1995a). The complex organic substrates (yeast extract and casamino acids) can substantially support the growth of both under either condition.

In *Chloroflexus aurantiacus*, the tricarboxylic acid (TCA) cycle appears to operate under either aerobic or anaerobic conditions, either to supply reductant for respiration or to support the reductive assimilation of substrates, respectively (Sirevåg and Castenholz, 1979). Krasil'nikova et al. (1986) found all enzymatic activities for the complete TCA cycle, whereas the activity was low for only a single enzyme, α-keto-glutarate dehydrogenase. The organism also contains the two key enzymes of the glyoxylate shunt, isocitrate lyase and malate synthetase, and both activities are increased when cells grow on acetate (Løken and Sirevåg, 1982; Krasil'nikova et al., 1986).

Chloroflexus aurantiacus has the Embden-Meyerhof pathway for glycolysis (Krasil'nikova et al., 1986; Krasil'nikova and Kondrat'eva, 1987b). The cells grown on glucose showed higher activities of phosphofructokinase and fructose-diphosphate aldolase than those grown on acetate. Two enzymes in the pentose monophosphate pathway, glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, were also detected (Krasil'nikova et al., 1986). Some strains can grow by fermentation of sugar or pyruvate (Krasil'nikova and Kondrat'eva, 1987b). End products of the fermenta-

tion on glucose are acetate, pyruvate, lactate, malate, ethanol, and occasionally formate (Krasil'nikova and Kondrat'eva, 1987b).

In the presence of sulfide and bicarbonate, *Oscillochloris trichoides* can grow photolithoheterotrophically on acetate, pruvate, casein hydrolysate, or yeast extract (Keppen et al., 2000). However, it can use only a limited number of organic compounds because it lacks a complete TCA cycle and a glyoxylate shunt. The organism lacks activities of 2-oxoglutarate hydrogenase and isocitrate lyase, which are key enzymes in the cycle and shunt. *Oscillochloris trichoides* is also incapable of chemoheterotrophic growth under aerobic or microaerobic conditions in the dark.

Roseiflexus castenholzii can grow photoheterotrophically and chemoheterotrophically. Yeast extract is a good substrate for growth under either aerobic or anaerobic conditions. Citrate, glucose, and casamino acids are each also used as a sole carbon and energy source, though only under anaerobic light conditions, but the cell yields are clearly less than that obtained with yeast extract.

Nitrogen Metabolism

Chloroflexus aurantiacus grows well when ammonia is the sole nitrogen source, but nitrate does not support its growth (Heda and Madigan, 1986). Heda and Madigan (1986) also reported that several amino acids (alanine, aspartate, glutamate, glutamine, glycine and serine) supported good growth in all *Chloroflexus* strains tested. Cysteine supported good growth for most strains. Tyrosine and valine supported growth for all strains but with lower growth yields than those supported by the amino acids listed above. Proline, adenine, and urea did not serve as nitrogen sources for any of the strains tested. Neither nitrogen fixation nor nitrogenase activity was detected in any strains of *Chloroflexus aurantiacus* (Heda and Madigan, 1986).

The pathways of nitrogen metabolism in this organism are partially understood. Ammonia assimilation apparently proceeds differently in *Chloroflexus aurantiacus* than in other phototrophic green or purple bacteria. The only enzyme present for ammonia assimilation is a glutamine synthetase, which is not repressed when cells are grown in high-ammonia culture media (Kaulen and Klemme, 1983). Although the glutamate synthase (GOGAT) generally collaborated with glutamine synthetase in assimilating ammonia, this enzyme was not detected in the same preparation. This may be due to problems of preparation (Klemme, 1989). Details of this aspect of nitrogen assimilation remain to be clarified.

In *Chloroflexus aurantiacus*, glutamate, alanine, and isoleucine are the main constituents of the intracellular amino acid pool in cells grown photosynthetically in minimal medium (Klemme et al., 1988). Two different enzymes with L-threonine (L-serine) dehydratase activity were found in *Chloroflexus aurantiacus* (Laakmann-Ditges and Klemme, 1986). One was sensitive to inhibition by isoleucine and could be biosynthetic for isoleucine, since the other key enzymes for its biosynthesis (asparto-kinase, homoserine dehydrogenase, and acetohydroxy acid synthase) were also present in cells grown photoautotrophically (Laakmann-Ditges and Klemme, 1988).

Although nitrogen metabolism has been little investigated in other FAPs, nitrogenase activity has been detected in *Oscillochloris trichoides* by an acetylene reduction assay (Keppen et al., 1989). This finding suggests that the freshwater mesophile fixes molecular nitrogen for its growth. The organism can also use ammonium salts, urea, glycine, glutamate, glutamine, asparagine, and casein hydrolysate as nitrogen sources.

Sulfur Metabolism

Chloroflexus aurantiacus can use sulfate as a good source of sulfur for biosynthesis, and thiosulfate can also be used during photoheterotrophic growth (Krasil'nikova, 1987a; Kondrat'eva and Krasil'nikova, 1988). Under photoheterotrophic conditions, cysteine, glutathione, methionine, or sulfide can serve as a sulfur source (Krasil'nikova, 1987a). With sulfate as a sulfur source, high levels of ATP sulfurylase activity were found, with optimal activity at 60–70°C (Krasil'nikova, 1987a).

The utilization of sulfur compounds as electron donors in photosynthetic growth has been reported by Madigan and Brock (1975) and Giovannoni et al. (1987). In some strains of *Chloroflexus aurantiacus*, sulfide was oxidized to elemental sulfur both photoautotrophically and photoheterotrophically. The produced sulfur was accumulated outside the cells. Sulfur granules affixed to the cells were observed frequently with a microscope.

Oscillochloris trichoides can also use sulfide as an electron donor for photosynthesis (Keppen et al., 1993). The oxidation product of sulfide is elemental sulfur, and further oxidation of sulfur does not occur. The organism utilizes sulfide, cystine, and cysteine as sources of sulfur. Sulfate, however, does not support its growth (Keppen et al., 2000).

Sulfide also appears to support photoautotrophy even in marine and hypersaline FAPs (Pierson et al., 1994).

Motility

Gliding motility, a feature common to all FAPs, is a way of moving on a solid or semisolid surface without flagella-like propulsive organs (Castenholz, 1982). It is a smooth movement observed typically among other multicellular filamentous bacteria (e.g., cyanobacteria and flexibacteria) or, sometimes, unicellular organisms (e.g., cytophaga and myxobacteria). The gliding rates vary among the FAPs: *Chloroflexus aurantiacus* glides at a rate of 0.01–0.04 μm/sec on a 1.5% agar surface (Pierson and Castenholz, 1974a); *Oscillochloris trichoides* glides at a rate of 0.2 μm/sec (Keppen et al., 1993); *Chloronema* species are fast gliders, achieving speeds of about 10 μm/sec (Gorlenko and Pierson, 2001); *Heliothrix oregonensis* exhibits a gliding rate of 0.1–0.4 μm/sec (Pierson et al., 1985b). Gliding motility enables the organisms to form microbial mats together with cyanobacteria and other bacteria in natural environments.

Chloroflexus aggregans isolated from bacterial mats in hot springs is able to form bacterial mat-like dense cell aggregates rapidly in an axenic culture (Hanada et al., 1995a; Hanada et al., 2002a). Aggregate formation, which was observed among growing cells in a liquid medium in a bottle, occurred every time within 20–30 min after the cells were dispersed by shaking. This has not been seen in any strains of the related species, *Chloroflexus aurantiacus*. However, *Heliothrix oregonensis* shows a similar rapid aggregation in cell suspensions (Pierson et al., 1984a). The bacterium has a fast gliding motility (1–3 μm/s) that is 100 times faster than that of *Chloroflexus aurantiacus* strains. The distinct rapid cell aggregation of this organism appears to be due to its fast gliding. The cell aggregation rate is accelerated by increased cyclic AMP concentration in the cells (Hanada et al., 2002a). The similar acceleration of gliding and cell aggregation by cAMP has been reported among some gliding cyanobacteria (Ohmori et al., 1992).

Gliding motility is also observed in the marine and hypersaline FAPs. These filaments show diel migration within microbial mats by their gliding movement (Mack and Pierson, 1988).

Cellular Lipids and Cell Envelope

The biochemical composition of the cell envelope and the composition of cellular lipids in *Chloroflexus aurantiacus* exhibit some unique properties. The polar lipids consist mainly of phosphatidylglycerol, phosphatidylinositol, monogalactosyldiglyceride, and diglycosyldiglyceride (Kenyon and Gray, 1974; Knudsen et al., 1982). The predominance of phosphatidylinositol in *Chloroflexus aurantiacus* is rarely found in other phototrophic bacteria.

The cellular fatty acids of *Chloroflexus aurantiacus* are predominantly straight-chain saturated and monounsaturated with $C_{16–20}$ chain lengths and with no detectable hydroxylated or cyclopropane-substituted chains (Knudsen et al., 1982). The major components of these acids are $C_{18:0}$, $C_{16:0}$, and $C_{18:1}$. The fatty acid profile of *Oscillochloris trichoides* is somewhat similar. The mesophile lacks longer-chain fatty acids ($C_{19–20}$) and contains a significant amount of unsaturated fatty acids. The ratio of unsaturated to saturated fatty acids was 3.3–3.8 in *Oscillochloris trichoides* and 0.63 in *Chloroflexus aurantiacus*, respectively (Keppen et al., 2000). The presence of highly saturated and somewhat longer-chain fatty acids is consistent with the thermophilic nature of *Chloroflexus aurantiacus*. The fatty acid profile was also determined in *Roseiflexus castenholzii*. The organism contained predominantly saturated fatty acids ($C_{14–16}$) and no unsaturated fatty acids (Hanada et al., 2002b). The thermophile grows at slightly lower temperatures than *Chloroflexus aurantiacus*. This difference may cause *Roseiflexus castenholzii* to include shorter-chain fatty acids than those found in *Chloroflexus aurantiacus*.

The lipid extract of *Chloroflexus aurantiacus* contains a large variety of wax esters (C_{28}–C_{38}; Knudsen et al., 1982). Similar wax esters (C_{37}–C_{40}) are found in *Roseiflexus castenholzii* (M. T. J. van der Meer, submitted). The presence of the wax esters is observed infrequently among other bacteria, with a few exceptions. Although not clear, the function or role of the wax esters in these bacteria might be related to thermophily.

The cell envelope of *Chloroflexus aurantiacus* apparently lacks the lipopolysaccharide (LPS) typical of Gram-negative bacteria. No hydroxylated fatty acids and no saccharides usually contained in outer-membrane LPS were detected in this organism (Knudsen et al., 1982). These features in the cell envelope of *Chloroflexus aurantiacus* are very unlike the structural organization found in typical Gram-negative bacterial envelopes and more strongly resemble the features found in Gram-positive bacterial walls (Jürgens et al., 1987). The abundant complex polysaccharide bound to the rigid peptidoglycan layer contains sugar O-methyl ethers of hexoses and contains rhamnose, mannose, glucose, galactose, xylose and arabinose (Jürgens et al., 1987). Although the peptidoglycan of *Chloroflexus* contains *N*-acetyl-glucosamine, *N*-acetyl-muramic acid (about 15% of which is phosphorylated), L-alanine, D-alanine, and D-glutamic acid, the presence of L-ornithine instead of diaminopimelic acid in the peptidoglycan of *Chloroflexus* also distinguishes it from the other

Gram-negative bacteria and substantiates the similarity in wall composition with Gram-positive bacteria (Jürgens et al., 1987). The unusual biochemical composition of the envelope of *Chloroflexus aurantiacus* is particularly interesting, since the cells stain Gram negative and ultrastructurally the envelope appears to be multilayered. Absent, however, is a well-defined outer membrane structure typical of Gram-negative cell envelopes (Pierson and Castenholz, 1974a; Staehelin et al., 1978).

Interestingly, cells of *Oscillochloris chrysea* stain Gram-positive and have a very thick peptidoglycan layer with no outer membrane (Gorlenko, 1988; Gorlenko, 1989a). Although the cells of *Oscillochloris trichoides* have the Gram-negative type cell wall, they are variably stained in Gram staining. The hypersaline organisms also lack a well-defined outer membrane and are Gram-variable when stained (Pierson et al., 1994). No well-defined outer membrane structure has been recognized in the cells of *Roseiflexus castenholzii*, which are apparently negatively stained.

Pigment Synthesis and Regulation

BACTERIOCHLOROPHYLLS *Chloroflexus* species contain bacteriochlorophylls *a* and *c* as photosynthetic pigments. These bacteriochlorophylls are generally esterified with some long chain alcohol: Bchl *a* is esterified to phytol. Takaichi et al. (1995) reported that Bchl *c* in *Chloroflexus aurantiacus* existed as mixtures of stearyl, phytyl, geranylgeranyl, and cetyl/oleyl esters. The mixing ratio of esters depended on light intensity. Phytyl and stearyl esters were dominant in low-light growth conditions, while phytyl and geranylgeranyl esters dominated at high light intensity (Takaichi et al., 1995).

These bacteriochlorophylls (both Bchl *a* and *c*) in *Chloroflexus aurantiacus* are synthesized via the glutamate-C_5 pathway as in the cyanobacteria and the green and purple sulfur bacteria, rather than via the pathway involving δ-aminolevulinic acid, as in some species of nonsulfur purple bacteria (Avissar et al., 1989; Kern and Klemme, 1989).

Little is known, however, about the regulation of pigment synthesis at the molecular level in *Chloroflexus aurantiacus*. However, the synthesis of bacteriochlorophylls is apparently controlled by light intensity and oxygen concentration. Bacteriochlorophyll content decreases in the presence of high light intensity or oxygen (Pierson and Castenholz, 1974b; Oelze, 1992a), and both light and oxygen affect the structural development of the photosynthetic apparatus containing these pigments (Schmidt et al., 1980b; Sprague et al., 1981a; Sprague et al., 1981b; Feick et al., 1982). The change in the ratio of Bchl *c* to *a* in cells grown at different light intensities and adapted to reductions in oxygen levels suggested independent regulation of the two pigments (Pierson and Castenholz, 1974b; Sprague et al., 1981b). Light intensity may influence pigment synthesis via an indirect effect on growth rate. By growing *Chloroflexus aurantiacus* in a chemostat and controlling the growth rate by regulating the dilution factor while keeping the light intensity constant, Oelze and Fuller (1987) showed that the specific contents of Bchl *a* and *c* increased at lower growth rates. Since light intensity has a direct effect on growth rate, it is difficult to distinguish the relationships among these parameters without a chemostat. Cell protein levels, as well as specific Bchl *a* content, increased linearly with a decreasing growth rate, while the specific Bchl *c* content increased exponentially with a decreasing growth rate. Oelze and Söntgerath (1992b) also reported that pigment synthesis was affected by amino acids supplemented in the growth culture. The addition of serine, glutamate, or alanine to the growth medium stimulated the synthesis of bacteriochlorophylls.

In a mesophilic FAP, *Oscillochloris trichoides*, a similar effect on the synthesis of bacteriochlorophylls by light and oxygen was also observed (Gorlenko and Pierson, 2001).

CAROTENOIDS *Chloroflexus aurantiacus* contains large amounts of carotenoids such as β- and γ-carotene as well as γ-carotene derivatives. Takaichi et al. (1995) revealed that the γ-carotene derivatives were OH-γ-carotene glucoside ester and its intermediates. Halfen et al. (1972) detected no OH-γ-carotene glucoside ester but rather OH-γ-carotene glucoside in *Chloroflexus* cells. However, the absence of carotenoid ester was probably due to saponification (which degrades carotenoid glucoside esters into carotenoid glucosides) in their preparation (Takaichi et al., 1995). Some of the β- and γ-carotenes were in the cytoplasmic membrane, but most were in the chlorosomes, while the OH-γ-carotene glucoside esters were the predominant carotenoid in the membrane (Schmidt et al., 1980b). This OH-γ-carotene derivative increased relative to the other carotenoids in cells grown at higher light intensities (Schmidt et al., 1980b) and may have a role in protecting the membrane-bound photochemical systems from the damaging effects of high light intensities.

Like the *Chloroflexus* species, *Oscillochloris trichoides* also contains primarily β- and γ-carotene. However, *Heliothrix oregonensis* and *Roseiflexus castenholzii* lack β-carotene and contain predominantly unique γ-carotene derivatives, i.e., myxocozanthin derivatives (Pierson et al., 1984a; Takaichi et al., 2001). Takaichi et al.

(2001) suggested that the absence of β-carotene resulted from the absence of chlorosomes in these organisms because the pigment is located mainly in chlorosomes in *Chloroflexus* species.

PHOTOCHEMICAL REACTION CENTER AND LIGHT-HARVESTING APPARATUS The photochemical reaction center and primary light-harvesting apparatus of *Chloroflexus aurantiacus* have very interesting similarities to components within two diverse groups of phototrophs, purple bacteria and green sulfur bacteria, respectively.

The photochemical reaction center of *Chloroflexus aurantiacus* is very similar to the reaction centers of the purple bacteria, despite some significant differences. The *Chloroflexus* reaction center is the smallest one known, being composed of two essential polypeptides, designated "L" and "M" subunits, and an additional membrane-bound cytochrome *c* complex. This reaction center apparently lacks a polypeptide, the H subunit, which is usually found in all purple bacteria (Pierson and Thornber, 1983; Shiozawa et al., 1987). The pigment composition also differs from that of purple bacterial reaction centers. *Chloroflexus* has a photoreactive special pair or dimer of Bchl *a* molecules as do the purple bacteria, but it has only one additional Bchl *a* molecule and three bacteriopheophytin *a* molecules, rather than the two additional Bchl *a* and two bacteriopheophytin molecules found in the purple bacteria (Pierson and Thornber, 1983; Blankenship et al., 1984). Furthermore, the *Chloroflexus* reaction center lacks carotenoid pigments (Pierson and Thornber, 1983), and menaquinone is the electron acceptor for photochemistry, rather than ubiquinone (Vasmel and Amesz, 1983). Functionally, the reaction center of *Chloroflexus aurantiacus* is very similar to that of purple bacteria, and the intermediate electron acceptor in both is bacteriopheophytin *a* (Blankenship et al., 1983; Blankenship et al., 1984; Kirmaier et al., 1983). The arrangement of the chromophores appears to be similar to that in purple bacteria, on the basis of spectroscopic measurements (Vasmel et al., 1986). The two subunits of the *Chloroflexus* reaction center are probably structurally similar to those of the purple bacteria, since the L subunits exhibit a 40% deduced amino acid sequence homology and the M subunits 42% (Ovchinnikov et al., 1988a; Ovchinnikov et al., 1988b; Shiozawa et al., 1989). Within the pigment-binding regions of the two subunits, the sequence homology is higher (59–75%; Shiozawa et al., 1989). Thus, although *Chloroflexus aurantiacus* is phylogenetically different from purple bacteria, their reaction centers have strong structural and functional similarities. The lack of the H subunit in the *Chloroflexus* reaction center, slight differences in pigment composition, and intrinsic thermal stability have little to do with the apparently highly conserved structural and functional characteristics of the sites directly involved in the primary photochemical act.

The molecular organization of the primary light-harvesting system is particularly interesting, since it has a complex antenna involving accessory Bchl *c* housed in chlorosomes adjacent to the cell membrane. Although the size, composition, and ultrastructure of the chlorosomes of *Chloroflexus aurantiacus* differ somewhat from those of green sulfur bacteria, both contain three low-molecular-weight chlorophyll-binding proteins, and the sequence homology between *Chloroflexus aurantiacus* and green sulfur bacteria is about 30% (Wechsler et al., 1985b; Wagner-Huber et al., 1988). The chlorosomes of *Chloroflexus* also appear to contain a small component of Bchl *a*, called a "baseplate" (Schmidt, 1980a; Sprague et al., 1981a; Feick et al., 1982), that appears to be involved in transferring excitation energy to additional antenna components in the cell membrane (Van Dorssen and Amesz, 1988). The baseplate was also found in green sulfur bacterial chlorosomes, but these bacteria transfer excitation energy to the reaction center via a unique water soluble Bchl *a* protein not found in *Chloroflexus*.

The green sulfur bacteria, however, do not have an intracytoplasmic membrane light-harvesting system similar to those found in *Chloroflexus aurantiacus* and purple bacteria. The Bchl *a* antenna in the cell membrane of *Chloroflexus aurantiacus* is very similar to that in the intracytoplasmic membranes of purple bacteria. In addition to harvesting light energy directly, however, this antenna also funnels excitation energy from chlorosomes to the reaction center (Brune et al., 1987; Van Dorssen and Amesz, 1988; Wittmershaus et al., 1988). The absorption properties of this light-harvesting complex, with maxima at 805 and 865 nm, are similar to those of many purple bacteria, and the two polypeptides that bind the Bchl *a* molecules show significant sequence homology (27–40%) to the comparable polypeptides in purple bacteria (Wechsler et al., 1985a; Wechsler et al., 1987). Watanabe et al. (1995), however, revealed that the transcriptional organizations differed between *Chloroflexus aurantiacus* and purple bacteria. In purple bacteria, genes of the Bchl *a*, containing light-harvesting polypeptides and reaction center polypeptides, form the same operon, but in *Chloroflexus aurantiacus*, the similar operon is divided into two. These two operons (genes for reaction center polypeptides on the one hand and, on the other, genes for hight-harvesting polypeptides and tetraheme cytochrome *c*554) are at least 3 kb distant from each other.

Among all other FAPs, very few attempts have been made at structural, functional, and genetic studies of photochemical reaction centers or light-harvesting apparatuses. However, recent structural and genetic studies of the reaction center in *Roseiflexus castenholzii* have been undertaken, and so far it has been made clear that the *Roseiflexus* reaction center resembles that of *Chloroflexus aurantiacus* in structural and spectroscopic respects (Takaichi et al., 2001). Further research on this organism would give useful information about the enigmatic photosynthetic nature of FAPs.

Electron Transport System

The electron transport chains of both phototrophically and chemotrophically grown cells of *Chloroflexus aurantiacus* were reviewed by Zannoni (1995). Phototrophic *Chloroflexus* cells contain multiple *b* and *c* type cytochromes, including the electron donor to the reaction center, tetraheme cytochrome c_{554} (Zannoni and Ingledew, 1985; Wynn et al., 1987). There is strong evidence for the presence of a putative cytochrome bc_1 complex in the membranes of phototrophically grown cells (Zannoni and Ingledew, 1985), as well as for the presence of cytochrome *c*-CO binding activity (Pierson, 1985a; Zannoni and Ingledew, 1985; Wynn et al., 1987). A membrane-diffusible quinone (menaquinone-10) is also abundantly involved in the cells.

The cells include neither a soluble cytochrome c_2 nor a high-potential iron protein (HiPIP; Zannoni, 1987), one and/or the other of which are essential electron transporters for either photosynthesis or respiration in purple bacteria. The *Chloroflexus* cells contain two types of the novel blue copper protein, designated "auracyanin," instead of these electron transporters (McManus et al., 1992). An analogous protein, plastocyanin, is present in cyanobacteria and chloroplasts. However, the crystal structure of an auracyanin (auracyanin B) recently reported by Bond et al. (2001) indicated that the blue copper protein was related more closely to azurin (a blue copper protein found in some proteobacteria; Baker, 1988) than to plastocyanin.

The electron cycle process in the photosynthesis of *Chloroflexus aurantiacus* would be as follows: Owing to excitation by photons, an electron in a "special pair" of Bchl *a* molecules is transferred to a bacteriopheophytin molecule (Becker et al., 1991) and then passes to a quinone within a reaction center core complex; a reduced quinone then diffuses from the reaction center into the membrane (Vasmel and Amesz, 1983; Mulkidjanian et al., 1998) and gives an electron to a putative membrane-bound cytochrome bc_1 complex; an electron is returned by a blue copper protein to the reaction center via a cytochrome *c*554 that binds directly to the reaction center.

Chemotrophically grown cells lack a photochemical reaction center and the tetraheme cytochrome *c*554 that closely binds to this core complex (Wynn et al., 1987). Also, a blue copper protein, auracyanin, is not present under the aerobic conditions (Trost et al., 1988). Two types of terminal oxidase for aerobic respiration have been reported, cytochrome aa_3 (Pierson, 1985a; Zannoni, 1986) and cytochrome *a* (Wynn et al., 1987; Knaff et al., 1988). Cytochrome aa_3 generally operates in cells grown at less than saturated oxygen level, and cytochrome *a* is present at higher oxygen levels (Zannoni, 1995).

As a membrane-diffusible electron transporter, menaquinone-10 is usually used in *Chloroflexus* species and *Oscillochloris trichoides*. However, *Roseiflexus castenholzii* uses mainly menaquinone-11 under both phototrophic and respiratory conditions (Hanada et al., 2002b).

Thermophily

The thermophilic aspects of the physiology of *Chloroflexus aurantiacus* have been studied in several systems. The photochemical reaction center of *Chloroflexus aurantiacus* also exhibits thermal stability (Pierson and Thornber, 1983; Nozawa and Madigan, 1991). The reconstituted membranes containing the isolated reaction centers can develop a proton motive force in the presence of light under anaerobic conditions (Speelmans et al., 1993).

Activities of some soluble enzymes, such as dehydrogenases of amino or organic acids and ATP sulfurylase, determined as a function of temperature, were found to be maximal between 45 and 70°C (Krasil'nikova et al., 1986; Krasil'nikova, 1987a; Laakmann-Ditges and Klemme, 1988). The functioning of membrane-bound proteins at elevated temperatures, however, depends on the properties of the membrane as well as on the temperature characteristics of the proteins themselves. Oelze and Fuller (1983) determined the temperature characteristics of growth and the membrane-bound enzyme activities of NADH oxidase, succinate 2,6-dichlorophenol-indophenol reductase, ATPase, and light-induced proton extrusion. Enzymatic activities were maximal at 65–70°C, and a major lipid phase transition occurred near 40°C when cells were grown at 50°C. Membrane phenomena were significantly altered at temperatures above 60°C, which may reflect the denaturation of bulk membrane proteins (Oelze and Fuller, 1983). Although individual enzyme activities were high in this

temperature range, proton extrusion was not thermostable above 60°C and growth rates did not increase in this range.

Tvermyr et al. (1998) succeeded in cloning of a DNA polymerase I gene in *Chloroflexus aurantiacus* and in expressing the recombinant protein in *Escherichia coli*. The recombinant *Chloroflexus* protein showed an efficient, heat-stable proofreading and polymerase activity at 70°C. The proofreading, i.e., 3-5 exonuclease activity, found in *Chloroflexus* polymerase is lost in some thermophilic DNA polymerases such as *Taq* polymerase (from *Thermus aquaticus*), *Bst* polymerase (from *Bacillus stearothermophilus*), and *Streptococcus pneumoniae* DNA polymerase I.

Genetics

While knowledge about the genetics of *Chloroflexus* species and other FAPs is limited, some gene sequences and their organization for various proteins, mainly relating to photosynthesis, have been investigated in *Chloroflexus aurantiacus* (see the section "Physiology" in this Chapter). Fundamental information about the genetic analysis of *Chloroflexus aurantiacus* was reviewed by Shiozawa (1995).

In *Chloroflexus aurantiacus*, chemical or UV mutagenesis appears to be one of several useful methods for obtaining mutants deficient in the production of bacteriochlorophylls or lacking carotenoids (Pierson et al., 1984b). Mutagenesis is helpful for the genetic analysis of pigment synthesis. Furthermore, using a similar technique, it would be possible to obtain mutants deficient in or lacking activities of enzymes other than those for the synthesis of photopigments. Susceptibility to antibiotics is also important for the screening of recombinants. The type strain of *Chloroflexus aurantiacus* is sensitive to penicillin and ampicillin but is resistent to carbenicillin up to 100 μg/ml (Pierson et al., 1984b).

The genome project on *Chloroflexus aurantiacus* is now progressing at the Joint Genome Institute operated by the University of California for the United States Department of Energy. Up to the present (May 2002), 3 million nucleotides have been determined, and more than 3000 candidate protein-encoding genes have been found in the determined sequence. The draft sequence data can be obtained at the web page (http://www.jgi.doe.gov/JGI_microbial/html/). In the near future, whole genome data will enable comparisons between *Chloroflexus aurantiacus* and other photosynthetic bacteria, and the findings obtained from this comparison will provide a number of keys to resolving the phylogenetically enigmatic nature of this organism as well as the complex evolutionary puzzle of photosynthesis.

Acknowledgments

We thank Yuji Sekiguchi in the National Institute of Advanced Industrial Science and Technology (AIST) for the phylogenetic analysis based on 16S rRNA sequence.

Medium Lists

Medium D, DG, DGN, and ND

Double-distilled water	1 liter
NTA (sodium nitrilotriacetate)	0.1 g
Micronutrient solution (see below)	0.5 ml
$FeCl_3$ solution (0.29 g/liter)	1.0 ml
$CaSO_4 \cdot 2H_2O$	0.06 g
$MgSO_4 \cdot 7H_2O$	0.10 g
NaCl	0.008 g
KNO_3	0.10 g
$NaNO_3$	0.70 g
Na_2HPO_4	0.11 g

Micronutrient Solution

Double-distilled water	1 liter
H_2SO_4 (concentrated)	0.5 ml
$MnSO_4 \cdot H_2O$	2.28 g
$ZnSO_4 \cdot 7H_2O$	0.50 g
H_3BO_3	0.50 g
$CuSO_4 \cdot 5H_2O$	0.025 g
$Na_2MoO_4 \cdot 2H_2O$	0.025 g
$CoCl_2 \cdot 6H_2O$	0.045 g

Medium DG is medium D to which 0.8 g of glycylglycine per liter has been added as buffer. The pH is adjusted to 8.2 before autoclaving. Medium DGN is medium D to which 0.8 g of glycylglycine and 0.2 g of NH_4Cl have been added per liter. Medium ND (lacks combined N except as NTA) is medium D without KNO_3 and $NaNO_3$, but with 0.07 g of Na_2HPO_4 and 0.036 g of KH_2PO_4 per liter.

Medium PE

Basal salts solution (see below)	5 ml
Phosphate solution	5 ml
Vitamin solution	1 ml
$(NH_4)_2SO_4$	0.5 g
Sodium glutamate	0.5 g
Sodium succinate	0.5 g
Sodium acetate	0.5 g
Yeast extract	0.5 g
Casamino acids	0.5 g
Sodium thiosulfate	0.5 g

Dilute with distilled water up to 1 liter and adjust pH to 7.2–7.5.

Basal Salts Solution

Na_3EDTA	4.12 g
$FeSO_4 \cdot 7H_2O$	1.11 g
$MgSO_4 \cdot 7H_2O$	24.65 g
$CaCl_2 \cdot 2H_2O$	2.94 g
NaCl	23.4 g
Trace elements solution	10 ml

Dilute with distilled water up to 1 liter.

Phosphate Solution

KH_2PO_4	75 g
K_2HPO_4	78 g

Dilute with distilled water up to 1 liter.

Vitamin Solution

Nicotinic acid	0.1 g
Thiamine	0.1 g
Biotin	0.005 g
p-Amino-benzoic acid	0.05 g
Vitamin B_{12}	0.001 g
Calcium panthothenate	0.05 g
Pyridoxine HCl	0.05 g
Folic acid	0.05 g
Na_3EDTA	0.02 g

Dilute with distilled water up to 100 ml.

Trace Elements Solution

$MnSO_4 \cdot 4H_2O$	5.58 g
$ZnSO_4 \cdot 7H_2O$	1.44 g
$Co(NO_3)_2 \cdot 6H_2O$	1.46 g
$CuSO_4 \cdot 5H_2O$	1.26 g
$Na_2MoO_4 \cdot 2H_2O$	1.21 g
H_3BO_3	1.55 g
Na_3EDTA	20.6 g

Dilute with distilled water to 500 ml.

Medium IM Solution A

$CaCl_2 \cdot 2H_2O$	0.32 g
$MgSO_4 \cdot 7H_2O$	0.40 g
KCl	0.5 g
NaCl	1.0 g
$(NH_4)_2SO_4$	0.5 g
KH_2PO_4	0.3 g
$FeCl_3$	0.292 mg
Micronutrient solution SL7	10 ml
Vitamin B_{12}	0.005 mg

Dilute with distilled water up to 1 liter and adjust pH to 7.6. Solution A and B are separately prepared and stored. Solution B contains 0.05 M $NaHCO_3$ (in water). It is sterilized by autoclaving, followed by bubbling vigorously with CO_2 for 1 h. A total of 250 ml of solution A is added to 650 ml of distilled water. After autoclaving and cooling, 100 ml of solution B is added.

Medium IMC is medium IM to which 0.25 g of glucose, 0.25 g of vitamin-free casamino acids and 0.5 ml of vitamin solution (see below) have been added per liter.

Vitamin Solution

Nicotinic acid	2 mg
Thiamine hydrochloride	1 mg
p-Amino-benzoic acid	0.2 mg
Biotin	0.02 mg

Dilute with distilled water up to 1 ml.

CHAPTER 10.2

The Genus *Thermoleophilum*

JEROME J. PERRY

Introduction

Thermoleophilum, a genus of eubacteria obligate for aerobiosis and thermophily, is distinguished by the ability to grow solely on *n*-alkane substrates ranging in length from C_{13} to C_{20} (Merkel et al., 1978a; Merkel et al., 1978b; Zarilla and Perry, 1984; Zarilla and Perry, 1986). Mud samples obtained from hot springs and from environmental niches generally considered nonthermal have both yielded isolates of *Thermoleophilum*. Thermal elution profiles of DNA duplexes delineate two species within the genus, *T. album* and *T. minutum* (Zarilla and Perry, 1984; Zarilla and Perry, 1986). The sequence of 16S rRNA from *T. album* strain NM indicated that these bacteria are unique phylogenetically (C. Woese, personal communication). Further study (Brown and Haas, 1997) placed this genus in a grouping with the green nonsulfur bacteria (Fig. 1). Then the gene sequence that encodes RNase P RNA was cloned and RNA transcribed from this clone was catalytically active in vitro when reconstituted with a specific oligonucleotide that regenerated the secondary structure. A phylogenetic tree based on the sequencing of the cloned RNase P RNA is consistent with the tree based on small subunit rRNA. The RNase P in *T. album* is of type A, the common ancestral form. Organisms in the green nonsulfur group are progeny of a deep divergence in the eubacterial line of descent. Isolation of strains from environments separated by considerable geographic distance indicates that *Thermoleophilum* strains may be of fairly common occurrence. Efforts to isolate a mesophilic counterpart of *Thermoleophilum* that would also be restricted to growth on *n*-alkane substrates have been unsuccessful.

Thermoleophilum species are Gram-negative, slow growing, small, nonmotile bacteria. They cannot utilize sugars, amino acids, fatty acids, or any substrate tested (except the *n*-alkanes) as source of carbon or energy. During active growth on *n*-heptadecane, the organism can incorporate a limited amount of acetate into cell material (less than 10% of total cell carbon). Members of this genus have a unique tetrahydrogenated menaquinone that has not been observed in the respiratory pigments of bacteria of any other species. The catalase from *Thermoleophilum* is a manganese-containing enzyme relatively resistant to cyanide inhibition.

Habitat

Thermoleophilum strains have been isolated from mud samples obtained from both thermal and nonthermal environments. The thermal environments included the outlet stream of hot springs in the states of Wyoming, Arkansas, and New Mexico (Table 1). The nonthermal environments were mud samples from Roanoke Rapids, NC, and Beaufort, NC. All mud samples were taken from aquatic environments and the temperature of sampling sites in Yellowstone, WY, and Hot Springs, AR, were near the optimum for growth of the strains isolated (YS-3, YS-4, and HS-5) (Merkel et al., 1978b; Zarilla and Perry, 1984). The nonthermal environmental samples were obtained from dark mud that was regularly exposed to the sun (strains PTA-1 and RR-D). Solar heating can raise the temperature of such dark surfaces to 60°C or higher (Brock, 1970). Growth of these obligate thermophiles in nonthermal environments would probably occur sporadically when the transient temperatures rose to a suitable level.

Attempts to isolate a mesophilic organism restricted to growth solely on *n*-alkane substrates have been unsuccessful. The presence of fast-growing, *n*-alkane-utilizing organisms in most environments of moderate temperature might well preclude the isolation of organisms with growth characteristics equivalent to *Thermoleophilum* species.

Isolation and Enrichment

The primary enrichment medium for the isolation of *Thermoleophilum* species was prepared by adding *n*-heptadecane at 0.1% (v/v) to a mineral (L [liquid]-salts) basal medium modified

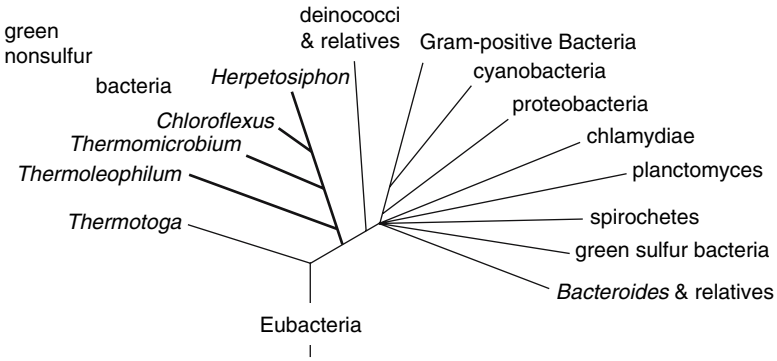

Fig. 1. The phylogenetic position of the genus *Thermoleophilum* based on 16S rRNA sequence analysis. Note the genus resides in the "green-nonsulfur-bacteria" branch of the Eubacteria (indicated by boldface). The tree was constructed based on maximum likelihood analysis.

Table 1. Locations where *Thermophilum* strains have been isolated.

Strain	Source of inoculum	Temperature
T. album		
HS-5	Hot Spring, AR	61°C
NM	Faywood Hot Springs, NM	>50°C[a]
YS-3	Yellowstone National Park, WY	60°C
RR-D	Roanoke Rapids, NC	Ambient
T. minutum		
YS-4	Yellowstone National Park, WY	63°C
PTA-1	Beaufort, NC	Ambient

[a]Close to the water source and above 50°C.
Adapted from Zarilla and Perry, 1984.

from that of Leadbetter and Foster (1958). The recipe for this medium is given below. Nitrogen was provided in the modified medium by adding 1 g/liter of each of NH_4Cl and $NaNO_3$ (Zarilla and Perry, 1984). Mud samples employed as inocula were obtained from both thermal and nonthermal environments (Table 1). Incubation was at 60°C in stationary culture until turbidity was apparent. After repeated transfer in the liquid medium, a pure culture was obtained by streaking on plates of 3.0% agar containing the modified L-salts medium. The *n*-heptadecane substrate was introduced by inverting the inoculated plate and placing 0.2-ml *n*-heptadecane in the cover (Perry, 1985). The plates were placed in plastic bags (to prevent desiccation) and incubated at 60°C for days. The colonies were small white, dry and flat. Axenic cultures were difficult to obtain as the organisms grow poorly on agar surfaces.

Mineral-Salts Medium (Modified L-Salts) for *Thermoleophilum* Species

NH_4Cl	11.0 g
$NaNO_3$	1.0 g
$MgSO_4 \cdot 7H_2O$	200 mg
Na_2HPO_4	210 mg
NaH_2PO_4	90 mg
$CaCl_2$	15 mg
KCl	140 mg

Distilled water 1 liter

Cultivation

Growth of the isolates occurred between 45 and 70°C (optimally at 58–62°C) and at a pH between 6.5 and 7.5 (Table 2). The generation time was difficult to determine accurately but exceeded 6 h in every case. Strains are all strict aerobes but do not respond favorably to increased oxygen availability. Under optimal conditions of temperature (60°C), pH (7.0), and substrate (*n*-heptadecane), the cell yield was 0.1–0.3 g/liter (Zarilla and Perry, 1984; Zarilla and Perry, 1986).

Substrate Utilization Patterns

None of the *Thermoleophilum* strains grew in the presence of any substrate tested other than *n*-alkanes (C_{13}–C_{20}). No growth occurred on shorter or longer chains of *n*-alkanes, nor on 1-alkenes or alcohols of a chain length C_{13}–C_{20}. Homologous ketones and branched alkanes (C_{13}–C_{17}) were not utilized. The following substrates did not support growth: arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, melibiose, rhamnose, ribose, sorbose, sucrose, trehalose, xylose, glycerol, mannitol, sorbitol, acetate, propionate, butyrate, citrate, pyruvate, succinate, acetone, nutrient broth, peptone, yeast extract, or tryptone plus yeast extract. All of the strains utilized ammonium chloride as a nitrogen source. Strains HS-5, NM and RR-D also could utilize sodium nitrate as sole nitrogen source. Two strains,

Table 2. Properties of *T. album* and *T. minutum*.

Strain	Cell length (μm)	Generation time (h)	n-Alkane substrate range	GC content (mol%)
T. album				
HS-5	0.9	6.5	C_{13}–C_{20}	70.4
NM	1.0	9	C_{14}–C_{20}	68.8
YS-3	0.7	6	C_{13}–C_{20}	69
RR-D	1.0	7.5	C_{14}–C_{20}	70
T. minutum				
YS-4	1.5	6	C_{13}–C_{20}	70
PTA-1	1.1	7.5	C_{14}–C_{19}	68.8

HS-5 and NM, could derive their nitrogen from glycine but growth was poor, and none of the carbon of the glycine was incorporated. Neither alanine nor glutamate could serve as source of nitrogen. Addition of growth factors, e.g., B-vitamins or amino acids, to the growth medium did not alter the growth rate or total growth. Mineral salts medium similar in composition to the hot springs water of the original sampling site in Yellowstone did not affect growth rate or cell yield.

Identification

Thermoleophilum species are very small, Gram-negative rods (Table 1 and Fig. 2). The organisms are nonmotile and have no pigmentation. They have been isolated only on *n*-alkane enrichment substrates (C_{13}–C_{20}) and are readily identified by their inability to grow on any other substrate. *Thermoleophilum* strains have a G+C content of 68.8 to 70.4 mol%. The major diamino acid in the cell wall peptidoglycan of the genus *Thermoleophilum* is diaminopimelic acid. All strains grew to confluence on agar surfaces with few individual colonies formed. Colonies were small, round, and white and generally dry and flaky. They were often closely associated with pink-pigmented thermophilic strains on original isolation, and separating the slow-growing *Thermoleophilum* species was a tedious process.

The DNA hybridization studies indicated that *T. album* and *T. minutum* are of the same genus but different species (Zarilla and Perry, 1986; Table 3). There was no detectable homology with *Thermomicrobium roseum*, *Bacillus thermoleovorans* (Zarilla and Perry, 1987) or *Thermus aquaticus*. Data presented in Fig. 3 confirm that there are two species within this genus.

Physiological Characteristics

Menaquinones are widely distributed in the plasma membranes of prokaryotes and are generally distinguished by the length of their isopre-

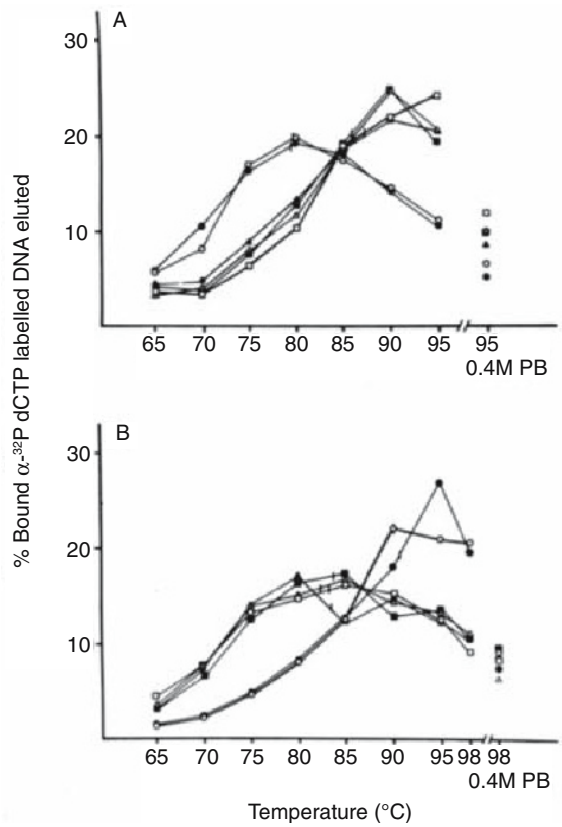

Fig. 3. Thermal elution profiles of *Thermoleophilum* DNA duplexes reassociated at 62°C. One strand of each DNA was made up of [α-^{32}P]deoxycytidine triphosphate (dCTP)-labeled DNA from either *Thermoleophilum album* strain HS-5T (A) or *Thermoleophilum minutum* strain YS–4T (B). The other strand was made up of DNA from strain HS-5T (□), YS-3 (▲), YS-4T (○), NM (▲), RR-D (■), or PTA-1 (●). The homologous duplex is indicated by a thick line. The thermal stability values are indicated by a vertical line on each curve and represent the temperature at which 50% of the double-stranded DNA was eluted from the hydroxyapatite. The DNA was eluted with 0.14 M phosphate buffer (PB) containing 0.1% sodium dodecyl sulfate until the maximum temperature was attained, at which point any remaining-bound DNA was eluted by using 0.4 M phosphate buffer. Adapted from Zarilla and Perry (1986).

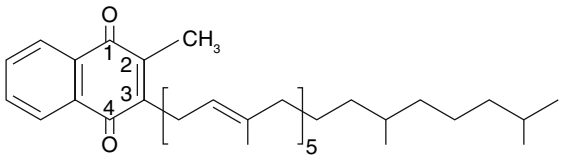

Fig. 4.

nyl side chain. The number of isoprenoid units varies from 1 to 15, and species also differ in the number of these isoprenoids that are saturated/unsaturated (Collins and Jones, 1981). Generally Gram-negative eubacterial menaquinones are composed of unsaturated isoprenoid units but a few Gram-negative bacterial species have dihydrogenated menaquinones. Examination of the respiratory quinones of *T. album* strain NM led to the isolation of a novel tetrahydrogenated menaquinone, 2 methyl-3-VI,VII-tetrahydrohepta-prenyl-1, 4-naphthoquinone, as depicted in Fig. 4 (Collins et al., 1986). The presence of this naphthoquinone in *T. album* readily distinguishes the genus from other Gram-negative, aerobic, obligately thermophilic groups. The genus *Thermus* and *Thermomicrobium roseum* contain saturated menaquinone as their major respiratory quinone.

Superoxide dismutase (SOD) is induced in aerobic bacteria by high oxygen stress. This enzyme, together with catalase and peroxidase, removes toxic oxygen intermediates generated as byproducts in the univalent reduction of molecular oxygen. These highly reactive intermediates of oxygen reduction are predominantly superoxide anion, hydrogen peroxide, and the hydroxyl radical. Growth of aerobic organisms at higher oxygen tensions or in the presence of methyl viologen (a superoxide generator) will effectively induce SOD (DiGuiseppi and Fridovich, 1984). Studies suggest that thermophilic bacteria generally react unfavorably to increased oxygen tension (Allgood and Perry, 1985b). As a consequence of this observation, an examination was made of the effect of oxygen stress on the level of SOD, catalase and peroxidase in *T. album* NM. Growth of strain NM in the presence of methyl viologen did not affect the level of cellular SOD but caused a marked increase in catalase activity. Peroxidase activity increased a small amount. Increasing the oxygen level also led to higher levels of catalase with a decrease in total growth (Allgood and Perry, 1985a; Allgood and Perry, 1985b; Allgood and Perry, 1986b). The level of oxygen defense enzymes is comparable with that in other aerobic bacteria. The products of O_2 reduction do not seem to be responsible for the negative response to increased aeration.

The catalase from *T. album* NM has been isolated, purified (>96%), and characterized (Allgood and Perry, 1986a). The major properties of the enzyme are presented in Table 4. For comparison the properties of the equivalent enzyme from *Escherichia coli*, *Rhodopseudomonas sphaeroides* and *Lactobacillus plantarum* are included. The catalase from *T. album* is thermoactive and thermostable. It has a low Mr, and the metal present is manganese. This is the only report (Allgood and Perry, 1986a) of a manganese-containing catalase in an aerobic

Table 4. Comparison of the properties of the catalase from *T. album* with that from other bacterial species.

Organism	Metal present	M_r	Number of subunits
Thermoleophilum album	Mn	141,000	4
Escherichia coli	Fe	337,000	4
Rhodopseudomonas sphaeroides	Fe	232,000	4
Lactobacillus plantarum	Mn	172,000	6

organism. The significance of such a catalase in this ancient thermophile is not understood at this time.

The electrophoretic mobilities of several enzymes in crude cell-free extracts from *T. album* strains were markedly different from the equivalent enzyme from other thermophiles (Zarilla and Perry, 1986). Among these enzymes of differing mobility were malate dehydrogenase, catalase, esterase and SOD. Electrophoresis of purified catalase and malate dehydrogenase from *T. album* NM resulted in an equivalent pattern.

Two enzymes from *Thermoleophilum* sp. were purified and characterized. These were the NADP-dependent isocitrate dehydrogenase (IDH) from *T. minutum* YS-4 (Novotny and Perry, 1991) and the malate dehydrogenase (MDH) from *T. album* NM (Novotny and Perry, 1990). Purification was by affinity chromatography and electroelution from a nondenaturing polyacrylamide gel. Both enzymes were thermostable and under nondenaturing conditions had distinctly different electrophoretic mobilities than the equivalent enzyme from other genera tested, including other thermophiles. The IDH had an Mr of 60,000 and was composed of two identical subunits. The optimum pH for activity was 7.2, at a temperature of 75°C. The enzyme required Mn^{+2} or Mg^{+2} for activity and NAD could not substitute for NADP. The amino acid composition of the IDH had an Arg/Lys ratio of 4.1 and very high levels of glycine. The purified MDH had an Mr of 61,000 and consisted of two subunits, each with an Mr of 32,500. Optimal activity occurred at 60°C and a pH of 7.5. The *T. album* MDH differed in amounts of arginine, lysine, glycine, proline, and histidine from the MDHs of other thermophilic and mesophilic microorganisms.

Other enzymes have been partially purified from *T. album* including a novel NADH-ferricyanide oxidoreductase (Vrana et al., 1999) and an alcohol dehydrogenase (Cacek et al., 1995). The NADH reductase catalyzes the transfer of electrons to mammalian cytochrome *c*.

The *T. minutum* YS-4 extracts contained all of the enzymes involved with the tricarboxylic acid cycle except α-ketoglutarate dehydrogenase (J. G. McCarthy and J. J. Perry, unpublished observation). Exhaustive attempts to demonstrate this enzyme in any of the *Thermoleophilum* strains have been unsuccessful. An active isocitrate lyase was present in extracts of *Thermoleophilum*, suggesting that an active glyoxylate cycle is present. All strains had NADH and NADPH oxidase activity. The *T. album* NM extracts had the large-sized citrate synthase typical of Gram-negative bacteria (Weaver et al., 1987). Addition of ^{14}C-acetate to nonproliferating cells of *T. album* NM resulted in little incorporation of radiolabel. Addition of radiolabeled acetate to a culture during active growth on *n*-heptadecane did result in some incorporation of acetate, but at a level of less than 10% of the total cell carbon. Increasing the level of acetate from 0.1 mM to 50 mM did not lead to any increase in incorporation (Weaver et al., 1987). The inability of the organism to incorporate more added acetate and the absence of α-ketoglutarate dehydrogenase are reminiscent of these activities in the obligate autotrophs. Possibly, the genus *Thermoleophilum* cannot obtain energy from substrates other than the *n*-alkanes normally utilized.

Polyamines are a constituent of the hyperthermophilic and the moderate thermophilic bacteria and the thermophilic Archaea (Hamana et al., 1998). The cellular polyamines present in *Thermoleophilum* sp. have been characterized (Hamana et al., 1990; Allgood and Perry, 1992; Allgood and Perry, 1998). Two strains of *T. album* (HS-5 and YS-3) and two of *T. minutum* (YS-4 and PTA-1) were examined and all four strains had an equivalent pattern of polyamines. The major polyamine in this genus was N^4-bis (aminopropyl) spermidine. The distribution pattern of polyamines in *Thermoleophilum* was unique when compared with other thermophiles. The role of these compounds in thermophilic microorganisms is not known at the present time.

CHAPTER 10.3

The Genus *Thermomicrobium*

JEROME J. PERRY

Introduction

Thermomicrobium roseum (ATCC 27502), the sole representative of a phylogenetically distinct branch of the eubacteria, is an obligate thermophile originally isolated from the effluent of a hot spring in Yellowstone National Park, WY (Jackson et al., 1973). The grouping of *T. roseum* with the green nonsulfur (GNS) bacteria is based on ribosomal RNA sequence comparisons (Oyaizu et al., 1987). The sequence of 5S rRNA from *T. roseum* (Van den Eynde et al., 1990) affirms that it should be clustered with *Chloroflexus*. *Herpetosiphon* and *Chloroflexus*, the other representatives in this branch, are markedly different phenotypically from *T. roseum* (for a review see Kristjansson and Alfredsson, 1992). Although the GNS bacteria share some common ribosomal characters, they are the progeny of a deep phylogenetic divergence (Gibson et al., 1985); *Herpetosiphon* is a mesophile and more rapidly evolving than either *Chloroflexus* or *Thermomicrobium*. The deepest branching in eubacterial evolution is predominantly represented by thermophiles (see Fig. 1, *Thermoleophilum* chapter) and these organisms evolved more slowly than the mesophiles. They have consequently retained more of their ancestral character (Achenbach-Richter et al., 1987). Recent results (Haas and Brown, 1998) indicate that most of the unusual structural elements of type B RNase P RNAs found in low G+C Gram-positive bacteria evolved independently (apparently by convergent molecular means) in *T. roseum*. The gene for heat shock protein (HSP70) present in *T. roseum* was cloned and the protein generated from this was sequenced. The results of sequencing affirm the relatedness of *T. roseum* to other GNS bacteria (Gribaldo et al., 1999; Gupta et al., 1997).

Isolation and Enrichment

The primary enrichment medium for *T. roseum* was composed of 0.1% tryptone and 0.1% yeast extract (TYE) in Allen's salts (see recipe below; Allen, 1959). Enrichment media were inoculated with samples of bacterial mat or water from various springs in Yellowstone National Park and were incubated at 70, 75, 80 and 85°C. After a suitable time, the enrichments were streaked on plates of TYE agar (3.0%) containing Castenholz's salts solution (Jackson et al., 1973; Castenholz, 1969). The enrichment culture of bacterial mat taken from Toadstool Spring in Yellowstone and incubated at 70°C was the only one that yielded unusual colonies. These compact pink colonies were distinctly different from colonies of other isolates, which appeared to be mostly of the genus *Thermus*. Transfer by streaking on the TYE agar medium at pH 8.5 with as much as 0.5% tryptone and yeast extract led to a pure culture of *T. roseum* (Jackson et al., 1973).

Allen's Salts Solution (mg/liter)

$(NH_4)_2SO_4$	1,300
KH_2PO_4	280
$MgSO_4 \cdot 7H_2O$	247
$CaCl_2 \cdot 2H_2O$	74
$FeCl_3 \cdot 6H_2O$	19
$MnC1_2 \cdot 4H_2O$	1.8
$Na_2B_4O_7 \cdot 10H_2O$	4.4
$ZnSO_4 \cdot 7H_2O$	0.22
$CuCl_2 \cdot H_2O$	0.05
$Na_2MoO_4 \cdot 2H_2O$	0.03
VCl_2	0.03

Dissolve in deionized distilled water and adjust the pH to 7.8.

Castenholz's Salts Solution (mg/liter)

Nitrilotriacetic acid	100
$CaSO_4 \cdot 2H_2O$	60
$MgSO_4 \cdot 7H_2O$	100
NaCl	9
KNO_3	103
$NaNO_3$	689
Na_2HPO_4	111
$FeCl_3$	0.28
$MnSO_4 \cdot H_2O$	2.2
$ZnSO_4 \cdot 7H_2O$	0.5
H_3BO_3	0.5
$CuSO_4$	0.016
$Na_2MoO_4 \cdot 2H_2O$	0.025
$CoCl_2 \cdot 6H_2O$	0.045

Dissolve in deionized distilled water.

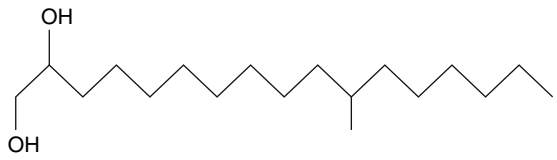

Fig. 1. Typical structure of a long chain 1,2 diol.

Habitat

Toadstool Spring (no longer active) was located in the Lower Geyser Basin of Yellowstone National Park. *Thermomicrobium roseum* was isolated from a sample taken near the source of the spring, where the water temperature was 74°C and pH was 8–9. The inoculum was from an orange/red bacterial mat attached to a silica substrate. The mat had accumulated under a piece of wax paper debris that may have offered some protection from the high light intensity and rapidly moving water. Although Jackson et al. (1973) suggested that glass slides immersed in the water near the source of the spring had exhibited microbial growth that appeared similar to *T. roseum*, microbes have not yet been cultivated from these sources. Biologically active layers of a cyanobacterial mat have been analyzed for various apolar lipid, glycolipid and phospholipid content (Zeng et al., 1992). At 1–2 and 2–4 mm intervals, long-chain diols were detected which were apparently derived from glycolipids of microorganisms such as *T. roseum.*

A thermophilic organism was isolated from soil by enrichment with *n*-alkanes as substrate and was tentatively assigned to the genus *Thermomicrobium* (Phillips and Perry, 1976). Subsequent DNA–DNA hybridization studies indicated that this isolate should be placed in an entirely different genus (Zarilla and Perry, 1986; Zarilla and Perry, 1987).

Substrate Utilization Patterns

Complex media are the preferred substrate for *T. roseum*. A maximum cell yield was attained with tryptone and yeast extract each added at 0.5%, with less (0.3%) supporting the most rapid growth. Little growth occurred with the substrates added at 1.0%. Levels higher than 1.0% completely inhibited growth. Growth on peptone, casein hydrolysate, brain heart infusion, nutrient broth, trypticase soy broth, and on tryptone or yeast extract (substrate at 0.2%) required inclusion of NH_4^+ (in Castenholz's salts solution) as nitrogen source. Of these, only nutrient broth and yeast extract yielded growth with NO_3^- (in Allen's salts solution) as the source of nitrogen. Growth on defined medium with selected substrates occurred only when 0.2% glutamate was added with nitrogen source NO_3^-. Glycerol and sucrose were adequate carbon sources under these conditions. Sparse growth occurred with glutamate as sole substrate (in Allen's salts solution). Fructose, succinate, mannitol, acetate and citrate were inadequate as growth substrates (Jackson et al., 1973). The organism grew consistently better with Allen's than with Castenholz's salts solution. Apparently, some ammonia was lost from the latter at this pH and temperature.

Cultivation

Growth was optimum at 70–75°C at pH 8.2–8.5 and was possible at temperatures as low as 45–48°C, at pH 7–8.7. Under optimum conditions with tryptone and yeast extract (0.3%) as substrates, the organism had a generation time of 5 to 5.5 h.

Identification

T. roseum cells are generally pleomorphic (with some that are dumbbell shaped) and occur as short, irregularly shaped (single or paired) rods. The organism is 1.3 to 1.8 μm in diameter and 3 to 6 μm in length. The G+C content of the DNA is 64.3 mol%. The colonies on agar are compact and pink-pigmented. Although some slight motility was observed by light microscopy, no flagella were seen by electron microscopy, and the organism is considered to be nonmotile (Jackson et al., 1973). Endospores are not visible in *T. roseum* by light, phase contrast or electron microscopy. The organism is Gram-negative, and thin sections viewed longitudinally have a layered cell wall consistent with this staining character. Electron-dense hexagonal structures were visible in thin sections that may have been bacteriophages, but no lytic activity was observed (Jackson et al., 1973).

DNA hybridization reactions were employed to determine whether *T. roseum* DNA reassociated with DNA from thermophilic *Bacillus* strains, *Thermus aquaticus* and *Thermoleophilum album*. The results confirmed that *T. roseum* is not related to any of these other organisms (Zarilla and Perry, 1986; Zarilla and Perry, 1987). Antibiotic sensitivity tests indicate that *T. roseum* is sensitive to kanamycin, neomycin and penicillin, but less sensitive to erythromycin and chloromycetin (Jackson et al., 1973).

The pigments extracted from *T. roseum* with acetone were analyzed spectrophotometrically. The absorbance maxima at 470, 494 and 530 nm indicate that *T. roseum* carotenoid pigments are

similar to torulene and 3,4-dehydrolycopene. Extracted pigment from the bacterial mats that served as the enrichment inocula had equivalent absorptive properties (Jackson et al., 1973).

Physiological Properties

Membrane Lipid Composition

Virtually all eubacterial and eukaryotic cells have membrane lipids composed of fatty acids esterified to glycerophosphate. The membranes of archaebacteria differ markedly in that the lipids of these organisms are composed of isoprenoid chains joined to glycerol by an ether linkage. The membrane lipids of *T. roseum* have neither ester nor ether linkages, but are composed of a series of straight-chain and internally branched l,2-diols. A typical 1,2-diol is shown in Fig. 1. The carbon length of the diols ranges from C_{18} to C_{23} (Pond et al., 1986). Similar long-chain 1,2 diols have been characterized from strains of the genus *Thermus* (Wait et al., 1997). These thermophiles also contained both glycerol-linked and diol-linked glycolipids.

The cellular lipids in *T. roseum* account for about 3% of the dry weight of the cell, and, of this, 22.6% is nonpolar neutral lipid and 77.1% is polar glycolipids or phospholipids. Polar lipids were hydrolyzed to remove the polar head groups, and the apolar residues were analyzed (Pond et al., 1986). The distribution of the l,2-diols present in the lipid of *T. roseum* are listed in Table 1. These structures are analogous to the glycero-lipids in that the terminal hydroxyl can link to the polar-head group, and long-chain fatty acids can be esterified to the secondary hydroxyl. This process provides the hydrophobic chains necessary for a lipid bilayer (Pond et al., 1986).

Analysis of the fatty acid constituents of these unusual lipids indicated that they too had normal and internally methylated hydrocarbon chains (Pond and Langworthy, 1987). The distribution of fatty acids in *T. roseum* grown at 70°C is presented in Table 2. Methyl-branched-chain fatty acids are also common constituents of eubacterial lipids but generally they are *iso-* or *anteiso-*methylated fatty acids.

The effect of temperature on the relative amounts of normal to branched-chain fatty acids and diols was determined (Pond and Langworthy, 1987) and the results are presented in Table 3. As the growth temperature was increased, the relative percentage of unbranched fatty acids and diols increased, while the relative amount of the methyl-branched constituents decreased (Pond and Langworthy, 1987). The longer chain, normal fatty acids have a higher melting point than the branched homologs, so increased branching as the temperature is lowered may be a mechanism whereby membrane fluidity is retained at lower temperatures.

Polyamines have been detected as constituents of *T. roseum* (Hamana et al., 1990). These unusual polyamines are penta- and hexamines and their function is not yet known.

Cell Wall Structure

Electron microscopy of negatively stained outer cell wall preparations from *T. roseum* indicated

Table 1. Distribution of 1,2-diols in the lipids of *Thermomicrobum roseum* after growth at 75°C.

Compound	Percent of total
11-Methyl-1,2-heptadecanediol	<0.5
1,2-Nonadecanediol	10.6
13-Methyl-1,2-nonadecanediol	21.1
1,2-Cosanediol	6.1
13-Methyl-1,2-cosanediol	2.5
15-Methyl-1,2-cosanediol	0.9
1,2-Eicosanediol	48.5
15-Methyl-1,2-eicosanediol	7.8
1,2-Docosanediol	1.0
1,2-Tricosanediol	1.1
1,2-Tetracosanediol	<0.5

Adapted from Pond *etal.* (1986).

Table 2. Distribution of fatty acids in *Thermomicrobium roseum* after growth at 70°C.

Compound	Percent of total
n-Hexadecanoic acid	1.2
10-Methyl-pentadecanoic acid	1.5
n-Heptadecanoic acid	0.5
10-Methyl-hexadecanoic acid	0.7
n-Octadecanoic acid	24.2
12-Methyl-heptadecanoic acid	57.3
n-Nonadecanoic acid	2.6
12-Methyl-octadecanoic acid	1.9
n-Cosanoic acid	8.4
14-Methyl-nonadecanoic acid	1.2

Adapted from Pond and Langworthy (1987).

Table 3. Effect of temperature on the percentage of normal and branched-chain fatty acids and diols in *Thermomicrobium roseum*.

Growth temperature (°C)	Percent normal	Percent branched
Fatty Acids		
60	24.1	75.6
75	46.3	52.4
Diols		
60	62.2	37.1
75	87.3	12.5

Adapted from Pond and Langworthy (1987).

Table 4. Amino acid composition of the two fractions of the cell wall of *Thermomicrobium roseum*.

Component	Fraction A (%)	Fraction B (%)
Threonine	8.1	3.6
Serine	6.2	4.0
Proline	8.1	14.0
Muramic acid	3.1	0
Glutamic acid	12.8	11.9
Glycine	19.3	33.8
Alanine	16.8	11.5
Valine	4.0	1.8
Diaminopimelic acid	1.2	0
Leucine	6.2	3.2
Isoleucine	0	1.8
Tyrosine	4.7	2.2
Galactosamine	3.1	0
Histidine	1.2	3.2
Arginine	3.7	Trace
Lysine	0	Trace
Ornithine	0	7.2
Phenylalanine	0	1.8

[a]Expressed as % of the total amino acid/sugar present. From Merkel et al., 1978.

that there were regular, repeating structures present in the cell envelope. These structures appear in a consistent mosaic pattern (Ramaley et al., 1978). Analysis of purified cell walls from *T. roseum* suggested that the organism, although sensitive to penicillin (Jackson et al., 1973), has low levels of peptidoglycan (Merkel et al., 1978; Merkel et al., 1980). Cell walls were removed from *T. roseum* and purified. This purified cell wall material was readily separated into two fractions (A and B), which were analyzed for amino acid composition (Table 4). Fraction A was composed of an array of amino acids with alanine, glutamic acid and glycine predominating; lesser amounts of diaminopimelic acid, galactosamine and muramic acid were detected.

Fraction B was a cell wall protein (M_r of 75,000) that accounted for 60% of the total cell wall amino-reactive material. The amino acid composition of this protein is presented in Table 4. This protein is probably the principal structural component of the cell wall revealed by electron microscopy (Ramaley et al., 1978; Merkel et al., 1980). How this protein might contribute to the thermostability of *T. roseum* is unknown.

Metabolism

Although *T. roseum* is a strict aerobe, it does not respond to increased oxygen levels by more rapid growth or higher cell yields. This is a common attribute of aerobic thermophiles and particularly of those that grow on hydrocarbon substrates (Allgood and Perry, 1985a; Allgood and Perry, 1985b; Allgood and Perry, 1986). Growth of *T. roseum* under higher oxygen (O_2) tension did result in increased cellular levels of superoxide dismutase (SOD) and catalase. Addition of methyl viologen to increase superoxide anion generation in cells had little effect on the level of SOD but resulted in increased catalase activity (Allgood and Perry, 1986). That higher O_2 levels do not lead to more rapid growth or cell yield is probably due to factors other than the accumulation of toxic products of O_2 such as superoxide or hydrogen peroxide. Most of the respiratory activity in *T. roseum* is cyanide insensitive. The respiratory pathways in *T. roseum* have not been elucidated further (Allgood and Perry, 1985a; Allgood and Perry, 1985b).

CHAPTER 10.4

The Genus *Herpetosiphon*

NATUSCHKA LEE AND HANS REICHENBACH

The *Herpetosiphon* species are aerobic, chemoorganotrophic, filamentous bacteria that are Gram negative but do not have a typical Gram negative cell wall. The filaments are very long, unbranched, and multicellular, between 0.5 µm and 1.5 µm wide and usually 100 µm to more than 1200 µm long (Fig. 1). Short transparent sections ("sleeves"; Fig. 2) are seen at the ends of many filaments.

Sleeves are also found in related organisms, like *Chloroflexus*. Depending on the strain, the medium, and the age of the culture, the filaments may fragment into much shorter pieces and ultimately into single cells. The cells in the filaments are tightly attached to one another, and in living filaments, their boundaries can only be seen with a microscope of high resolution at a high magnification, by phase or interference contrast (Fig. 2). They become clearly recognizable if the filament has been fixed to the slide and stained. The cells have the same width as the filaments and measure 1.5–5 µm in length, rarely more. The filaments may perform slow gliding movements; thus, on suitable substrates, the colonies develop into large spreading swarms (Fig. 3). The surface of the swarm is usually felt-like. Long flame-like projections or protruding strands of curled filaments are seen at the edge (Fig. 3). Normally the colonies are colored in shades of yellow, orange, or brick red, but unpigmented strains, especially among *Herpetosiphon*-like strains, do occur (Lee, 2004). A film showing the movements of the filaments and the development of the colonies is available (Reichenbach et al., 1980).

Apparently, *Herpetosiphon* was first discussed in the scientific literature under the name "*Flexibacter giganteus*" (Soriano, 1945; Soriano, 1947). Soriano's isolation techniques, choice of habitats, and description of the filaments, the swarm colonies, and their color correspond to those of the cultures now called "*Herpetosiphon*." However, the first valid description of the genus *Herpetosiphon*, with one species, *H. aurantiacus* (ATCC 23779^T), was provided by Holt and Lewin (1968). The definition was based on three isolates of E. E. Jeffers obtained from the slime coat of a green alga, *Chara* sp., from Birch Lake in Minnesota. Later, a dispute arose about the presence of a sheath in *Herpetosiphon*, and the genus definition was slightly modified to exclude a sheath (Reichenbach and Golecki, 1975). Also, Reichenbach and Golecki (1975) proposed that the species name *aurantiacus* be abandoned in favor of the name *giganteus*, which antedates it. This change could have been done without danger of confusion since Soriano's strain is no longer available. However, since more than one *Herpetosiphon* species may exist, one could argue that Soriano's "*H. giganteus*" was different from *aurantiacus*. The possible existence of different species of *Herpetosiphon* was indicated by another study already during this period when a specimen was isolated from the walls of a sluice of the Neckar River near Heidelberg (Germany). This specimen showed a strong resemblance with *Herpetosiphon aurantiacus* but was not identified as such because of some minor differences in phenotypic characteristics (Brauss et al., 1969). Thus, it was decided to give up the name *giganteus* until more had been discovered about the taxonomy of the genus. In 1970, four new species, one from the vicinity of a hot spring (*H. geysericola* ATCC 23076^T) and three from marine habitats (*Herpetosiphon cohaerens* ATCC 23123^T, *Herpetosiphon nigricans* ATCC 23147^T and *Herpetosiphon persicus* ATCC 23167^T) were added to the genus (Lewin, 1970). However, all three marine species have recently been transferred to a new genus, *Lewinella*, in the phylum *Flexibacter-Bacteroides-Cytophaga* (Sly et al., 1998). Since 1998, over 30 new *Herpetosiphon* and *Herpetosiphon*-like isolates have been described from different environmental habitats, such as freshwater lake systems (Lake Constance, Germany; the strains were previously described as a new *Vitreoscilla* species, *V. proteolytica*; Gräf and Perschmann, 1970; Lee et al. (manuscript in preparation)), sewage plants (Trick and Lingens, 1984; Senghas and Lingens, 1985; Bradford et al., 1996; Kohno et al, 2002; Lee et al. (manuscript in preparation)), and different soil systems (Lee et al. (manuscript in

preparation)). The G+C content of the DNA of about half of these isolates is 48–53 mol%, and the 16S rRNA gene similarity among these isolates is 96.4–99.5% (Sly et al., 1998; Lee et al. (manuscript in preparation)). However, the G+C content of the rest of the *Herpetosiphon*-like isolates, e.g., the strains of Senghas and Lingens (1985) and the strains Hp g6 (DSM 15710), Hp g16 (DSM 15736) and Hp g207 (DSM 15737), are higher (59–75%), which suggests that these isolates may represent novel genera among chloroflexi (Lee et al. (manuscript in preparation)).

A comparison of all present *Herpetosiphon* 16S rRNA gene sequences with all other available 16S rRNA gene sequences from culturable and as yet not cultivatable organisms clearly shows a phylogenetic relationship of *Herpetosiphon* to the third of the four suggested subphyla of the phylum *Chloroflexi*, previously non-green sulfur bacteria (Gibson et al., 1985; Woese et al., 1985; Hugenholtz et al., 1998a; Garrity and Holt, 2001; Lee et al. (manuscript in preparation)). The chloroflexi are well separated from all other bacteria and represent one of the main branches (a phylum) in the bacterial tree of descent. The similarity to other filamentous, gliding bacteria, such as *Vitreoscilla*, *Beggiatoa* and *Leucothrix*, which belong to the Betaproteobacteria and Gammaproteobacteria or the filamentous cyanobacteria, is significantly low (Reichenbach, 1981a; Reichenbach et al., 1986; Lee et al. (manuscript in preparation)). Interestingly, the relationship of *Herpetosiphon* to some chloroflexi members, e.g., *Chloroflexus*, is also reflected in other genes such as the elongation factor Tu or the ATP-synthase beta-subunit genes (Ludwig et al., 1993), as well as in the very unusual structure and composition of the cell walls of the two organisms. Both organisms contain a peptidoglycan in which *meso*-diaminopimelic acid is replaced by L-ornithine and to which a polysaccharide is covalently bound. In addition, both organisms lack a lipopolysaccharide (Jürgens et al., 1987; Jürgens et al., 1989).

Habitats

Typical *Herpetosiphon* strains are regularly found in freshwater, soil, and decaying organic matter (such as rotting wood, dung of herbivorous animals, and compost). *Herpetosiphon* appears to be rather common everywhere in aerobic environments, in the neutral pH range and

Fig. 2. Filaments of the type strain of *Herpetosiphon aurantiacus* at high magnifications. a) Filaments from CY agar. Note the enormous variability of the filaments' diameter, which is especially pronounced on peptone media. Slight constrictions at the filaments' surface and dark bands in the interior indicate cell boundaries, which can be particularly clearly recognized in the thick filament in the upper left sector; dark dots seen in many cells may be mesosome-like membrane bodies. b) The translucent segments seen next to the filaments are empty cell-wall cylinders and correspond to the sleeves often found at the ends of the filaments; here, as in other figures of this table, parallel running filaments approach one another very closely, which seems to exclude the presence of a sheath of any significance. c) The knots in the filaments testify to their incredible flexibility; the filament on the left contains a necridium (a dead cell); from VY/2 agar. d) The filament has a short sleeve at the end and a necridium which is almost ready to snap. e) A short filament with sleeves at both ends and a necridium. f) In several filaments, cross-walls are recognizable; there is a one- and a two-celled segment, the latter with a living and a dead cell; from CY agar. g) Decaying filament fragmenting into cell-wall cylinders, each corresponding to one cell. Because the cylinders separate cleanly, there can be no sheath. All micrographs were taken with Zeiss Axiomat, in phase contrast. Bars = 10 µm.

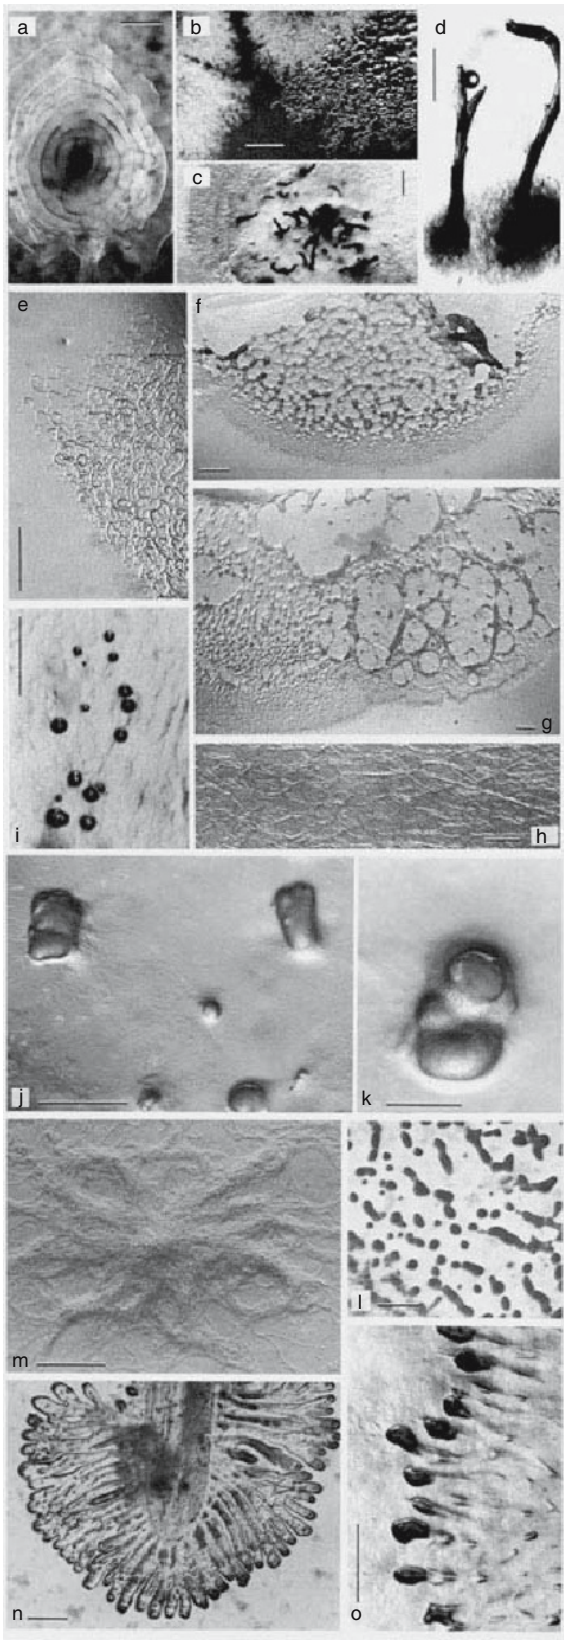

Fig. 3. Various swarm colony types of *Herpetosiphon aurantiacus*. The colonies of *Herpetosiphon* are very variable and occasionally show striking patterns. a) Swarm with a rhythmic growth pattern, on VY/2 agar. Bar = 1 mm. b) Swarm showing surface growth (right), as well as penetration into the agar (light areas). Bar = 1 mm. c) and d) Colonies with proboscis-like protuberances; c) survey picture; d) protuberances at higher magnification. Bar = 1 mm in both c) and d). e) Swarm growing from a streak of autoclaved *Escherichia coli* on water agar; the curly pattern is characteristic for this kind of culture; the cloudy areas in the lower part indicate penetration of the organism into the agar. Bar = 1 mm. f) and g) Large swarm on VY/2 agar; the swarm sheet tends to contract and peel off the agar surface, producing large holes surrounded by ridges; this growth pattern is very characteristic for *Herpetosiphon*. Bar = 1 mm in both f) and g). h) Delicately plicated surface of a swarm sheet on VY/2 agar; this is a relatively unusual pattern. Bar = 100 µm. i) to l) Knobs; they are sometimes produced in large numbers and arranged in patterns (i, l) that make their resemblance to myxobacterial fruiting bodies even more striking; also, their size is in the range of fruiting bodies. Bar = 1 mm in i) and l), 500 µm in j), and 200 µm in k). m) Microcolony showing its composition of long, coiling and interwoven filaments on CY agar. Bar = 100 µm. n) Swarm on a streak of autoclaved *E. coli* (center) on water agar spreading in an uncommon pattern of broad, tape-like tongues. Bar = 1 mm. o) Edge of a swarm growing on a streak of living *E. coli* on water agar; in contrast to the usual pattern on this medium, as shown in b) and e), here the swarm ends in a series of compact knobs with delicate, flame-like extensions (swarm center is to the right). Bar = 1 mm. Pictures made with Leitz Aristophot (a to g); Zeiss Axiomat (h, j, k and m); and Olympus SZH Stereo Microscope (i, l, n and o).

under mesophilic conditions. A study on the distribution of *Herpetosiphon* in the surface layers of Lake Constance (a large, deep, fairly oligotrophic lake in southwestern Germany) demonstrated the organism only in contaminated areas close to cities or at the mouths of rivers, while it was absent in clean stretches of water in the middle of the lake or along uninhabited and undisturbed shores (Gräf and Perschmann, 1970). This suggests that the *Herpetosiphon* population at the lake surface has its origin in the soil of the surrounding area and in contaminated waters running into the lake. The examples mentioned in the introduction show however that *Herpetosiphon* also thrives in the benthos of freshwater bodies. Therefore, its absence in the surface layers may be best explained by a fast sedimentation of the flocs of entangled filaments, which can stay in suspension only in vigorously agitated liquids.

Herpetosiphon and *Herpetosiphon*-like bacteria have also been observed and isolated from activated sludge of sewage plants on several occasions in different parts of the world (Salcher et al., 1982; Trick and Lingens, 1984; Senghas and Lingens, 1985; Bradford et al., 1996; Kohno et al., 2002; Björnsson et al., 2002; Lee et al. (manuscript in preparation)). *Herpetosiphon* may, however, have been observed on many more occasions in sewage material, but it has not been recognized as such. For instance, the organism described from a Dutch sewage plant as belonging to group III (Van Veen, 1973) may have been *Herpetosiphon* (strain Rz in Van Veen's Fig. 12, which shows the typical empty sleeves at the ends of the filaments). Interestingly, those bacteria were practically always present in activated sludge. The role of *Herpetosiphon* in sewage plants is unknown. However, if the filaments observed by Van Veen (1973) were indeed *Herpetosiphon*, it may represent one of the many biological agents for the "bulking" problems in sewage plants (for a review, see Eikelboom [1983] or Jenkins et al. [2003]). On the other hand, recently Björnsson et al. (2002) and later Lee et al. (manuscript in preparation) speculated that filaments belonging to the chloroflexi and, thus among others, *Herpetosiphon*, may be one of the crucial agents for the important backbone structure of activated sludge flocs, thus suggesting a positive role for at least some chloroflexi filaments in sewage plants.

One species, *H. geysericola* (ATCC 23076^T), has been described from the surroundings of a hot spring (Lewin, 1969a; Lewin, 1970). It is represented by just one strain, which in addition appears to be thermotolerant rather than thermophilic (the literature is completely mute about that important point; but the American Type Culture Collection [ATCC] catalog lists a growth temperature of 30°C for the strain). The environment from which *H. geysericola* was isolated is of interest insofar as this is the typical habitat of the related thermophilic phototroph *Chloroflexus*. In a study in a Yellowstone hot spring (Yellowstone National Park, United States), it was shown that the bacterial mat contained two other types of filamentous bacteria besides *Chloroflexus* (Tayne et al., 1987). Unfortunately, the antiserum used to identify *Chloroflexus* was not tested for crossreactions to *Herpetosiphon*. It is thus still unknown whether *Herpetosiphon* may be more common in such environments than has so far been assumed. Even though several molecular surveys on the microbial population in different hot springs and microbial mats have not retrieved any *Herpetosiphon*-related 16S rRNA gene sequences (e.g., Pierson et al., 1994; Hugenholtz et al., 1998b; Boomer et al., 2002; Nübel et al., 2002), this is still not a final proof for their nonexistence in these systems in particular since many of these studies used molecular markers specific only for phototrophic members of chloroflexi (Pierson et al., 1994; Boomer et al., 2002; Nübel et al., 2002). Lee et al. (manuscript in preparation) showed that although it was possible to isolate *Herpetosiphon* from activated sludge as well as observe it *in situ* by microscopy using *Herpetosiphon*-specific oligonucleotide probes, no *Herpetosiphon* affiliated clones could be retrieved from a 16S rRNA clone library based on general *Bacteria* polymerase chain reaction (PCR) primers, although 10% of the obtained clones were indeed affiliated to other as yet not cultivatable members among the chloroflexi. This suggests that *Herpetosiphon* may not be so easily retrieved from the environment in 16S rRNA clone library surveys on the basis of general PCR primers.

While *Herpetosiphon* obviously may be a common inhabitant of freshwater, it is equally at home in nonaquatic environments. One of us has isolated (as a byproduct of myxobacteria isolation) in the course of 20 years more than 400 *Herpetosiphon*-like strains from soil samples, dung pellets, rotting wood, and similar materials collected all over the world in various climate zones, including decidedly hostile, dry, and hot environments, like semi-deserts in Tunisia and Arizona, steppe habitats in Mediterranean countries, the Canary Islands, and gypsum hills on Cyprus (H. Reichenbach, unpublished observations). Twenty-eight of these isolates have been further examined. Ten of these isolates were related to *H. aurantiacus* (16S rRNA gene similarity >97%), whereas the rest most likely represent novel genera among chloroflexi (Lee et al. (manuscript in preparation)). It seems that the diversity of *Herpetosiphon* is larger in soil than in aquatic environments, since all isolates obtained so far from freshwater environments or sewage plants (with the exception of some iso-

lates of Senghas and Lingens [1985], which are unfortunately no longer available for further comparison) are closely related to *H. aurantiacus*, whereas some of the soil isolates represent most likely novel genera (Lee et al. (manuscript in preparation)).

Isolation

Herpetosiphon may be isolated from any of the sources mentioned in the section Habitats in this Chapter. The terrestrial strains usually survive desiccation so that dry samples can also be used. One of us was able to obtain *Herpetosiphon* from rotting wood after eight years storage, from filter-paper preserves of contaminated myxobacteria after six years, and from soil after two years of storage in the dry state at room temperature (H. Reichenbach, unpublished observations). It has been noted that strains from sewage plants may also be extremely resistant to desiccation (Trick and Lingens, 1984).

No specific enrichment techniques are known. The strains on which the definition of the genus is based were isolated by making a single streak from the slimy coat of *Chara* on a plate with 0.3% peptonized milk (Difco) and 1.5% agar. The culture was incubated at room temperature. Evidently, this relatively rich medium can be used only if the sample contains few other microorganisms (Holt and Lewin, 1968). Therefore, for a more successful isolation, use is made of the ability of the organism to glide away from the inoculum and to produce a typical swarm pattern. To elicit gliding and to suppress excessive growth of contaminants, media very low in organic constituents are recommended. The simplest medium is plain water agar, to which cycloheximide may be added to prevent the development of fungi:

WAT Agar

$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

Dissolve the ingredients in distilled water and adjust the pH to 7.2 with KOH. The pH adjustment is much easier if HEPES (20 mM) is added as a buffer. For crude cultures, use WCX agar, which is WAT agar plus a filter-sterilized stock solution of cycloheximide (25 µg/ml of medium).

Several small samples of soil or other sources of inoculum (size of a lentil) are placed on the surface of the dry plate, a few cm from each other, and the culture is incubated at 30°C. After 2–20 days, the typical swarm colonies with long flares and coils of entangled filaments at the edge may be observed (Fig. 3). The very delicate pattern can only be seen if an oblique light beam produced by a tiltable mirror is applied from below. We have had success with WAT agar plates with three thin, parallel streaks of living *Escherichia coli*, each of which is inoculated at one end. *Herpetosiphon* grows in a spreading fashion within the streaks, usually without lysing the *E. coli* cells, and often only appears along the edges of the streaks in the form of long flame-like structures or a loose pattern of separate, coiling strands of filaments. Sometimes, large and more or less dense swarm sheets are produced that spread over much of the plate. An especially high yield of *Herpetosiphon* can sometimes be obtained if such cultures are incubated at 38°C.

For the isolation of planktonic *Herpetosiphon* in freshwater, between 0.5 and 1 liter of lake or river water is passed through a sterile membrane filter (pore size, 0.4 µm). The filter is then cut into pieces, and the segments are placed on a low-nutrient agar medium. In the original study, rabbit dung agar was used but any other lean medium would certainly also do.

Rabbit Dung Agar (Gräf and Perschmann, 1970)

Boil dry dung pellets from wild rabbits (20 g) in 1 liter of distilled water for 20 min. Add 15 g of agar to 1 liter of filtrate. Adjust the pH to 7.2.

The cultures are incubated at 33°C. After about 6 days, swarm colonies begin to spread from the edges of the filter.

Different procedures have been applied for the isolation of *Herpetosiphon* from activated sludge. One procedure consists of streaking a drop of the sludge sample on agar plates or embedding it in agar itself (Trick and Lingens, 1984; Senghas and Lingens, 1985). Another procedure is based on micromanipulation of filaments in the activated sludge (Bradford et al., 1996). Different media have been used, ranging from complex but rather nutrient-poor media, such as BG-11 agar (originally designed for the isolation of cyanobacteria), I agar (Trick and Lingens, 1984; Senghas and Lingens, 1985) or R2A (Bradford et al., 1996) to sludge-based media (Senghas and Lingens, 1985; Lee et al. (manuscript in preparation)). As sewage organisms are notoriously fastidious and adapted to very low nutrient levels, we have listed below all the media used; whether they are really required or could be replaced by simpler recipes has not been determined. The cultures are incubated at 25°C and examined with a phase contrast microscope over several weeks (Salcher et al., 1982; Bradford et al., 1996). Pure cultures can be obtained by transferring filaments from the advancing swarm edge to the same media again, or, as soon as the culture is sufficiently pure, to richer media (see the section Cultivation in this Chapter). We often have good results with transfers to streaks of autoclaved *E. coli* on water agar, although some *Herpetosiphon* strains do

not grow on autoclaved bacteria (see the section Cultivation in this Chapter). As the organism has to be carefully removed from the contaminated plate, transfers are made best by cutting out a piece of the swarm edge on a small agar block using a drawn-out glass rod or, more conveniently, a fine steel injection needle (e.g., on a 1-ml disposable syringe). The procedure is repeated until the strain is pure. Two properties of *Herpetosiphon* may substantially speed up purification: We have found that all *Herpetosiphon* strains tested so far grew at 38°C and are resistant to 250 mg of kanamycin sulfate per liter.

BG-11 Agar (Stanier et al., 1971)

$NaNO_3$	1.5 g
K_2HPO_4	0.04 g
$MgSO_4 \cdot 7H_2O$	0.075 g
$CaCl_2 \cdot 2H_2O$	0.036 g
Citric acid	0.006 g
Ferric ammonium citrate	0.006 g
EDTA(Na_2-Mg salt)	0.001 g
Na_2CO_3	0.02 g
Trace element solution A5	1 ml
Agar	15 g
Distilled water	1 liter

The trace element stock solution A5 contains per liter: H_3BO_3, 2.8 g; $MnCl_2 \cdot 4H_2O$, 1.8 g; $ZnSO_4 \cdot 7H_2O$, 0.2 g; $Na_2MoO_4 \cdot 2H_2O$, 0.4 g; $CuSO_4 \cdot 5H_2O$, 0.08 g; and $Co(NO_3)_2 \cdot 6H_2O$, 0.05 g.

I Agar (modified from Van Veen, 1973; Salcher et al., 1982)

Glucose	0.15 g
$(NH_4)_2SO_4$	0.5 g
$Ca(NO_3)_2$	0.01 g
K_2HPO_4	0.05 g
$MgSO_4 \cdot 7H_2O$	0.05 g
KCl	0.05 g
$CaCO_3$	0.1 g
Agar	15 g
Distilled water	1 liter

After autoclaving, add 10 ml of a filter-sterilized vitamin solution. The vitamin solution contains per liter: Ca pantothenate, 10 mg; nicotinic acid, 10 mg; biotin, 0.5 mg; cyanocobalamin, 0.5 mg; folic acid, 0.5 mg; pyridoxine·HCl, 10 mg; *p*-aminobenzoic acid, 10 mg; thiamine pyrophosphate, 10 mg; thiamine, 10 mg; inositol, 10 mg; and riboflavin, 10 mg.

R2A Agar (Reasoner and Geldreich, 1985)

Enzymatic digest of casein	0.25 g
Enzymatic digest of animal tissue	0.25 g
Acid hydrolysate of casein	0.5 g
Yeast extract	0.5 g
Glucose	0.5 g
Soluble starch	0.5 g
$KH_2 PO_4$	0.3 g
$MgSO_4 \cdot 7H_2O$	0.1 g
Sodium pyruvate	0.3 g
Agar	15 g
Distilled water	1 liter

Adjust pH to 7.2.

Sludge-based Media (Fuhs and Chen, 1975)

CH_3COOH-Na	5 g
$(NH_4)_2SO_4$	2 g
$MgSO_4 \cdot 7H_2O$	0.5 g
KH_2PO_4	0.25 g
$CaCl_2 \cdot 2H_2O$	0.2 g
Agar	15 g
Mixed liquor (sewage/sludge)	200 ml
Distilled water	800 ml

Adjust pH to 7.0.

VY/2 Agar

Bakers' yeast (fresh weight)	0.5%
$CaCl_2 \cdot 2H_2O$	0.1%
Cyanocobalamin	0.5 mg/liter
Agar	1.5%

Dissolve ingredients in distilled water and adjust to pH 7.2.

CY Agar

Casitone (Difco)	0.3%
Yeast extract	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
Agar	1.5%

Dissolve ingredients in distilled water and adjust to pH 7.2.

CYCAS Agar

Casitone (Difco)	0.3%
Yeast extract	0.3%
$CaCl_2 \cdot 2H_2O$	0.1%
Cellulose powder	0.1%
Soluble starch	0.1%
Acetate	0.1%
Agar	1.5%

Dissolve ingredients in distilled water and adjust to pH 7.2.

ATCC Medium 810 (Myxo 810 Medium)

Skim milk powder	0.5%
Yeast extract	0.05%
Agar	1.5%

Dissolve ingredients in distilled water. Do not adjust the pH.

EC Medium (Enriched Cytophaga Medium; Pate and Chang, 1979)

Tryptone (Difco)	0.2%
Yeast extract (Difco)	0.05%
Na acetate	0.02%
Agar	1.5%

Dissolve ingredients in distilled water and adjust to pH 7.5.

Escherichia coli Overlay Agar

Suspend the growth of four culture plates of *E. coli* (on any suitable medium) in 100 ml of water agar (WAT agar; see the section Isolation in this Chapter). Autoclave the suspension and pour as a thin layer on top of water agar plates.

Medium 2 (Lewin and Lounsbery, 1969b)

Casamino acids	0.1%
Na glycerophosphate	0.01%
Tris buffer	0.1%

KNO3	0.01%
$CaCl_2 \cdot 2H_2O$	0.01%
$MgSO_4 \cdot 7H_2O$	0.01%
Thiamine	1 mg/liter
Cyanocobalamin	1 mg/liter
Agar	1%
Glucose	0.1%

Dissolve all ingredients except for glucose in distilled water and adjust to pH 7.5. Add separately autoclaved glucose after autoclaving the solution of the other ingredients.

Most of the cultivable strains also grow in liquid media, in shake flasks, and in fermentors. A good medium for many strains is HP74 liquid medium. Other strains grow equally well or better in peptone-containing media, e.g., in CAS liquid medium, R2A liquid medium, or MDl liquid medium.

HP74 Liquid Medium

Na glutamate	1%
Yeast extract (Difco)	0.2%
$MgSO_4 \cdot 7H_2O$	0.2%
Glucose	1%

Autoclave the glucose separately as a 20% stock solution. Add 20 ml per liter of separately autoclaved phosphate buffer (50 mM, pH 6.5) to give 1 mM.

CAS Liquid Medium

Casitone (Difco)	1%
$MgSO_4 \cdot 7H_2O$	0.1%

The pH should be 6.8; do not adjust.

MDl Liquid Medium

Casitone (Difco)	0.3%
$CaCl_2 \cdot 2H_2O$	0.07%
$MgSO_4 \cdot 7H_2O$	0.2%
Cyanocobalamin	0.5 mg/liter

Add trace element solution (see below) after autoclaving the MD1 medium. The pH should be 6.8; do not adjust. If Casitone (Difco) is replaced by other enzymatically digested casein peptones, adjust pH to about 7.

Trace Element Solution

$MnCl_2 \cdot 4H_2O$	100 mg
$CoCl_2$	20 mg
$CuSO_4$	10 mg
$Na_2MoO_4 \cdot 2H_2O$	10 mg
$ZnCl_2$	20 mg
LiCl	5 mg
$SnCl_2 \cdot 2H_2O$	5 mg
H_3BO_3	10 mg
KBr	20 mg
KI	20 mg
EDTA, Na-Fe_3^+ salt (trihydrate)	8 g
Water	1 liter

Sterilize by filtration and add 1 ml per liter of medium. The filter-sterilized solution is stable for months at room temperature because of its high EDTA content.

Cultivation

In general, *Herpetosiphon* prefers low nutrient levels. Thus, one of our strains, Hp g175, produced good growth over six transfers on plain water agar, obviously living off minute quantities of contaminating material in the agar but without visibly attacking the agar itself. Rich media, like nutrient agar or nutrient broth, are often not suitable at all. About one out of three strains isolated from soil on streaks of living *E. coli* can be cultivated without difficulty on complex media, such as VY/2 agar, CY agar, CYCAS agar, milk-based agar media (e.g., ATCC medium 810) or R2A agar (see the section Isolation in this Chapter). Isolates obtained from freshwater or sewage systems may also be cultivated on these media and in addition on EC and I agar media (see section Isolation in this Chapter). *Herpetosiphon geysericola* (ATCC 230767^T) was cultivated on medium 2 (Lewin, 1970). This medium was used as a standard medium for the cultivation of many different organisms; thus, not every component may be required by *H. geysericola* (e.g., thiamine). *Herpetosiphon geysericola* however also grows on all of the media mentioned above.

Many strains produce heavy growth and often spread within a few days over the entire plate. Some strains tend to penetrate the agar (Fig. 3). The yeast in VY/2 agar may or may not be lysed. However, a significant number of the soil isolates obtained from water agar media with streaks of living *E. coli* cannot be further cultivated on other media. Only a few of them respond favorably to a reduction of the nutrient concentration and can be grown on media like VY/5 agar (such as VY/2 agar but with yeast concentration reduced to 0.2%). Others grow more or less poorly on *E. coli* overlay agar, but most of them can barely be kept alive on streaks of autoclaved *E. coli* on water agar. Some of these strains survive only on living bacteria, presumably because they require some labile growth factor. The alternative explanation (i.e., *E. coli* removes some inhibiting component) seems less likely because the filaments often creep far away from the *E. coli* streak. All our efforts to identify growth factors have been unsuccessful, although many possibilities have been tested (different vitamins, sugars, and amino acids; plant oil; chitin, catalase, and cell fractions of *E. coli* and of cultivable *Herpetosiphon* strains; anaerobic and microaerophilic conditions; different agar concentrations, temperatures, and pH values; illumination). Recently, we found that four of these fastidious strains, Hp g122 (DSM 15874); Hp g124 (DSM 15875); Hp g150 (DSM 15876), and Hp g174 (DSM 15877) were only distantly related to the type strain *Herpetosiphon aurantiacus* ATCC

23779^T (ca. 80% 16S rRNA gene sequence similarity), which strongly indicates that they represent a new genus among chloroflexi (Lee et al. (manuscript in preparation)).

In agitated cultures the organisms may grow as homogeneous suspensions, but often the filaments stick together to form flakes or tight spherules. One of our strains, Hp a2 (DSM 589), a member of the *H. aurantiacus* species group, forms flakes when inoculated into HP74 liquid medium; the cultures become completely uniform after a few days, but the organism forms flakes again upon transfer into fresh medium. Growth is not particularly fast: The doubling time is in the range of 15–20 h, and the cultures do not enter the stationary phase before 4–6 days of cultivation (30°C, HP74 liquid medium, shake flasks). Wet-weight yields are in the order of 1–3 g/liter in shake flasks and 2–4.5 g/liter in fermentors (HP74 liquid medium). The dry weight amounts to roughly 20% of the wet cell mass. Trick and Lingens (1984) and Senghas and Lingens (1985) obtained similar values (doubling time 20–25 h; cell yield after 5–6 days, 2–3.5 g wet weight per liter and 0.5–1 g dry weight per liter) with their sewage isolates when cultivating them on EC medium at 25°C, their temperature optimum.

All known strains are strictly aerobic. The temperature range differs with different strains. In general, the freshwater strains seem to prefer lower temperatures, around 25°C, while the soil and some freshwater strains grow very well at 30°C and above. All *Herpetosiphon* and *Herpetosiphon*-like soil strains tested by us grew at 38°C, and some *Herpetosiphon*-like strains still grew at 45°C (e.g., Hp g207, DSM 15737; Lee et al. (manuscript in preparation)). The sewage strains showed a temperature minimum at 15°C, a maximum at 37°C, and an optimum at 25°C (Trick and Senghas, 1984; Senghas and Lingens, 1985; Lee et al. (manuscript in preparation)). *Herpetosiphon geysericola* comes from the vicinity of a hot spring but can be cultivated at 30°C (see the section Habitats in this Chapter). The optimal pH range is 7–7.5, although pH values of 8–9 seem occasionally to be tolerated.

Preservation

Most *Herpetosiphon* strains survive on agar media at 30°C or room temperature for up to 3 months. Slant cultures stored at 4°C have been successfully subcultured after 14 months. However, some *Herpetosiphon*-like strains, such as Hp g6 (DSM 15710), Hp g16 (DSM 15736) and Hp g207 (DSM 15737), which represent more likely novel genera of chloroflexi rather than *Herpetosiphon*, are more sensitive to long-term storage at room temperature or at 4°C. These, as well as stock cultures, should be transferred every 3–4 weeks (Lee et al. (manuscript in preparation)).

Herpetosiphon strains may be preserved by any of the standard procedures. A convenient and reliable method is storage at –80°C. The bacteria are suspended in 1 ml of CAS or HP74 liquid medium and simply put into the deep freeze. Thawing should be fast, best accomplished by immersing the tube in cold water, and transfers to a suitable growth medium have to be made immediately after thawing. We have been able to reactivate such preserved cultures with no problems after 8 years of storage, the longest period tested. Alternatively, the bacteria can be frozen in liquid nitrogen. In one study, the filaments were suspended in growth medium (medium 2 as above, without agar), supplemented with 10% of either glycerol or dimethyl sulfoxide (Sanfilippo and Lewin, 1970). All strains survived freezing and thawing with both additives. Only the glycerol preserves were tested again after 1 year, and all strains were still viable. When stored in growth medium without additives at –22°C, three out of four strains survived for 21 weeks (the longest period tested) and one for 6 weeks. Strains dried in skim milk could always be reactivated after storage for up to 12 years (unpublished data). We do not freeze-dry the organism itself but only the skim milk: A few drops of a thick suspension of *Herpetosiphon* filaments, taken from a young plate culture, are added to a plug of freeze-dried skim milk in an ampoule. The plug absorbs the liquid without liquefying itself. The ampoule is then dried at room temperature in a desiccator on a vacuum pump for several hours. After filling the desiccator with nitrogen gas, the ampoules are sealed.

Herpetosiphon strains are currently available from six different cultures collections: ATCC (the American Type Culture Collection, Rockville, USA), ACM (the Microbial Culture Collection of the University of Queensland, Brisbane, Australia), CCUG (Culture Collection University of Göteborg, Sweden), DSMZ (Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig, Germany), NCIMB (the National Collection of Industrial Food and Marine Bacteria, University of Aberdeen, Scotland), and TISTR (the Culture Collection of Bangkok, MIRCEN, Thailand). The largest collection is deposited at DSMZ, encompassing the "Hans Reichenbach Collection" of 460 *Herpetosiphon* and *Herpetosiphon*-like strains; however, only around 30 of these strains have been further characterized (Lee et al. (manuscript in preparation)).

Morphological Characteristics

The filamentous morphology and the "sleeves" of *Herpetosiphon* are rather distinct so that the bacterium can readily be recognized under the microscope. However, some of the other gliding filamentous genera among chloroflexi, e.g., *Chloroflexus*, *Heliothrix* and *Roseiflexus*, share certain morphological features with *Herpetosiphon* (Garrity and Holt, 2001; Lee et al. (manuscript in preparation)). Fortunately, since most of these latter mentioned filaments are mainly thermophilic and facultative phototrophic, a certain distinction may still be possible by knowing the habitat, the physiology or the pigmentation of the organism. Nevertheless, for a final identification, a molecular method, such as 16S rRNA gene analysis or fluorescence in situ hybridization (FISH) using oligonucleotide probes is strongly recommended (for a review of oligonucleotide probes used for detecting different members of *chloroflexi*, see Björnsson et al. [2002] and Lee et al. (manuscript in preparation)).

General Morphology

The morphology of the two acknowledged species (*aurantiacus* and *geysericola*) of *Herpetosiphon* is rather similar. *Herpetosiphon* forms extremely long, unbranched, multicellular filaments of uniform diameter (Fig. 1). The filaments often measure 100 μm to more than 1200 μm in length. The cells in a filament cohere tenaciously so that the filament does not break easily. Unconstrained filaments in a liquid medium appear straight and stiff, but in fact they are extremely flexible and can sharply bend back and twist around themselves in a rope-like fashion or intertwine into plait-like masses (Fig. 1). The width of the filaments varies with different strains (0.5–1.7 μm), mostly between 0.7 μm and 1.2 μm. There is also considerable variation within the same culture (Fig. 2). For instance, we have measured filament diameters between 0.7 μm and 1.6 μm in an 11-day-old culture of the type strain of *H. aurantiacus* on CY agar. In older cultures or under unfavorable conditions, the filaments often swell substantially and may become completely irregular in outline. Furthermore, the filaments are often locally inflated and form large, spherical structures, or "bulbs," with a diameter of 2.5–3.5 μm (Reichenbach and Golecki, 1975; Trick and Lingens, 1984; Fig. 4). Under the electron microscope a membrane body at the end of a septum-like stalk can always

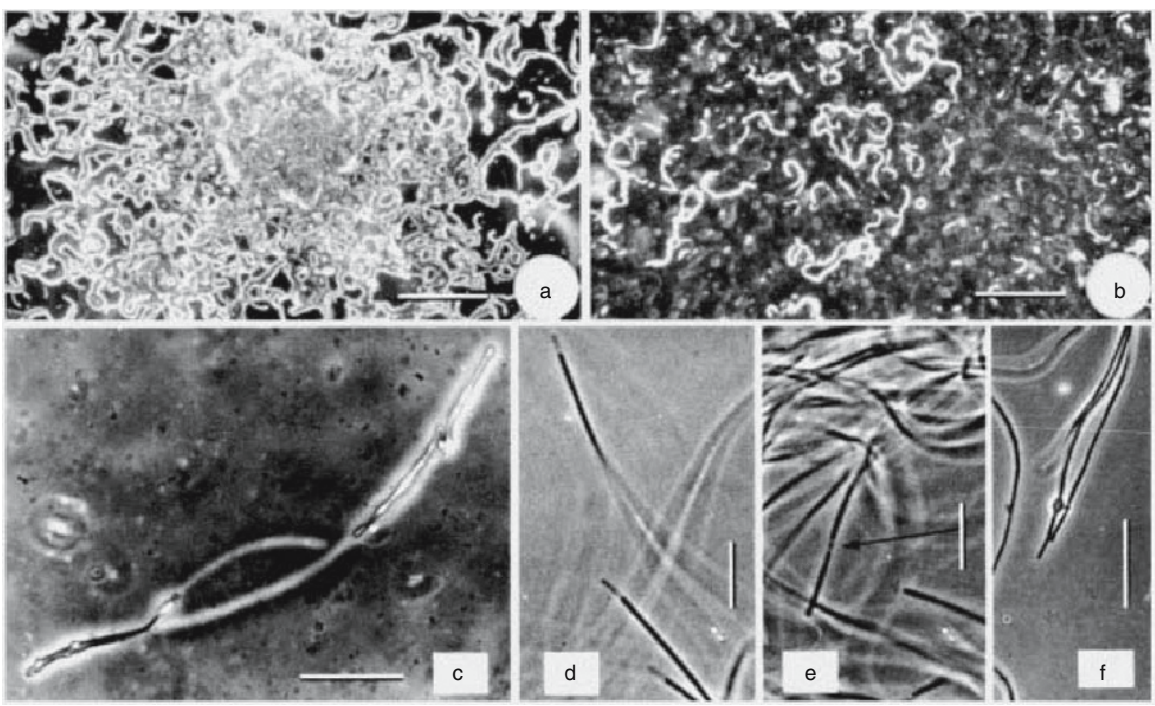

Fig. 4. Special structures of *Herpetosiphon aurantiacus*. (a to c) Desiccation-resistant filaments in a chamber culture. a) and b) Survey pictures; dark field; Bars = 200 μm: a) 9 days old, with the filaments still essentially intact; b) 32 days old, with only remnants of the filaments left. Bar = 200 μm. c) At high magnification, the remaining segments of the old filaments appear irregular in outline and optically refractile; there are conspicuous slime tracks. Bar = 30 μm. d) The empty sleeves, which are visible here at the ends of many filaments, are easy to recognize, even at a relatively low magnification, and thus help to quickly identify an isolate as a *Herpetosiphon*. Bar = 10 μm. e) A necridium (arrow). Bar = 10 μm. f) Bulbs. Bar = 20 μm. Zeiss Standard Microscope (a to c). Zeiss Axiomat (d to f); (c to f) in phase contrast.

be seen within the bulb. Those bulbs seem to be a degeneration phenomenon, and outgrowth or further development has never been observed from them. In old cultures, the filaments also tend to become shorter, especially on peptone-containing media, simply because more and more cells die and the filaments snap at such sites. The fragments can be as short as one cell. In old cultures, particularly on agar, short, optically refractile, irregular filaments are often seen (Fig. 4). As those are the only structures left in old, drying, but still viable cultures, they appear to be desiccation-resistant resting forms. However, their germination has not been directly observed so far.

The filaments consist of cylindrical cells that have the same diameter as the filament, and they are so closely attached to one another that only exceptionally shallow notches can be seen at the surface. Under a microscope with a high resolution using phase or interference contrast, the cells can sometimes be seen in living filaments (Fig. 2). The septa become more conspicuous in older cultures, particularly when the organism is grown on a peptone-rich medium, like CY agar. In such filaments the intracellular membrane bodies (see below) can often also be recognized (Fig. 2). The cells become clearly distinguishable if the filaments are first dried to the slide and then stained, e.g., with Loeffler's methylene blue, crystal violet, or alcoholic fuchsin (rosaniline). The lengths of the cells vary even within one filament, which suggests that the cells do not divide synchronously. The cell length may also vary with the culture medium, the culture age, and the strain. With many strains, cell lengths between 1.5 μm and 4.5 μm have been measured. The type strain of the genus appears to have especially long cells, measuring between 3 μm and 7 μm and sometimes 10 μm.

In wet mounts, *Herpetosiphon* filaments often can be seen to bend slowly and sometimes to slowly oscillate back and forth. In contact with a suitable interface, i.e., one to which the organism can stick, like a glass or an agar surface, the filaments glide slowly and, during this movement, deposit characteristic slime tracks (Fig. 1). Gliding filaments often bend laterally to form hairpin-like loops (Fig. 1). In liquid media, the filaments apparently move along themselves. They may coil around themselves or one another and produce all kinds of loops and knots (Figs. 1 and 2).

Sleeves or Sheathes

A most characteristic feature of *Herpetosiphon* is the presence at the ends of many filaments of transparent sections, which we call sleeves (Fig. 2). The sleeves have the same diameter as the filaments (1.4–5.5 μm) and are usually 1.5–3.5 μm long (the measurements are those for strain Hp a2, DSM 589, member of the *H. aurantiacus* group). The role of those sleeves is still controversial. Some investigators have regarded them as an indication of a sheath (Holt and Lewin, 1968; Skerman et al., 1977) or at least of a microsheath (Trick and Lingens, 1984). We prefer a different explanation (Reichenbach and Golecki, 1975): The filaments appear to multiply by breaking at the sites of necridia, i.e., dead cells along the filament. Such necridia can occasionally be observed in young cultures, and their number increases substantially with the age of the culture (Fig. 2). Their length (1.5–3.7 μm) is in the size range of ordinary cells. Trichome division by breakage at necridial cells is well known from other bacteria and has been described, e.g., for *Oscillatoria* (Lamont, 1969) and *Beggiatoa* (Strohl and Larkin, 1978). When a filament snaps, the empty cell wall cylinder of the necridium remains attached to the end of one daughter filament and gives rise to a sleeve. In strain Hp a2 (DSM 589), the outer wall seems to rupture at one of the ends of the necridium (near the cross-wall rather than across its middle), for the shortest and the longest sleeves correspond exactly to the lengths of the shortest and the longest cells. This would also explain why only some of the filaments' ends bear a sleeve, although it seems that the sleeves may also be shed; often empty sleeves can be seen lying in between the filaments. With the type strain of *H. aurantiacus*, on the other hand, the sleeves are exceptionally short, with a size distribution corresponding approximately to one-half that of the cell length, so that here the necridia seem to break preferentially in their center.

There are at least six more arguments against the presence of a sheath: 1) The filament glides as a whole, with its empty end-pieces in position, which would seem unlikely if the cells were enclosed in a sheath. 2) There is no movement of cells within the filament, e.g., at the site of a necridium, nor a release of cells at the ends of the filament. This was observed by Holt and Lewin (1968) and also by the present authors. But the literature is not in complete agreement on these points. Movement of a filament within its sheath has been described and verified by time-lapse photography (Skerman et al., 1977); however, it is our impression that what was described as a sheath may really have been a slime trail. Also, it was stated that single, gliding cells were released from the filaments (Brauss et al., 1969), but in this case what was seen may simply have been short fragments that broke off the ends of the filament. 3) If the sleeve were a piece of a sheath, it would be difficult to understand why, as a rule, it does not exceed the length

of a cell. 4) If a sheath were present, one could expect an occasional false branching of the filaments. 5) When a whole filament dies and decays, it falls apart into cell-sized pieces (Fig. 2). Obviously, there is no sheath to hold them together. 6) We have never been able to demonstrate anything resembling a real sheath under the electron microscope, with specimens prepared by freeze-etching, negative contrast, metal shadowing, or thin-sectioning after several different fixation protocols (Reichenbach and Golecki, 1975; see also Gräf and Perschmann, 1970). This is also true for the type strain (Fig. 5). The thin, tube-like structure composed of fibrils, which has been described by several investigators and has been interpreted as a microsheath (Skerman et al., 1977; Senghas and Lingens, 1985; Holt, 1989), probably has a different explanation.

How can these differences of opinion about the existence of a sheath in *Herpetosiphon* be reconciled? Differences among strains can probably be ruled out, for we included the type strain in our studies and found no significant divergence from strain Hp a2 (DSM 589). A sheath is a morphologically distinct structure, a hollow cylinder with a discrete outer boundary, excreted by the cells and not covalently bound to their surface. Under the light microscope, a sheath should be clearly recognizable, e.g., after negative staining with nigrosin or India ink. Under the electron microscope, a sheath may be difficult to visualize in thin sections because of poor contrast with the usual techniques, but with negative contrast or metal shadowing, it should be seen. Like all gliding bacteria, *Herpetosiphon* excretes slime, and slime fibrils can always be observed in the neighborhood of the trichomes, but this material is more or less diffuse. Under certain conditions this slime may condense, perhaps as a consequence of dehydration during fixation, and then it may appear as a dense tube. This is probably what has been taken as evidence for a sheath by various investigators (Skerman et al., 1977; Senghas and Lingens, 1985; Holt, 1989). Typically in all those cases cited, a wide gap opens between the filament and the thin, dense tube. Senghas and Lingens (1985) made efforts to demonstrate a sheath in their *Herpetosiphon*-like strains by first lysing the cells in the filament with lysozyme and then staining the remains with crystal violet. In that case, indeed, a long thin tube-like structure could be produced. However, this is still not an unequivocal proof of a sheath, for the technique requires as a prerequisite for reliable results that the organism has a normal bacterial cell wall.

Electron microscopy of thin sections of Hp a2 (DSM 589) reveals, however, that *Herpetosiphon* has an unusual cell wall structure (Reichenbach and Golecki, 1975). Outside the cytoplasmic membrane there is a well-defined peptidoglycan layer, 4–6 nm thick, but no outer membrane can be resolved. In fact, that membrane seems to be absent. Rather there is a thin additional layer, 21–25 nm thick, granular in thin sections, fibrillar in freeze-etch preparations, on top of the peptidoglycan. This layer follows the peptidoglycan into the shallow notches between adjoining cells but not into the cross-septa where only the peptidoglycan layer can be distinguished. We have never found any other defined layer outside the fibrillar layer, and in particular, have found no layer running smoothly across the cell junctions, as would be expected for a sheath. This peculiar wall structure is corroborated by chemical analyses of the cell envelope (see below) and may be directly connected with the sheath problem. Apparently, the additional layer is considerably more resistant to decomposition than the usual lipopolysaccharide-containing outer membrane, and it may give the peptidoglycan, to which it seems to be covalently bound, a higher stability. Within the cells there are extensive intracellular membrane systems, some of which originate at the cross-septa, others from the cytoplasmic membrane along the longitudinal walls. They become especially conspicuous when the negative-contrast technique is applied. As mentioned above, under certain conditions they can even be seen in the light microscope. Recent studies on the cell envelopes of Hp a2 (DSM 589) have revealed further interesting features, showing that ion-permeable channels, formed by a 45-k-Da protein, were present in the cell wall. This suggests that this strain has a permeability barrier on its surface similar to the outer membrane of Gram-negative bacteria, a feature which it shares with certain other Gram positive organisms, such as *Mycobacterium chelonae*, *Corynebacterium glutamicum*, *Streptomyces griseus* and *Micromonospora purpurea* (Harwardt et al., 2004).

Colony Morphology

The colonies, or swarms, usually spread quickly over agar surfaces and may completely cover a culture plate within a few days. *Herpetosiphon*-like strains, such as Hp g16 (DSM 15736) and Hp g207 (DSM 15737) grow more slowly, and may need up to 2–3 weeks to produce a significant spreading growth, although the plate is rarely completely covered (Lee et al. (manuscript in preparation)). On poor media, the migrating filaments remain more or less separate and appear in the form of characteristic curls and whirls (Fig. 3). Such colonies may become extremely delicate and are barely recognizable even if oblique illumination is applied. On media that allow good growth, dense and tough swarm sheets arise, with

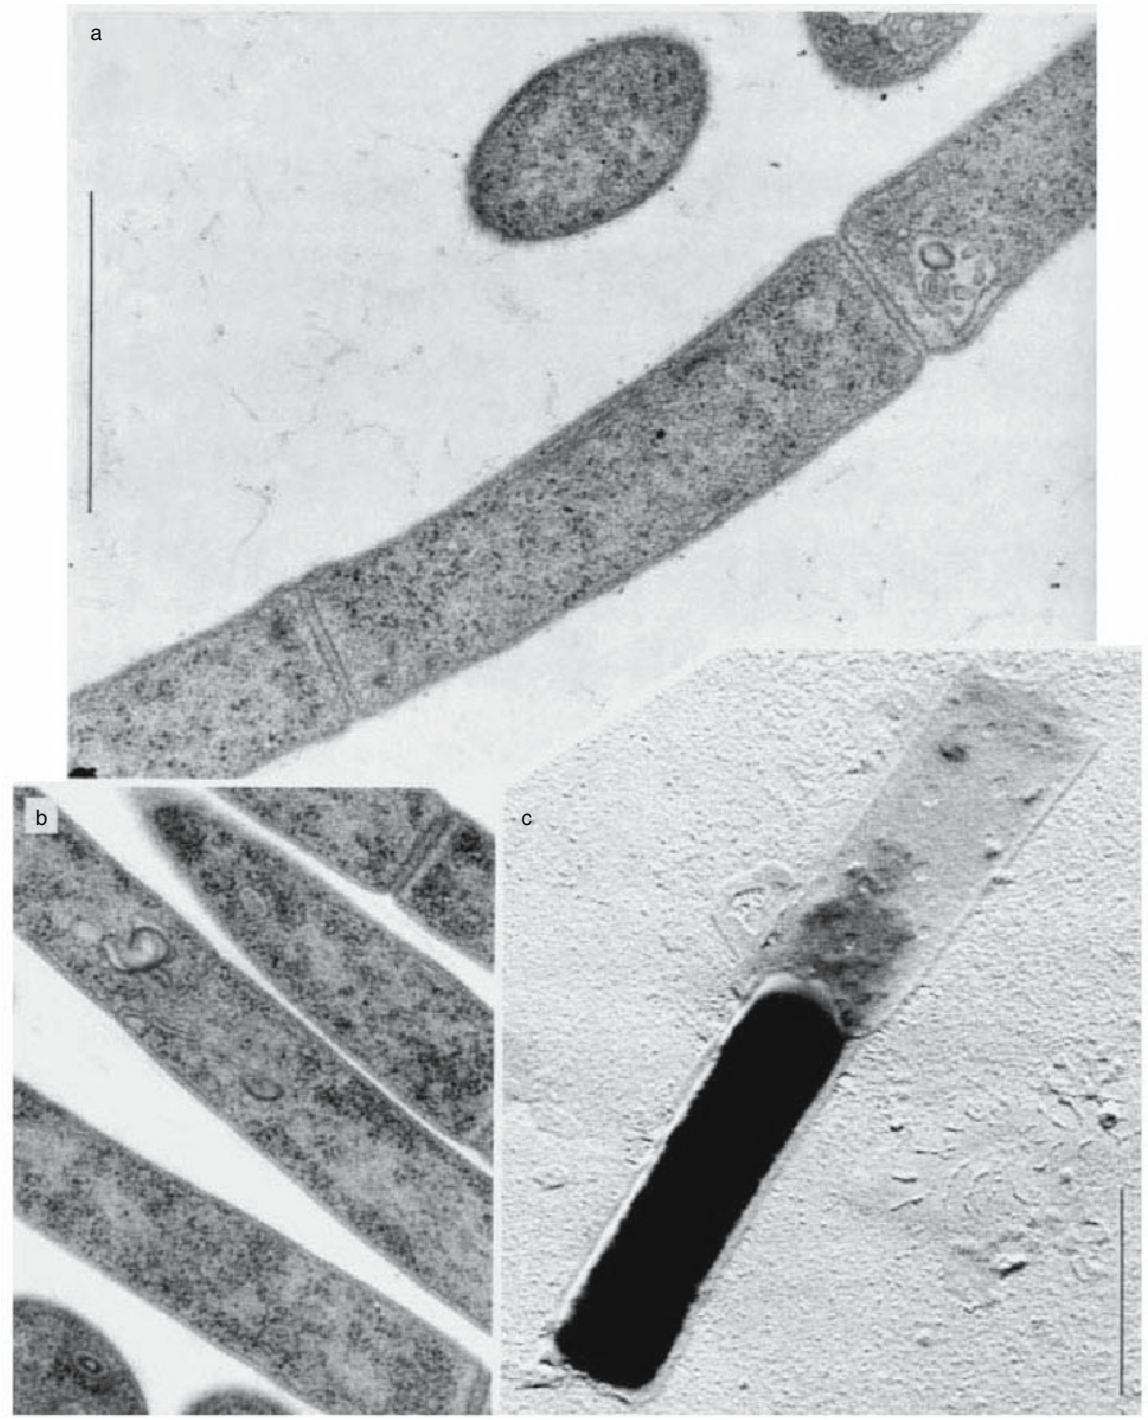

Fig. 5. Electron micrographs of the type strain of *Herpetosiphon aurantiacus*. a) and b) Ultrathin sections; the peptidoglycan layer can be clearly distinguished, but while there is plenty of extracellular slime material, no structure resembling a sheath can be located on the surface; also, the close juxtaposition of the filaments in b) speaks against a sheath. Within the cells, membrane bodies can be seen. c) Shadowed preparation; an end piece with an empty cell-wall cylinder, or sleeve, is visible; again there is no sign of a sheath. Zeiss EM 10B electron microscope. Bars = 1 μm; the magnification is identical for a) and b). (Courtesy of H. J. Hirsch.)

a rough, dry, felt-like surface. Sometimes the swarm surface is completely uniform, with an even, curly, or felt texture. But often elegant networks, massive concentric ridges, a pattern of large and small holes, or large, massive knobs are produced (Fig. 3). These last-mentioned knobs are particularly impressive and have been observed with many different isolates (Holt and Lewin, 1968; Brauss et al., 1969; Reichenbach and Golecki, 1975; Trick and Lingens, 1984; Lee et al. (manuscript in preparation)). Their diameter varies between 200 μm and 2000 μm, and as was noticed repeatedly, they strikingly resemble myxobacterial fruiting bodies, especially since they often are bright red or orange. But the filaments inside those knobs seem not to differ from those in other parts of the swarm, either morphologically or physiologically. Also, the ridges and knobs are not permanent structures but shift continuously from place to place and may even dissolve completely again. This can be seen, e.g., in the movie mentioned earlier (Reichenbach et al., 1980). All those structures seem to originate from chance interactions of the long, migrating filaments that locally pull together, tangle, and pile up. The dynamics of the excreted, drying, and contracting slime may also be involved. Even more spectacular are long, sometimes branched, finger-like protuberances rising up to 5 mm above the swarm surface (Fig. 3). They consist of interwoven filaments and seem to be produced only by certain strains.

Phenotypical and Molecular Characterization

Cell Wall Composition Chemically, the cell wall of *Herpetosiphon aurantiacus* (represented by the type strain ATCC 23779^T and the strain Hp a2 DSM 589) consists of a peptidoglycan that contains L-ornithine in place of diaminopimelic acid, a rather unusual character for a Gram-negative bacterium (Jürgens et al., 1989). A heteropolysaccharide composed of heptose, hexoses, pentoses and *O*-methyl sugars appears to be covalently bound to the peptidoglycan via muramic acid-6-phosphate. This heteropolysaccharide is probably the material seen in electron micrographs as the granular-fibrillar layer on the surface of the longitudinal walls. The peptidoglycan-polysaccharide complex amounts to 20% of the cell dry weight, with a polysaccharide portion of 70%. No evidence for a lipopolysaccharide was found, which would explain the absence of an outer membrane in thin sections; nor was there evidence for the presence of additional sheath material. Unfortunately, the cell wall composition has only been determined for two representants of the *aurantiacus* species group. Nevertheless, the cell wall of *H. aurantiacus* closely resembles that of *Chloroflexus* in both its electron microscopic appearance (Pierson and Castenholz, 1974) and its chemical composition (Jürgens et al., 1987; Meissner et al., 1988). Incidently, the filaments of *Chloroflexus* also often end with a sleeve, which for this organism also has been taken to suggest the existence of a sheath (Pierson and Castenholz, 1974). Hydrolysates of extracellular slime yielded arabinose and glucosamine as the main constituents (for sewage strains; Trick and Lingens, 1984).

Respiratory Quinones The respiratory quinones have only been determined for two strains from the *H. aurantiacus* species group (the type strain *H. aurantiacus* ATCC 23779^T and Hp a2 DSM 589), and for a *Herpetosiphon*-like activated sludge isolate, Wie2, whose genetic relatedness to *Herpetosiphon* (see the sec-tion Taxonomy in this Chapter) is unknown. Mainly menaquinones were detected in these three strains (Kleinig and Reichenbach, 1977; Reichenbach et al., 1978; Senghas and Lingens, 1985). The main menaquinone in *H. aurantiacus* and Hp a2 (DSM 589) is MK-6, and 10% of the respiratory quinone content is MK-7 (Kleinig and Reichenbach, 1977). The respiratory quinones have only been investigated in a few of the culturable representants among chloroflexi. The main common factor seems to be that they contain menaquinones. *Roseiflexus* contains mainly menaquinone-11 (Hanada et al., 2002), *Caldilinea* contains mainly menaquinone-10 under aerobic conditions, whereas no quinones were detected in *Anaerolinea* (Sekiguchi et al., 2003).

Fatty Acid Composition The two type strains of *aurantiacus* and *geysericola* contain the same fatty acids (C16:1, C16:0 and C18:1, cyclopropane C17:0, C17:0 and C18:0), whereas *Herpetosiphon*-like strains show some significant differences to the two type strains (Table 1). Branched-chain fatty acids, which are so typical for many other gliding bacteria, are essentially absent. Hydroxy fatty acids are completely lacking. The novel sulfonolipids, or capnoids, discovered in gliding bacteria of the *Cytophaga* group, were not found in *Herpetosiphon* (Godchaux and Leadbetter, 1983). Only a few fatty acid analyses have been performed on other members of chloroflexi, such as *Chloroflexus*, *Roseiflexus*, *Anaerolinea* and *Caldilinea* (see review in Garrity and Holt [2001] and see Hanada et al. [2002] and Sekiguchi et al. [2003]). However, the results obtained so far clearly indicate that C16:0 is the only common fatty acid present in significant amounts in all these strains and that each strain shows significant differences to the other strains in terms of the composition of other fatty acids.

Table 1. Fatty acid composition in the different species groups of *Herpetosiphon*.

Species	No. of strains	Fatty acid composition
H. aurantiacus[a,b]ATCC 23779[T]	12	C16:1,[a,b] C16:0,[a,b] cyclopropane C17:0,[b] C17:0,[b]C18:1,[a,b] C18:0,[a,b]
H. geysericola[b]ATCC 23076[T]	1	Same composition as the *H. aurantiacus* group
Herpetosiphon-like strains		
Sludge strain Wie2[a]	3	C16:0, C16:1, C18:1, C18:0, C19:0, 8-methyl C17:0
"Soil strains"[b]	10	C14:0, C16:1, C16:0, cyclopropane C17:0, C17:0, C18:1, C18:0, C18:2, C19:1, C19:0, *anteiso* C16

Abbreviation: [T], type strain; C14:0, tetradecanoic acid; C16:0, hexadeconic acid; C17:0, heptadecanoic acid; C18:0, octadecaonic acid; C19:0, nonadecanoic acid.

Pigment Patterns The harvested cell mass and dense colonies on agar plates of *Herpetosiphon* may be brightly colored in shades of yellow-orange to brick-red, but unpigmented strains, especially among *Herpetosiphon*-like strains, do occur (Lee et al. (manuscript in preparation)). However, the pigmentation often depends on the growth medium and is usually more intense on peptone-containing substrates. The pigments are cell bound. Chemically, they are carotenoids (Kleinig and Reichenbach, 1977; Reichenbach et al., 1978). The pigment pattern has so far only been determined for seven strains of the aurantiacus group, including the type strain and two different *Herpetosiphon*-like sludge strains. One of these sewage strains is most likely (unfortunately, these strains are no longer available), on the basis of several phenotypical traits and G+C content, related to the *H. aurantiacus* species group (Trick and Lingens, 1984), whereas the affiliation of the other sewage strain is unknown and is thus placed in an undefined species group (Senghas and Lingens, 1985; see the section Taxonomy in this Chapter). The pigment patterns obtained so far seem however to be uniform since only quantitative (but no qualitative) variation has been observed. The dominant compound has a 4-oxo-beta-psi-chromophore, with a hydroxyl in C-1' to which a disaccharide consisting of glucose is connected via a glycoside bond. One of the sugars bears an ester-bonded fatty acid, in strain Hp a2 (DSM 589) mainly C16:0 and C18:1 (Fig. 6). Composite carotenoids of this type are well known from myxobacteria, but in these latter organisms, only monosaccharides are found as sugar constituents. Carotenoids with a disaccharide component are unique so far among prokaryotic pigments.

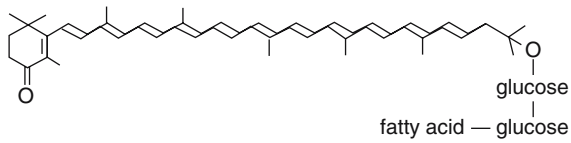

Fig. 6. Chemical structure of the main pigment of *Herpetosiphon aurantiacus*. (From Kleinig and Reichenbach, 1977.)

Metabolic Characteristics Although all known *Herpetosiphon* strains are aerobic, they seem to prefer microaerophilic conditions. All strains, except for the *Herpetosiphon*-like sludge strain of Senghas and Lingens (1985), are catalase- and oxidase positive (Lee et al. (manuscript in preparation)). The nutritional requirements, physiology, and biochemical capabilities of *Herpetosiphon* are not yet fully understood. *Herpetosiphon* is a strict organotroph, but because it is often able to grow on media very low in organic constituents (even on pure water agar, WAT agar; see the section Isolation in this Chapter), the results of substrate-utilization experiments must be interpreted with great care. However, some of the *Herpetosiphon* strains, as well as the *Herpetosiphon*-like sludge strains reported by Senghas and Lingens (1985), do seem to be able to utilize, but not acidify, various hexoses, pentoses and sugar alcohols (Lee et al. (manuscript in preparation)). Organic acids, with the exception of β-hydroxybutyrate, do not support growth.

Apparently, many strains are able to grow on inorganic nitrogen sources (NH_4^+ or NO_3^-), but unequivocal data are often not available. Nitrate reduction to nitrite has only been detected in strains of the *H. aurantiacus* group and some of the *Herpetosiphon*-like sludge organisms (Senghas and Lingens, 1985; Lee et al. (manuscript in preparation)), but only under anaerobic conditions (i.e., in the absence of molecular oxygen), which did not allow growth. Nitrogen fixation has been ruled out in all cases that have been investigated.

Herpetosiphon may contain granules of poly-β-hydroxybutyrate and under certain conditions also of polyphosphate (Trick and Lingens, 1984; Senghas and Lingens, 1985; Lee et al. (manuscript in preparation)), but analytical details have not been given for a final chemical verification of this observation.

Many *Herpetosiphon* strains show impressive hydrolytic capabilities (e.g., of casein, cellulose, chitin, esculin, gelatin, pectin, starch, tributyrin and xylan; Lee et al. (manuscript in preparation)), while some *Herpetosiphon*-like sludge organisms (Trick et al., 1984; Senghas and Lingens, 1985) and sluice strains (Brauss et al., 1969) are less active in this respect. It should be understood that the results of those digestion experiments sometimes critically depend on the medium and the material used. In the case of pectin, a wide variety of preparations are available that give quite different results. With pectin from apple (38% methyl ester), we found pectin degradation by some of the *Herpetosiphon* strains we tested. Cellulose digestion by different *Herpetosiphon* strains is often seen when using the quick agar test based on CEL1 agar (see below), on which large lysis zones are produced within a few days, reaching far beyond the swarm colony. This suggests that cellulose decomposition by *Herpetosiphon* is achieved by diffusible exoenzymes (Lee et al. (manuscript in preparation)). However, only *H. geysericola* (ATCC 23076^T), Hp a1 (DSM number in preparation) and strain So97 (DSM 14854) decompose filter paper, but decomposition is usually slow (recognizable only after 20–30 days at 30°C on ST6 Agar; Lewin, 1970; Lee et al. (manuscript in preparation)).

CEL1 Agar

Cellulose powder	0.5%
$(NH_4)_2SO_4$	0.1%
Agar	1%

Dissolve ingredients in distilled water, adjust to pH 7.2. After autoclaving, pour the medium as a thin layer on top of ST6 agar plates. A suitable cellulose powder, MN 300, is produced by Macherey and Nagel (Germany).

ST6 Agar

Part A

$(NH_4)_2SO_4$	0.1%
$MgSO_4 \cdot 7H_2O$	0.1%
$CaCl_2 \cdot 2H_2O$	0.1%
$MnSO_4 \cdot 2H_2O$	0.01%
$FeCl_3 \cdot 6H_2O$	0.02%
Trace element solution (same as for medium MD1)	1 ml/liter

Ingredients of part A should be dissolved in one-third of the water (*distilled*) volume. Ingredients of part B should be dissolved in two-thirds of the water volume.

Part B

K_2HPO_4	0.1%
Yeast extract	0.002%
Agar	1%

After autoclaving parts A and B separately, combine them and pour the mixture into plates.

With many strains, we have also observed DNA hydrolysis on DNA agar, but in some studies of *Herpetosiphon*-like sludge organisms, tests for DNase were negative (Senghas and Lingens, 1985). Not all strains show β-hemolysis of sheep and human erythrocytes (Gräf and Perschmann, 1970; Trick and Lingens, 1984; Lee et al. (manuscript in preparation)).

Most investigators report that *Herpetosiphon* organisms lyse dead bacteria but also in a few cases live bacteria. However, not all types of bacteria are equally sensitive. For instance, Quinn and Skermann (1980) have reported that some *E. coli*, as well as some Gram-positive strains (*Bacillus subtilis*, *Lactobacillus casei* and *Streptococcus mutans*), turned out to be particularly recalcitrant (Lee et al. (manuscript in preparation)). Not all *Herpetosiphon* strains show identical lysis patterns. The *Herpetosiphon*-like sludge organisms of Trick and Lingens (1984) and Senghas and Lingens (1985) do not lyse bacteria at all; however, the *Herpetosiphon aurantiacus* type sludge organism FC16a (DSM number in preparation) of N. Lee et al. (manuscript in preparation) does lyse bacteria. The autoclaved yeast cells in VY/2 agar are often but not always destroyed. Other yeast species may also be lysed, such as *Pichia stipitis* or *Candida albicans* (Lee et al. (manuscript in preparation)).

The H_2S, indole and acetoin tests were negative for all strains tested, whereas the phosphatase and the urease tests were positive for some of the strains tested (Trick and Lingens, 1984; Senghas and Lingens, 1985; Lee et al. (manuscript in preparation)). Tyrosine in tyrosine agar is often degraded.

Tolerance Tests

The *Herpetosiphon*-like sludge organisms tolerate up to 2% NaCl, but most other *Herpetosiphon* strains are rather sensitive to elevated salt concentrations; growth is rarely observed above 1.5% NaCl. Optimum pH for all strains is around 7; however, growth is tolerable in the pH range 4–10. Optimum temperature for all *Herpetosiphon* strains is 20–30°C, but growth is generally seen in the range 10–37°C. *Herpetosiphon*-like strains (e.g., Hp g207, DSM 15737) may grow at 45°C (Trick and Lingens, 1984; Senghas and Lingens, 1985; Lee et al. (manuscript in preparation)). All *Herpetosiphon* strains investigated so far are resistant to high levels of kanamycin sulfate (250 mg/liter).

Molecular Characterization

The G+C content of the two *Herpetosiphon* species groups (*aurantiacus* and *geysericola*) is 48–53 mol%. However, as already mentioned in the introduction, the G+C content of some *Herpetosiphon*-like isolates, e.g., the strain of Senghas and Lingens (1985), and the strains Hp g6 DSM

15710, Hp g16 DSM 15736 and Hp g207 DSM 15737 is higher (59–75%), which suggests that at least some of these isolates may represent new genera among chloroflexi (Lee et al. (manuscript in preparation)).

The unique multicopy single-stranded DNA (msDNA) common in gliding myxobacteria and also found in *Flexibacter* could not be demonstrated in *Herpetosiphon* (Dhundale et al., 1985). The base sequence of the 5S rRNA gene has only been determined for one of the *Herpetosiphon*-like sludge organisms (strain Wie 2; Van den Eynde et al., 1987). While this 5S rRNA gene sequence corresponds, in general, quite well with the model of eubacterial 5S rRNA structure, there are several deviations—in two cases in highly conserved sites not modified in any other eubacterium. The base sequence of the 16S rRNA gene has been determined for 15 different *Herpetosiphon* strains (Oyaizu et al., 1987; Bradford et al., 1996; Sly et al., 1998; Kohno et al., 2002; Lee et al. (manuscript in preparation)). Comparative 16S rRNA gene sequence analyses confirmed that they all form a specific *Herpetosiphon* cluster within chloroflexi (see the section Taxonomy in this Chapter).

Table 2. 16S rRNA gene sequence similarity values of *Herpetosiphon* strains and other culturable chloroflexi strains.

Culturable chloroflexi strains	Similarity to 16S rRNA gene[a] (%)
H. aurantiacus strains (14 strains[b])	97.8–99.5
H. geysericola	96.4
Herpetosiphon-like strains (7 strains[c])	79–94
Chloroflexus aurantiacus	81.6
Chloroflexus aggregans	80.3
Chloronema giganteum	81.8
Kouleothrix aurantiacus	82.8
Roseiflexus castenholzii	82.6
Oscillochloris trichoides	82.8
Eikelboom type 1851 Ben52	81.3

[b]Hp g8 (DSM 6205), Hp g10 (DSM 6207), HrsBendi 15 FO18 (Bradford et al., 1996), OSI-B2 (Kohno et al., 2002), FC16a (DSM number in preparation), Hp al (DSM number in preparation), Hp a2 (DSM 589), Hp g5 (DSM number in preparation), Hp g156 (DSM 15901), Hp g158 (DSM 15902), Hp g254 (DSM 15903), Hp g269 (DSM 15712), Hp g277 (DSM 15713), and Hp g278 (15714).
[c]Hp g6 (DSM 15710), Hp g16 (DSM 15736), Hp g207 (DSM 15737), Hp g122 (DSM 15874), Hp g124 (DSM 15875), Hp g150 (DSM 15876), and Hp g174 (DSM 1587).
The data for *H. geysericola* are from Sly et al., 1998, whereas the rest of the data are preliminary and from N. Lee et al. (manuscript in preparation).

Taxonomy

The closest culturable relatives of *Herpetosiphon* are only distantly related to *Herpetosiphon* (e.g., *Chloroflexus aurantiacus* and *Roseiflexus aurantiacus*, showing around 81–83% 16S rRNA gene similarity; Table 2). This has been deduced from different comparative 16S rRNA gene sequence studies, from analyses of oligonucleotide catalogs via binary association coefficients (S_{AB} values), through early oligonucleotide signatures (Gibson et al., 1985; Oyaizu et al., 1987) and from a recent comparison of the nearly full 16S rRNA gene sequence of around 15 different strains of *Herpetosiphon* (Lee et al. (manuscript in preparation)), as well as from comparative sequence analysis of elongation factor Tu and ATP–synthase beta-subunit genes (Ludwig et al., 1993). Together with *Anaerolinea* gen. nov., *Caldilinea* gen. nov., *Chloronema*, *Heliothrix*, *Roseiflexus*, *Oscillochloris*, "the Eikelboom type 1851 sludge strain" (Beer et al., 2002), and the *Nostocoida limicola*-like strains of Schade et al. (2002), they represent the few culturable organisms in chloroflexi (<10% of all submitted chloroflexi-affiliated sequences in general molecular databases, June, 2004). Interestingly, most of these culturable strains consist mainly of thermophilic phototrophs (*Chloroflexus*, *Chloronema*, *Heliothrix*, *Roseiflexus* and *Oscillochloris*) or thermophilic organotrophs (*Anaerolinea* gen. nov. and *Caldilinea* gen. nov.). The only exceptions are *Herpetosiphon*, the sludge strains Eikelboom type 1851, the *Nostocoida limicola*-like strains of Schade et al. (2002), and a few strains in different thermophilic genera that are mesophilic organotrophs. At the present stage, the *Herpetosiphon* strains represent the largest group of culturable, nonthermophilic, nonphotosynthetic organisms among the chloroflexi.

Since the discovery of the first *Herpetosiphon* strain in 1968 by Holt and Lewin, the genus *Herpetosiphon* is today still only represented by two rather similar species, *H. aurantiacus* and *H. geysericola,* and some *Herpetosiphon*-like sludge strains (Trick and Lingens, 1984; Senghas and Lingens, 1985; Bradford et al., 1996), whose genetic relatedness to *Herpetosiphon* can no more be determined since the strains are no longer existent. Thus, *Herpetosiphon* is the only genus in the family Herpetosiphonaceae in the second order of the class *Chloroflexi*, *Herpetosiphonales*. As mentioned earlier (see the section Habitats in this Chapter), the three marine "*Herpetosiphon*" strains, which were discovered by Lewin (1970), have recently been transferred to another phylum, *Flexibacter-Bacteroides-Cytophaga* (Sly et al., 1998). Since the discovery of the second culturable *representative of the Class Chloroflexi, Chloroflexus aurantiacus* (Pierson et al., 1974), a vast amount of as yet not cultivatable strains of *chloroflexi*-affiliated organisms have been detected (see, e.g., the review of Björnsson et al., 2002). Only a few of these studies have reported any *Herpetosiphon*-

Table 3. Fatty acid composition, G+C content, 16S rRNA gene similarity and DNA-DNA similarity in different *Herpetosiphon* and *Herpetosiphon*-like strains.

Species groups of *Herpetosiphon*	No. of strains	FA[a]	G+C mol%	16S rRNA similarity[b] (%)	DNA-DNA similarity[b] (%)
H. aurantiacus[c] ATCC 230779^T	12	I	48.1–52.9	97.8–99.5	65.3–95
H. geysericola[c,d] ATCC 23076^T	1	I	51.8	96.4	67.8
Herpetosiphon-like strains:					
"Sludge strains"[e]	3	II	59	ND	ND
"Sludge strains"[f]	5	ND	48.7–49.0	ND	ND
"Soil strains"[c]	10	III	62–75	81–95	<15

Abbreviations: FA, fatty acid composition category; ^{T}, type strain; and ND, not determined, strains no longer available.
[a]Each group (I to III) represent a unique composition; see Table 1.

[f]Trick and Lingens (1984).

like organisms, which suggests that the *Herpetosiphon* group might represent a rather stagnant evolutionary group of organisms with a low diversity among the *chloroflexi*. However, recent studies by Lee et al. (manuscript in preparation)) showed that the genetic diversity among the *Herpetosiphon*-like strains is much larger than previously expected, differing up to 19% in 16S rRNA gene sequence from the type strain of *H. aurantiacus*, which suggests that some of these strains represent novel genera among chloroflexi. Thus, the taxonomy of the phylum *Chloroflexi* and the order *Herpetosiphonales* may have to be re-evaluated in the future. Table 3 gives the distinguishing characteristics of the two recognized *Herpetosiphon* species and the *Herpetosiphon*-like organisms.

Summary of the Species Groups of *Herpetosiphon*

H. AURANTICUS. This species group, represented by the type strain ATCC 23779^T and isolated by Lewin and Holt (1968), contains the largest number of strains (14, listed below). The G+C content is 48.1–52.9 mol%. 16S rRNA gene similarity to the type strain is between 97.8% and 99.5% (Table 2). However, the DNA-DNA similarity to the type strain may vary from 65.3% to 95% (Table 3). The fatty acid composition is similar in all strains (Table 1), but the strains may differ in some single phenotypical characteristics (Lee et al. (manuscript in preparation)). Strains have been isolated from freshwater lakes (Lake Constance, Germany: Hp g8 [DSM 6205], Hp g10 [DSM 6207]; Gräf et al., 1970; Lee et al. (manuscript in preparation)); from activated sludge in different parts of the world: HrsBendi 15 FO18 (Bradford et al., 1996), OSI-B2 (Kohno et al., 2002), FC16a [DSM 15711] (Lee et al. (manuscript in preparation)); and from soil from different parts of the world: Hp a1 (DSM number in preparation), Hp a2 (DSM 589), Hp g5 (DSM number in preparation), Hp g156 (DSM 15901), Hp g158 (DSM 15902), Hp g254 (DSM 15903), Hp g269 (DSM 15712), Hp g277 (DSM 15713), Hp g 278 (DSM 15714) by H. Reichenbach and by Lee et al. (manuscript in preparation).

H. GEYSERICOLA. This species is represented by only one strain, the type strain *H. geysericola*, ATCC 23076^T (described by Lewin, 1970). Originally it was suggested (Lewin, 1970) that *H. geysericola* is identical with *Phormidium geysericola* (Copeland, 1936), but this appears very unlikely, because *Phormidium geysericola* was found at the rim of a geyser and in 60–84°C water from various alkaline hot springs in Yellowstone. It thus is definitely a thermophile and would hardly grow at 30°C, as does *H. geysericola*. The validity of *H. geysericola*´s species status has been discussed, since it shares several common phenotypical characteristics (exceptions: urease reaction, nitrate reduction, and hydrolysis of cellulose filter paper), G+C content, and fatty acid composition with the *H. aurantiacus* group (Reichenbach, 1992; Lee et al. (manuscript in preparation)). Recent studies have shown that the 16S rRNA similarity (96.4%; Sly et al., 1998; Table 2) and the DNA-DNA similarity (67.8%, Lee et al. (manuscript in preparation); Table 3) to *H. aurantiacus* is on the border of the present species definition (Stackebrandt et al., 2002). Since the DNA similarity between some of *H. aurantiacus* strains may also range from 65.3% to 95% (Table 3), it is questionable whether *H. geysericola* should remain a distinct species. The main difference between *H. geysericola* and all 14 *H. aurantiacus* strains is that *H. geysericola* was isolated from the vicinity of a hot spring and thus was defined as "thermophilic," although the proper characterization should be thermotolerant. However, thermotol-

erance is not unusual with *aurantiacus* strains, which may also grow at 38–40°C Lee et al. (manuscript in preparation). Further taxonomical studies on *H. geysericola* (in particular investigation of chemotaxonomical characteristics) and, if possible, on more *geysericola*-like strains retrieved from sites in and around hot springs will be needed to determine whether *H. geysericola* should remain a separate species or be included in the *H. aurantiacus* group. Another theoretical possibility is also that some of the present strains within the *H. aurantiacus* group should be transferred to *geysericola*, although they were not isolated from sites in and around hot springs but from soil. The reason for this is that their DNA-DNA similarity values to the *H. aurantiacus* type strain approximates that of the present species definition (i.e., slightly below 70% similarity). Further DNA-DNA similarity studies with these strains would be needed to clarify this question.

Herpetosiphon-LIKE STRAINS. In the first attempt after isolation, several strains have been identified as *Herpetosiphon*-like, but further studies, in particular, utilizing molecular techniques (16S rRNA gene sequence analysis), have revealed that the diversity of *Herpetosiphon*-like strains is much larger than expected. The 16S rRNA gene similarity between *Herpetosiphon*-like strains and *H. aurantiacus* (ATCC 23779^T) is around 79–94%, and the G+C content is around 62–75% (Lee et al. (manuscript in preparation); Table 3). Thus, these strains represent most likely new genera among the chloroflexi, e.g., the strains Hp g6 (DSM 15710), Hp g16 (DSM 15736), Hp g207 (DSM 15737), Hp g122 (DSM 15874), Hp g124 (DSM 15875), Hp g150 (DSM 15876), and Hp g174 (DSM 1587). All these strains have been isolated from soil Lee et al. (manuscript in preparation). The 16S rRNA genes of the *Herpetosiphon*-like sludge organisms described by Trick and Lingens (1984) and Senghas and Lingens (1985) unfortunately cannot be sequenced, since these strains are no longer available. However, previous studies, based on analysis of oligonucleotide catalogs via binary association coefficients (S_{AB} values), showed that the *Herpetosiphon*-like sludge organisms isolated by Senghas and Lingens (1985) are clearly related but not identical to *Herpetosiphon* (S_{AB} values with *Herpetosiphon*: 0.39, for *Chloroflexus*: 0.40, and *Herpetosiphon-Chloroflexus*: 0.31). This is also indicated by the significantly higher G+C mol% value obtained for these organisms (Table 3).

Microbial Ecology

We know virtually nothing about the true distribution, dynamics and activity of *Herpetosiphon* in the environment, as well as about its interactions with other organisms, such as other bacteria or eukaryotic grazers. No reports on bacteriophages of *Herpetosiphon* have been published. All we know is that *Herpetosiphon* may be found in freshwater and sewage systems, in the vicinity of hot springs, as well as in diverse types of soil systems in different countries and islands in many parts of the world (Africa, America, Australia, Europe, India, Japan and Mexico). Our knowledge about the biogeography of *Herpetosiphon* is mainly based on isolation studies or surveys using different chloroflexi specific probes detected by means of FISH (Björnsson et al., 2002; Lee et al. (manuscript in preparation)). Only a few 16S rRNA clone library or denaturing gradient gel electrophoresis screening studies on the microbial community composition in freshwater lakes or sewage systems have reported *Herpetosiphon*-like 16S rRNA genes (Gich et al., 2001; Kohno et al., 2002), despite the fact that a constantly increasing amount of novel, in most cases, chloroflexi-like sequences (from as yet noncultivable organisms, not related to *Herpetosiphon*) are being found in nearly all kinds of environments all over the world (e.g., Pierson et al., 1985; Giovannoni et al., 1996; Snaidr et al., 1997; Chandler et al., 1998; Dojka et al., 1998; Hugentholtz et al., 1998a; Hugentholtz et al., 1998b; Gordon et al., 2000; Sekiguchi et al., 2001; Alfreider et al., 2002; Bano and Hollibaugh, 2002; Boomer et al., 2002; Dunbar et al., 2002; Furlong et al., 2002; Hentschel et al., 2002; Juretschko et al., 2002; Lee et al. (manuscript in preparation)). However, as pointed out earlier (in the section Habitats in this Chapter), this does still not provide the final evidence for the nonexistence of *Herpetosiphon* in any of these systems. It may be that search for *Herpetosiphon* is negatively biased in general molecular screening studies (Lee et al. (manuscript in preparation)), so that specific molecular markers for *Herpetosiphon* must be used to detect them. In those cases, where a large attempt has been undertaken to isolate bacteria from the environment, none of the media used were optimal for the isolation of *Herpetosiphon*.

Whereas virtually nothing is known about the abundance of *Herpetosiphon* in soil, some observations, albeit contradictory, on the abundance of *Herpetosiphon* and other filamentous chloroflexi have been made in sewage plants using different chloroflexi-specific oligonucleotides in FISH (Fig. 7). Björnsson et al. (2002) reported that the amount of chloroflexi filaments in subphylum III (to which *Herpetosiphon* is affiliated) was considerably higher than the amount of other chloroflexi filaments affiliated to other subphyla. N. Lee et al. (manuscript in preparation) found the contrary. Unfortunately, nothing is

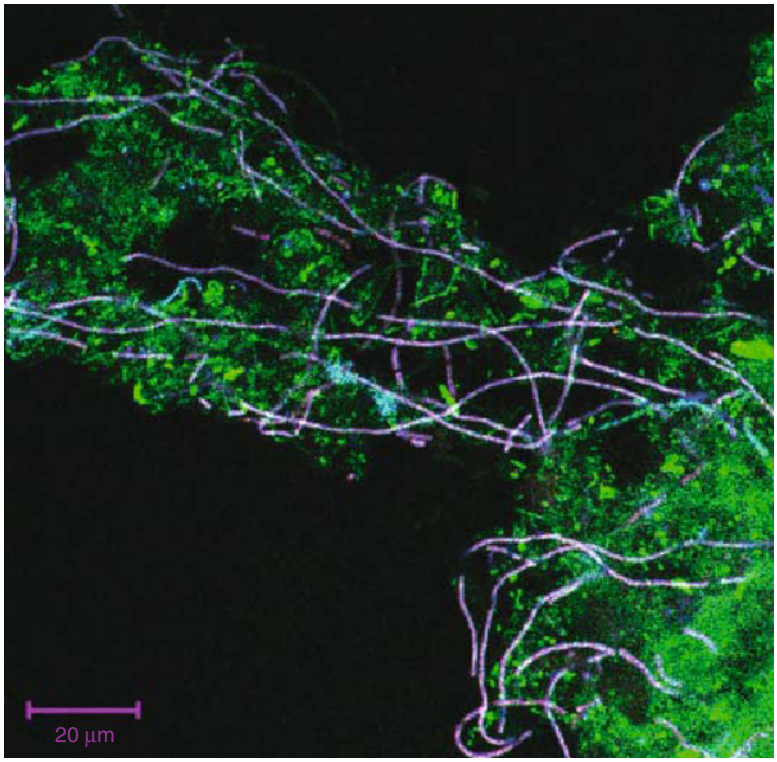

Fig. 7. Image of fluorescence *in situ* hybridization using oligonucleotide probes targeting chloroflexi filaments on the phylum level (probe CFX1223 in Cy3, red) and on the subphylum III level (to which *Herpetosiphon* belongs, CFX784 probe in Cy5, blue) and Bacteria (EUB338, in FLUOS-Prime, green) in activated sludge (photo: N. Lee; for probe references, see Björnsson et al., 2002). The purple-colored filaments are a result of overlapping Cy3 (red) and Cy5 (blue) stained cells. Bar = 20 µm.

known about the *in situ* abundance of *Herpetosiphon* in other sewage systems where sequences of other culturable and as yet not cultivable chloroflexi strains have been obtained (e.g., Bradford et al., 1996; Beer et al., 2002; Juretschko et al., 2002; Kohno et al., 2002; Onuki et al., 2002; Schade et al., 2002). In those cases where isolation attempts were undertaken, no media were used that were optimal for *Herpetosiphon*, and in those cases where FISH was used, no probes targeting specifically *Herpetosiphon* were applied, and so no definitive conclusions about their nonexistence in these systems can be drawn. Thus, the contradiction between the observations made by Björnsson et al. (2002) and Lee et al. (manuscript in preparation) is most likely explained by the effect of unknown geographical factors or operational differences between the different sewage systems. As long as nothing is known about the role of *Herpetosiphon* in sewage systems and about whether significant physiological differences exist among these sewage *Herpetosiphon* strains, any attempt to explain the differences in abundance of *Herpetosiphon* will remain speculative. Considering the hydrolytic capabilities of *Herpetosiphon*, it may however be assumed that the bacterium participates in the degradation of macromolecules and perhaps in the control of microbial populations in nature (Quinn and Skerman, 1980; Lee et al. (manuscript in preparation)).

Molecular Genetics

Nothing is known about the genetics of *Herpetosiphon*. Also, whether *Herpetosiphon* possesses mobile genetic elements or is able to acquire plasmids through lateral gene transfer is unknown. The genome of *Herpetosiphon* has not been sequenced, but the genome of its closest culturable relative, the photosynthetic *Chloroflexus*, is currently being sequenced in a vast program aimed at investigating the evolution and genetics of photosynthesizing prokaryotes (DOE Joint Genome Institute, United States Department of Energy). Future sequencing of the genome of *Herpetosiphon* might however yield interesting insights into the evolution of early life on earth and the divergence of the different members among the present representatives in chloroflexi. A possible case for lateral gene transfer in *Chloroflexus* has already been indicated by a comparative phylogenetic analysis of circadian clock genes in *Archaea* and *Bacteria* showing that these genes might have been laterally transferred from cyanobacteria to different taxa (among them *Chloroflexus*) in *Archaea* and *Bacteria* (Dvornyk et al., 2003).

Given the unique position of the phylum *Chloroflexi*, it is not unlikely that further studies on the molecular genetics and biochemistry of *Herpetosiphon* may reveal interesting facts. This has been shown to be the case in screening studies of

two different enzymes in some *Herpetosiphon* strains from the *H. aurantiacus* species group: the endoribonucleases (Haas and Brown, 1998) and the restriction endonucleases (Mayer and Reichenbach, 1978). The ribonuclease P has been sequenced for several classical phyla of *Bacteria* (encompassing 145 different strains, including three chloroflexi strains, *Chloroflexus*, *Herpetosiphon* and *Thermomicrobium*) for further evolutionary comparisons and revealed interesting insights into the structural evolution of the RNA molecule (Haas and Brown, 1998). A whole family of 17 restriction endonucleases has been more or less completely characterized with respect to their recognition and cleavage specificities (Brown et al., 1980; Kröger et al., 1984; Düsterhöft et al., 1991). All appear to be class II endonucleases, producing cohesive ends, either in the 5′-strand or, in the cases of endonucleases *Hgi* AI and *Hgi* JII, in the 3′-strands, and seem to be located in the periplasm. Most of them interact with hexanucleotide sequences and some with pentanucleotide sequences, but virtually all recognition sequences are degenerate. The availability of such a large family of endonucleases is of considerable theoretical interest because it allows a comparative study of the mechanisms of protein-DNA interaction as well as of molecular evolution. The known *Herpetosiphon* enzymes can be arranged in such a way that their recognition sequences overlap and the whole set thus becomes a continuous system (Kröger et al., 1984). One of the enzymes, *Hgi* EII, has a unique recognition sequence of 2×3 bases separated by 6 unspecified nucleotides. When the recognized bases are read in sequence, they give the recognition sequence of *Hgi* CI, and it has been proposed that enzyme *Hgi* EII originated by an inversion of the two enzyme subunits so that the recognition sites are now on the surface rather than in the center of the enzyme. Isoschizomeres can be found for almost all *Herpetosiphon* recognition sequences, e.g., *Sal* I enzyme is isoschizomere to *Hgi* CIII and *Hgi* DII. Interestingly, no hybridization was found between *Sal* I gene probes and *Herpetosiphon* DNA, whereas two other producers of *Sal* I isoschizomeres, *Rhodococcus rhodochrous* and *Xanthomonas amaranthicola*, showed clear DNA similarity under stringent conditions (Rodicio and Chater, 1988). While this suggests that the latter organisms and *Streptomyces albus* G have at least partially homologous enzymes, the high G+C difference of 20 mol% between *Herpetosiphon* and *Streptomyces* could have obscured, through codon replacement, a structural relationship between their enzymes. A comparison of the base sequences of the genes or of the amino acid sequences of the various enzymes should answer the question.

Acknowledgements. We thank all current and previous members of the Lee and Reichenbach laboratories. NL is indebted to the Alexander von der Humboldt Foundation for a post doc grant that was critical for initiating the research on *Herpetosiphon* and other members of *Chloroflexi*.

CHAPTER 11.1

The Phylum Verrucomicrobia: A Phylogenetically Heterogeneous Bacterial Group

HEINZ SCHLESNER, CHERYL JENKINS AND JAMES T. STALEY

Introduction

General Phylogeny and Taxonomy

The Verrucomicrobia were proposed as a new division within the bacterial domain by Hedlund et al. (1997) and more recently ranked as a phylum (Garrity and Holt, 2001). They represent a distinct lineage within the phylogenetic trees and contain a number of environmental species as well as a small number of cultured species assigned to four genera (Table 1): *Verrucomicrobium* (Fig. 1a, b), *Prosthecobacter* (Fig. 2), *Opitutus* and *Victivallis*.

Verrucomicrobia have shown a moderate degree of relationship to the Planctomycetes and Chlamydiae, but the significance of the common branching is low and the relationships among the three phyla may change as additional species are characterized. The comparative phylogenetic analyses of members of the order Planctomycetales and the type strains of *Verrucomicrobium spinosum* and *Prosthecobacter fusiformis*, as well as *Prosthecobacter* sp. strain FC-2, did not indicate a statistically significant phylogenetic relationship between the Planctomycetes and the Verrucomicrobia and further provided evidence that the Chlamydiae are no more related to both phyla than they are to members of other bacterial lineages.

Knowledge of the phylum Verrucomicrobia is limited owing to the relatively few species that have been obtained in pure culture and characterized. However, through the application of molecular ecology techniques it has become apparent that the Verrucomicrobia are ubiquitous in a wide range of aquatic and terrestrial habitats. The phylogenetic tree based on sequence analyses of the 16S rDNA is dominated by sequences derived from the extraction of total DNA from various habitats. Hugenholtz et al. (1998a) recognized five subdivisions, of which three were characterized by clone sequences only. Since then the phylogenetic tree has been expanded to seven subdivisions, although only three contain validly described taxa (Fig. 3).

The genera of the prosthecate bacteria *Verrucomicrobium* and *Prosthecobacter* are grouped in subdivision 1. Bacteria designated "*Candidatus* Xiphinematobacter" are in subdivision 2. These bacteria are obligate endosymbionts of nematodes in the genus *Xiphinema* (Vandekerckhove et al., 2000). Another group of bacteria living in close connection to eukaryotes are the epixenosomes (Figs. 4 and 5), which are obligate ectosymbionts living on the dorsal surface of marine ciliates of the genus *Euplotidium*. They possess so-called "extrusomes," harpoon-like organelles, and so provide their hosts with a weapon against predatory protozoa (Petroni et al., 2000; Chin et al., 2001). The epixenosomes are members of subdivision 4 together with *Opitutus terrae* (Chin et al., 2001) and three strains of ultramicrobacteria with dwarf cells isolated from anoxic rice paddy soil. The latest described organism, *Victivallis vadensis*, is placed in subdivision 7.

Only a few other strains have been isolated. Janssen et al. (2002) were able to cultivate strain Ellin 428 from Australian pasture soil (which could be grouped in subdivision 2), and Sakai et al. (2003) reported of a fucoidan-degrading marine bacterium (provisional name "*Fucophilus fucoidanolyticus*") from the gut contents of the sea cucumber *Stichopus japonicus*.

Ecology

Verrucomicrobia were first observed in aquatic habitats (Henrici and Johnson, 1935) but are now known to exist in many other habitats, the majority of which are eutrophic or even heavily polluted (Table 2). They were found not only at moderate temperatures but also at cold temperatures in the deep sea and in Antarctica. A member of the Verrucomicrobia was also identified from a hot spring (75–95°C). Several reports are of Verrucomicrobia from extreme environments such as sulfide-rich water and sediments and a soda lake. Interestingly, a member of the Verrucomicrobia was identified in the chitin tubes of the giant vent worm *Riftia pachyptila*, illustrating another connection between this group and thermal environments, such as the hydrothermal vent fauna of the deep sea.

Table 1. Characteristics differentiating the genera of the phylum Verrucomicrobia.

Genus	Habitat	Cell morphology	Color	Motility	Oxygen requirement	G+C (mol%)	References
Verrucomicrobium	Freshwater	Rods with numerous fimbrated prosthecae	Light yellow	–	Aerobic and fermentative	59	Schlesner, 1987
Prosthecobacter	Freshwater; Raw sewage	Fusiform shaped cells with 1 polar prostheca	White or yellow	–	Obligate aerobe	54–60	Staley et al., 1976
Opitutus	Rice paddy soil	Coccoid dwarf cells (0.4–0.6 μm)	Colorless	+	Obligate anaerobe, fermentative	74	Chin et al., 2001
Victivallis	Human fecal sample	Coccoid, 0.5–1.3 μm	Colorless	–	Obligate anaerobe, fermentative	59	Zoetendal et al., 2003
"*Candidatus* Xiphinematobacter"	Ectosymbionts in nematodes	Rod-shaped, 0.7–1.0 $\times$ 2.1–3.2 μm	ND	ND	ND	ND	Vandekerckhove et al., 2000

Molecular Ecology Studies

Since novel groups of bacteria were first revealed by analysis of genetic material obtained from forest soil (Liesack and Stackebrandt, 1992), a large number of sequences of 16S rDNA have been obtained from a variety of sources (Table 2). Another method that enables the study of bacterial communities in the environment is fluorescence in situ hybridization (FISH), which entails the application of appropriate fluorescence-labeled gene probes. With this method Ravenschlag et al. (1999) identified members of the Verrucomicrobia in permanently cold sediment in the Arctic Ocean off the coast of Spitsbergen, Norway. Since these probes bind to ribosomal RNA, only physiologically active cells are detected. Because the DNA is much more stable even after the death of the cell, it is not easy to prove the activity of cells in a biotope at the time of sampling. Similarly, Gremion et al. (2003) identified in heavy metal-contaminated bulk and rhizosphere soil clones belonging to the phyla Verrucomicrobia, *Firmicutes*, and *Cytophaga-*

Flavobacterium-Bacterioides (but only in rDNA clone libraries, not in rRNA libraries originating from the same samples). On this basis, they concluded that these bacteria might not represent active constituents in their samples.

Morphology and Physiology

The isolated members of the phylum Verrucomicrobia are Gram-negative bacteria with a coccoid or rod-shaped morphology. Cells in the genera *Verrucomicrobium* and *Prosthecobacter* are prosthecate (Figs. 1 and 2; Table 1). Multiplication occurs by binary fission or unequal cell division (e.g., in *Verrucomicrobium*).

The most discriminating physiological character of the genera is the oxygen requirement. Organisms are strict aerobes, facultative anaerobes, or strict anaerobes (Table 1). The carbon and energy sources are mainly carbohydrates as sugars. *Opitutus terrae* strain ACB hydrolyzes cellulose and "Fucophilus fucoidanolyticus" degrades fucoidan, a mixture of sulfated fucose-containing polysaccharides, which are components of many seaweeds.

Genus *Verrucomicrobium*

Introduction

Bacteria with multiple prosthecae are grouped in different phyla: the phototrophic *Ancalochloris* (Gorlenko and Lebedeva, 1971) and *Prosthecochloris* (Gorlenko, 1970) are members of the phylum Chlorobi (Garrity and Holt, 2001), while the heterotrophic bacteria *Ancalomicrobium*, *Prosthecomicrobium* (Staley, 1968) and *Stella* (Vasilyeva, 1985) are *Proteobacteria* (Garrity and Holt, 2001).

New isolates of heterotrophic bacteria with bundles of fimbriae extending from the tips of the prosthecae were described as *Verrucomicrobium spinosum* (Schlesner, 1987; Schlesner, 1992).

Phylogeny

Oligonucleotide cataloguing and reverse transcriptase sequencing of 16S rRNA (Albrecht et al., 1987) as well as sequencing of the 5S rRNA (Bomar and Stackebrandt, 1987) indicated that *V. spinosum* is a representative of a novel phylum. This finding was supported by the 16S rDNA sequence (Ward-Rainey et al., 1995).

Taxonomy

Verrucomicrobium spinosum is the only species of the genus *Verrucomicrobium*.

Habitat

Prosthecate bacteria with fimbriae extending from the tips of prosthecae have rarely been observed. Such bacteria occurred in an enrichment culture of Lake Plußsee water to which vitamin solution no. 6 (see below) was added (P. Hirsch, personal communication). Lake Plußsee is a small eutrophic lake near Plön, Holstein, Germany. The type strain of *V. spinosum* was isolated from Lake Vollstedter See (Holstein, Germany), a shallow (max. depth 2 m) eutrophic lake. Another strain came from the "Schrevenparkteich," a pond in a public park in Kiel, Germany. This pond was very eutrophic because flocks of water fowl lived there and were fed by visitors to the park.

Isolation

Verrucomicrobium spp. can be enriched in Erlenmeyer flasks with 50 ml of enrichment medium over a sediment of $CaCO_3$.

Verrucomicrobium Enrichment Medium

N-Acetylglucosamine	1.0 g
Hutner's basal salts	20 ml
Vitamin solution no. 6	10 ml
Distilled water	1 liter

Combine ingredients, dilute to 1 liter with distilled water, and adjust pH to 9.7. Autoclave, cool to room temperature, then add $NaH_2PO_4 \cdot H_2O$ aseptically to give a concentration of 0.65 mmol/liter.

Hutner's Basal Salts (Cohen-Bazire, 1957)

Nitrilotriacetate (NTA)	10.00 g
$MgSO_4 \cdot 7H_2O$	29.70 g
$CaCl_2 \cdot 2H_2O$	3.34 g
$NaMoO_4 \cdot 2H_2O$	12.67 g
$FeSO_4 \cdot 7H_2O$	99.00 mg
Metal salt solution "44"	50.00 ml
Double distilled water	900.00 ml

Dissolve the NTA first by neutralization with KOH. Add the other salts. Adjust pH to 7.2 with KOH or H_2SO_4. Adjust volume to 1000 ml with double distilled water. Store cold (5°C) and clean. The solution is clear.

Metal Salts Solution "44"

Ethylene diaminotetraacetate (EDTA)	250.0 mg
$ZnSO_4 \cdot 7H_2O$	1095.0 mg
$FeSO_4 \cdot 7H_2O$	500.0 mg
$MnSO_4 \cdot H_2O$	154.0 mg
$CuSO_4 \cdot 5H_2O$	39.2 mg
$CoCl_2 \cdot 6H_2O$	20.3 mg
$Na_2B_4O_7 \cdot 10H_2O$	17.7 mg
Double distilled water	1000.0 ml

Add a few drops of H_2SO_4 to retard precipitation before diluting to volume. Store cold (5°C).

Vitamin Solution No. 6 (Staley, 1968)

Biotin	4.0 mg
Pyridoxine hydrochloride	20.0 mg
Thiamine hydrochloride	10.0 mg
Ca-pantothenate	10.0 mg
p-Aminobenzoic acid	10.0 mg
Folic acid	4.0 mg
Riboflavin	10.0 mg
Nicotinamide or nicotinic acid	10.0 mg
Vitamin B_{12}	0.2 mg
Double distilled water	1000 ml

Stir the mixture to improve dissolution. Sterilize by filtration only. Store dark and cold (5°C).

When subsequent microscopic checks indicate an increase in prosthecate bacteria, streak onto agar-solidified medium M 13 (Schlesner, 1986):

M 13

Peptone	0.25 g
Yeast extract	0.25 g
Glucose	0.25 g
Hutner's basal salts	20 ml
Vitamin solution no. 6	10 ml
Buffer (0.1 M Tris/HCl, pH 7.5)	50 ml
Artificial seawater	250 ml
Distilled water	670 ml

Artificial Sea Water (Lyman and Fleming, 1940)

NaCl	23.477 g
$MgCl_2$	4.981 g
Na_2SO_4	3.917 g
$CaCl_2$	1.102 g
KCl	0.664 g
$NaHCO_3$	0.192 g
KBr	0.096 g
H_3BO_3	0.026 g
$SrCl_2$	0.024 g
NaF	0.003 g

Upcoming colonies have to be examined microscopically for prosthecate cells. This is conveniently done by applying the time-saving toothpick-procedure (Hirsch et al., 1977) which even allows the examination of very small colonies: A sterile wooden toothpick is dipped onto a colony and then on the agar surface of a Petri dish containing the appropriate medium, thus inoculating the agar. To allow inoculation of a single Petri dish with bacteria from a large number of colonies, a grid can be drawn with a marker on the backside of the Petri dish with areas of about 5×5 mm. After inoculation of the agar medium the toothpick generally contains enough bacteria to prepare a smear for microscopic examination. Three specimens can be placed on one slide.

Identification

When studied with a phase contrast microscope, *Verrucomicrobium* spp. resemble *Prosthecomicrobium* spp., i.e., the unicellular organisms have conical prosthecae extending in all directions from the cell surface. These prosthecae are about 0.5 µm long (Fig. 1a). Occasionally, one or two longer prosthecae (up to 2 µm) may occur, and often one of them is polarly inserted (Fig. 1b). Under the electron microscope, bundles of fimbriae of varying number and length protruding from the tips of the prosthecae are detected. The Gram-negative cells are nonmotile. Colonies on medium M 13 are light yellow. Growth of *V. spinosum* is optimal between 26°C and 33°C, and the maximum growth temperature is 34°C. The organism is stenohaline (i.e., able to tolerate 50% artificial seawater or 1% NaCl). The cell wall contains *m*-diaminopimelic acid. The main respiratory quinone is MK10 (a menaquinone with 10 isoprenoid units); MK9, MK10(H_2), and MK11 are minor quinones. Characteristic fatty acids are n14/15:1d11 and n16/17:1d5 (Sittig and Schlesner, 1993). The following phospholipids were identified: phosphatidylglycerol and phosphatidylmethylethanolamine as major components, biphosphatidylglycerol in less amounts, and phosphatidylethanolamine and phosphatidylcholine only in traces. Phosphatidyldimethylethanolamine was not detected (Sittig and Schlesner, 1993). The DNA base composition is 58.6 ± 0.2 mol% G+C (T_m) for strain IFAM 1439^T = DSM 4136^T = ATCC 43997^T. The presence of *dnaK* (HSP70) multigene family was reported (Ward-Rainey et al., 1997).

Cultivation

The strains are growing aerobically with medium M 13 at a temperature of 30°C. Liquid cultures can be shaken.

Preservation

The strains can be kept on agar slants at 4–6°C for several months. For long term preservation, lyophilization or storage in liquid nitrogen is recommended. Deep freezing at –70°C with 50% glycerol is also possible.

Physiology

Verrucomicrobium spinosum is a facultative anaerobe. Various sugars are fermented without gas formation, but nitrate is not reduced under anaerobic conditions.

Only a limited number of substrates can be utilized as sole carbon and energy source, mainly hexoses, di- or trisaccharides or derivatives of glucose. C_1- or C_2-compounds are not utilized,

nor are fatty acids or amino acids (Schlesner, 1987). Carbon sources include: maltose, mannose, melibiose, melizitose, rhamnose, raffinose, trehalose, cellobiose, fructose, galactose, glucose, lactose, xylose, sucrose, *N*-acetylglucosamine, glucuronate, amygdalin, salicin, esculin and glycerol. Carbon sources not utilized are: D-arabinose, L-arabinose, sorbose, inulin, lyxose, fucose, ribose, methanol, ethanol, mannitol, sorbitol, inositol, acetate, adipate, butyrate, caproate, 2-oxoglutarate, pyruvate, succinate, valerate, formate, β-hydroxybutyrate, lactate, malate, propionate, aspartate, aspartic acid, glutamine, glutamic acid, histidine, proline, serine and threonine. The following carbohydrates could be utilized fermentatively (acid, but no gas formation): glucose, lactose, sucrose, maltose, mannose, melibiose, rhamnose, trehalose, cellobiose, fructose, galactose, xylose, and *N*-acetylglucosamine. Ammonia, urea, nitrate, and *N*-acetylglucosamine are suitable nitrogen sources. *Verrucomicrobium spinosum* produces exoenzymes which can be demonstrated by the hydrolysis of gelatin and starch. However, casein or Tween 80 is not hydrolyzed. Catalase, cytochromoxidase, phosphatase, and urease are produced. H_2S from thiosulfate or NH_3 from peptone is not produced.

Genus *Prosthecobacter*

Introduction

The genus *Prosthecobacter* contains nonmotile fusiform-shaped bacteria (Fig. 2). Since the previous edition of *The Prokaryotes* (Staley, 1992) and *Bergey's Manual of Systematic Bacteriology* (Poindexter and Staley, 1989), much has been learned about the phylogenetic diversity of these bacteria and their position as members of the phylum Verrucomicrobia in the Tree of Life (Hedlund et al., 1996).

Prosthecobacter was first reported and photographed by Henrici and Johnson (1935) attached to glass slides that had been submerged and incubated in situ in lakes. However, pure culture isolates were not reported until 1970 (DeBont et al., 1970). Strains were subsequently isolated from ponds, lakes and raw sewage (Staley et al., 1976). Similar organisms have also been observed in sea ice samples from Antarctica (Sullivan and Palmisano, 1984) but, to our knowledge, none yet has been cultivated. Cells undergoing division elongate and differentiate to produce a second prostheca at the dividing pole. Typically at the time of cell division, the two daughter cells are mirror images of one another.

Phylogeny

On the basis of 16S rDNA sequence analyses, the genus *Prosthecobacter* belongs to the same subgroup of the Verrucomicrobia as the genus *Verrucomicrobium* (Fig. 3). These two genera resemble one another in that they are both aerobic, prosthecate bacteria. In contrast to *Verrucomicrobium spinosum*, which has several prosthecae per cell, *Prosthecobacter* has only a single polar prostheca.

Prosthecobacter is the only genus among the Bacteria or Archaea so far known to contain the genes *btuba* and *btubb*, which are homologs for α- and β-tubulin genes, respectively (Jenkins et al., 2002). Reverse transcriptase polymerase chain reaction (RT-PCR) results indicate that the genes are expressed, but the proteins have not as yet been identified in cells. The evolution of these genes is poorly understood and the topic of ongoing investigation. Likewise, their function has not yet been studied.

Taxonomy

Four strains, each representing a separate species, have been cultivated. In terms of their 16S rDNA sequences, the four strains are sufficiently different from one another that they comprise different species (Hedlund et al., 1997). *Prosthecobacter fusiformis* $FC4^T$ is the type strain and species for the genus. The other species are *P. vanneervenii* strain FC2, *P. debontii* FC3 and *P. dejongeii* FC1.

Habitat

Prosthecobacter spp. have been isolated from ponds in Michigan and Washington states as well as a lake and raw sewage (North Carolina in the United States), indicating they are widespread and likely common freshwater organisms. Electron micrographs of water samples from Lake Washington indicate that they are commonly found attached to other organisms including diatoms.

Marine organisms resembling *Prosthecobacter* species have also been reported from sea ice communities (Sullivan and Palmisano, 1984; J. T. Staley, unpublished observation), but to our knowledge, strains have not yet been isolated in pure culture.

Isolation

Dilute peptone enrichment cultures have been used to isolate *Prosthecobacter* strains. These are typically set up in sterilized 150-ml beakers covered with aluminum foil lids. The beakers are inoculated with 100 ml of water from the site of

interest and an autoclaved solution of Bacto-Peptone is added to provide a final concentration of 0.01% (w/v). The enrichment cultures are incubated at room temperature for one to two weeks and observed by phase microscopy periodically to determine if fusiform cell shapes typical of the genus are present. If positive, the material is streaked onto Dilute Peptone Agar (see the chapter The Genera Prosthecomicrobium, Ancalomicrobium, Stella and Blastobacter in Volume 5) plates. Following incubation, wet mounts are made of small white to yellow colonies, which should be examined using the microscope to determine whether they have the characteristic morphology of the organism. They can be readily distinguished from *Caulobacter* cells because they are nonmotile and have a wider prostheca with a distinctly bulbous tip. Furthermore, prior to cell division, a prostheca can been seen to extend from the pole of each cell undergoing division, making the dividing cells symmetrical at this stage, unlike that of dividing *Caulobacter* spp. Appropriate colonies or wet mount preparations are restreaked until a pure culture is achieved.

For routine maintenance, *Prosthecobacter* spp. can be grown on MMB medium (see the chapter The Genera *Prosthecomicrobium*, *Ancalomicrobium*, *Stella*, and *Blastobacter* in the second edition). Slant cultures can be maintained in the refrigerator for about one month, and lyophilization or deep freezing can be used for longer storage.

Identification

The four different species can be differentiated from one another by phenotypic tests (Table 3). In addition, their 16S rDNA sequences are sufficiently different to possibly be of use in distinguishing novel strains.

Morphology

Morphologically the cells are about 0.5–1.0 μm in diameter and 3–10 μm in length. Cells may be straight to curved, fusiform shapes. The cells may aggregate to form small rosettes in pure culture. The tip of the prostheca is bulbous and the prostheca diameter is about 0.2 μm, somewhat wider than those of *Caulobacter* and *Asticacaulis*. Also, the *Prosthecobacter* prostheca has crossbands unlike those of *Caulobacter* and *Asticacaulis*.

Nutrition

A variety of mono- and disaccharides are used as sole carbon sources for growth and are helpful in distinguishing known species (Table 3).

Genus *Opitutus* and the Ultramicrobacteria

The recently named genus, *Opitutus*, has at least three strains (PB90-1^T, PB90-3 and ACB90) of obligately anaerobic bacteria isolated from rice paddy soil (Chin et al., 2001). Also isolated from this habitat are three strains of "ultramicrobacteria" (strains VeCb1, VeGlc2 and VeSm13), anaerobic dwarf cells with cell volumes of 0.03–0.04 μm^3 (Janssen et al., 1997). Unlike members of the genera *Verrucomicrobium* and *Prosthecobacter*, *Opitutus* and the ultramicrobacteria are non-prosthecate.

Phylogeny

Both the genus *Opitutus* and the ultramicrobacteria belong to subdivision 4 of the Verrucomicrobia, as proposed by Hugenholtz et al. (1998a). Of all the Verrucomicrobia strains isolated in pure culture, members of the genus *Opitutus* are most closely related to the ultramicrobacteria. *Opitutus* and ultramicrobacteria strains share 96–97% 16S rDNA sequence similarity, and thus they may be sufficiently similar to be considered members of the same genus. Phylogenetic trees based on partial (~275 bp) 16S rDNA sequences indicate that the ultramicrobacteria are also

Table 3. Differentiation among *Prosthecobacter* species.

closely related to the soybean soil clone, pad7 (Janssen et al., 1997).

Also in subdivision 4 of the Verrucomicrobia are ectosymbionts of ciliated protozoa termed "epixenosomes" (Petroni et al., 2000; Chin et al., 2001). The epixenosomes of the ciliate hypotrich, *Euplotidium arenarium*, share 83% sequence similarity with *Opitutus* strains.

Taxonomy

The genus *Opitutus* is currently represented by a single species, *Opitutus terrae*. The three strains of *O. terrae* (PB90-1^T, PB90-3 and ACB90) contain identical 16S rDNA sequences. PB90-1^T is the type strain of *O. terrae*.

Given the level of 16S rDNA sequence similarity between *O. terrae* and the ultramicrobacteria, it is likely that the ultramicrobacteria are also members of the genus *Opitutus* but may represent separate species.

Habitat

All strains of *O. terrae* and ultramicrobacteria in pure culture were isolated from anoxic (flooded) rice paddy soil microcosms where they appear to be relatively abundant. In the environment from which they were isolated, *Opitutus* spp. were found to comprise a significant proportion of the population (5%) of polysaccharolytic or saccharolytic fermenting bacteria (Chin et al., 1999). Furthermore, the discovery of 16S rDNA sequences of related organisms in clone libraries constructed from soybean field soil and peat bog soil (Rheims et al., 1996a) suggests that these organisms may be widespread in anoxic terrestrial environments.

Isolation

Both members of the genus *Opitutus* and the ultramicrobacteria can be isolated using liquid serial dilution culture (most probable number [MPN]) techniques. Rice plants (*Oryzae sativa*, var. Roma, type japonica) are grown in the laboratory using flooded soil obtained from wetland rice fields. Rice plants should be grown for 90 days before the soil is sampled. Soil samples are taken using a coring device to a depth of approximately 15 cm. Only the lower 10-cm portion of the soil core is used as inoculum. MPN tubes containing sulfide-reduced, bicarbonate buffered medium (SM) supplemented with pectin or amorphous cellulose as carbon source are used for the isolation of *Opitutus* strains. Dilute medium can be used for the isolation of ultramicrobacteria.

SM Medium

Mineral Salts Solution	
NaCl	1.0 g
$MgCl_2 \cdot 6H_2O$	0.40 g
NH_4Cl	0.10 g
KH_2PO_4	0.20 g
$CaCl_2 \cdot 2H_2O$	0.10 g
KCl	0.50 g
Distilled water	1 liter

Dissolve ingredients and dilute up to 1 liter with distilled water. Autoclave the mineral salts solution at 121°C for 45 min and cool under a headspace of N_2/CO_2 (80:20 [vol/vol]). Supplement the medium with 30 mL of 1 M sodium bicarbonate solution, which has been autoclaved under a headspace of CO_2, 3 ml of 0.5 M Na_2S (autoclaved under N_2), and 1 ml of each vitamin solution. Adjust the medium to pH 7.2–7.3 and dispense into either sterile screw capped bottles or serum bottles. Add carbon sources (such as pectin or amorphous cellulose). If the medium is to be dispensed into MPN tubes, gas the headspace with N_2/CO_2 and add sodium dithionate to a final concentration of 100 μM.

Vitamin Solution 1

4-Aminobenzoic acid	40 mg
D(+)-Biotin	10 mg
Calcium D(+)-pantothenate	100 mg
Nicotinic acid	50 mg
Pyridoxine hydrochloride	100 mg
Folic acid	30 mg
DL-*a*-Lipoic acid	10 mg
Sodium phosphate buffer (50 mM, pH 7.1)	1 liter

Dissolve ingredients and dilute in sodium phosphate buffer up to a 1 liter. Dissolve the vitamins in sodium phosphate buffer and filter sterilize.

Vitamin Solution 2

Cyanocobalamin	50 mg
Distilled water	1 liter

Dissolve cyanocobalamin and dilute up to 1 liter with distilled water. Filter sterilize this solution.

Vitamin Solution 3

Thiamine chloride dihydrochloride	10 mg

Dissolve vitamin powder in 100 ml of 25 mM sodium phosphate buffer (pH 3.4) and filter sterilize.

Trace Element Solution

HCl (2M)	50 ml
$FeCl_2 \times 4H_2O$	1000 mg
$CoCl_2 \cdot 6H_2O$	130 mg
$MnCl_2 \cdot 2H_2O$	80 mg
$ZnCl_2$	70 mg
H_3BO_3	6 mg
$Na_2MoO_4 \cdot 2H_2O$	36 mg
$NiCl_2 \cdot 6H_2O$	24 mg
$CuCl_2 \cdot 2H_2O$	2 mg
Distilled water	1 liter

Dissolve the $FeCl_2 \cdot 4H_2O$ in the HCl, then add the distilled water and the rest of the components up to a total of 1 liter. Autoclave this solution under air.

Dilute Medium

Mineral Salts Solution	
NaCl	0.25 g
$MgCl_2$	0.20 g
KCl	0.10 g
NH_4Cl	0.10 g
KH_2PO_4	0.05 g
$CaCl_2 \cdot 2H_2O$	0.10 g
Distilled water	1 liter

Dissolve components and dilute up to 1 liter with distilled water. Autoclave the mineral salts solution at 121°C for 40 min and cool under a headspace of N_2/CO_2 (80:20 [vol/vol]) with an overpressure of 6 kPa. Once the mineral salts solution is cool, add 30 ml of 1 M sodium bicarbonate and 3 ml of 0.5 M Na_2S, which have been autoclaved in vessels sealed with rubber stoppers under headspaces of CO_2 and N_2, respectively. In addition, add 5 ml of vitamin solution 1 and 1 ml each of vitamin solution 2, trace element solution, and selenite/tungstate solution. Then, adjust pH to 7.2 with sterile HCl or 0.5 M Na_2CO_3. Fill serum bottles part way with medium and seal. Gas the headspace with N_2/CO_2 (80:20 [vol/vol]). Alternatively, dispense the medium into sterile screw capped bottles, leaving only a small gas bubble. Add appropriate carbon sources as desired. Different combinations of carbon sources have been used to isolate ultramicrobacteria, including glucose at [4 mM], cellobiose at [2 mM] and a mixture of seven sugars (1 mM each of glucose, cellobiose, fructose, xylose, arabinose, maltose and galactose).

Vitamin Solution 1

4-Aminobenzoate	40 mg
(+)-Biotin	10 mg
Nicotinic acid	100 mg
Hemicalcium D-(+)-pantothenate	50 mg
Pyridoxamine hydrochloride	150 mg
Thiamine chloride hydrochloride	100 mg
Cyanocobalamin	50 mg
Distilled water	1 liter

Dissolve and dilute ingredients up to 1 liter with distilled water. Filter sterilize this solution.

Vitamin Solution 2

DL-6,8-thioctic acid	10 mg
Riboflavin	10 mg
Folic acid	4 mg
Distilled water	1 liter

Dissolve and dilute ingredients up to 1 liter with distilled water. Filter sterilize this solution.

Trace Element Solution

HCl (25%)	10 mL
$FeCl_2 \cdot 4H_2O$	1.5 g
$CoCl_2$	190 mg
$MnCl_2 \cdot 4H_2O$	100 mg
$ZnCl_2$	70 mg
H_3BO_3	6 mg
$Na_2MoO_4 \cdot 2H_2O$	36 mg
$NiCl_2 \cdot 6H_2O$	24 mg
$CuCl_2 \cdot 2H_2O$	2 mg
Distilled water	1 liter

Dissolve the $FeCl_2 \cdot 4H_2O$ in the HCl, then add the distilled water and the rest of the components up to 1 liter. Autoclave this solution under air.

Selenite/Tungstate Solution

NaOH	0.5 g
$Na_2SeO_3 \cdot 5H_2O$	3 mg
$Na_2WO_4 \cdot 2H_2O$	4 mg
Distilled water	1 liter

Dissolve and dilute ingredients up to 1 liter with distilled water. Autoclave this solution under air.

Identification

Morphological and Cytological Characteristics

Opitutus terrae Unlike some other cultured members of the Verrucomicrobia, *O. terrae* strains are non-prosthecate. Cells are coccoid but sometimes have the appearance of short rods under the phase contrast microscope because of the formation of chains of three or four cells. Diplococci are commonly observed, with one cell of the pair possessing a subpolar flagellum. Cells of *O. terrae* are 0.4–0.6 μm in diameter. Cells stain Gram negative and test positive for the aminopeptidase reaction and the KOH test. In agar deeps, *Opitutus* colonies appear granular and are nonpigmented. Spore formation has not been observed. Mol% G+C of the type strain is 73.7 ± 0.3.

Ultramicrobacteria
As with *Opitutus* strains, the ultramicrobacteria are non-prosthecate. Cells are ellipsoid to spherical in shape and often appear as diplococci. Cells are approximately 0.5 μm long and 0.35 μm wide. By definition, ultramicrobacteria have cell volumes of less than 0.1 μm^3; ultramicrobacteria in the phylum Verrucomicrobia typically have cell volumes of between 0.03 and 0.04 μm^3. Mature cells are motile via a single subpolar flagellum that can be up to 8.5 μm in length. Cells stain Gram negative and test positive for the KOH test. Colonies in agar deeps are white and lens-shaped. Spores have not been observed. Mol% G+C ratio ranges from 63.3–63.5.

Metabolic and Biochemical Properties

Opitutus strains possess a fermentative metabolism and are obligate anaerobes. Ultramicrobacteria strains are also fermentative but are oxygen tolerant. Growth of the type strain of *O. terrae* and the ultramicrobacteria is supported by mono-, di- and polysaccharides (Table 4).

Substrates that do not support the growth of any strains listed in Table 4 include ribose, cellulose (although *O. terrae* strain ACB90 hydrolyzes cellulose), pyruvate, lactate, fumarate, malate, citrate, crotonate, tartrate, glycerol (with or without acetate), alanine, glutamate, lysine, aspartate and leucine. Of the compounds tested, ultramicrobacteria strains VeCb1 and VeGlc2 have identical substrate ranges for growth, while VeSm13

Symbols: +, present; –, absent; and ND, no data.

has a more limited range. *Opitutus terrae* PB90-1^T is capable of using almost all of the same substrates as VeCb1 and VeGlc2 but is able to use more monosaccharides.

For all three ultramicrobacteria strains, the fermentation end products are acetate, propionate and succinate. *Opitutus terrae* produces propionate and acetate as the major end products of fermentation but also produces smaller amounts (0.2 mol per mol of growth substrate) of succinate, lactate, ethanol and H_2. When grown on pectin, *O. terrae* also produces methanol. *Opitutus terrae*, but not the ultramicrobacteria strains, can use nitrate as an electron acceptor which is reduced solely to nitrite.

Sulfur, sulfate and thiosulfate are not reduced by any strains. The ultramicrobacteria hydrolyze urea and esculin, while *O. terrae* is only capable of esculin hydrolysis. Gelatin is not hydrolyzed by any strains, and catalase activity was not detected for any of the strains.

The type strain of *O. terrae* grows optimally at a pH of 7.5–8.0 but is able to grow within the range of 5.5–9.0. Ultramicrobacteria strain VeGlc2 is able to grow at pH values between 6.6 and 8.0, although other values have not been tested. *Opitutus terrae* PB90-1^T and VeGlc2 are capable of growth at temperatures between 10°C and 37°C but not at 40°C. Growth of *O. terrae* was possible in media supplemented with NaCl (30 g but not 40 g per liter). Ultramicrobacteria strain VeGlc2 tolerated NaCl (15 g but not 20 g per liter).

Strain VeGlc2 is resistant to bacitracin and benzylpenicillin at 1000 $\mu g \cdot ml^{-1}$ but is sensitive to ampicillin and other antibiotics.

Epixenosomes

Epixenosomes are Verrucomicrobia that reside as ectosymbionts on the dorsal surface of marine hypotrich ciliates in the genus *Euplotidium*. As epixenosomes are obligate symbionts, they have not been isolated in pure culture and therefore studies on these organisms have been limited. Studies to date have involved the epixenosomes of *E. itoi* and *E. arenarium*. These epixenosomes possess a complex internal ultrastructure consisting of a ribbon-like extrusive apparatus and bun-

dles of associated microtubule-like structures (Rosati et al., 1993; Fig. 4). In the natural environment the harpoon-like extrusomes of epixenosomes (Fig. 5) are believed to perform a defensive role for the host ciliates against predatory protozoa such as *Litonotus lamella*. Indeed, *in vitro* experiments have demonstrated that *Euplotidium* sp. containing epixenosomes are never ingested by *Litonotus* unless the extrusive apparatus is inhibited. In contrast, ingestion of *Euplotidium* occurs readily when their adhering epixenosomes have been removed (Rosati et al., 1999).

Phylogeny

The complexity of the internal organization of epixenosomes combined with the presence of microtubule-like structures initially led to confusion about whether these organisms were prokaryotic or eukaryotic in nature. More recently, the 16S rRNA gene of the *E. arenarium* epixenosome was sequenced, and phylogenetic trees constructed using these data showed that these organisms are bacteria that cluster in Verrucomicrobia subdivision 4 along with *Opitutus* and ultramicrobacteria strains (Petroni et al., 2000; Chin et al., 2001). The *E. arenarium* epixenosome 16S rRNA gene shares 83–84% sequence similarity with those from other members of subdivision 4 but only 74–78% sequence similarity with members of the other subdivisions (Chin et al., 2001).

Taxonomy

The epixenosomes of *E. arenarium* and *E. itoi* have not been isolated in pure culture and therefore have not been officially named.

Habitat

Epixenosomes reside on the dorsal surface of their ciliate hosts and are arrayed in a well defined cortical band. While only the epixenosomes of *E. arenarium* and *E. itoi* have been studied in detail, symbionts resembling epixenosomes have been observed on the surface of other marine ciliates in the *Euplotidium* genus. *Euplotidium* spp. are prevalent in marine coastal waters.

Life Cycle and Cell Structure

While epixenosomes are not necessary for host cell survival in a noncompetitive environment, they have been shown to influence the morphogenesis of the cortical band region, where they reside. The cortical region of the host differs when epixenosomes are present versus absent. Similarly, epixenosomes have been shown to possess two distinct developmental phases linked to the host cell cycle.

Stage I epixenosomes divide by binary fission and possess a simple bacteria-like ultrastructure. Cells are spherical and measure 1 μm in diameter. Stage II epixenosomes are ovoid and larger in size (2.5 μm × 1.2 μm) and develop by gradually acquiring a more complex internal structure (Fig. 4). Internal structures that are present in stage II epixenosomes but absent from stage I epixenosomes include an electron-dense region composed of DNA and protein, a ribbon-like extrusive apparatus, and a "basket-like" structure composed of regularly arrayed microtubule-like tubules. During the transition from stage I to stage II, the tubules appear randomly distributed throughout the cytoplasm, but once the extrusive apparatus is completely formed they are arranged in a basket-like formation around the extrusome. Cell division ceases once the epixenosomes reach stage II.

Ejection of the extrusive apparatus (Fig. 5) occurs when *Euplotidium* species encounter predatory protozoa and can be stimulated in the laboratory with adrenalin (Rosati et al., 1997). Extrusion is mediated when external signals of unknown origin are detected via membrane receptors on the top of the bacterium. These receptors are involved in signal transduction and activation of the adenylate cyclase-cAMP system (Rosati et al., 1997). The tubular structures surrounding the extrusive apparatus also appear to be directly involved in the ejection process. Experiments in which the tubules are disrupted using either nocodazole or cold treatment (both of which have been shown to cause microtubule depolymerization) result in loss of the ejection capability (Rosati et al., 1993).

"*Candidatus Xiphinematobacter*"

The candidate genus "*Candidatus Xiphinematobacter*" was proposed to incorporate three species of Verrucomicrobia that are obligate endosymbionts of nematodes in the genus *Xiphinema* (Vandekerckhove et al., 2000). These bacteria reside inside the epithelial cells of the nematode ovarial walls, where they are believed to influence the reproductive mechanism of their host.

Phylogeny

"*Candidatus Xiphinematobacter*" strains belong to subdivision 2 of the Verrucomicrobia (Hugenholtz et al., 1998a; Vandekerckhove et al., 2000). Their closest relatives are represented by uncultured clones from a hydrocarbon and chlorinated-solvent containing reactor and from soil and freshwater. The three species of "*Xiphinematobacter*" share a mean 16S rDNA similarity of 93%, but share less than 87% simi-

larity with their nearest relative, aquifer clone WCHD3-88.

Taxonomy

As "*Xiphinematobacter*" are endosymbionts and have never been isolated in pure culture, the genus remains at *Candidatus* status. "*Candidatus Xiphinematobacter*" contains three species: "*Candidatus Xiphinematobacter brevicolli*," the type species, "*Candidatus Xiphinematobacter americanum*" and "*Candidatus Xiphinematobacter rivesi*."

Habitat

"*Xiphinematobacter*" species live as endosymbionts in the ovarial and intestinal epithelium of nematodes in the *Xiphinema americanum* group. These symbioses are host specific, and thus *Xiphinema brevicollum*, *Xiphinema americanum* and *Xiphinema rivesi* are host to "*Xiphinematobacter brevicolli*," "*Xiphinematobacter americanum*" and "*Xiphinematobacter rivesi*," respectively.

"*Xiphinematobacter*" species are maternally inherited via transovarial transmission and therefore their survival is dependent on the host sex ratio. Interestingly, nematodes belonging to the symbiont-containing *Xiphinema americanum* group all reproduce via thelytokous (mother-daughter) parthenogenesis, while *Xiphinema* species that are uninfected can reproduce either sexually or via parthenogenesis, depending on the species. Therefore, it has been suggested that "*Xiphinematobacter*" species may be responsible for manipulating the sex ratio of the host via induction of thelytokous parthenogenesis, in a similar manner to the α-proteobacterium, *Wolbachia pipientis* (Coomans et al., 2000).

Morphology

"*Xiphinematobacter*" species are rod-shaped with rounded ends and are nonmotile, nonprosthecate and nonsporulating. Cell dimensions are 0.7–1.0 μm × 2.1–3.2 μm. Cells stain Gram negative with no peptidoglycan layer discernable in thin-section electronmicroscopy. Instead, a hexagonally arrayed layer of 10-nm proteins, similar to those seen in *Chlamydia* sp., are associated with the inner edge of the outer membrane. As with *Prosthecobacter* species, cell division is unipolar.

Genus *Victivallis*

The genus *Victivallis* contains one species, *V. vadensis* with the type strain Cello^T (named for its ability to utilize cellobiose). This species was isolated from a human fecal sample and is a strict anaerobe. *Victivallis vadensis* is the most recently isolated member of the phylum Verrucomicrobia.

Phylogeny

Victivallis vadensis does not fall into any of the Verrucomicrobia subdivisions proposed by Hugenholtz et al. (1998a) but forms a separate cluster with several uncultured clones obtained from anaerobic digesters (see Fig. 3). Thus, *V. vadensis* represents a seventh subdivision of the Verrucomicrobia, of which it is the only cultured member. Anaerobic digester clones AA08 and vadinHB65 share only 94% sequence similarity with *V. vadensis*, indicating that they form separate species.

Taxonomy

Victivallis vadensis is the only species in the genus *Victivallis* and is represented by a single strain, Cello^T.

Habitat and Isolation

Victivallis vadensis was isolated from a human fecal sample. A density gradient gel electrophoresis (DGGE) profile of the same sample indicated that *V. vadensis* was not a dominant member of the fecal flora (Zoetendal et al., 2003); however, the detection of the 16S rRNA genes of related organisms in an anaerobic digester indicates that these organisms may be ubiquitous.

To isolate *V. vadensis*, a bicarbonate buffered anaerobic medium supplemented with cellobiose is employed (see below). One notable characteristic of *V. vadensis* is its inability to grow on solid media. *Victivallis vadensis* can be cultivated in broth or semisolid (0.75%) agar media.

Bicarbonate-buffered Anaerobic Medium (Stams et al., 1993)

Basal Medium	
$NaHPO_4 \cdot 2H_2O$	0.53 g
KH_2PO_4	0.41 g
NH_4Cl	0.30 g
$CaCl_2 \cdot 2H_2O$	0.11 g
$MgCl_2 \cdot 6H_2O$	0.10 g
NaCl	0.30 g
$NaHCO_3$	4.0 g
$Na_2S \cdot 9H_2O$	0.48 g
Distilled water	1 liter

Dissolve and dilute ingredients up to 1 liter with distilled water. Autoclave the medium and dispense into serum vials with a headspace of N_2/CO_2 or H_2/CO_2 (80:20 [vol/vol]). Add 1 ml each of acid and alkaline trace element solution and 0.2 ml of vitamin solution. Supplement the medium with 10 mM cellobiose (filter sterilized) and 0.7% (vol/vol) sterile clarified rumen fluid.

Acid Trace Element Solution

$FeCl_2$	7.5 mM
H_3BO_4	1.0 mM
$ZnCl_2$	0.5 mM
$CuCl_2$	0.1 mM
$MnCl_2$	0.5 mM
$CoCl_2$	0.5 mM
$NiCl_2$	0.1 mM
HCl	50 mM

Filter sterilize the solution.

Alkaline Trace Element Solution

Na_2SeO_3	0.1 mM
Na_2WO_4	0.1 mM
Na_2MoO_4	0.1 mM
NaOH	10 mM

Filter sterilize the solution.

Vitamin Solution

Biotin	20 mg
Niacin	200 mg
Pyridoxine	500 mg
Riboflavin	100 mg
Thiamine	200 mg
Cyanocobalamin	100 mg
p-Aminobenzoic acid	100 mg
Pantothenic acid	100 mg

Filter sterilize the solution.

Identification

Morphological and Cytological Characteristics *Victivallis vadensis* is a strict anaerobe. Cells are coccoid with diameters of 0.5–1.3 μm and are nonmotile. An extracellular slime layer is produced. Cells stain Gram negative and do not produce spores. Strain Cello^T has a mol% G+C ratio of 59.2%.

Metabolic and Biochemical Properties *Victivallis vadensis* is a strict anaerobe that grows well on a variety of sugars including cellobiose, glucose, fructose, galactose, lactose, lactulose, maltose, maltotriose, mannitol, melibiose, *myo*-inositol, raftilose, rhamnose, ribose, sucrose and xylose. Compounds that do not support growth include cellulose, fucose, gelatin, pectin, raffinose, starch, fumarate, casamino acids, oleate, pyruvate, yeast extract, methanol, ethanol, 1-propanol, 2-propanol, 2-butanol, casein, peptone, tryptone and H_2/CO_2. *Victivallis vadensis* is not able to use sulfate or nitrate as electron acceptor. Glucose is converted to acetate, ethanol, bicarbonate and H_2.

On cellobiose, temperatures between 20°C and 40°C and pHs between 5 and 7.5 support the growth of *V. vadensis*; however, optimal growth occurs at 37°C and pH 6.5, conditions that mimic those of the human intestinal tract.

CHAPTER 12.1

Thermotogales

ROBERT HUBER AND MICHAEL HANNIG

Introduction

Members of the Thermotogales represent a very deep phylogenetic branch within the 16S rRNA gene tree. Within the order, members of the genus *Thermotoga* have an upper temperature border of growth at 90°C and represent, together with members of the order *Aquificales*, the bacteria with the highest growth temperatures known so far. Representatives of the Thermotogales are widespread and cosmopolitan, and they thrive mainly in volcanically or geothermally heated environments. Owing to their strictly organotrophic way of life, they are consumers of microbial biomaterial within high temperature ecosystems.

For the Thermotogales, the following order criteria are characteristic: thermophilic, non-sporeforming, rod-shaped cells with an outer sheath-like envelope ('toga'); Gram-negative, but *meso*-diaminopimelic acid not present in the peptidoglycan; strictly anaerobic, fermentative bacteria; acetate, carbon dioxide, and hydrogen metabolites from glucose fermentation; inhibition of growth by hydrogen; lysozyme-sensitive; unusual long-chain dicarboxylic fatty acids present in the lipids; and G+C content, 29–50 mol%.

Phylogeny

By 16S rRNA gene sequence comparison it was shown first in 1987 that *Thermotoga maritima* represents a slowly evolving lineage and a deep phylogenetic branch within the bacterial domain (Huber et al., 1986; Woese, 1987; Fig. 1). On the basis of this result, a thermophilic origin of the bacterial domain was proposed (Achenbach-Richter et al., 1987). The outstanding phylogenetic placement of *T. maritima* was strengthened by comparative analysis of other macromolecules such as 23S rRNA, elongation factor Tu and G, ß-subunit of the ATPase, *fus* gene and of ferredoxins (Bachleitner et al., 1989; Schleifer and Ludwig, 1989; Tiboni et al., 1991; Ludwig et al., 1993; Blamey et al., 1994; Darimont and Sterner, 1994) and by whole genome-based phylogenetic analysis (Fitz-Gibbon and House, 1999). In contrast, sequence comparisons of bacterial RNA-polymerase large subunits placed *T. maritima* next to the chloroplasts, and the analysis of the bacterial DNA polymerase III, class II, placed *T. maritima* next to *Clostridium acetobutylicum* (Palm et al., 1993). Furthermore, a 16S rRNA phylogenetic tree based on the most conserved positions proposed that the Planctomycetales is the first branching bacterial group and not a hyperthermophilic bacterium (Brochier and Philippe, 2002). On the basis of conserved inserts and deletions found in various proteins, Gupta and Griffith (2002) placed *T. maritima* phylogenetically within the Gram-positive Bacteria. However, owing to biochemical and ultrastructural features, *T. maritima* is considered to be a true Gram-negative bacterium (see also Identification).

Taxonomy

Owing to the outstanding phylogenetic position of *T. maritima* in combination with unique morphological, physiological and biochemical criteria, the order Thermotogales consisting of the single family Thermotogaceae was described (Huber et al., 1992b). Within the Thermotogaceae, the genera *Thermotoga* (Huber et al., 1986; Huber and Stetter, 2001b), *Thermosipho* (Huber et al., 1989a; Ravot et al., 1996b; Huber and Stetter, 2001b), *Fervidobacterium* (Patel et al., 1985a; Huber et al., 1990; Huber and Stetter, 2001b), *Geotoga*, *Petrotoga* (Davey et al., 1993a; Davey et al., 2001a; Davey et al., 2001b) and *Marinitoga* (Wery et al., 2001) have been described. The species belonging to the different genera of the Thermotogales are listed in Table 1; their phylogenetic relationship is shown in Fig. 2. On the basis of 16S rRNA gene sequence analysis, *T. maritima*, *Thermotoga neapolitana*,

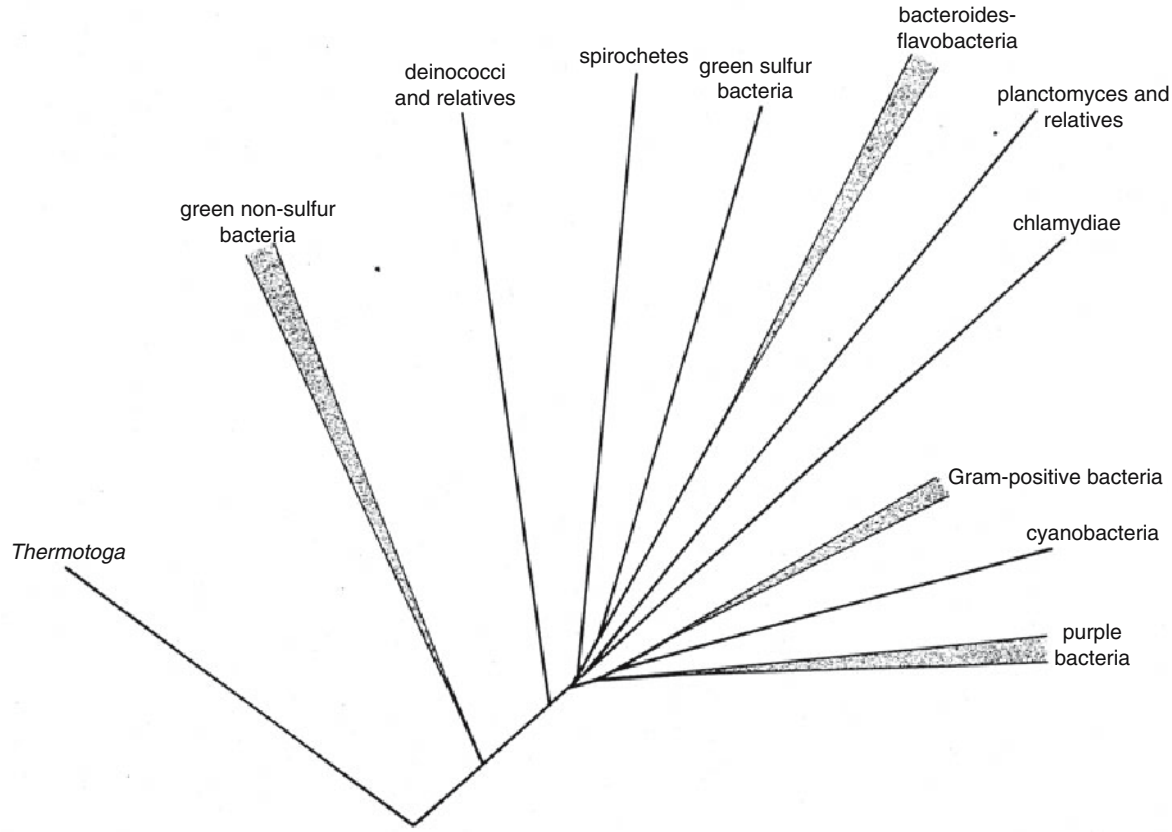

Fig. 1. Phylogenetic tree based upon 16S rRNA gene sequence comparison showing the phylogenetic position of the species *Thermotoga maritima* at the root of bacterial tree. (From Woese, 1987; courtesy of C. W. Woese.)

Thermotoga petrophila and *Thermotoga naphthophila* show a very close relationship (Fig. 2). However, based on specific sequence signatures in the 16S rRNA gene (*Escherichia coli* numbering; Brosius et al., 1981; Woese, 1987), the *T. maritima – T. neapolitana* group (position 1031, C; 1290, G; 1364, U) can be distinguished from the *T. naphthophila – T. petrophila* group (position 1031, U; 1290, A; 1364, C). Recently, the phylum Thermotogae, consisting of the single class Thermotogae was proposed (Reysenbach, 2001).

Habitat

Members of the Thermotogales are widespread and cosmopolitan. They thrive within continental solfatara springs of low salinity, shallow and deep-sea marine hydrothermal systems and high-temperature marine and continental oil fields.

From the genus *Thermotoga*, the type species *T. maritima* had been originally isolated from a geothermally heated, shallow marine sediment at Vulcano, Italy (Huber et al., 1986). The second species of this genus, *T. neapolitana*, was obtained from a submarine thermal vent at Lucrino near Naples, Italy (Belkin et al., 1986; Jannasch et al., 1988). Members of the marine *T. maritima – T. neapolitana* group are widespread within high temperature ecosystems and have also been isolated from shallow submarine hydrothermal systems on Sangeang Island (Indonesia), Ribeira Quente, Sao Miguel Island (the Azores), Kunashir Island (north of Japan) and the Fiji Island (Huber and Stetter, 1992b). Additional isolates were obtained from the Kolbeinsey Ridge north of Iceland in a depth of 106 m and from deep-sea hot sediments in a depth of 2000 m (Guaymas, Mexico; Huber and Stetter, 1992a; Huber and Stetter, 1992b). *Thermotoga thermarum* was originally isolated from continental solfataras with low ionic strength at Lac Abbé, Djibouti, Africa (Windberger et al., 1989). The closest cultivated relative of *T. thermarum* is the so far undescribed new *Thermotoga* species BB13-1-L6A, which thrives in the geothermally heated water (68°C; pH 6.8)

Table 1. List of the described species within the Thermotogales.

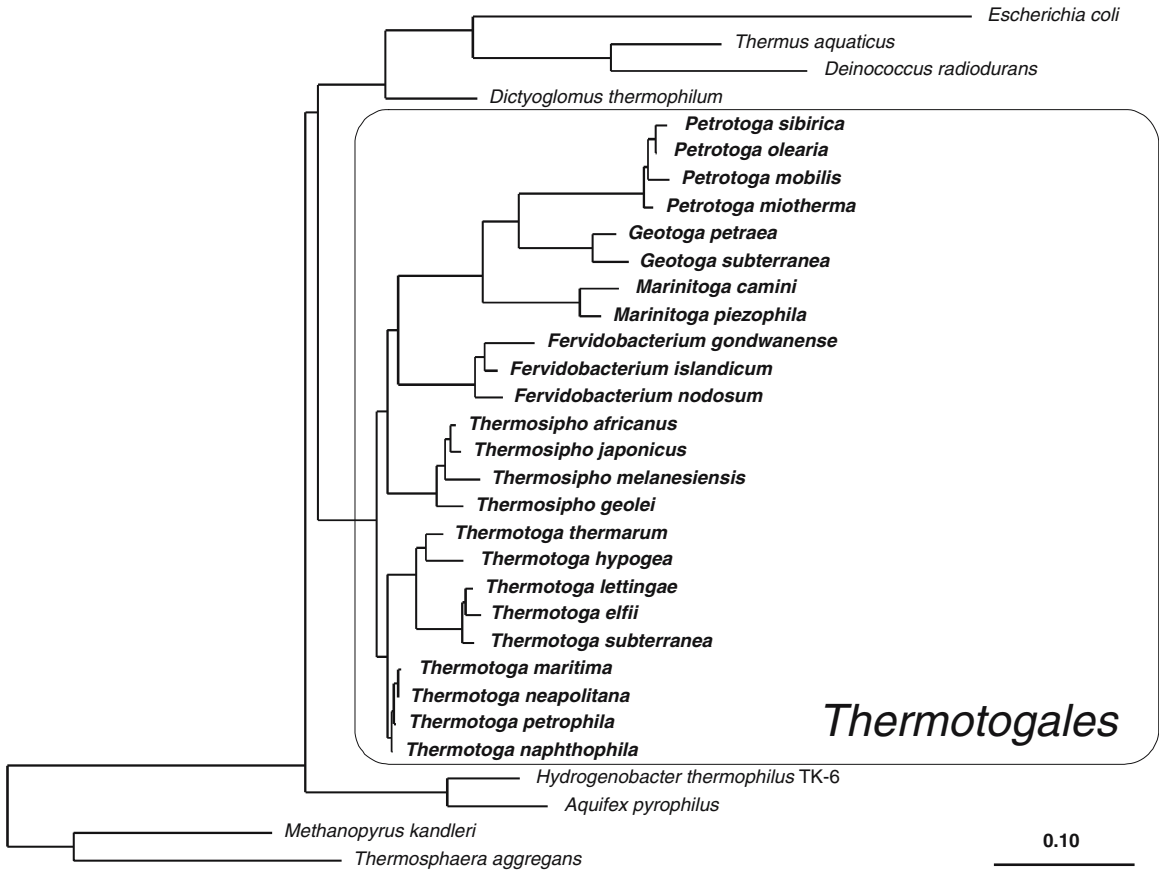

Fig. 2. 16S rRNA-based phylogenetic tree of the Thermotogales. The tree topology is based on the ARB database of 11,800 sequence entries and was reconstructed using the ARB parsimony tool. A filter defining positions that share identical residues in at least 50% of all included sequences from the Thermotogales was used for reconstructing the tree. Reference sequences were chosen to represent the broadest diversity of bacteria. Accession numbers for the sequences are given in Table 1. The scale bar represents 0.10 fixed mutations per nucleotide position.

of the Friedrichstollen in Baden-Baden (Germany; Fig. 3).

Evidence for the presence of Thermotogales relatives in deep-subsurface petroleum reservoirs was reported for the first time by Stetter et al. (1993). *Thermotoga*-related organisms (designated "Pb-isolates") were obtained from seawater flooded oil fields, about 3000 m below the permafrost surface of the North Slope of Alaska (Prudhoe Bay, Endicott and Kuparuk oil fields; Stetter et al., 1993; Stetter and Huber, 2000). By 16S rRNA gene sequence comparison and sequence signature analysis, these Pb-isolates were found to group together with the recently described *T. petrophila* and *T. naphthophila* from the Kubiki oil reservoir in Niigata (Japan; Takahata et al., 2001). Further *Thermotoga* isolates from oil production wells were described as *Thermotoga elfii* (Africa; Ravot et al., 1995), *Thermotoga subterranea* (East Paris Basin; Jeanthon et al., 1995) and *Thermotoga hypogea* (Africa; Fardeau et al., 1997). *Thermotoga*-like organisms have been also reported from a continental oil reservoir (L'Haridon et al., 1995), and Thermotogales relatives were also found during a systematic survey in high temperature oil reservoirs with different salinities (Grassia et al., 1996).

Members of the genus *Fervidobacterium* seem to be restricted to biotopes with low salinity. *Fervidobacterium nodosum* was originally isolated from a hot spring in New Zealand (Patel et al., 1985a). *Fervidobacterium islandicum* was obtained from a continental solfatara field at Hveragerthi (Iceland; Huber et al., 1990) and further, so far undescribed *Fervidobacterium* relatives were isolated from continental hot springs in Tibet (Huber and Stetter, 1992a), from Nadi, Viti Levu (Fiji Island), and from Octopus Spring (Yellowstone National Park, United States). *Fer-*

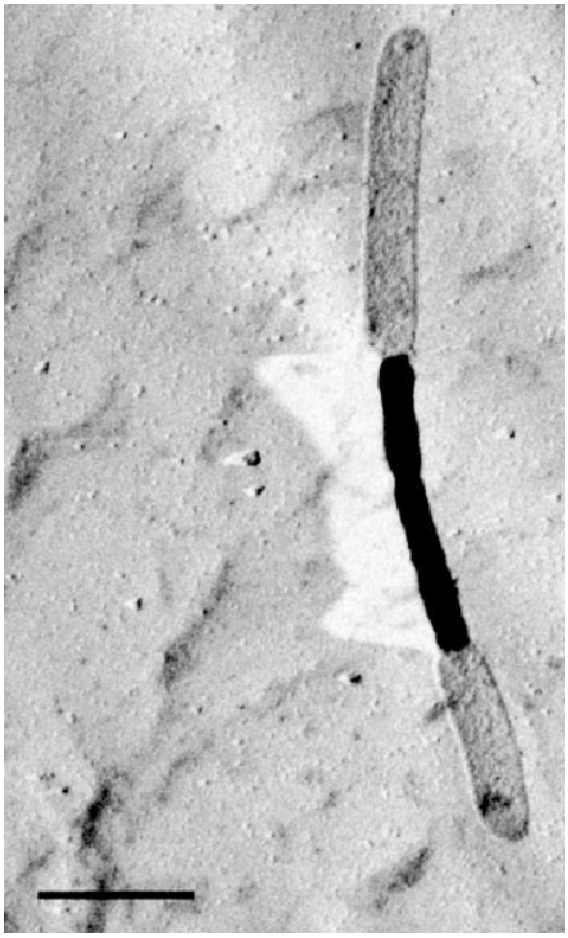

Fig. 3. The new *Thermotoga* species BB13-1-L6A, isolated from geothermally heated water from the Friedrichstollen in Baden-Baden, Germany. The rod-shaped cell is covered by an elongated sheath-like outer membrane ("toga"), overballooning at both ends. Bar, 1 μm.

vidobacterium gondwanense was obtained from a sample taken from a runoff channel of the Great Artesian Basin of Australia (Andrews and Patel, 1996), *Fervidobacterium pennivorans* from a hot spring on San Miguel (the Azores, Portugal; Friedrich and Antranikian, 1996).

From marine hydrothermal springs and sandy sediments of the Gulf of Tadjoura southwest of Obock (Djibouti, Africa), three strains belonging to the genus *Thermosipho* have been isolated. They represented a single species, *Thermosipho africanus* (Huber et al., 1989a). *Thermosipho melanesiensis*, the second species within this genus, was obtained from the gills of *Bathymodiolus brevior*, a deep-sea hydrothermal vent mussel. This invertebrate was collected at the bottom of a black smoker in the Lau Basin (depth 1832 m), Southwest Pacific Ocean (Antoine et al., 1997). Recently, *Thermosipho japonicus* was isolated from a deep-sea hydrothermal vent in the Iheya Basin (Japan; Takai and Horikoshi, 2000a). Members of the genus *Thermosipho* thrive also in hot oil reservoirs. A so far undescribed, new *Thermosipho* species was obtained from reservoir fluids taken at the Thistle oil production platform (East Shetland Basin, North Sea; Stetter et al., 1993; Stetter and Huber, 2000), and recently, *Thermosipho geolei* from a continental petroleum reservoir in Western Siberia was published (Russia; L'Haridon et al., 2001).

From petroleum reservoirs located in Oklahoma and Texas, members of *Geotoga* and *Petrotoga* have been isolated for the first time (Davey et al., 1993a). The isolates have been described as *Geotoga petraea*, *Geotoga subterranea* and *Petrotoga miotherma*. *Petrotoga mobilis* was obtained from a North Sea oil production well (Lien et al., 1998) and two recent isolates were obtained from a continental petroleum reservoir in Western Siberia, namely *Petrotoga olearia* and *Petrotoga sibirica* (L'Haridon et al., 2002).

The type species of *Marinitoga*, *Marinitoga camini*, was isolated from a deep-sea hydrothermal chimney sample on the Mid-Atlantic Ridge (Wery et al., 2001) and *Marinitoga piezophila* was isolated from a chimney rock on the East-Pacific Rise (Alain et al., 2002).

Isolation

Members of the Thermotogales can be enriched in anaerobic culture media with a pH around 7 (Table 2) under a gas phase consisting of 300 kPa N_2 or 300 kPa N_2/CO_2 (80:20; vol/vol). Depending on the salt requirement of the organism, either half strength seawater media or media with low ionic strength are used (Table 2). The media, supplemented with a defined carbon source (e.g., maltose or starch; Table 3) and complex organic material (e.g., yeast extract or peptone; Table 3), are inoculated with original sampling material. Members of the *T. maritima NT. neapolitana* group can be selectively enriched at an incubation temperature of 85°C with starch as the only carbon and energy source. Keratinophilic (feather-degrading) *Fervidobacterium* species might be obtained in yeast extract/tryptone medium with native feathers from chickens, ducks or geese (Leuschner and Antranikian, 1994). For enrichment of *G. petraea*, *G. subterranea* and *P. miotherma*, alpha-glycerophosphate and starch should be added to petroleum reservoir brines (Davey et al., 1993a). *Marinitoga piezophila* can be selectively enriched heterotrophically under a hydrostatic pressure of 30 MPa (Alain et al., 2002).

The enrichment bottles are incubated at the appropriate temperatures (45–85°C; Table 2)

and monitored for growth over a certain time period (e.g., two weeks) by phase contrast microscopy. When rod-shaped cells with an outer sheath-like structure or with a single terminal bleb become visible, the enrichments are serially diluted. The isolates are obtained by plating under anaerobic conditions and at an incubation temperature between 45 and 80°C (Table 2). For plating, a stainless steel anaerobic jar (Balch et al., 1979) and plates, solidified with Gelrite (0.7–1.0%; Huber and Stetter, 2001a) or agar (0.8–3%), can be used. Other methods for isolation are agar shake tubes (2%) or phytagel roll tubes (4%). For *T. neapolitana*, mean plating efficiencies up to 84% on 0.7% Gelrite have been reported. For growth, the plates were incubated at 77°C in a glass canning jar containing a packet of palladium pellets as a catalyst (Childers et al., 1992; Vargas and Noll, 1994). Colonies of the Thermotogales are uniformly round with a diameter of about 1–2 mm. Colonies of the genera *Thermotoga*, *Fervidobacterium*, *Geotoga* and *Petrotoga* appear whitish, while colonies of *Thermosipho* are colorless or brownish.

From liquid cultures, Thermotogales relatives can be also isolated by a plating-independent, newly developed isolation procedure (selected cell cultivation technique) based on optical trapping of single cells using a strongly focused infrared laser beam ("optical tweezers"; Huber et al., 1995; Beck and Huber, 1997; Huber, 1999; Huber and Stetter, 2001a).

In the future, a new isolation strategy might be used to isolate specifically Thermotogales relatives from their biotopes (Huber et al., 1995; Huber et al., 2000). This method combines 16S

Table 2. Physiological properties of the described species within the Thermotogales.

[a]For degradation, yeast extract is stimulatory or obligately required.

rRNA gene sequence analysis in situ, specific whole-cell hybridization within enrichments, and the cultivation of cells selected by the use of the laser microscope (Huber et al., 1995).

Identification

Cells of Thermotogales representatives are rod-shaped, about 1.0–50.0 µm long and 0.4–1.0 μm in diameter. They form an outer sheath, ballooning over the ends ('toga'), visible in all phases of growth (Figs. 4 and 5). Usually, they grow singly and in pairs (Fig. 4); members of the genus *Thermosipho* form short chains of up to 12 individuals surrounded by a sheath (Fig. 6). The majority of the *Fervidobacterium* cells form a characteristic terminal bleb ('spheroids') on one end of the cells, which occurs during all stages of growth (diameter 1.0–4.0 µm; Fig. 7). Furthermore, growth in short chains is observed, and *F. islandicum* frequently forms aggregates of up to 50 cells. Besides spheroids, *Fervidobacterium* species form spheres (diameter 5.0–8.0 μm; Fig. 8), membrane-bound structures containing one to seven individual cells. All members of the Thermotogales exhibit a Gram-negative staining reaction, but diamino-pimelic acid, typical for Gram-negative bacteria, is absent.

Thermotogales species either are immotile or possess flagella and are motile (Huber and Stetter, 1999; Huber and Stetter, 2001b; Fig. 4). Motility of *T. maritima* was observed at 60–90°C after heating the microscopic slide. At the optimal growth temperature of 80°C, the maximum speed was approximately 3 mm/min. Furthermore, a thermotactic response to temporal temperature changes was reported for *T. maritima* and thermostable chemotaxis proteins have been identified (Gluch et al., 1995; Swanson et al., 1996). Recently, the crystal structure of CheA, a signal-transducing histidine kinase, and the crystal structures of the middle and C-terminal domain of the flagellar rotor protein FliG from *T. maritima* have been published (Bilwes et al., 1999; Brown et al., 2002).

So far, there is only one report of film formation within the Thermotogales. During continuous cultivation of *T. maritima*, exopolysaccharides were produced under optimal growth conditions. Concomitantly, a thin and white, but not further specified film below the liquid level of the medium was observed (Rinker and Kelly, 2000). Very recently, we found biofilm formation by *Thermotoga* sp. SG1-L2A, produced under physiological growth conditions in batch cultures at the end of the logarithmic growth phase. The cells formed free-floating, white-colored biofilms in the medium with a length of up to 1 cm (Fig. 9).

The ultrastructure of *T. maritima* (Huber et al., 1986) and related species, as determined by transmission electron microscopy by freeze-etching and in ultrathin sections, can only be interpreted as *Thermotoga* being a true Gram-negative bacterium (Rachel et al., 1990). A sheath-like outer membrane and overballooning ends give the cells their characteristic appearance. The porin of the outer membrane has been purified and its specific functional properties characterized after insertion into artificial lipid bilayers (Engel et al., 1993); in addition, its secondary structure contains predominantly beta-sheets and the amino acid composition is characteristic for porins (for a review, see Schirmer,

1998). Outer membrane protein (Omp) alpha is a rod-shaped spacer that spans the periplasm, connecting the outer membrane to the inner body (Engel et al., 1992; Lupas et al., 1995). So far, it is not clear how Omp alpha is connected to the peptidoglycan or the cytoplasmic membrane. It is likely that the COOH-terminal hydrophobic tail of the protein is associated with the porin layer in the "balloon" portion of the cell wall. *Thermotoga* cells have an unusual thin and labile murein layer, presumably owing to a low degree of cross-linking; it is not synthesized in the presence of penicillin G or ampicillin and is sensitive to lysozyme. After addition of lysozyme, the rod-shaped cells of *T. maritima* round up within some minutes, which was also observed for *Ts. africanus* and *F. islandicum*. The murein of *T. maritima* consists of muramic acid, *N*-acetylglucosamine, glutamic acid, alanine and lysine (molar ratio = 0.41:0.69:1.00:1.43:0.89). D- and L-Lysine are present and not found so far in Gram-negative bacteria.

Recently, the crystal structure of the cell division protein FtsA and of the cell division inhibitor MinC was reported from *T. maritima* (van den Ent and Löwe, 2000; Cordell et al., 2001). Biochemical and structural investigations gave evidence that the *T. maritima* MreB protein is the bacterial homolog to the physiological polymer of the eucaryotic F-actin (van den Ent et al., 2001).

Electron microscopic studies showed that the cell envelope of *Fervidobacterium* is composed of two layers. The outer layer protrudes to form spheres (Patel et al., 1985a). In *F. nodosum*, the two layers have an irregular convoluted structure and are connected with regular junctions, and the outer layer is susceptible to lysis by SDS. The cells are able to grow and multiply within the spheres (Patel et al., 1985a).

About 50% of the total polar lipids of *T. maritima* are two amphipathic monopolar glycolipids with a very rare alpha-(1-4) diglucosyl structure (Manca et al., 1992). Unusual long-chain dicarboxylic fatty acids are present in the core lipids of the Thermotogales (Huber et al., 1986; Huber et al., 1989a; Huber et al., 1990; Jeanthon et al., 1995). In *T. maritima*, a total of 37 different fatty acids, including the novel 13,14-dimethyloctacosanedioic acid (Carballeira et al., 1997) and a new ether core lipid, 15,16-dimethyl-30-glyceroloxytriacontanoic acid (DeRosa et al., 1988), have been identified. Comparative analysis showed that this core lipid is characteristic for the genus *Thermotoga* (Huber et al., 1986; DeRosa et al., 1988; Windberger et al., 1989; Jeanthon et al., 1995; Fig. 10).

Members of the Thermotogales differ in their sensitivity to antibiotics (Table 4). For *T. elfii* and *F. pennivorans*, no information on antibiotic sensitivity was reported. Thermotogales representatives are significantly different in their sensitivity to the antibiotic rifampicin, which blocks transcription initiation (Huber and Stetter, 1992a; Table 4). Growth of some species is inhibited by only 1 μg/ml (e.g., *T. thermarum*), while other species (e.g., *T. maritima* and *T. neapolitana*) are resistant even against 100 μg/ml. Unusual for bacteria, the purified RNA polymerase of *T. maritima* is resistant to rifampicin (1 μg/ml), and only 80% of its activity is inhibited by 200 μg/ml (Huber et al., 1986). Growth of *T. maritima* is also not inhibited by 10 μg/ml of the aminoglycoside antibiotics paromomycin, neomycin, streptomycin, gentamicin and kanamycin (Huber et al., 1986). Unprecedented for bacteria, the purified ribosomes of *T. maritima* are resistant to these antibiotics, too (Londei et al., 1988). Another unusual feature of *T. maritima* is the resistance of the elongation factor EF-G to fusidic acid (Huber and Stetter, 1992a).

Cultivation

Owing to the anaerobic nature of the Thermotogales, anaerobic media must be prepared for their cultivation. First, the medium (e.g., 1 liter volume) is flushed with nitrogen for about 20 min to get rid of oxygen. Afterwards, the medium is chemically reduced by the addition of unsterile sodium sulfide and/or cysteine-HCl or after dispension in small portions (see Culture Media) from a sterile, anaerobic stock (see

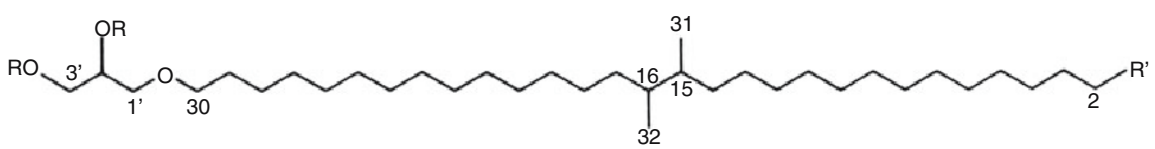

Fig. 10. The new 15,16-dimethyl-30 glyceryloxytriacontanoic acid from *Thermotoga maritima* (courtesy A. Gambacorta).

Table 4. Influence of antibiotics on growth of the Thermotogales species.

Antibiotic (μg/ml)	Ampicillin			Chloramphenicol			Cycloserine		Fusidic acid	Gentamycin		Hygromycin	Kanamycin		Nalidixic acid	Neomycin	Novobiocin	Paromomycin		Penicillin G		Phosphomycin		Polomyxin B	Rifampicin				Spectinomycin	Streptomycin			Tetracyclin	Vancomycin

Symbols and abbreviations: –, growth inhibited; (–), temporary inhibition; (+), slight growth; +, growth not inhibited; and n, not reported.

Culture Media). After pH-adjustment, the media are dispensed in 10–20 ml portions in an anaerobic chamber into the culture bottles. They are closed by rubber stoppers and the gas atmosphere is changed to the desired gas mixture (see Culture Media). Thermotogales relatives grow well using 28-ml serum tubes (borosilicate glass; Schott, Mainz, Germany) or 120-ml soda-lime-silicate bottles (Stute GmbH, Rheinbreitbach, Germany). All media were autoclaved for 20 min at 121°C, and the stock-solutions were filter-sterilized.

At large scale, members of the Thermotogales are routinely grown in batch cultures, using enamel-protected fermentors with an operating volume up to 300 liters (HTE, Bioengineering, Wald, Switzerland; Huber et al., 1986). The inhibitory hydrogen gas produced during growth should be removed by continuously flushing the fermentor with nitrogen or argon gas (Huber et al., 1986; Huber et al., 2000).

Culture Media

MSH-Medium for *T. maritima* and *T. neapolitana*

KH_2PO_4	0.5 g
$(NH_4)_2SO_4$	0.5 g
$NaHCO_3$	0.1 g
Yeast extract (BD Difco™)	0.5 g
Starch	5 g
Trace mineral solution (see Trace Mineral Solution)	10 ml
Resazurin	1 mg
Artificial sea water (see Artificial Sea Water)	250 ml
$Na_2S \cdot 9H_2O$	0.5 g
H_2O, double distilled	700.0 ml

Adjust pH to 7.0 with 25% H_2SO_4 and volume to 1 liter with double-distilled water. The headspace of the culture bottles consisted of N_2 (300 kPa).

Trace Mineral Solution (modified; Balch et al., 1979)

Nitrilotriacetic acid	1.5 g
$MgSO_4 \cdot 7H_2O$	3.0 g
$MnSO_4 \cdot H_2O$	0.5 g
NaCl	1.0 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CoSO_4$	0.1 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$CuSO_4 \cdot 5H_2O$	0.01 g
$AlK(SO_4)_2$	0.01 g
H_3BO_3	0.01 g
$ZnSO_4$	0.1 g
$Na_2WO_4 \cdot 2H_2O$	0.01 g
$Na_2MoO_4 \cdot 2H_2O$	0.01 g
Na_2SeO_4	0.01 g
$(NH_4)_2Ni(SO_4)_2$	0.2 g
H_2O, double distilled	950.0 ml

Adjust pH of the solution to 6.5 with 5N KOH and volume to 1 liter with double-distilled water. Store at 4°C in the dark.

Artificial Sea Water (Huber et al., 1990)

NaCl	27.7 g
$MgSO_4 \cdot 7H_2O$	7.0 g
$MgCl_2 \cdot 6H_2O$	5.5 g
KCl	0.6 g
NaBr	0.1 g
H_3BO_3	0.03 g
$SrCl_2 \cdot 6H_2O$	0.015 g
KI	0.05 mg
$CaCl_2 \cdot 2H_2O$	1.5 g
H_2O, double distilled	950.0 ml

Adjust pH to 5.5–6.0 and volume to 1 liter with double-distilled water.

LA3 Medium for *T. thermarum*

NaCl	3.46 g
$MgSO_4 \cdot 7H_2O$	0.88 g
$MgCl_2 \cdot 6H_2O$	0.69 g
KH_2PO_4	0.5 g
$CaCl_2$	0.09 g
KCl	0.08 g
NaBr	12.50 mg
H_3BO_3	3.75 mg
$SrCl_2 \cdot 6H_2O$	1.9 mg
KI	0.006 mg
$(NH_4)_2Ni(SO_4)_2$	3 mg
Trace mineral solution (see Trace Mineral Solution)	15 ml
EDTA · Na_4-salt	0.9 g
Starch	5 g
Yeast extract (BD Difco™)	0.5 g
Resazurin	1 mg
$Na_2S \cdot 9H_2O$	0.5 g
H_2O, double distilled	950.0 ml

Adjust pH to 7.0 with 25% H_2SO_4 and volume to 1 liter with double-distilled water. The headspace of the culture bottles consisted of N_2 (300 kPa).

Trace Mineral Solution (Balch et al., 1979)

Nitrilotriacetic acid	1.5 g
$MgSO_4 \cdot 7H_2O$	3.0 g
$MnSO_4 \cdot 2H_2O$	0.5 g
NaCl	1.0 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CoCl_2$	0.1 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$ZnSO_4$	0.1 g
$CuSO_4 \cdot 5H_2O$	0.01 g
$AlK(SO_4)_2$	0.01 g
H_3BO_3	0.01 g
$Na_2MoO_4 \cdot 2H_2O$	0.01 g
H_2O, double distilled	950.0 ml

Adjust pH of the solution to 6.5 with 5N KOH and the volume to 1 liter with double-distilled water. Store at 4°C in the dark.

MB Medium for *T. elfii*

NH_4Cl	1.0 g
K_2HPO_4	0.3 g
KH_2PO_4	0.3 g
$MgCl_2 \cdot 6H_2O$	0.2 g
$CaCl_2 \cdot 2H_2O$	0.1 g
NaCl	10.0 g
KCl	0.1 g
Sodium acetate	0.5 g

Trace mineral solution (see LA3-medium)	10 ml
Yeast extract (BD Difco™)	2.0 g
Bio-Trypcase (bioMérieux)	2.0 g
Resazurin	1 mg
Cysteine · HCl	0.5 g
$Na_2S \cdot 9H_2O$	0.4 g
Na_2CO_3	2.0 g
H_2O, double distilled	950.0 ml

Dissolve all components except the $Na_2S \cdot 9H_2O$ and Na_2CO_3. Adjust pH to 8.0 with 10M KOH and volume to 1 liter with double-distilled water. Autoclave (121°C, 20 min) the medium, then add the $Na_2S \cdot 9H_2O$ and Na_2CO_3 (from sterile, anaerobic stocks). Store or incubate medium in a gas phase of N_2/CO_2 (80:20 v/v; 200 kPa).

Medium for *T. subterranea*

NaCl	12.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g
PIPES (piperazine-*N*, *N*′-bis[ethanesulfonic acid])	3.4 g
KCl	2.0 g
NH_4Cl	0.1 g
$CaCl_2 \cdot 2H_2O$	25 mg
K_2HPO_4	20 mg
Trace mineral solution (see LA3 medium)	10 ml
Vitamin solution (see Vitamin Solution	10 ml
Yeast extract	0.5 g
Peptone	1.0 g
Resazurin	1 mg
$Na_2S \cdot 9H_2O$	0.5 g
H_2O, double distilled	950.0 ml

Add the $Na_2S \cdot 9H_2O$ from a sterile, anaerobic stock to the autoclaved (121°C, 20 min) solution of all other components. Adjust the pH to 7.0 with 25% H_2SO_4 and the volume to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2 (100 kPa).

Vitamin Solution (Balch et al., 1979)

Biotin	2 mg
Folic acid	2 mg
Pyridoxine · HCl	10 mg
Thiamine · HCl	5 mg
Riboflavin	5 mg
Nicotinic acid	5 mg
DL-Calcium pantothenate	5 mg
Vitamin B_{12}	0.10 mg
p-Aminobenzoic acid	5 mg
Lipoic acid	5 mg
H_2O, double distilled	950.0 ml

Adjust volume to 1 liter with double-distilled water, filter-sterilize, and store in the dark at 4°C.

Modified MB Medium for *T. hypogea*

NaCl	10.0 g
NH_4Cl	1.0 g
K_2HPO_4	0.3 g
KH_2PO_4	0.3 g
$MgCl_2$	0.5 g
$CaCl_2$	0.1 g
KCl	0.2 g
Trace mineral solution (see LA3 Medium)	10 ml
Yeast extract (BD Difco™)	2.0 g
Bio-Trypcase (bioMérieux)	2.0 g
Xylan	10.0 g
Resazurin	1 mg
Na_2CO_3	2.0 g
$Na_2S_2O_3 \cdot 5H_2O$	20 mM
Cysteine · HCl	0.5 g
$Na_2S \cdot 9H_2O$	0.4 g
H_2O, double distilled	950.0 ml

Add the Na_2CO_3, $Na_2S_2O_3 \cdot 5H_2O$, and $Na_2S \cdot 9H_2O$ (from sterile, anaerobic stocks) to the autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 8.0 with 10M KOH and the volume to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2/CO_2 (80:20 v/v; 100 kPa).

Modified DSMZ Medium No. 664 for *T. lettingae*

NH_4Cl	1.0 g
K_2HPO_4	0.3 g
KH_2PO_4	0.3 g
$MgCl_2 \cdot 6H_2O$	0.2 g
$CaCl_2 \cdot 2H_2O$	0.1 g
KCl	0.1 g
NaCl	10.0 g
Na_2CO_3	2.0 g
$Na_2S_2O_3 \cdot 5H_2O$	5.0 g
Yeast extract	0.5 g
Glucose	4.0 g
Trace mineral solution (see Trace Mineral Solution [DSMZ Medium 141])	10.0 ml
Resazurin	0.5 mg
Cysteine · HCl	0.5 g
$Na_2S \cdot 9H_2O$	0.4 g
$NaHCO_3$	2.0 g
H_2O, double distilled	950.0 ml

Add the Na_2CO_3, $Na_2S_2O_3 \cdot 5H_2O$, glucose, $Na_2S \cdot 9H_2O$, and $NaHCO_3$ (from a sterile, anaerobic stocks) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust the pH to 7.0 with 10M KOH and the volume to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2/CO_2 (80:20 v/v; 100 kPa).

Trace Mineral Solution (DSMZ Medium 141)

Nitrilotriacetic acid	1.5 g
$MgSO_4 \cdot 7H_2O$	3.0 g
$MnSO_4 \cdot 2H_2O$	0.5 g
NaCl	1.0 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CoSO_4 \cdot 7H_2O$	0.18 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$ZnSO_4 \cdot 7H_2O$	0.18 g
$CuSO_4 \cdot 5H_2O$	0.01 g
$AlK(SO_4)_2 \cdot 12H_2O$	0.02 g
H_3BO_3	0.01 g
$Na_2MoO_4 \cdot 2H_2O$	0.01 g
$NiCl_2 \cdot 6H_2O$	0.025 g
$Na_2SeO_3 \cdot 5H_2O$	0.3 g
H_2O, double distilled	950.0 ml

Prior to adding nitrilotriacetic acid to the other solution components, adjust its pH to 6.5 with 5N KOH. Adjust pH to 7.0 with 10 M KOH and volume to 1 liter with double-distilled water.

YE Medium for *T. petrophila* and *T. naphthophila*

Yeast extract	2.0 g
$Na_2S \cdot 9H_2O$	0.4 mM
Artificial sea water (ASW; see Artificial Sea Water)	950.0 ml

Add the $Na_2S \cdot 9H_2O$ (from a sterile, anaerobic stock) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 7.0 with 6M HCl and the volume to 1 liter with artificial sea water. Store or incubate medium in an atmosphere of N_2 (100kPa).

Artificial Sea Water (ASW; Jannasch et al., 1995)

NaCl	20.0 g
$MgCl_2 \cdot 6H_2O$	3.0 g
$MgSO_4 \cdot 7H_2O$	6.0 g
$(NH_4)_2SO_4$	1.0 g
$CaCl_2 \cdot 2H_2O$	0.3 g
KH_2PO_4	0.2 g
KCl	0.5 g
NaBr	0.05 g
H_3BO_3	0.025 g
$SrCl_2 \cdot 6H_2O$	0.02 g
Ferric ammonium citrate	0.01 g
Bis-tris-propane	2.25 g
Trace mineral solution (see Trace Mineral Solution)	10 ml
Vitamin solution (see Vitamin Solution)	10 ml
Resazurin	0.6 mg
H_2O, double distilled	950.0 ml

Adjust volume to 1 liter with double-distilled water.

Trace Mineral Solution (Wolin et al., 1963)

Nitrilotriacetic acid	1.5 g
$MgSO_4$	3.0 g
$MnSO_4$	0.5 g
NaCl	1.0 g
$FeSO_4$	0.1 g
$CoCl_2$	0.1 g
$CaCl_2$	0.1 g
$ZnSO_4$	0.1 g
$CuSO_4$	0.01 g
$AlK(SO_4)_2$	0.01 g
H_3BO_3	0.01 g
Na_2MoO_4	0.01 g
H_2O, double distilled	950.0 ml

Adjust volume to 1 liter with double-distilled water.

Vitamin Solution (Bazylinski et al., 1989)

Niacin	10 mg
Calcium pantothenate	10 mg
p-Aminobenzoic acid	10 mg
Thiamine	10 mg
Riboflavin	10 mg
Pyridoxine	10 mg
Cobalamin	10 mg
Thioctic (alpha-lipoic) acid	10 mg
Folic acid	4 mg
Biotin	4 mg
H_2O, double distilled	950.0 ml

Filter sterilize and store solution in the dark at 4°C.

MG Medium for *Ts. africanus*

NaCl	18.0 g
$MgSO_4 \cdot 7H_2O$	3.45 g
$MgCl_2 \cdot 6H_2O$	4.30 g
KCl	0.34 g
NH_4Cl	0.25 g
$CaCl_2 \cdot 2H_2O$	0.14 g
$K_2HPO_4 \cdot 3H_2O$	0.14 g
$(NH_4)_2Fe(SO_4)_2$ (0.2%)	1.0 ml
$(NH_4)_2Ni(SO_4)_2$ (0.2%)	1.0 ml
Sodium acetate $\cdot 3H_2O$	1.0 g
Trace mineral solution (see: MSH Medium)	10 ml
Vitamin solution (see: *T. subterranea* Medium)	10 ml
Yeast extract (BD Difco™)	2.0 g
Peptone (pancreatic digest of casein; Merck) (pankreatisch verdaut verwendet)	2.0 g
Resazurin (0.1%)	0.5 ml
$Na_2S \cdot 9H_2O$	0.5 g
H_2O, double distilled	950.0 ml

Add the trace mineral solution (from a sterile, anaerobic stock) to an autoclaved (121°C, 20 min) solution of the remaining components.Adjust pH to 6.5 with 25% formic acid and volume to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2 (300 kPa).

DSMZ Medium No. 343 for *Ts. melanesiensis*

NaCl	20.0 g
KH_2PO_4	0.5 g
$NiCl_2 \cdot 6H_2O$	2.0 mg
Trace mineral solution (see *T. lettingae* Medium)	15.0 ml
Yeast extract (BD Difco™)	0.5 g
Starch	5.0 g
Resazurin	1.0 mg
$Na_2S \cdot 9H_2O$	0.5 g
Artificial sea water (see: MSH Medium)	250 ml
H_2O, double distilled	700.0 ml

Adjust pH to 6.5 with 25% formic acid and volume to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2 (100 kPa).

MJDYP Medium for *Ts. japonicus*

Yeast extract	2.0 g
Trypticase peptone	2.0 g
Resazurin	1.0 mg
$Na_2S \cdot 9H_2O$	0.5 g
MJD synthetic water (see MJD Synthetic Water)	1000.0 ml

Adjust pH to 7.5 with 6N HCl. Store or incubate medium in an atmosphere of N_2 (200 kPa).

MJD Synthetic Water

NaCl	30.0 g
K_2HPO_4	0.14 g
$CaCl_2 \cdot 2H_2O$	0.14 g
$MgSO_4 \cdot 7H_2O$	3.4 g
$MgCl_2 \cdot 6H_2O$	4.18 g
KCl	0.33 g
$NiCl_2 \cdot 6H_2O$	0.5 mg

$Na_2SeO_3 \cdot 5H_2O$	0.5 mg
$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	0.01 g
Trace mineral solution (see LA3 Medium)	10 ml
DHV mineral solution (see DHV Mineral Solution)	1 ml
H_2O, double distilled	950.0 ml

Adjust volume to 1 liter with double-distilled water.

DHV Mineral Solution

$Na_2SiO_3 \cdot 9H_2O$	2.3 g
$SrCl_2 \cdot 6H_2O$	1.1 g
$CoSO_4 \cdot 7H_2O$	1.1 g
$Na_2MoO_4 \cdot 2H_2O$	0.97 g
$MnSO_4 \cdot 2H_2O$	0.96 g
$NiCl_2 \cdot 6H_2O$	0.95 g
$Na_2WO_4 \cdot 2H_2O$	0.66 g
$ZnSO_4 \cdot 7H_2O$	0.58 g
$CuSO_4 \cdot 5H_2O$	0.50 g
$VSO_4 \cdot xH_2O$	0.25 g
Na_2SeO_3	0.17 g
$LiSO_4 \cdot H_2O$	0.13 g
H_2O, double distilled	950.0 ml

Adjust volume to 1 liter with double-distilled water.

Medium for *Ts. geolei*

NaCl	15.0 g
$MgCl_2 \cdot 6H_2O$	0.5 g
PIPES	3.4 g
KCl	0.2 g
NH_4Cl	1.0 g
$CaCl_2 \cdot 2H_2O$	0.1 g
K_2HPO_4	0.35 g
KH_2PO_4	0.35 g
Sodium acetate $\cdot 3H_2O$	2.72 g
Yeast extract	2.0 g
Bio-Trypcase (bioMérieux)	2.0 g
Resazurin	1.0 mg
Maltose	2.0 g
$Na_2S \cdot 9H_2O$	1.0 g
H_2O, double distilled	950.0 ml

Add the maltose and $Na_2S \cdot 9H_2O$ (from sterile, anaerobic stocks) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 7.0 with 5M HCl and volume to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2 (100 kPa).

TYEG Medium for *F. nodosum*, *F. islandicum* and *F. gondwanense*

NH_4Cl	0.9 g
$MgCl_2 \cdot 6H_2O$	0.2 g
KH_2PO_4	0.75 g
K_2HPO_4	1.5 g
$FeSO_4 \cdot 7H_2O$ (10%)	0.03 ml
Trace mineral solution (see Trace Mineral Solution)	9.0 ml
Vitamin solution (see *T. subterranea* Medium)	5.0 ml
Yeast extract (BD Difco™)	3.0 g
Peptone (from tryptically digested meat; Merck)	10.0 g
Glucose	5.0 g
Resazurin (0.2%)	1.0 ml
$Na_2S \cdot 9H_2O$	1.0 g
H_2O, double distilled	950.0 ml

Add the vitamin solution and glucose (from a sterile, anaerobic stock) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 7.2 with 25% H_2SO_4 and the volume up to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2 (300 kPa).

Trace Mineral Solution (Patel et al., 1985a)

Nitrilotriacetic acid	12.5 g
$FeCl_3 \cdot 4H_2O$	0.2 g
$MnCl_2 \cdot 4H_2O$	0.1 g
$CoCl_2 \cdot 6H_2O$	0.017 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$ZnCl_2$	0.1 g
$CuCl_2$	0.02 g
H_3BO_3	0.01 g
$Na_2MoO_4 \cdot 2H_2O$	0.01 g
NaCl	1.0 g
Na_2SeO_3	0.02 g
H_2O, double distilled	950.0 ml

Prior to adding to the trace mineral solution, adjust pH of the nitrilotriacetic acid to 6.5 with 5N KOH. Adjust pH of the trace mineral solution to 6.5 with 5N KOH and the volume of the trace mineral solution to 1 liter with double-distilled water. Store medium at 4°C in the dark.

TF Medium for *F. pennivorans*

NH_4Cl	0.50 g
$MgSO_4 \cdot 7H_2O$	0.16 g
K_2HPO_4	1.6 g
$NaH_2PO_4 \cdot H_2O$	1.0 g
$CaCl_2 \cdot 2H_2O$	0.06 g
Trace mineral solution (see: LA3 Medium)	10 ml
Vitamin solution (see *T. subterranea* Medium)	10 ml
Yeast extract	2.0 g
Trypticase	2.0 g
Resazurin	1 mg
$Na_2S \cdot 9H_2O$	0.3 g
Cysteine $\cdot$ HCl	0.3 g
Glucose or starch	3.0 g
H_2O, double distilled	950.0 ml

Add the $CaCl_2 \cdot 2H_2O$ (from a sterile, anaerobic stock) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 6.8 with 10N KOH and the volume up to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2.

MSH Medium for *P. miotherma*, *G. petraea* and *G. subterranea*

See MSH Medium for *T. maritima* and *T. neapolitana*

Medium for *P. mobilis*

NaCl	30.0 g
$MgSO_4 \cdot 7H_2O$	7.0 g
KCl	0.34 g
NH_4Cl	0.25 g
$CaCl_2 \cdot 2H_2O$	0.14 g
KH_2PO_4	0.14 g
Yeast extract (BD Difco™)*	0.2 g
Trace element solution SL-10 (see Trace Element Solution SL-10)	1.0 ml
Vitamin solution (see *T. subterranea* Medium)*	10 ml

Resazurin (0.02%)	0.5 ml
$Na_2S \cdot 9H_2O$ (0.5 M)	4 ml
H_2O, double distilled	950.0 ml

Add the yeast extract and the vitamin solution (from a sterile, anaerobic stock) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 6.5 with 6M HCl and the volume up to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of argon (200 kPa).

Trace Element Solution SL-10 (Widdel et al., 1983)

HCl (25% w/w, 7.7 M)	10 ml
$FeCl_2 \cdot 4H_2O$	1.5 g
$CoCl_2 \cdot 6H_2O$	190 mg
$MnCl_2 \cdot 4H_2O$	100 mg
$ZnCl_2$	70 mg
H_3BO_3	6 mg
$Na_2MoO_4 \cdot 2H_2O$	36 mg
$NiCl_2 \cdot 6H_2O$	24 mg
$CuCl_2 \cdot 2H_2O$	2 mg
H_2O, double distilled	950.0 ml

Adjust volume up to 1 liter with double-distilled water.

Medium for *P. olearia* and *P. sibirica*

NaCl	25.0 g
$MgCl_2 \cdot 6H_2O$	0.5 g
PIPES	3.4 g
KCl	0.2 g
NH_4Cl	1.0 g
$CaCl_2 \cdot 2H_2O$	0.1 g
K_2HPO_4	0.35 g
KH_2PO_4	0.35 g
Peptone	1.5 g
Tryptone	1.5 g
Yeast extract	1.5 g
Maltose	2.0 g
Resazurin	1.0 mg
$Na_2S \cdot 9H_2O$	1.0 g
H_2O, double distilled	950.0 ml

Add the maltose and $Na_2S \cdot 9H_2O$ (from sterile, anaerobic stocks) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 7.0 with 5M HCl and the volume up to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of N_2 (100 kPa).

YPCS Medium for *M. camini*

Yeast extract (BD Difco™)	0.5 g
Peptone (BD Difco™)	1.0 g
Cellobiose (Sigma-Aldrich)	5.0 g
Sea salt (Sigma-Aldrich)	30.0 g
PIPES buffer (Sigma-Aldrich)	6.05 g
Resazurin	1.0 mg
$Na_2S \cdot 9H_2O$	0.5 g
H_2O, double distilled	950.0 ml

Adjust pH to 7.5 with 5M HCl and the volume up to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of $N_2/H_2/CO_2$ (90:5:5 v/v/v, 100 kPa).

RC+ Medium for *M. piezophila*

NaCl	30.0 g
MES (2-[*N*-morpholino]ethanesulfonic acid); Sigma-Aldrich)	10 mM
NH_4Cl	1.0 g
K_2HPO_4	0.3 g
$MgCl_2 \cdot 6H_2O$	0.2 g
$CaCl_2 \cdot 2H_2O$	0.1 g
KCl	0.1 g
Sodium acetate $\cdot 3H_2O$	0.83 g
Yeast extract (BD Difco™)	5.0 g
Bio-Trypcase (BD Difco™)	5.0 g
Maltose (Sigma-Aldrich)	20 mM
L-Cystine	12.0 g
Resazurin	1.0 mg
$Na_2S \cdot 9H_2O$	0.5 g
H_2O, double distilled	950.0 ml

Add the L-cystine and $Na_2S \cdot 9H_2O$ (from sterile, anaerobic stocks) to an autoclaved (121°C, 20 min) solution of the remaining components. Adjust pH to 6.0 with 5M HCl and the volume up to 1 liter with double-distilled water. Store or incubate medium in an atmosphere of $N_2/H_2/CO_2$ (90:5:5 v/v/v, 100 kPa up to 40 MPa).

Preservation

Under anaerobic conditions, members of the Thermotogales can be stored for several months at 4°C. For long-term preservation, storage at –140°C in liquid nitrogen in the presence of 5% dimethylsulfoxide is recommended (Malik, 1999). No loss of cell viability of *Thermotoga*, *Thermosipho* and *Fervidobacterium* was observed after storage over a period of more than ten years. *Thermotoga subterranea* was stored at –80°C in the same medium containing 20% (w/v) glycerol (Jeanthon et al., 1995).

Physiology

Members of the Thermotogales are strictly anaerobic, extremely thermophilic or hyperthermophilic bacteria with optimal growth in the neutral pH range (Huber and Stetter, 1999; Table 2). With an optimal growth temperature around 80°C and a maximum growth temperature of 90°C, the hyperthermophilic species *T. maritima* and *T. neaplitana* represent the organisms with the highest growth temperatures within the order. Growth of some Thermotogales species is restricted to low salinity, while other species exhibit a broad salt tolerance, reflecting their adaptation to the natural biotope (Huber and Stetter, 1992a; Huber and Stetter, 1999; Table 2). Detailed physiological properties of the Thermotogales are listed in Table 2.

All members of the Thermotogales are strict organotrophs, fermenting preferentially simple and complex carbohydrates or complex organic matter (Table 3). When grown on defined carbon sources, the addition of yeast extract and/or peptone/bio-trypticase to the medium is often stimulatory or required for growth (Table 3; see

also Culture Media). In addition, cell homogenates of bacteria (e.g., *Lactobacillus bavaricus*) and archaea (e.g., *Pyrodictium brockii*) can be used as substrates (Huber et al., 1986). Furthermore, *T. lettingae* is able to degrade methanol, but only in the presence of yeast extract, which is required for growth (Balk et al., 2002).

With glucose as growth substrate, Thermotogales representatives form L(+)-lactate, acetate, ethanol, L-alanine, carbon dioxide, and hydrogen as major final products. Some of the isolates form traces of isovaleric acid, isobutyric acid, alpha-aminobutyrate, hydroxy-phenylacetate and phenylacetate in addition. The L-alanine production of members of the Thermotogales is a trait in common with members of the archaeal order Thermococcales. Therefore, it has been proposed that L-alanine production from sugar fermentation is a remnant of an ancestral metabolism (Ravot et al., 1996a). The pathway of arginine synthesis is the only biosynthetic reaction studied in the Thermotogales so far. *Thermotoga maritima* generates arginine from glutamate via *N*-acetylated intermediates in an eight-step pathway, as in mesophilic bacteria (Van de Casteele et al., 1990).

Thermotoga maritima degrades glucose mainly via the Embden-Meyerhof glycolytic pathway and, to a lesser extent, via the Entner-Doudoroff pathway (Schröder et al., 1994; Selig et al., 1997). In *T. neapolitana*, it was shown that D-glucose is taken up via an active transport system, energized by an ion gradient. This gradient is generated by ATP, derived from substrate-level phosphorylation (Galperin et al., 1996). The role of this gradient is not known since glucose (and maltose) periplasmic binding proteins appear to be involved in transport (Nanavati et al., 2002).

Hydrogen, which accumulates during fermentation processes, can be a potent inhibitor of growth of the Thermotogales. This inhibition can be overcome by the addition of sulfur or inorganic sulfur-containing compounds, depending on the species. Under these culture conditions, H_2S is formed as final product. Therefore, H_2S formation may be a kind of detoxification reaction of H_2 (Huber et al., 1986; Huber et al., 1992a). A general trait of different Thermotogales is the production of H_2S when grown in the presence of thiosulfate, except for *Ts. geolei*, *M. piezophila*, *P. olearia* and *P. sibirica* (Ravot et al., 1995; L'Haridon et al., 2001; L'Haridon et al., 2002; Alain et al., 2002). In addition to removal by sulfurous compounds, hydrogen can be removed by gassing the media with nitrogen or argon (Huber et al., 1986; Huber and Stetter, 1999) or by interspecies hydrogen transfer during cocultivation of the Thermotogales with hydrogen-consuming hyperthermophiles (e.g., *Methanococcus*, *Methanopyrus*, *Archaeoglobus* or *Ferroglobus*; Huber et al., 2000).

Recently, respiratory growth of *T. maritima* had been reported, with hydrogen as electron donor and Fe(III) as the electron acceptor, forming Fe(II) as final product (Vargas et al., 1998). In contrast, growth of *T. maritima* with similar doubling times and final cell densities, in the absence of both hydrogen and Fe(III) in the same culture medium, was observed (Huber and Stetter, 2001a). Furthermore, when *T. maritima* was cultivated in the presence of hydrogen (100 kPa) and Fe(III), Fe(II) was formed without obvious growth stimulation (Huber and Stetter, 2001a). These results indicate that *T. maritima* may not gain energy by iron-respiration but may use Fe(III) in place of sulfur as an additional electron sink to get rid of inhibitory hydrogen during fermentation (Huber et al., 1986; Schröder et al., 1994).

Different low-molecular-weight organic compounds, serving as compatible solutes, are present in the different members of the Thermotogales (Martins et al., 1996; Ramakrishnan et al., 1997). However, the accumulation of solutes in response to either salt stress or supraoptimal temperatures is restricted to Thermotogales species that grow in saline media containing over 0.4% sodium chloride (Martins et al., 1996).

An enormous variety of enzymes (and proteins) from the order Thermotogales, especially *T. maritima*, has been isolated and intensively studied since the late 1980s. In general, these enzymes exhibit a high thermostability, with denaturation temperatures often above the optimum growth temperature of the bacterium. Despite the strict anaerobic nature of *T. maritima*, these enzymes are apparently not oxygen sensitive. A comprehensive overview of the biochemistry and biophysics of these "hyperthermophilic enzymes and proteins" was published recently in volumes 330, 331 and 334 of *Methods in Enzymology* (2001).

Genetics

So far, the only plasmids discovered in the Thermotogales are in *Thermotoga* sp. RQ7, an isolate obtained from the hot sea-floor of Ribeira Quente (the Azores), and in *Thermotoga maritima* MC24, an isolate from hydrothermal vents near the Kuril Islands (Huber et al., 1986; Harriott et al., 1994; Akimkina et al., 1999). These small cryptic miniplasmids, pRQ7 and pMC24, are very closely related and were shown to be the smallest natural replicon so far described (846 bp). Both were shown to be negatively supercoiled (Harriott et al., 1994; Akimkina et al., 1999). The plasmid pRQ7 replicates by the

rolling-circle mechanism (Yu and Noll, 1997). With pRQ7, a vector system was developed and a genetic transformation of *T. maritima* and *T. neapolitana* spheroplasts was achieved using cationic liposomes (Yu et al., 2001).

For genetic studies, auxotrophic and antimetabolite-resistant mutants of *T. neapolitana* have been isolated by the use of mutagenic agents (Vargas and Noll, 1994).

The rather small, 1.8-Mb genome from *T. maritima* has been sequenced at The Institute for Genomic Research (TIGR; Rockville, MD, USA; Nelson et al., 1999). It is a single circular chromosome and contains 1877 predicted coding regions. Fifty-four percent of these coding regions have functional assignments, while 46% are of unknown function (Nelson et al., 1999; Nelson et al., 2001). Genome analysis has identified metabolic pathways involved in the degradation of sugar and plant polysaccharides. About 7% of the predicted codon sequences in the genome are involved in the metabolism of simple and complex sugars, a percentage more than twice that seen in the genomes of other bacteria or archaea (Nelson et al., 2001). The metabolism and transport in *T. maritima* (Fig. 11) were elucidated from the genome sequence data.

Comparison of total genome sequences of different organisms showed that about 24% of the *T. maritima* genes are of archaeal origin (Nelson et al., 1999). Therefore, the authors have claimed that hyperthermophilic archaea and bacteria have often exchanged genes, particularly by lateral gene transfer (Aravind et al., 1998; Nelson et al., 1999; see chapter on Aquificales in this Volume). On the other hand, it was argued that if *Thermotoga* (and *Aquifex*; see chapter on Aquificales in this Volume) are truly deep branching, it is equally parsimonious to suppose that some of the genes are primitive features shared by these hyperthermophilic bacteria with archaea. They have retained ancestral genes that have since been lost in most bacteria as they adapted to mesophilic environments (Kyrpides and Olson, 1999; Logsdon and Faguy, 1999). On the basis of recent phylogenetic analyses of archaeal genes in different bacteria, it was hypothesized that lateral gene transfer in hyper-

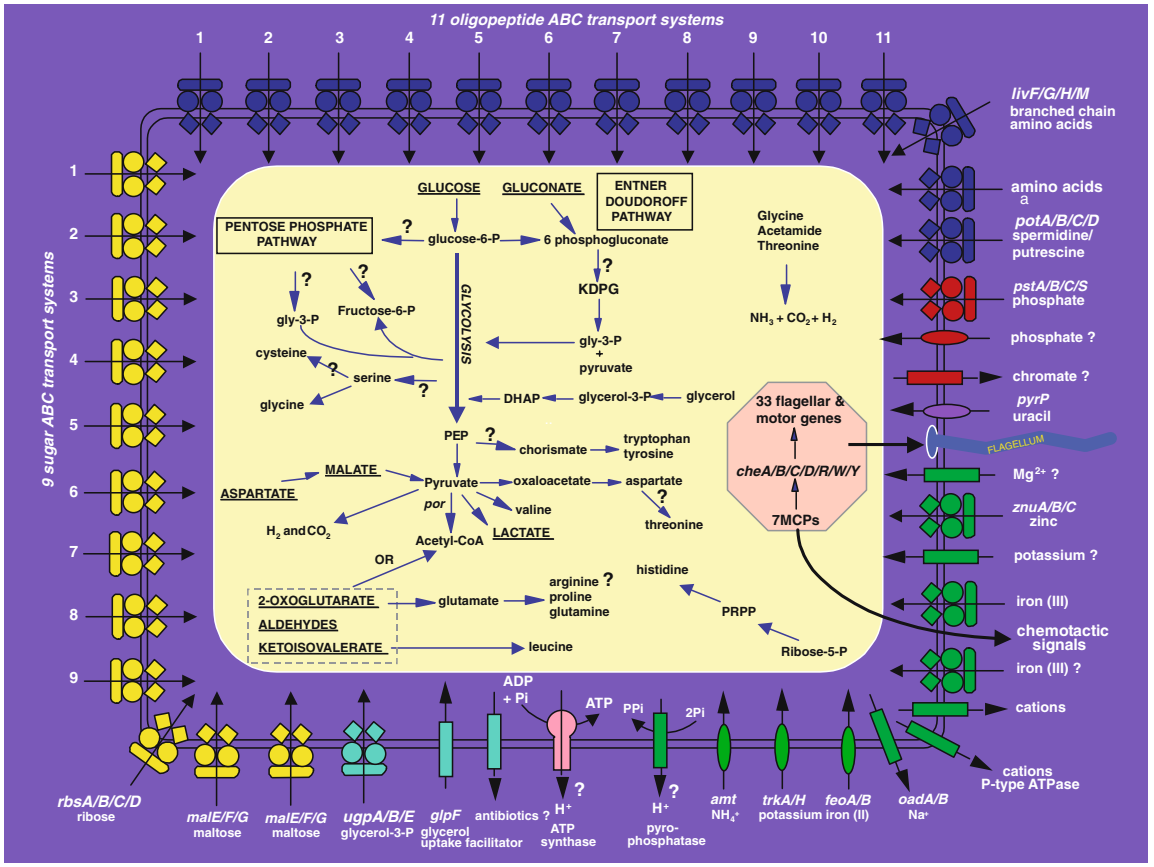

Fig. 11. Overview of metabolism and transport in *Thermotoga maritima*. Pathways for energy production and the metabolism of organic compounds, acids and aldehydes are shown. (From Nelson et al., 1999, with permission from Nature, http://www.nature.com.)

thermophiles may be as much the consequence as the cause of adaptation to hyperthermophily (Nesbø et al., 2001). By using suppressive subtractive hybridization, extensive genomic diversity in *T. maritima* was reported recently and frequent lateral gene transfer within the order Thermotogales was suggested (Nesbø et al., 2002).

Very recently, a high-throughput structural genomics pipeline and its application to the proteome of *T. maritima* were designed and implemented. By using this pipeline, 1376 of the predicted 1877 genes (73%) were successfully cloned, their expression was attempted, and the crystallization conditions for 432 proteins (23% of the *T. maritima* proteome) were identified (Lesley et al., 2002).

Biotechnology

Enzymes active at high temperatures are sought for industrial processes. Intra- and extracellular enzymes of Thermotogales are highly thermostable and might be of great interest as biocatalysts, e.g., in the chemical or food industry. A recombinant xylanase from *T. maritima* was shown to be active for several hours at 100°C and efficient in releasing lignin from kraft pulp (Chen et al., 1997). Therefore, such xylanases have a high potential for use in the pulp and paper industry. Highly thermostable amylases might be used in starch processing and high-temperature glucose isomerases in the production of corn syrup. From *T. maritima*, the recombinant Ultma™ DNA polymerase with proofreading activities is commercially available. The 70-kDa enzyme is highly thermostable and has a half-life of 40–50 min at 97.5°C. In addition, the sequencing of the total genome of *T. maritima* makes available the use of its genes as tools for a variety of biotechnological applications (Nelson et al., 2001).

Acknowledgments

The authors thank K. O. Stetter for continuous support. Furthermore, we thank C. Rudolph and C. Moissl for phylogenetic analysis and R. Rachel for electron microscopy. Furthermore, we are grateful to K. M. Noll for critical reading of the manuscript.

CHAPTER 13.1

Aquificales

ROBERT HUBER AND WOLFGANG EDER

Introduction

Members of the order Aquificales represent a very deep phylogenetic branch within the 16S rRNA tree of the domain Bacteria. Within the order, members of the genus *Aquifex* have an upper temperature border of growth at 95°C and represent the bacteria with the highest growth temperatures known so far. Aquificales representatives are widespread and cosmopolitan, and they thrive mainly in volcanically or geothermally heated environments. Owing to their chemolithoautotrophic way of life, they are primary producers of bacterial biomass within high temperature ecosystems. In their energy-yielding reactions, they preferentially perform the "Knallgas" reaction, the oxidation of hydrogen and reduction of oxygen.

Phylogeny

By 16S rRNA gene sequence comparisons, it was shown that the Aquificales represent one of the deepest and earliest branching groups within the phylogenetic tree (Burggraf et al., 1992; Huber et al., 1992b; Fig. 1) along with the separate phylogenetic branch of the Thermotogales order (Huber and Stetter, 1992a; Huber and Stetter, 1999b; see also Thermotogales in this Volume). However, phylogenetic analysis of other gene and protein sequences of the genus *Aquifex* showed that placement with respect to other bacterial groups was variable (Acca et al., 1994; Klenk et al., 1994; Wetmur et al., 1994; Bocchetta et al., 1995; Bocchetta et al., 2000; Brown and Doolittle, 1995; Baldauf et al., 1996; Pennisi, 1998; Pennisi, 1999; Klenk et al., 1999; Snel et al., 1999; Schütz et al., 2000). Also the analysis of different genes from the completely sequenced genome of "*Aquifex aeolicus*" gave no consistant picture of the Aquificales phylogeny (Deckert et al., 1998).

Taxonomy

Recently, the phylum Aquificae, consisting of a single class and the single order Aquificales, was created (Reysenbach, 2001). Based on 16S rRNA gene sequence comparisons, the Aquificales are composed of the Aquificaceae and the "Hydrogenothermaceae" (Fig. 1). Within the "Hydrogenothermaceae," the only cultivated representatives are isolate EX-H1 and *Hydrogenothermus marinus* VM1 (*Ht. marinus*; Reysenbach et al., 2000a; Eder and Huber, 2002; Stöhr et al., 2001; Fig. 1). In addition, the new family contains environmental sequences from different locations on earth (Hugenholtz et al., 1998; Yamamoto et al., 1998; Reysenbach et al., 2000b; Reysenbach et al., 2000c; Skirnisdottir et al., 2000; Graber et al., 2001). Within the Aquificaceae, the genera *Calderobacterium* (Kryukov et al., 1983), *Hydrogenobacter* (Kawasumi et al., 1984), *Aquifex* (Huber et al., 1992b), *Hydrogenobaculum* (Stöhr et al., 2001) and *Thermocrinis* (Huber et al., 1998) have been described. *Calderobacterium* is very similar to *Hydrogenobacter* in phylogenetic, phenotypic and biochemical properties, which resulted in the transfer of *C. hydrogenophilum* to *Hydrogenobacter hydrogenophilus* comb. nov. (Stöhr et al., 2001), as previously proposed with the "*Hydrogenobacter-Calderobacterium*" group (Aragno, 1992b; Pitulle et al., 1994). Within the Aquificaceae, the acidophilic *Hydrogenobacter acidophilus* forms a separate lineage (Shima et al., 1994; Fig. 1). Owing to its phylogenetic position and its low pH optimum for growth, *Hydrogenobacter acidophilus* was recently reclassified and named *Hydrogenobaculum acidophilum* (*Hb. acidophilum*; Stöhr et al., 2001). One genus, *Desulfurobacterium*, was provisionally placed within the phylum Aquificae, but may represent another, currently undefined phylum (Reysenbach, 2001). In Table 1, representatives belonging to the different genera within the Aquificales are listed.

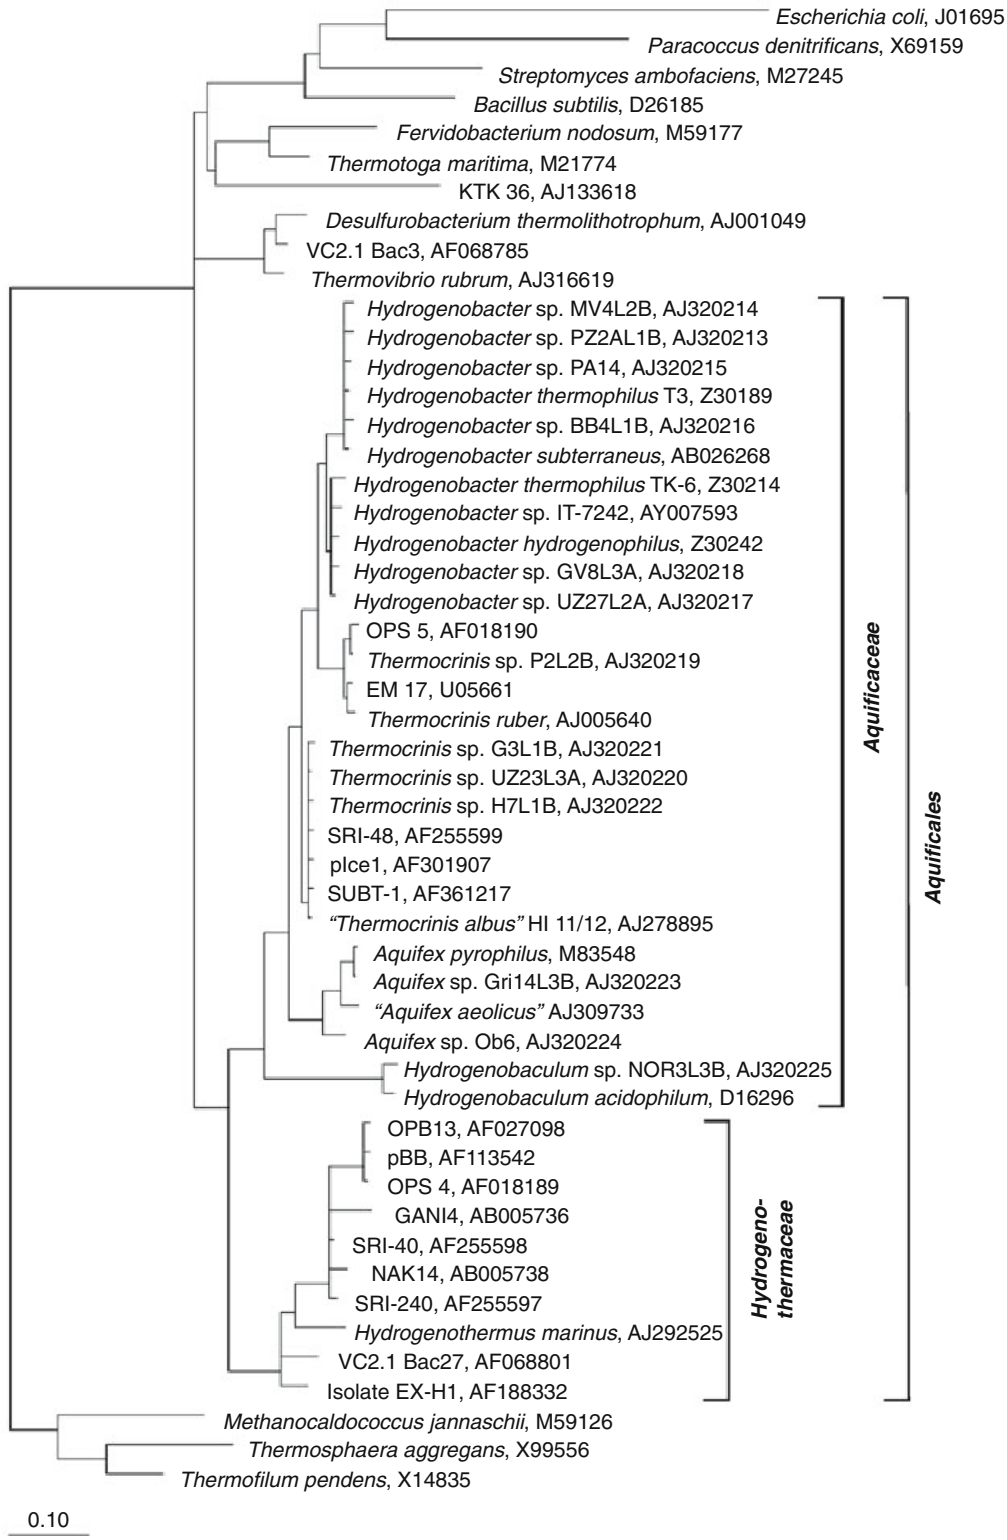

Fig. 1. 16S rRNA-based phylogenetic tree of the Aquificales. The tree topology is based on the ARB database (http://www.arb-home.de) of 11,000 sequence entries and was reconstructed using the ARB parsimony tool. A filter defining positions that share identical residues in at least 50% of all included sequences from the Aquificales was used for reconstructing the tree. Multifurications indicate that a (statistically) significant relative branching order could not be determined or is not supported by other treeing methods. Reference sequences were chosen to represent the broadest diversity of bacteria. Accession numbers for the sequences are indicated. The scale bar represents 0.10 fixed mutations per nucleotide position.

Table 1. List of the different representatives within the Aquificales.

Habitat

Almost all cultivated members of the Aquificales have been found in geothermally and volcanically heated environments. *Hydrogenobacter* and *Thermocrinis* relatives have been isolated mainly from continental solfatara fields with low ionic strength. In contrast, members of the genus *Aquifex* have been obtained exclusively from marine hydrothermal systems (Huber and Stetter, 1999b; Eder and Huber, 2002).

Hydrogenobacter thermophilus TK-6 was originally isolated from a hot spring in Japan, whereas *H. hydrogenophilus* was obtained from a thermal spring in the Geyser Valley, Kamchatka, Russia (Kryukov et al., 1983; Kawasumi et al., 1984). Organisms similar to *Hydrogenobacter* were subsequently isolated from other geothermal areas, located in Iceland, Italy, Japan, the Azores, the United States and New Zealand (Kawasumi et al., 1984; Kristjansson et al., 1985; Bonjour and Aragno, 1986; Aragno, 1992b; Skirnisdottir et al., 2001). *Hydrogenobacter thermophilus* T3 was obtained from a geothermal spring in Tuscany, Italy (Bonjour and Aragno, 1986; Pitulle et al., 1994). Recently, new *Hydrogenobacter* isolates were reported, which were isolated from Pemba (Lake Tanganyika), Kamchatka (Russia), Pozzuoli (Italy) and Baden-Baden (Germany; Eder and Huber, 2002). From a deep subsurface geothermal water pool (depth: 1,500 m), the new species *H. subterraneus* was isolated recently (Takai et al., 2001). The only halophilic strain within the genus *Hydrogenobacter*, *H. halophilus*, was obtained from a seaside saline hot spring in Izu Peninsula, Japan (Nishihara et al., 1990). Further, *Hydrogenobacter* relatives were cultivated from hot compost (Beffa et al., 1996).

Hydrogenobaculum acidophilum was originally isolated from a solfataric field in Tsumagoi, Japan (Shima and Suzuki, 1993). Recently, another acidophilic *Hydrogenobaculum* isolate was isolated from an acidic hot spring of Norris Geyser Basin, Yellowstone National Park, Wyoming, United States. This indicates that acidophilic Aquificales form a phylogenetically tight group and are widely distributed (Eder and Huber, 2002; Fig. 1).

In nature, members of the genus *Thermocrinis* grow in large, streamer-like cell accumulations, macroscopically visible as bacterial masses thriving in the hot water current. From biomass of pink filamentous streamers ("pink filaments") occurring in the upper outflow channel (temperature: 82–88°C) of Octopus Spring, Yellowstone National Park, Wyoming (Brock, 1967; Brock, 1978; Brock, 1998; Marler, 1973), the type species *Thermocrinis ruber* (*T. ruber*) was isolated (Huber et al., 1998). A second species was obtained from grayish filaments present in the volcanic Hveragerthi area (temperature: up to 88°C), Iceland, and described as *Thermocrinis albus* (Huber et al., 1998; Eder and Huber, 2002; Fig. 1). Further, so far undescribed *Thermocrinis*

isolates have been obtained from grayish-colored cell masses taken in the Uzon Valley (temperature: 75–80°C), Kamchatka, Russia, and from whitish filaments of a hot spring (temperature: 72°C) in Graendalur, Iceland (Eder and Huber, 2002). Moreover, environmental 16S rRNA gene sequences related to *Thermocrinis* were derived from water samples and different filamentous streamers of hot springs (Reysenbach et al., 1994; Skirnisdottir et al., 2000; Graber et al., 2001; Marteinsson et al., 2001a; Marteinsson et al., 2001b; Takacs et al., 2001). However, Thermocrinis relatives were also frequently found in usual hot ponds of Iceland and in Yellowstone National Park (United States), not containing visible streamers. This indicates that these organisms, in addition to their ability to form streamers, may play in general an important role in high temperature ecosystems (Huber et al, 1998; Huber et al, 2000b; Eder and Huber, 2002).

Within the marine genus *Aquifex*, the type species *Aquifex pyrophilus* (*A. pyrophilus*) was originally isolated from a submarine hydrothermal vent system (depth: 106 m) at the Kolbeinsey Ridge north of Iceland (Huber et al., 1992b). A further species, "*A. aeolicus*," was obtained from a shallow submarine hydrothermal system at Vulcano, Italy (Huber and Stetter, 2000a). Novel *Aquifex* relatives were isolated from white Anhydrite Smokers with temperatures up to 250°C, detected at a depth of 400 m near Grimsey Island, north of Iceland, and from a coastal hot spring in Obock, Gulf of Tadjoura, Djibouti (Huber and Stetter, 1999b; Eder and Huber, 2002).

From a shallow marine hydrothermal area of Vulcano Island, Italy, *Hydrogenothermus marinus* was isolated, whereas isolate EX-H1 was obtained from sulfide chimneys, taken in a deep-sea hydrothermal system at the Mid-Atlantic Ridge (Reysenbach et al., 2000a; Stöhr et al., 2001).

Isolation

To enrich cultures for Aquificales, inorganic, liquid media and a pH around 7 (3.5 for *Hb. acidophilum*) are recommended. Depending on the environment sampled, either media with low ionic strength or sea water media can be used (Table 2; for details, see Culture Media). Owing to the microaerophilic nature of most Aquificales, the enrichment cultures should contain a gas mixture with reduced oxygen content (for details, see Culture Media). For the enrichment of a particular member of the Aquificales, an incubation temperature close to the optimal growth temperature is recommended (Table 2). Owing to the high incubation temperature and the use of inorganic media, the enrichments are selective and Aquificales should be obtained. Alternatively, *Thermocrinis* species might be selectively enriched in a medium at 85°C, containing formamide or formate as single carbon and energy sources (Huber et al., 1998; Eder and Huber, 2002). The enrichment media are incubated with original sampling material (e.g., water, sediment, mud, and microbial streamer biomass) and monitored for growth over a certain period (e.g., two weeks) by phase contrast microscopy. When rod-shaped cells become visible in the enrichments, the isolates are obtained by plating or by the use of "optical tweezers."

For plating, a stainless steel anaerobic jar and microaerophilic incubation conditions might be used (Balch et al., 1976). The media are solidified with 1–1.5% Gelrite (Roth, Karlsruhe, Germany; Kang et al., 1982; Huber et al., 2000c), and the plates are incubated at the corresponding temperature. Colony formation of *Hydrogenobacter thermophilus* TK-6 with very low plating efficiencies have been reported (Ishii et al., 1987). As an alternative, *Hydrogenobacter* relatives can be isolated on 2.5% agar plates and thiosulfate, incubated either under a H_2-containing gas mixture or under air (Alfredsson et al., 1986; Aragno, 1992a). *Aquifex* species and *Thermocrinis ruber* grow well on Gelrite plates, and with "*Aquifex aeolicus*," plating efficiences up to 100% were obtained. Aquificales colonies are round with a diameter of about 1 mm. Colonies of the *Aquifex* species are brownish yellow, of *T. ruber* brownish red, while colonies of *Hydrogenobacter* relatives appear bright yellow. *Hydrogenothermus marinus* was obtained by serial dilutions; no plating procedure for isolation was reported (Stöhr et al., 2001).

From liquid cultures, Aquificales also can be isolated by a plating-independent isolation procedure (selected cell cultivation technique; Beck and Huber, 1997; Huber et al., 1998; Eder and Huber, 2002). This method is based on optical trapping of single cells by the use of a strongly focused infrared laser beam ("optical tweezers"; Huber et al., 1995; Huber et al., 2000c; Huber, 1999a; see Thermoproteales in Volume 3).

Identification

Members of the Aquificales are nonspore-forming, Gram-negative rods. Cells of *Hydrogenobacter* are about 0.3–0.9 × 2.0–8.0 μm (Reysenbach, 2001; Takai et al., 2001), while the *Aquifex* cells have a length between 2.0 and 6.0 μm and a diameter of 0.4–0.5 μm (Huber and Stetter, 2000a; Huber et al., 2000b). Members of *Hydrogenobacter*, *Hydrogenobaculum*, *Ther-*

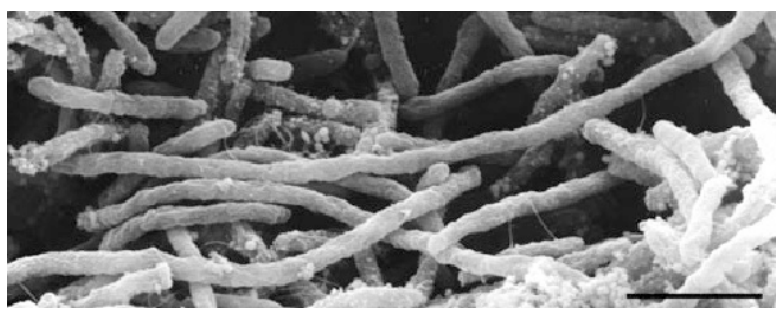

Fig. 2. Scanning electron micrograph of long filaments of *Thermocrinis ruber* from a pinkish streamer network formed at the outflow of a growth chamber during growth in a permanent flow of medium under exposure to air. Bar, 2 µm.

mocrinis, *Aquifex* and *Hydrogenothermus* usually grow singly and in pairs (Kryukov et al., 1983; Kawasumi et al., 1984; Kristjansson et al., 1985; Bonjour and Aragno, 1986; Nishihara et al., 1990; Aragno, 1992a; Huber et al, 1992b; Shima and Suzuki, 1993; Beffa et al., 1996; Huber et al., 1998; Eder and Huber, 2002; Stöhr et al., 2001; Takai et al., 2001). In addition, *Aquifex* and *Thermocrinis* species form large cell aggregates, containing up to about 100 individual cells. Growth in aggregates was also reported for *Hydrogenothermus marinus* (Stöhr et al., 2001). In the exponential growth phase, the *Aquifex* species form wedge-shaped polar or central refractile areas, which disappear in the stationary growth phase (Huber et al., 1992b). Within a permanent flow of medium under exposure to air, the *Thermocrinis* species grow in streamer-like cell masses predominantly composed of long filaments (Fig. 2). *Thermocrinis ruber* forms pink, and *T. albus* white, cell masses, which is in agreement with their growth behavior in the environment (see also Habitat; Huber et al., 1998; Eder and Huber, 2002). The pink-colored cell masses of *Thermocrinis ruber* formed in batch culture also form in a growth chamber under a perma-

nent flow of medium (Huber et al., 1998). The formation of the pink color is independent of the light regime, the oxygen concentration or the electron donor used (hydrogen, sulfur, thiosulfate or formate; Eder and Huber, 2002). *Thermocrinis albus* builds up filaments up to 60 micrometer under a permanent flow of medium (Eder and Huber, 2002).

Motility has been observed for *Hydrogenobacter subterraneus*, *Hydrogenobaculum acidophilum* and *Hydrogenothermus marinus*, which are all polarly flagellated (Shima and Suzuki, 1993; Stöhr et al., 2001; Takai et al., 2001). Some *Hydrogenobacter* isolates from hot composts were also motile, whereas most *Hydrogenobacter* isolates were reported to be immotile (Beffa et al., 1996; Reysenbach, 2001; Ishii et al., 2001). In contrast, the *Aquifex* species and single cells of the *Thermocrinis* species are polarly flagellated and highly motile (Fig. 3a, b). Cultures of *Aquifex pyrophilus* even remain motile when stored for 2 weeks at 4°C. The 19-nm-diameter flagellar filaments of *A. pyrophilus* are composed of a 54-kDa flagellin monomer, which exhibits high thermostability (Behammer et al., 1995). In the genome of "*A. aeolicus*," more than 25 genes involved in flagellar structure and biosynthesis are present. However, no homologs of the bacterial chemotaxis system were identified (Deckert et al., 1998; Swanson, 2001).

Diaminopimelic acid is present in *Aquifex* and *Thermocrinis* species. In contrast, diaminopimelic acid is absent in *Hydrogenobacter* (Huber et al., 1992b; Huber et al., 1998; Eder and Huber, 2002). A regular surface layer was identified in *A. pyrophilus*, in *Hydrogenobacter hydrogenophilus* and in different *Hydrogenobacter* isolates, but is absent in *T. ruber* and *T. albus* (Kristjansson et al., 1985; Huber et al., 1992b; Huber et al., 1998; Ludvik et al., 1994; Eder and Huber, 2002). *Aquifex pyrophilus* contains a complex cell envelope consisting of a peptidoglycan layer (murein type A1 gamma), an outer membrane, and a surface layer protein (Huber et al., 1992b).

The fatty acid composition of *Hydrogenobacter thermophilus* TK-6, *H. subterraneus*, *H. halophilus*, *Hydrogenobaculum acidophilum* and *Hydrogenothermus marinus* is quite similar (Kawasumi et al., 1984; Nishihara et al., 1990; Shima and Suzuki, 1993; Stöhr et al., 2001; Takai et al., 2001). A very similar distribution of fatty acids was found in *Hydrogenobacter thermophilus* TK-6 and in the *Thermocrinis* and *Aquifex* species (Jahnke et al., 2001; Table 3). The presence of glycerol monoethers is a characteristic feature of *Hydrogenobacter thermophilus* TK-6 and the *Thermocrinis* species under autotrophic culture conditions, whereas the lipids of the *Aquifex* species are composed of alkyl glycerol

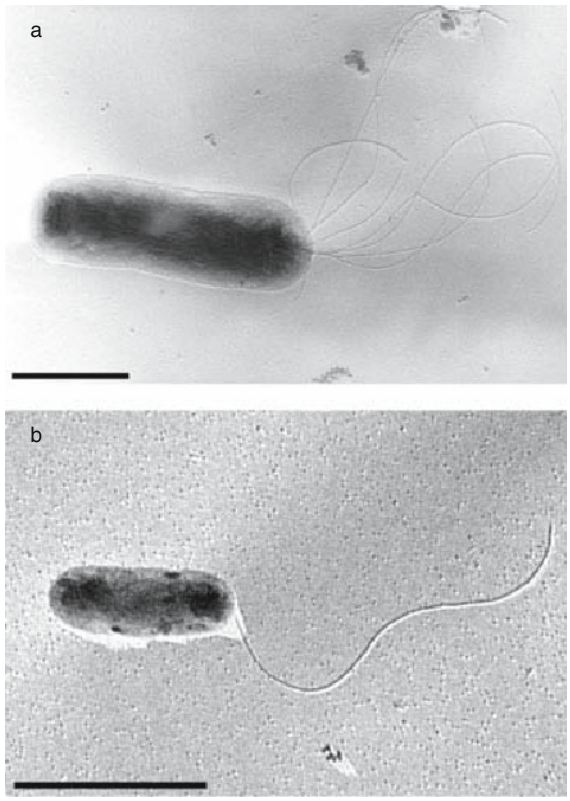

Fig. 3 a) Transmission electron micrograph of a platinum-shadowed, multi-flagellated cell of *Aquifex pyrophilus*. Bar, 1 µm. b) Transmission electron micrograph of a platinum-shadowed, single-flagellated cell of "*Thermocrinis albus*" (static culture). Bar, 1 µm.

diethers and glycerol monoethers (Huber and Stetter, 1992a; Jahnke et al., 2001; Table 3). The detailed fatty acid analysis of different Aquificaceae representatives verified that the Aquificaceae are a monophyletic group within the bacteria, which is in line with the 16S rRNA data. Also, *n*-$C_{20:0}$, *n*-$C_{20:1}$, *n*-$C_{21:0}$, *cy*-C_{21}, *n*-$C_{22:0}$ and *n*-$C_{22:1}$ fatty acids were identified as signature lipids for the Aquificales, which could be used as biomarkers (Jahnke et al., 2001).

A novel type of lipid A, indicative of lipopolysaccharide, was identified in *Aquifex pyrophilus*. This lipid A contains D-galacturonic acid, which replaces phosphate residues (Plötz et al., 2000).

The DNA-dependent polymerase of *Hydrogenobacter hydrogenophilus* exhibits a typical bacterial subunit pattern, is rifampicin resistant and is thermostable (no loss of activity at 100°C for 40 min; Andera et al., 1991). In addition, a reverse gyrase (optimal reaction temperature: 90°C) was isolated from *H. hydrogenophilus* (Andera et al., 1993). In the genome of *A. aeolicus*, two genes for reverse gyrase were detected (Deckert et al., 1998). From *Hydrogenobacter*

[a]Lipid distribution is given in % wt.

[b]Acyl-alkyl chain nomenclature designates carbon number as saturated (:0) or monounsaturated (:1) with double bond of *cis* (*c*) or *trans* (*t*) configuration and position relative to carboxyl end (Δ) or cyclopropyl ring (*cy*), with *iso*- (*i*) or *anteiso*- (*ai*) methyl branching.

[c]Designates presence of multiple GDE isomers with saturated and/or unsaturated alkyl chains (:1 or *cy*). Adapted from Jahnke et al. (2001); for a more detailed analysis of *T. ruber* lipids and methods, see Jahnke et al. (2001).

thermophilus TK-6, an ATP-citrate lyase and a membrane-bound hydrogenase were identified (Ishii et al., 1989). A variety of enzymes from *Aquifex* have been cloned, expressed and characterized, including superoxide dismutase, glutamate racemase, a [2Fe-2S] protein, a serine-type protease, glutamine phosphoribosylpyrophosphate, glycinamide ribonucleotide synthase, an alternative sigma factor, a *NifA*-like protein, and a DNA ligase (Lim et al., 1997; Kim et al., 1999; Chatelet et al., 1999; Choi et al., 1999; Yoo et al., 1999; Bera et al., 2000; Studholme and Buck, 2000a; Studholme et al., 2000b; Lim et al., 2001).

Cytochromes *b*, *c* and *o*, but no cytochrome *a*/*a*3 have been identified in strains of *Hydrogenobacter* (Aragno, 1992b). The terminal oxidase is an *o*-type cytochrome. The cytochrome c_{552} from *H. thermophilus* TK-6 is extremely thermostable and can restore its conformation even after being autoclaved for 10 min. at 121°C. Type *b* and *c* cytochromes and methionaquinone are reduced by a membrane-bound hydrogenase activity (Ishii et al., 2001). For oxygen respiration, the following enzymes were identified in "*Aquifex aeolicus*": ubiquinol cytochrome *c* oxidoreductase (bc_1 complex), cytochrome *c* and cytochrome *c* oxidase. The alternative system with cytochrome *bd* ubiquinol oxidase was also detected (Deckert et al., 1998). The cytochrome *bc* complex in "*A. aeolicus*" was characterized in detail and belongs to a group of (low-potential) menaquinol-oxidizing enzymes (Schütz et al., 2000). The sulfide:quinone oxidoreductase of "*A. aeolicus*" belongs to the glutathione reductase family of flavoproteins. The electron transport from sulfide to oxygen employs the cytochrome *bc* complex via the quinone pool (Nübel et al., 2000).

In *Hydrogenobacter thermophilus* TK-6 and *H. halophilus*, the main quinonic component is an unusual sulfur-containing quinone, 2-methylthio-3-VI, VII-tetrahydromultiprenyl-1,4-naphthoquinone (i.e., methionaquinone; Aragno, 1992a; Ishii et al., 2001). *Hydrogenothermus marinus* appears to contain a new menathioquinone, the structure of which is currently not known (Stöhr et al., 2001).

Cultivation

Aquificales grow well using 120-ml soda-lime-silicate glass (Stute GmbH, Rheinbreitbach, Germany) or 28-ml serum tubes (borosilicate glass, Schott, Mainz, Germany) for cultivation. For growth of more oxygen-tolerant Aquificales, the medium can be dispensed in air. The medium for more oxygen-sensitive Aquificales (e.g., *Aquifex pyrophilus*) should be flushed with nitrogen for 20 min. to get rid of oxygen. Afterwards, the medium is dispensed in 10–20 ml portions in an anaerobic chamber. The bottles are closed by rubber stoppers and the gas atmosphere is changed to the desired gas mixture (see Culture Media). If not mentioned otherwise, the atmosphere in the bottles consists of 300 kPa gas.

On a large scale, growth of members of the Aquificales are routinely in batch cultures, using enamel-protected fermentors with an operating volume of up to 300 liters (HTE, Bioengineering, Wald, Switzerland; Huber et al., 1992b; Huber et al., 1998; Jahnke et al., 2001). Furthermore, continuous cultivation of *Hydrogenobacter thermophilus* ITI 553 at low partial hydrogen pressures was reported (Manelius et al., 1997).

$NaHCO_3$	2.0 g
KCl	0.65 g
$CaCl_2 \cdot 2H_2O$	0.50 g
$K_2HPO_4 \cdot 3H_2O$	0.15 g
NH_4Cl	0.15 g
NaBr	0.10 g

Trace mineral solution *Aquifex*, 10 × 1.0 ml

H_2O (double-distilled, add up to the total volume) 1000.0 ml

Gas phase ($H_2/CO_2/O_2$) should be 79:20:1 (v/v/v; 300 kPa) and pH is adjusted to 6.5 with H_2SO_4. For the growth of "*A. aeolicus*," the medium should be supplemented with 0.1% thiosulfate.

Trace Mineral Solution *Aquifex*, 10 ×

Titriplex 1 (Nitrilotriacetic acid)	15.0 g
$MgSO_4 \cdot 7H_2O$	30.0 g
$MnSO_4 \cdot H_2O$	5.0 g
NaCl	10.0 g
$FeSO_4 \cdot 7H_2O$	1.0 g
$CoSO_4 \cdot 7H_2O$	1.8 g
$CaCl_2 \cdot 2H_2O$	1.0 g
$ZnSO_4 \cdot 7H_2O$	1.8 g
$CuSO_4 \cdot 5H_2O$	0.1 g
$KAl(SO_4)_2 \cdot 12H_2O$	0.18 g
H_3BO_3	0.1 g
$Na_2MoO_4 \cdot 2H_2O$	0.1 g
$(NH_4)_2Ni(SO_4)_2 \cdot 6H_2O$	28.0 g
$Na_2WO_4 \cdot 2H_2O$	0.5 g
Na_2SeO_4	0.5 g
H_2O (double-distilled, add up to the total volume)	1000.0 ml

Adjust pH to 6.5 with 5N KOH and store at 4°C in the dark.

OS Medium for *Thermocrinis ruber* and *T. albus*

$NaHCO_3$	1.0 g
NaCl	256.0 mg
Na_2SO_4	23.0 mg
KCl	15.0 mg
H_3BO_3	10.3 mg
$(NH_4)_2SO_4$	10.0 mg
KH_2PO_4	1.7 mg
$CaCl_2 \cdot 2H_2O$	0.8 mg
$NaNO_3$	0.3 mg
$FeCl_3 \cdot 6H_2O$ (0.05%)	0.2 ml
$MnSO_4 \cdot H_2O$ (0.03%)	0.2 ml
Thiosulfate	1.0 g

Trace mineral solution, modified, 10 × 1.0 ml

H_2O (double-distilled, add up to the total volume) 1000.0 ml

Gas phase ($N_2/H_2/O_2$) should be 96:3:1 (v/v/v; 300 kPa), and pH is adjusted to 6.5–7.0 with H_2SO_4.

Trace Mineral Solution, Modified, 10 ×

Titriplex 1 (Nitrilotriacetic acid)	15.0 g
$MgSO_4 \cdot 7H_2O$	30.0 g
$MnSO_4 \cdot H_2O$	5.0 g
NaCl	10.0 g
$FeSO_4 \cdot 7H_2O$	1.0 g
$CoSO_4 \cdot 7H_2O$	1.8 g
$CaCl_2 \cdot 2H_2O$	1.0 g
$ZnSO_4 \cdot 7H_2O$	1.8 g
$CuSO_4 \cdot 5H_2O$	0.1 g
$KAL(SO_4)_2 \cdot 12H_2O$	0.18 g
H_3BO_3	0.1 g
$Na_2MoO_4 \cdot 2H_2O$	0.1 g
$(NH_4)_2Ni(SO_4)_2 \cdot 6H_2O$	2.80 g
$Na_2WO_4 \cdot 2H_2O$	0.1 g
Na_2SeO_4	0.1 g
H_2O (double-distilled, add up to the total volume)	1000.0 ml

Adjust pH to 6.5 with 5N KOH and store at 4°C in the dark.

TK-6 Medium for *Hydrogenobacter thermophilus*

TK-6

$(NH_4)_2SO_4$	3.0 g
$K_2HPO_4 \cdot 3H_2O$	2.0 g
KH_2PO_4	1.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g
NaCl	0.25 g
$CaCl_2 \cdot 2H_2O$	0.03 g
$FeSO_4 \cdot 7H_2O$	0.014 g

Trace mineral solution, modified, 10 × (see: OS medium) 0.75 ml

H_2O (double-distilled, add up to the total volume) 1000.0 ml

Gas phase ($H_2/CO_2/O_2$) should be 79:20:1 (v/v/v; 300 kPa) and pH is adjusted to 7.0 with H_2SO_4.

Medium for *Hydrogenobacter halophilus*

$(NH_4)_2SO_4$	2.0 g
K_2HPO_4	2.5 g
KH_2PO_4	0.5 g
$MgSO_4 \cdot 7H_2O$	0.2 g
NaCl	29.3 g
$CaCl_2 \cdot 2H_2O$	10.0 mg
$FeSO_4 \cdot 7H_2O$	10.0 mg
$NiSO_4 \cdot 7H_2O$	0.6 mg

Trace element solution 2.0 ml

H_2O (double-distilled, add up to the total volume) 1000.0 ml

Gas phase ($H_2/CO_2/O_2$) should be 7:1:1 (v/v/v; 100 kPa) and pH is adjusted to 7–7.5.

Trace Element Solution

$MnSO_4 \cdot 5H_2O$	1.0 mg
$CoCl_2 \cdot 6H_2O$	1.0 mg
$ZnSO_4 \cdot 7H_2O$	7.0 mg
$CuSO_4 \cdot 5H_2O$	0.5 mg
H_3BO_3	1.0 mg
MoO_3	1.0 mg
H_2O (double-distilled, add up to the total volume)	1000.0 ml

Medium for *Hydrogenobaculum acidophilum*

$(NH_4)_2SO_4$	1.0 g
K_2HPO_4	1.0 g
Sulfur	5.0 g
$MgSO_4 \cdot 7H_2O$	0.3 g
NaCl	1.0 g
$CaCl_2$	1.0 mg
$FeSO_4 \cdot 7H_2O$	1.0 mg
Trace element solution; see medium for *H. halophilus*	2.0 ml
H_2O (double-distilled, add up to the total volume)	1000.0 ml

Gas phase ($H_2/CO_2/O_2$) should be 8:1:1 (v/v/v, 100 kPa) and pH adjusted to 3.0 with HCl.

mjYPGS Medium for *Hydrogenobacter subterraneus*

NaCl	3.0 g
$MgSO_4 \cdot 7H_2O$	0.34 g
$MgCl_2 \cdot 6H_2O$	0.42 g
$Na_2SiO_3 \cdot 9H_2O$	1.0 g
$Na_2S_2O_3 \cdot 5H_2O$	2.48 g
KCl	33 mg
$CaCl_2 \cdot 2H_2O$	14.0 mg
K_2HPO_4	14.0 mg
$NiCl_2 \cdot 6H_2O$	0.05 mg
$Na_2SeO_3 \cdot 5H_2O$	0.05 mg
$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	0.001 mg
Sodium succinate	0.2 g
Yeast extract	1.0 g
Peptone	1.0 g
Glucose	0.2 g
Trace mineral solution, 10 ×	1.0 ml
H_2O (double-distilled, add up to the total volume)	1000.0 ml

Gas phase should be air and pH is adjusted to 7.5 with H_2SO_4.

Trace Mineral Solution, 10 ×

Titriplex 1 (Nitrilotriacetic acid)	15.0 g
$MgSO_4 \cdot 7H_2O$	30.0 g
$MnSO_4 \cdot 2H_2O$	5.0 g
NaCl	10.0 g
$FeSO_4 \cdot 7H_2O$	1.0 g
$CoSO_4 \cdot 7H_2O$	1.8 g
$CaCl_2 \cdot 2H_2O$	1.0 g
$ZnSO_4 \cdot 7H_2O$	1.8 g
$CuSO_4 \cdot 5H_2O$	0.1 g

$KAl(SO_4)_2 \cdot 12H_2O$	0.18 g
H_3BO_3	0.1 g
$Na_2MoO_4 \cdot 2H_2O$	0.1 g
H_2O (double-distilled, add up to the total volume)	1000.0 ml

Adjust pH to 6.5 with 5N KOH and store at 4°C in the dark.

Medium for *Hydrogenothermus marinus*

NaCl	19.4 g
$MgCl_2 \cdot 6H_2O$	12.6 g
$NaHCO_3$	0.16 g
KCl	0.56 g
Na_2SO_4	3.24 g
Sulfur	0.5 g
NH_4Cl	0.30 g
$CaCl_2 \cdot 2H_2O$	2.38 g
Resazurin (1%)	1.0 ml

Trace element solution (10 ×; see medium for *H. halophilus*) 10.0 ml

H_2O (double-distilled, add up to the total volume) 1000.0 ml

Gas phase (H_2/CO_2) should be 80:20 (v/v; 300 kPa) with 20 ml of air and pH adjusted to 7 with H_2SO_4.

Preservation

Hydrogenobacter strains can be preserved by lyophilization using 0.1 M phosphate buffer (pH 7) containing 3% sodium glutamate as the suspending medium (Ishii et al., 2001). For short-time storage, Aquificaceae relatives can be stored at 4°C for several months. For long-time storage, preservation in liquid nitrogen at –140°C in the presence of 5% dimethylsulfoxide is recommended. No loss of cell viability of *Aquifex* and *Hydrogenobacter* strains was observed after a storage over a period of six years. A cryopreservation method for Aquificales representatives was described by Malik (1999).

Physiology

Members of the order Aquificales are extremely thermophilic or hyperthermophilic bacteria with optimal growth in the neutral pH range (except *Hydrogenobaculum acidophilum* and *Hydrogenobaculum* sp. NOR3L3B; Eder and Huber, 2002; Table 2). With optimal growth temperature around 85°C and a maximum growth temperature of 95°C, the hyperthermophilic species *Aquifex pyrophilus* and "*A. aeolicus*" represent the organisms with the highest growth temperatures within the domain Bacteria. The physiological properties of the Aquificales are listed in detail in Table 2.

Most Aquificales can grow with hydrogen as sole electron donor and oxygen as electron acceptor, performing the "Knallgas" reaction, the reduction of O_2 with H_2:

$$2H_2 + O_2 \rightarrow 2H_2O$$

The final product of this metabolic reaction is the formation of water (*Aquifex* meaning "water-maker"). Instead of hydrogen, most Aquificales can use thiosulfate or sulfur as a single energy source, and sulfuric acid is formed as the final product. *Aquifex*- and *Thermocrinis* species produce H_2S in addition to sulfuric acid in the presence of sulfur. Hydrogen-dependent growth was first reported for "*A. aeolicus*" (Huber and Stetter, 1999b) and was recently also described for *Hydrogenothermus marinus*, which requires sulfur for growth in addition (Stöhr et al., 2001). *Hydrogenobaculum acidophilum* and *Hydrogenobacter* sp. IT-7242 grow only when sulfur or thiosulfate is present in the medium (Shima and Suzuki, 1993; Skirnisdottir et al., 2001). Most of the Aquificales are strictly aerobic, growing preferentially under microaerophilic culture conditions. Interestingly, *Aquifex pyrophilus* can grow by using oxygen as low as 7.5 ppm (Deckert et al., 1998). *Aquifex pyrophilus* was the first representative of the Aquificales shown to grow anaerobically by nitrate reduction, forming N_2 as final product (denitrification; Huber et al., 1992b). Recently, growth of *Hydrogenobacter thermophilus* TK-6 on nitrate was reported (Suzuki et al., 2001). This is also true for *Hydrogenobacter* sp. PA14, isolated from Lake Tanganyika (Eder and Huber, 2002).

Most of the Aquificales are obligate autotrophs, using carbon dioxide as carbon source. It has been shown for *Hydrogenobacter thermophilus* TK-6 and the *Aquifex* species that carbon dioxide is fixed via the reductive citric acid cycle (Shiba et al., 1985; Beh et al., 1993; Deckert et al., 1998). More recently, the same CO_2 fixation pathway was proposed for *Thermocrinis ruber* (Jahnke et al., 2001).

Reports on heterotrophic growth of Aquificales are very rare (Eder and Huber, 2002). *Thermocrinis ruber* was the first organism shown to grow chemoorganoheterotrophically on formate and formamide under microaerophilic growth conditions. Both compounds were used simultaneously as carbon and energy sources (Huber et al., 1998). Recently, the ability to grow on formate and formamide was also reported for *Hydrogenobacter thermophilus* TK-6 (Eder and Huber, 2002). Furthermore, it was shown that *H. subterraneus*, a strictly aerobic heterotroph, is capable of utilizing a number of substrates such as yeast extract, peptone, tryptone, carbohydrates, sugars, amino acids and organic acids. As an electron donor for growth, sulfur, thiosulfate, sulfide or cysteine-HCl is required (Takai et al., 2001).

Genetics

A physical map was established from genomic DNA from *Aquifex pyrophilus*, and a random sequence analysis was performed (Shao et al., 1994; Choi et al., 1997). The complete genome sequence of "*A. aeolicus*" was determined (Deckert et al, 1998). It is a relatively small genome for a free-living bacterium, with a genome length of only 1.55 million base pairs. The most striking feature of the genome is the organizational relationship of the genes relative to one another. The majority of the genes appear to be organized within operons. Some genes are clustered in operons of common function. However, many pathway components are scattered throughout the genome or appear in novel operons (Deckert et al., 1998; Swanson, 2001). In addition, a single extrachromosomal element present at roughly twice the copy number of the chromosome was identified. The element has a length of 39,456 base pairs and a protein-coding region of 53% (Deckert et al, 1998). No introns or inteins were detected in the genome (Deckert et al., 1998). However, the intein Aae RIR2 was identified in the genome of "*A. aeolicus*" recently and deposited in the New England Biolabs Intein Database. Comparison of total genome sequences of different organisms showed that about 16% of the "*A. aeolicus*" genes are of archaeal origin (Aravind et al., 1998). Owing to this result, the authors have claimed that hyperthermophilic bacteria and archaea have exchanged genes particularly often by lateral gene transfer (Aravind et al., 1998; Nelson et al., 1999; see also Thermotogales in the second edition). On the other hand, it was argued that if *Aquifex* and *Thermotoga* (see also Thermotogales in the second edition) are truly deep branching, it is equally parsimonious to suppose that some of the features specified by the shared genes of these hyperthermophilic bacteria and archaea are primitive. They have retained ancestral genes which have since been lost in most bacteria as they have adapted to mesophilic environments (Kyrpides and Olson, 1999; Logsdon and Faguy, 1999). Based on recent phylogenetic analyses of archaeal genes in different bacteria, it was hypothesized that lateral gene transfer in hyperthermophiles may be as much a consequence as the cause of adaptation to hyperthermophily (Nesbø et al., 2001).

Biotechnology

Enzymes that are active at high temperatures are sought for industrial processes. Therefore, the highly thermostable enzymes of the Aquificales might be of great interest as biocatalysts, e.g., in the food or chemical industry. In addition, the sequencing of the total genome of "*A. aeolicus*" offers now the opportunity to use its genes as tools for a variety of biotechnological applications.

Acknowledgments. The authors thank K. O. Stetter for continuous support and critical discussions. Furthermore, we thank G. Wanner and R. Rachel for electron microscopy and L. Jahnke and R. Summons for providing lipid data.

CHAPTER 14.1

Morphologically Conspicuous Sulfur-Oxidizing Eubacteria

JAN W. M. LA RIVIÈRE AND KARIN SCHMIDT

This chapter deals with the genera *Achromatium*, *Macromonas*, *Thiobacterium*, *Thiospira*, and *Thiovulum* (see Fig. 1). They all belong to chemotrophic microbial populations generally encountered in natural habitats that are characterized by the simultaneous presence of H_2S and O_2, i.e., at the border between aerobic and anaerobic zones in surface waters and in the outflows of H_2S-bearing springs. It will be useful to introduce this discussion with some general remarks on the special nature of this ecological niche to help explain the embarassing paucity of knowledge we possess about its inhabitants.

In nature, the coexistence of H_2S and O_2 can only be sustained in systems subject to continuous inputs of both substances, because H_2S is not stable in the presence of O_2. H_2S can be rapidly oxidized without the intervention of living organisms, the rate of oxidation depending on pH, temperature, and the presence of catalysts and/or inhibitors (Chen and Morris, 1972a, 1972b); reaction products range from sulfur and polysulfides to thiosulfate, sulfite, and sulfate. Thus, this habitat contains an array of reduced sulfur compounds that are all potential substrates for chemolithotrophic oxidation but that differ greatly in their stability in the presence of O_2.

The chemotrophic segment of the microbial population occupying this special niche includes—in addition to accidental "interlopers" such as H_2S-tolerant microaerophilic heterotrophs—a group of organisms called *colorless sulfur bacteria,* which appear to interact directly with the reduced-sulfur compounds characterizing this habitat.

These colorless sulfur bacteria include in the first place *Sulfolobus, Thiobacillus*, and *Thiomicrospira* (see The Order Thermoproteales and The Genera *Thiobacillus*, *Thiomicrospira* and *Thiosphaera* both in the second edition), which have been shown to possess the capacity to chemolithotrophically oxidize reduced-sulfur compounds. Secondly, the group includes the five genera to be discussed here—*Achromatium*, *Macromonas*, *Thiobacterium*, *Thiospira*, and *Thiovulum*—as well as *Beggiatoa*, *Thiothrix,* and *Thioploca* (see 16 and 166). These eight genera are included among the colorless sulfur bacteria because the observed appearance and disappearance of sulfur inclusions suggest the possession of at least the capacity to oxidize sulfide and sulfur. The nutritional status of these genera is by no means certain and their relationship to reduced-sulfur compounds may range from obligate chemolithotrophy to protective, detoxifying sulfide oxidation or to merely gratuitous sulfide oxidation. Another argument for inclusion of this group is the observed absence of these genera in habitats devoid of H_2S. Finally, there are an indefinite number of colorless sulfur bacteria that are not recognized in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Buchanan and Gibbons, 1974) or discussed in this Handbook because they have been described poorly or no more than once. The works of the old masters, such as Gicklhorn, Hinze, Kolkwitz, Lauterborn, Molisch, Nadson, Warming, and Winogradsky, offer clear indications that several genera and even more species of colorless sulfur bacteria exist that cannot now be recognized usefully.

Thus the 11 genera discussed in this book represent only the most accessible part of the inhabitants of this ecological niche; even so, only five of them exist at the moment in pure culture: *Thiobacillus*, *Sulfolobus,* and *Thiomicrospira*, which can be cultivated with the stable compounds thiosulfate and/or sulfur as oxidizable substrates, *Macromonas*, of which only heterotrophic strains exist in pure culture, and *Beggiatoa*, from marine and freshwater habitats. Only the marine *Beggiatoa* strains seem to be facultative autotrophs (Nelson, 1989). The other six genera have not yielded pure cultures most probably because they are obligate sulfide-oxidizers, which, in view of the autoxidizability of H_2S, renders the use of solid media impossible and that of liquid media extremely cumbersome, since continuous inputs of H_2S and O_2 have to be maintained. Thus, for the moment, these six

This chapter was taken unchanged from the second edition.

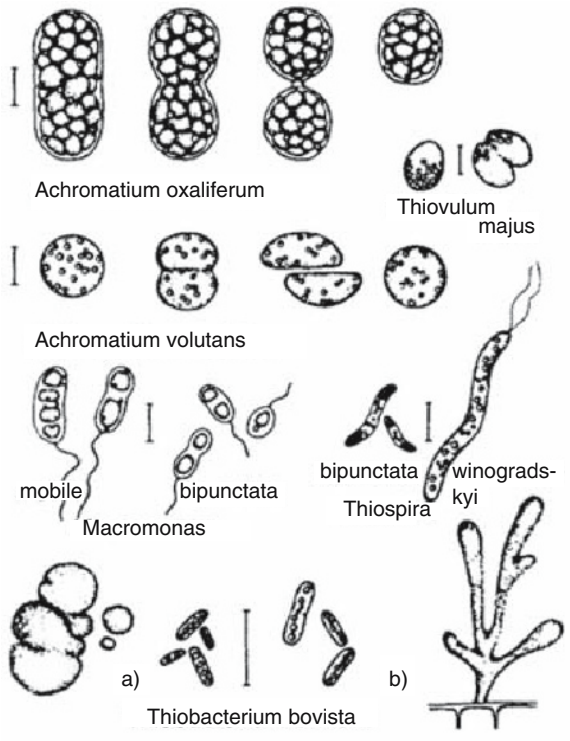

Fig. 1. Composite drawing of the described organisms, redrawn from the original literature. Bars = 10 µm—except for the typical colonies of the *Thiobacterium* species: (a) "puffball" shape, (b) dendroid shape, Bars = 5 µm.

genera exist only by virtue of their morphological recognizability. The morphological characteristics are the only basis for the division into different genera.

In nature, quite often the predominance of one or a few colorless sulfur bacteria can be observed. Knowledge of the factors determining such predominance would obviously be of great help in isolation studies, but so far we have no clue as to the determinants of competition and survival of these diverse organisms, which have to compete not only among one another, but very likely also against the chemical oxidation of H_2S.

Thus we are faced with a vicious circle: lack of knowledge of the physiology of these organisms impedes the design of effective isolation procedures, which, in turn, are the very requirement for obtaining such physiological knowledge through pure culture study. The riddle they pose is further complicated by the complexity of their natural habitat. In addition to natural aeration, when exposed to light, the medium also receives O_2 from photosynthesis, subject to diurnal fluctuations. Furthermore, H_2S can originate from groundwaters poor in organic matter, as well as from sulfate reduction in mud layers, in which case it is invariably accompanied by organic compounds. The mineral contents of the water also appear to play an important role. A relatively high Ca^{2+} concentration or the presence of solid $CaCO_3$ characterizes many of the habitats in which the organisms are found; the relationship is most obvious for *Achromatium* and *Macromonas*, which both can have $CaCO_3$ inclusions.

Enrichment and Cultivation Methods

Imitation of the natural conditions in the laboratory appears to be the best approach to enrichment, cultivation, and isolation of *Achromatium*, *Macromonas*, *Thiobacterium*, *Thiospira*, and *Thiovulum,* the five genera under discussion in this chapter. The enrichment methods consist essentially of using Winogradsky columns (Winogradsky, 1888) that are kept in the dark and that contain sediments in which H_2S is generated through sulfate reduction. Hence, adequate, i.e., slowly decaying, organic material—and in the case of freshwater enrichments, $CaSO_4$—has to be included in the sediment; in seawater enrichments, a considerable amount of sulfate is already present in the water phase. Besides stationary columns, flow-through variations have been used in which the water phase is continuously and slowly replenished, which provides a means of controlling the position of the H_2S/O_2 border zone and of eliminating contaminants. This method has led to reproducible enrichment procedures for *Thiovulum,* while a more classical enrichment method could be used for the heterotrophic *Macromonas bipunctata*. For the other three genera, enrichment is still extremely difficult and at best capricious.

In the design of effective enrichment and cultivation methods, some guidelines can be further derived from specific ecological attributes of the organisms themselves:

1. The presence of elemental sulfur inclusions, a stored energy source, implies that the culture can survive periods of absence of H_2S but not of O_2 (all genera).
2. Possession of strong chemotactic properties introduces the possibility of exerting selection through water flow (*Thiovulum, Thiospira*).
3. Limited motility, or its absence in some genera, calls for stability of the position of the H_2S/O_2 border zone in the place where the organism is expected to accumulate (*Achromatium*: at the bottom; *Thiobacterium*: at the surface).
4. Capacity for attachment to solid surfaces permits selection by water flow, provided the water contains the proper mix of H_2S and O_2 (*Thiobacterium*, *Thiothrix).*

5. The organism permitting, application of low temperatures (10–17°C) appears favorable, as this slows down chemical H_2S oxidation and thus leads to greater stability.

In conjunction with these methods, purification of cell material has been undertaken by taking advantage of chemotaxis *(Thiovulum)* and of selective sedimentation based on high specific gravity (*Achromatium*). Suspending the cells in sterile solutions followed by transfer to fresh sterile solution after separation had taken place could be carried out repeatedly, the "washing efficiency" depending on the initial degree of contamination and the endurance of the cells to repeated washings.

Such purified material, derived from nature or enrichment cultures, can then be subjected to cultivation in aseptic, controlled systems in which constant inputs of H_2S and O_2 are maintained. A great deal of ingenuity has gone into the design of such systems, based, for instance, upon the use of gas mixtures, semipermeable membranes, controlled pumping of sterile nutrient solutions, and solid/liquid phase systems in which the solid phase provides H_2S. So far, the use of sulfide-charged ion-exchangers or badly soluble sulfides as a constant source of H_2S has not been found practicable, nor has the use of inhibitors of chemical H_2S oxidation. Important examples of devices successfully used in specific instances are presented by Devidé (1954), Keil (1912), la Rivière (1963, 1965), and Perfil'ev and Gabe (1961). Wirsen and Jannasch (1978) described a variety of cultivation systems for *Thiovulum* (see below) in which full advantage was taken of modern materials and equipment. It is likely that these systems are also suitable for cultivation of other recalcitrant sulfur bacteria.

Presently, however, our knowledge is still restricted to such data as can be obtained from observations on natural populations and on enrichment cultures in the laboratory, both macro- and microscopically. In addition, laboratory cultures have in several cases produced sufficient quantities of cell material, sufficiently free from contamination, to make electron microscopy of whole cells and thin sections possible. Similarly, such cell material has permitted the determination of sometimes important physiological data. The main target of studies in complex culture systems remains, however, the acquirement of knowledge about the organism that will lead to the design of simpler cultivation methods. After all, one should keep in mind that one successful petri dish culture offers more promise for isolation and subsequent work than any of the culture systems mentioned above.

Significance of the Colorless Sulfur Bacteria

This group of organisms poses the question of how such a great morphological diversity has evolved in a very specialized and restricted niche in competition with chemical sulfide oxidation. One might well speculate that this niche must have been much larger at the time when, during the evolution of the present biosphere, the first oxygen appeared on an initially anaerobic stage and that, for a long time since, a much smaller O_2 concentration prevailed in the atmosphere than at present. However this may be, it is certain that microbial activity, including that of colorless sulfur bacteria, has played and is still playing an important role in the biogeochemical cycle of sulfur (Jørgensen, 1989; Kuenen, 1975; SCOPE 19, 1983; SCOPE 39, 1989; Kuenen and Bos, 1989; la Rivière, 1966). It is, for instance, generally accepted that the sulfur deposits that are mined today are biogenic and have been formed by sulfate reduction followed by an oxidation step that may have involved colorless sulfur bacteria. The well-known *sulfuretum,* in which sulfur is still accumulating today, offers an opportunity for determining the additional contributions of chemical and photosynthetic sulfide oxidation. Furthermore, sulfide oxidation to sulfate is an important step in the regeneration of oxidizing power within water bodies where sulfate plays a role in anaerobic mineralization. Also, the release of H_2S into the atmosphere from oceanic, marshy, and estuarine areas is at the moment a matter of concern on a global scale in judging the impact of artificial SO_2 emissions that are superimposed on it (Svensson and Söderlund, 1976). The magnitude of the biogenic H_2S emissions is presently not well known, but it is certain that the colorless sulfur bacteria codetermine it to a large extent. Finally, biological sulfide oxidation is responsible for the generation of certain types of acid soils and the formation of acid mine effluents. In the mining industry, so-called microbial leaching is presently being practiced for improving the yield of various metals from sulfide ores. For this purpose, *Thiobacillus* species are frequently being used (see The Genus *Thermoplasma* in the second edition). Furthermore, the microbiological methods for removing sulfur from coal, and removing hydrogen sulfide from biogas, generated by anaerobic digestion, are growing in industrial importance.

In the situation as outlined in this introduction, more detailed presentation of available information that follows can offer no more than some springboards and roadsigns for those who want to penetrate further into a fascinating and as yet unconquered territory of the microbial kingdom. Such endeavors also offer the rare

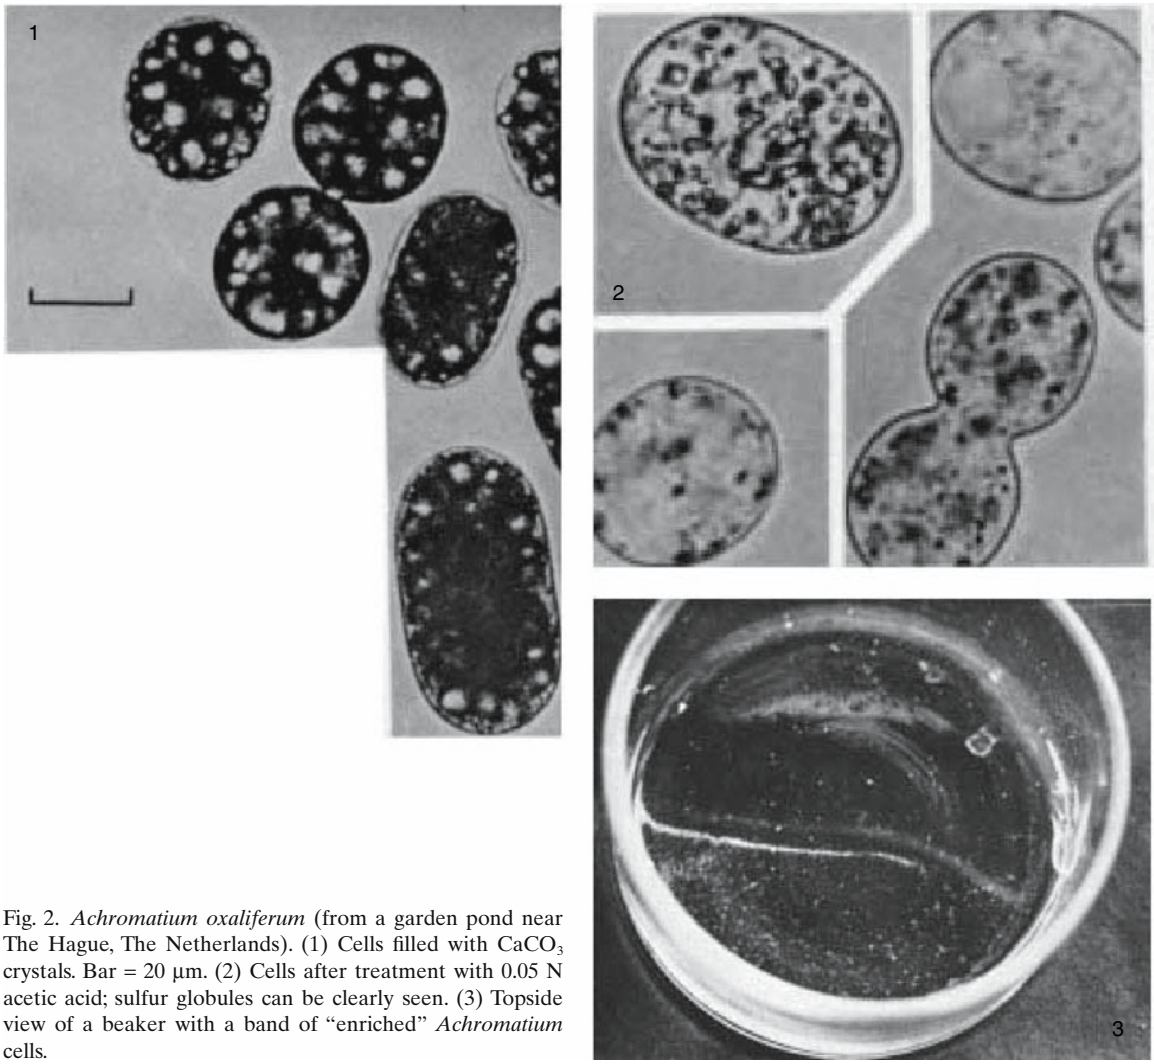

Fig. 2. *Achromatium oxaliferum* (from a garden pond near The Hague, The Netherlands). (1) Cells filled with $CaCO_3$ crystals. Bar = 20 µm. (2) Cells after treatment with 0.05 N acetic acid; sulfur globules can be clearly seen. (3) Topside view of a beaker with a band of "enriched" *Achromatium* cells.

sensation of reading the works of the old masters as valuable guidebooks of undiminished contemporary relevance. In order to facilitate such reading, pertinent references as well as earlier used names of organisms have been included.

The Genus *Achromatium*

Two species of Achromatium are known (La Rivière and Schmidt, 1989): *Achromatium oxaliferum*, which occurs in fresh waters and marine environments, and *Achromatium volutans*, which is less well known and has been found in marine muds only.

Achromatium oxaliferum

Achromatium oxaliferum (Figs. 1 and 2) was described for the first time by Schewiakoff (1893). Since then the organism has temporarily also carried the names *Hillhousia mirabilis* (West and Griffiths, 1909), *Hillhousia palustris* (West and Griffiths, 1913), and *Achromatium gigas* (Nadson, 1913). Its cells are conspicuous because of their massive $CaCO_3$ inclusions occurring together with much smaller sulfur globules. In addition, their large size immediately attracts attention: the cells are spherical, ovoid, or cylindrical with a minimum length of the small axis of 5 µm and a maximum length of the long axis of 100 µm. Division is by constriction. The cells are slowly motile on solid surfaces only. It is, therefore, not surprising that the organism has tantalized numerous observers, none of whom, however, has so far succeeded in developing an effective enrichment method.

Ecology. In all cases, the cells were encountered in or on the bottom mud of fresh and saline waters, as is to be expected from the high specific weight of these organisms, which prevents them from moving vertically in the water. Since they are not at all commonly found among the macroscopically recognizable white masses that usu-

ally guide the investigator most effectively to natural populations of colorless sulfur bacteria, it appears useful to list here some of the habitats in which the organism was found, all the more so because no useful common characteristic of these habitats has as yet emerged.

Gicklhorn (1920), Bersa (1920), and Bavendamm (1924) found *Achromatium* in ponds in the botanical garden in Graz where the alga *Chara* also occurred in large numbers. The bottom mud of Swedish lakes was the source for Skuja (1948), and that of Lake Windermere was the source for Skerman (Starr and Skerman, 1965). Lackey and Lackey (1961) found the organism in fresh and brackish waters in Florida as well as in salt marshes at Woods Hole. It was also found in a small concrete garden pond in Pacific Grove, California, and in 2 out of 14 garden ponds examined near The Hague (J. la Rivière, unpublished). These were made of concrete, had a depth of 40 cm, and contained very loosely packed mud with much organic matter as well as cells of algae and cyanobacteria. Nadson and Visloukh (1923) found *Achromatium* in marine muds. Some of these waters were high, others low, in Ca^{2+} concentration.

Since all authors agree that the organism is an obligate aerobe and the high weight of its cells restricts it to the bottom habitat, it seems obvious that in all of the above-mentioned locations the borderzone between H_2S and O_2 must have resided in the mud or on top of it, indicating that the H_2S generation in the sediment must have been relatively weak, or, alternatively, aeration consistently strong. This appears to make *Achromatium oxaliferum* the counterpart to *Thiobacterium*, which (as a "puffball" type) floats at the surface. There is, however, one important difference in that *Achromatium* possesses some means of locomotion while *Thiobacterium* does not. This motility is very slow and restricted to jerky rolling movements on solid surfaces, most probably effected by means of peritrichous filaments moving about in the slime layer that surrounds the cells (de Boer et al., 1971). In this way, the cells are capable of migrating chemotactically through the mud, where, depending on the distribution of localized microsources of H_2S, concentration gradients exist over short distances that are manageable by the organisms.

Lauterborn (1915) noted that cells were packed with $CaCO_3$ and had few sulfur inclusions when encountered on top of the mud, while cells below the surface contained little or no $CaCO_3$ and much more sulfur. This suggests that the restricted capacity for chemotaxis is somewhat complemented by the storage of sulfur but does not explain the significance that $CaCO_3$ storage could have for the organism beyond keeping it in the bottom layers by sheer weight. In this respect, any possible interaction with surrounding photosynthetic organisms appears important, as these exert a considerable influence not only on the O_2 concentration but also on the $CO_2/CaCO_3$ equilibrium, which are both subject to diurnal changes. In addition, $CaCO_3$ might exert a buffering effect with respect to H_2SO_4 formed by sulfur oxidation.

Enrichment and Cultivation. Most observations on the organism have been done on material taken directly from nature. No effective laboratory enrichment culture methods are available; at best the natural populations can be kept alive in the laboratory for 6–10 months. Schewiakoff (1893) used a watch glass containing mud, *Achromatium* cells, and some supernatant water from the natural habitat. After placing it in sunlight he observed "energetic multiplication" (perhaps chemotactic accumulation?) and formation of white agglomerations of 50–100 cells each. West and Griffiths (1913) placed the mud with overlaying tap water in small cylinders (15 cm wide, 5 cm high) and stirred the mud from time to time; in this way they kept the organisms alive for 9 months. They stated that the cells had a doubling time of 24–48 h under these conditions and that death resulting from O_2 deficiency was accompanied by the loss of the $CaCO_3$ inclusions. De Boer et al. (1971) maintained natural populations for 10 months by placing the loosely packed mud from a pond in closed plastic bottles at 5°C. The overlaying pond water column was about four times higher than the mud layer. The same authors used a very simple method, suggested to them by C. B. van Niel, for concentrating the cells in such a mud-water system. It is based on the heavy weight and white color of the *Achromatium* cells:

Collecting and Concentrating *Achromatium* Cells Found in Nature (de Boer et al., 1971)

> Material from the upper part of the sediment was collected. Lightweight particles were removed by repeated decanting in tap water. Layers of heavier mud particles, approximately 0.5 cm thick, were subjected to gentle swirling in a tilted beaker that at the same time was rotated slowly along its vertical axis (Fig. 2). This treatment led to further fractionation of the particles according to their specific gravity and the heavy Achromatium cells soon became visible as a narrow white band very close to that of the sand-particle fraction. The cells were pipetted off and transferred to a smaller beaker and further purified by the same method. This procedure was repeated several times until a dense mass of Achromatium cells was obtained. This no longer contained cells of algae, protozoa, or sand particles, and the number of smaller bacteria present had been reduced to a very small minority, as shown by microscopic examination.
>
> The method was obviously only successful for *Achromatium* cells that actually contained appreciable quantities of $CaCO_3$ inclusions.

At least 50% of the cells obtained in this way were viable, as shown by their motility observed

under the microscope. They proved to be quite suitable for electron microscopy and some elementary physiological tests.

Further Characteristics. The organism is very easy to identify by the morphological characteristics already mentioned. Healthy cells are almost completely filled with highly refractile $CaCO_3$ crystals, which makes it difficult to observe the sulfur globules. These are best seen after selective removal of the $CaCO_3$ by treating the cells with 0.05 N acetic acid (de Boer et al., 1971) (Fig. 2).

Cells collected by the method described above remained contaminated by heterotrophs even after repeated washings with sterile water. Nevertheless, indications were obtained that the cells moved and multiplied more actively in the presence of organic acids, casamino acids, or both. The experiments, however, could not be pursued further because of overgrowth by more rapidly multiplying heterotrophs (K. Schmidt, unpublished). The cells could be lysed by lysozyme and proved to be Gram-negative and catalase-negative.

Achromatium volutans

Achromatium volutans (Fig. 1 and 3) was first described by Hinze (1903) under the name of *Thiophysa volutans* and later by Nadson (1913, 1914) under the name of *Thiophysa macrophysa.* The organism was found in saline waters only: in association with mud and decaying seaweeds from the Bay of Naples (Hinze, 1903, 1913), in the saline sulfur spring "Solgraben von Artern" (Kolkwitz, 1918), and in a saline spring in Florida (Lackey and Lackey, 1961). The best description is probably that of Hinze (1903), who obtained his cell material from marine mud placed in a flat dish; within 1 h, many cells were found at the mud surface, concentrated through chemotaxis into a thin white layer.

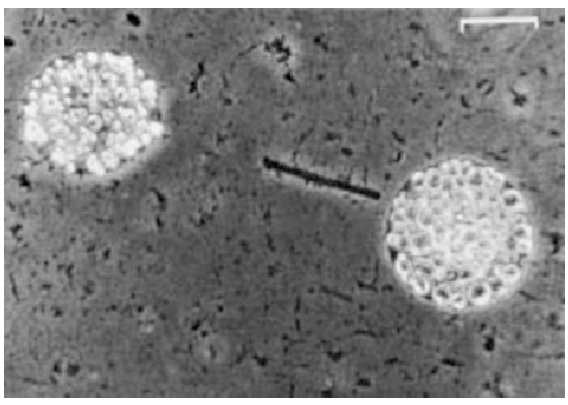

Fig. 3. *Achromatium* (= *Thiophysa*) *volutans* (from Solgraben in Artern, Germany). Bar = 20 μm.

The organism was very similar to *Achromatium oxaliferum* with respect to cell shape, motility, and mode of division. A striking difference was the total lack of $CaCO_3$ inclusions and the presence of far more and larger sulfur globules. Also the cells were consistently smaller, ranging from spheres with a diameter of 5 μm, when young, to ovals up to 40 μm in length. Right after division cells were flat at one end, which was never observed in *Achromatium oxaliferum* (Fig. 1).

The observations of Hinze (1903) suggest that this organism is more sensitive to environmental conditions like H_2S and O_2 concentrations than is *Achromatium oxaliferum*. This appears plausible because its lower specific gravity is likely to permit more rapid chemotactic response.

The Genus *Macromonas*

Cells of *Macromonas* are often found in habitats where *Achromatium oxaliferum* also occurs (Bavendamm, 1924; Gicklhorn, 1920; Lauterborn, 1915; Skuja, 1956). To the knowledge of the authors, only one attempt at enrichment of these organisms has been described (Dubinina and Grabovich, 1984). Hence, most available data originate from observations on material directly taken from natural sources.

The cells are colorless, cylindrical or bean shaped and sluggishly motile with one polar flagellum. Since flagellation was observed in the light microscope, presence of a tuft of flagella is more likely. Their typical characteristic is the presence of several large refractile spherules, which have been thought to consist of $CaCO_3$; definite proof for this is lacking, however. In addition, small sulfur globules may be present.

Two species have been recognized (la Rivière and Dubinina, 1989).

Of the two species *Macromonas mobilis* (Fig. 1) was first described by Lauterborn (1915) under the name *Achromatium mobile* and later by Gicklhorn (1920) as *Microspira vacillans.* The cells are ellipsoidal or cylindrical and slightly curved, measuring usually 9 by 20 μm. Smaller cells are often present and are believed to be daughter cells (Gicklhorn, 1920). The single polar locomotor organ (tuft of flagella?) measures 20–40 μm and can be observed by light microscopy. It provides for motility at a rate of 800 μm/min. Besides small sulfur inclusions, usually between 5 and 15, one to four large refractile bodies occur, which closely resemble the $CaCO_3$ inclusions of *Achromatium oxaliferum* and, therefore, are provisionally considered to consist of $CaCO_3$. No methods for isolation are known.

Macromonas bipunctata (Fig. 1) was first described by Gicklhorn (1920) as *Pseudomonas bipunctata* and renamed *Macromonas bipunctata* by Utermöhl and Koppe (Koppe, 1923). Dubinina and Grabovich (1984) reported the isolation of heterotrophic bacteria answering the description of *Macromonas bipunctata* by these authors. The cells are single or in pairs, pear-shaped, cylindrical or curved; they measure 2.2–4 × 3.3–6.5 μm. They are motile by a polar tuft of flagella, Gram-negative, strictly aerobic and catalase-positive. Sulfur inclusions are produced when the cells are grown in media containing sulfide, which is oxidized by hydrogen peroxide and thus offers no useful energy to the cell.

While recognizing the valid description of *Macromonas bipunctata* by Dubinina and Grabovich, la Rivière and Dubinina (1989) still maintain *Macromonas mobilis* as type species because "… now that the way has been paved, it is felt that isolation of Macromonas mobilis may take place in the near future and thus complete the taxonomy of the genus with a minimum of alterations."

Enrichment and Isolation of *Macromonas bipunctata* (Dubinina and Grabovich, 1984)

> The white mat found on the surface of bottom sediments in a sewage treatment plant was used for inoculating 10 ml portions of the following semisolid medium contained in test tubes:
>
> | | |
> |---|---|
> | Sodium acetate | 1 g/l |
> | Calcium chloride | 0.1 g/l |
> | Casein hydrolysate (Difco) | 0.1 g/l |
> | Yeast extract (Difco) | 0.1 g/l |
> | Agar (Difco) | 1 g/l |
>
> After sterilization, a mixture of vitamins and of trace-elements (Pfennig and Lippert, 1966) was added, as well as 0.2 mg freshly prepared FeS per 10 ml medium as source of sulfide. The pH was adjusted to 7.2–7.4.
>
> After two to three days at 28°C, a white surface film appeared, which contained a large number of typical Macromonas cells. Streaks were made from a suspension of this film on agar plates containing the medium described above solidified with 1 g agar/l. After two to three days flat Macromonas colonies appeared with a diameter of 1 to 4 mm and a finegrained structure. These colonies were used for subsequent purification by re-streaking on solid medium.

The Genus *Thiobacterium*

The organisms of this genus are nonmotile rods that form sulfur inclusions. The cells are embedded in gelatinous masses that are either "puffball"-shaped or dendroid. Spherical, "puffball"-shaped gelatinous masses may be found freely floating in stagnant, H_2S-bearing waters (Fig. 1; *Thiobacterium* a). Dendroid gelatinous masses may be found attached to solid surfaces that are exposed to flowing, H_2S-containing waters (Fig. 1; *Thiobacterium* b).

Their lack of motility prevents these organisms from following chemotactically the spatial fluctuations of the zone of optimal H_2S and O_2 concentrations. This suggests that they are capable of growing under a wider range of H_2S and O_2 concentrations than acceptable to most of the motile colorless sulfur bacteria, or, alternatively, that they are confined to growth in locations where their optimal conditions more or less continuously prevail. The latter alternative appears to be supported by the fact that they are found floating at water-air interfaces or attached to solid surfaces. The first case is likely to occur when H_2S generation is consistently so high that the zone of optimal conditions is kept automatically at the top of the anaerobic water column. The second case arises when a water stream with more or less constant H_2S and O_2 concentrations is maintained for longer periods of time; this is the situation one finds in certain sections of the outflows of sulfur springs.

In *Bergey's Manual* (Buchanan and Gibbons, 1974; la Rivière and Kuenen, 1989a), only one species, *Thiobacterium bovista*, was recognized. It comprised the bacteria embedded in spherical, gelatinous masses, first described by Molisch (1912) under the name of *Bacterium bovista,* as well as those embedded in dendroid structures, first described by Lackey and Lackey (1961) under the name of *Thiodendron mucosum*. Observations in nature of *Thiobacterium bovista* have been reported by Scheminzky et al. (1972) and by Caldwell and Caldwell (1974).

Molisch obtained the spherical colony type (Fig. 1) of *Thiobacterium* at the surface of Winogradsky column enrichments prepared with seawater plus a sediment consisting of black mud mixed with decaying algae, all ingredients originating from the harbor of Trieste, in which the organism was also directly observed. The diameter of the spherical structures ranged from microscopic dimensions to about 4 mm and the structures were sometimes clustered together. The lengths of the cells were between 2 and 5 μm, their width between 0.6 and 1.5 μm. They usually contained four sulfur globules per cell. These cells were embedded in the gelatinous skin of the spherical masses, the inside of which was filled with water. The nature of the mucoid matrix was not elucidated.

The dendroid forms (Fig. 1) were found by Lackey and Lackey (1961) in saline, H_2S-bearing waters in Florida at temperatures between 13 and 30°C. The dendroid matrix, of as yet unidentified material, had the shape of branching filaments with a varying thickness of up to 20μm, individual branches sometimes being clubshaped. Thus, the colonies acquired treelike

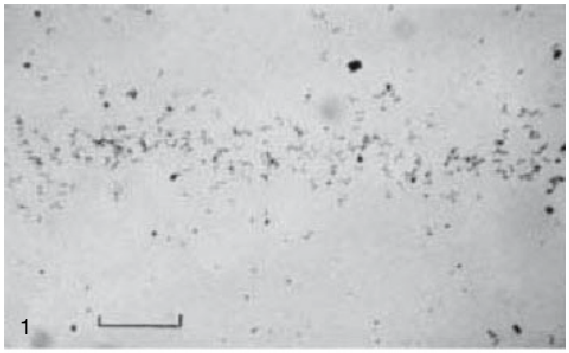
structures, reaching a width of up to 3 mm. Most of the colonies were found attached to algal and cyanobacterial cells (generally of the genus *Lyngbya*), which raises the question of a possible interaction involving O_2.

The cells were randomly arranged throughout the branches and consisted of rods, normally 3–5 μm and 1.5 μm wide; in the swollen ends of the branches, however, cells three times that size were found. Most cells contained three to eight sulfur globules arranged on a longitudinal axis.

The organism could not be grown in enrichments in the laboratory but was kept alive for 3 months in jars with water of the original habitat at 20°C.

The Genus *Thiospira*

Thiospira cells consist of typical colorless spirilla with sulfur inclusions. Their polar flagella are in some cases united in a tuft, visible in the light microscope. The cells are chemotactic with respect to O_2 and H_2S. They can arrange themselves in characteristic agglomerations located in regions of optimal H_2S and O_2 concentrations, forming "Bakterienplatten" in liquid columns and "Atmungsfiguren" in covered slide preparations (Fig. 4). The members of the genus have been found in fresh waters and marine environments in which H_2S was present.



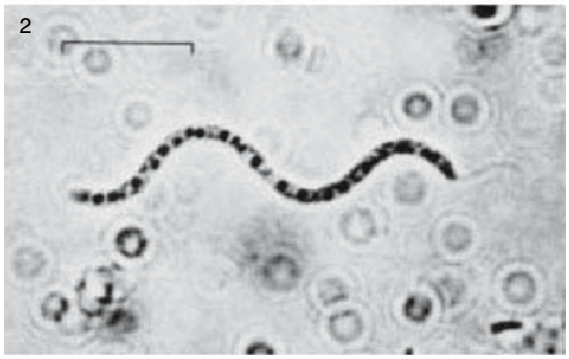


Fig. 4. *Thiospira* sp. (from upwelling groundwater near Delft, The Netherlands). (Courtesy of J. Klein, IHE, Delft.) (1) Cells accumulating at the optimum O_2/H_2S-zone. Bar = 100 μm. (2) Dividing cell with a flagellum. Bar = 10 μm.

At the moment, two species are recognized (la Rivière and Kuenen, 1989b).

Thiospira bipunctata (Fig. 1) was first described by Molisch (1912) and at that time named *Spirillum bipunctatum*. Its cells are slightly twisted rods forming short spirilla with a width of 1.7–2.4 μm and a length of 6.6–14 μm. They are most probably polarly flagellated. Each end of the cell typically contains a large granule of some storage material, described as volutin, leaving a clear space in the middle normally filled with two or three sulfur globules. The latter are sometimes also found at the ends.

Thiospira winogradskyi (Fig. 1) was first described by Omelianski (1905) and at that time named *Thiospirillum winogradskii.* It is a colorless spirillum containing numerous sulfur globules that may disappear when the H_2S in the medium is exhausted. It is 2–2.5 μm wide and can reach a length of 50 μm. "Volutin" bodies are absent. The cells have polar flagella and are strongly chemotactic.

Dubinina and Grabovich (1983) reported the isolation of heterotrophic spirilla under the name of *Thiospira bipunctata*. These were morphologically similar to *Thiospira bipunctata* as described by Molisch since they formed sulfur inclusions when grown in media containing sulfide. The sulfur was formed by nonspecific sulfide oxidation by metabolically produced hydrogen peroxide. Since other heterotrophs have also been found to form sulfur inclusions in sulfide-containing media (Skerman et al., 1957), further study is required for determining the proper taxonomic status of these isolates, which may well prove to be identical to existing *Spirillum* species.

Enrichment Procedures

All enrichments for *Thiospira* have been carried out in Winogradsky columns (Winogradsky, 1888) in which H_2S was released from a sediment.

Molisch (1912) enriched *Thiospira bipunctata* from mud from a Black Sea estuary (a liman) in cylinders (5–15 × 10–30 cm) filled with seawater and a sediment of mud mixed with dying or dried algae. The columns were kept for several weeks at room temperature in the dark or under dim light.

Omelianski (1905) enriched *Thiospira winogradskyi* using tap water and a mixture of liman mud, $CaSO_4$, and fragmented rhizomes in cylinders 7 cm wide and 40 cm high. After some months' incubation at room temperature in the dark, "Bakterienplatten" appeared in the lower part of the columns, which moved up and down

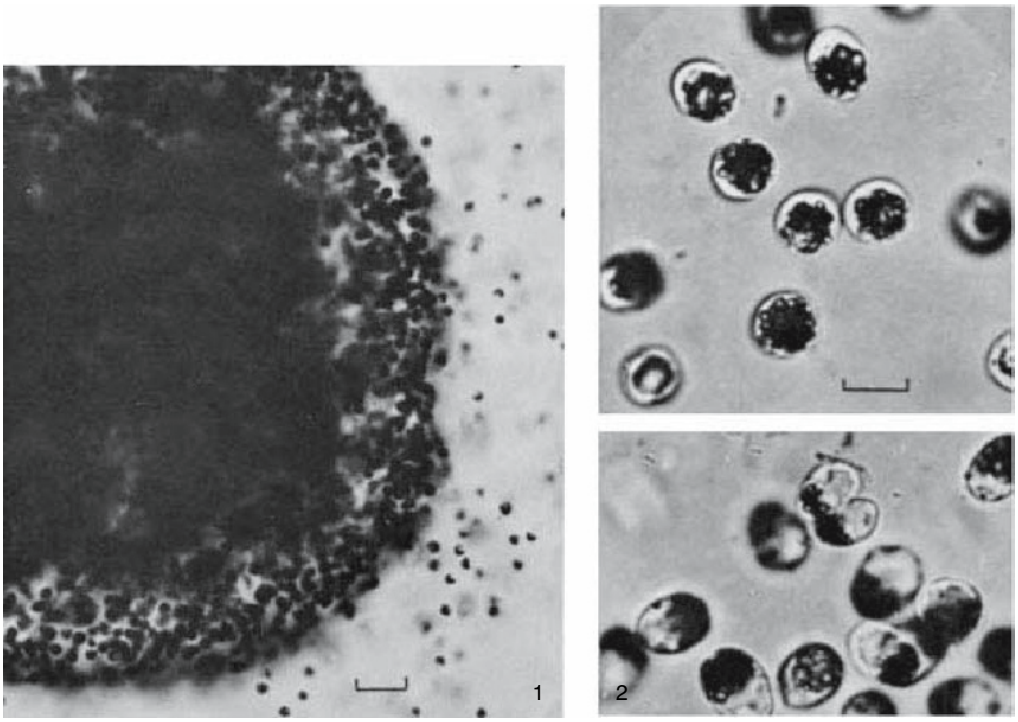

Fig. 5. *Thiovulum majus* (from Bergen op Zoom, The Netherlands). (1) Periphery of a veil of *Thiovulum majus.* Bar = 50 μm. (2) Swarming cells. Bar = 20 μm. (From Schlegel, 1976.)

with the prevailing H_2S concentration. When the cells had settled to the bottom, the sediment was stirred up, which apparently led to renewed H_2S production and prolongation of the lifetime of the culture, which in this way could be kept for 2 years. The present authors had occasion to observe a *Thiospira* species among the colorless sulfur bacteria at 7°C in the outflow of an upwelling, H_2S-bearing groundwater near Delft, The Netherlands (Fig. 4). The cells formed "Atmungsfiguren" in slide preparations and could be kept viable for at least 6 weeks at 4°C in the dark, in cylinders containing groundwater and some mud from the location of origin.

The Genus *Thiovulum*

The cells of this spectacular genus (Figs. 1 and 5) are ovoid and measure 5–25 μm in length. They normally contain sulfur inclusions, often concentrated at one end. The cells multiply by longitudinal fission preceded by constriction. The cells have peritrichous flagella that provide strong chemotactic motility, the cells rotating around an axis coinciding with the path of travel; they never reverse direction and concentrate at places of optimum O_2 and H_2S concentrations in sharply defined characteristic veils or webs consisting of separate, ever moving, individual cells, to some extent held together by a very loose slime matrix (Fig. 5).

Because of this strong chemotaxis, the development of methods for enrichment and cultivation has been more successful for *Thiovulum* than for the other genera discussed in this chapter.

Only one species, *Thiovulum majus,* is recognized (la Rivière and Kuenen, 1989c). This includes the former species *Thiovulum minus* (Hinze, 1913). Other obsolete names are *Monas muelleri* (Warming, 1875) and *Thiovulum muelleri* (Lauterborn, 1915).

Ecology

Thiovulum has been observed in marine environments and saline springs by Warming (1875), Hinze (1903, 1913), Molisch (1912), Bavendamm (1924), Fauré-Fremiet and Rouiller (1958), Lackey and Lackey (1961), and la Rivière (1963). Freshwater forms were reported by Lauterborn (1915) and Lackey and Lackey (1961). In all instances, *Thiovulum* is found in very sharply localized white masses in situations where H_2S meets with O_2. Since it appears restricted to low concentrations of each substance for optimal growth, the patterns it forms provide a macroscopic visualization of this borderline, even in slowly flowing waters, as the cells

rapidly follow changes of the concentration gradient. This makes it sometimes possible to identify *Thiovulum* accumulations in nature by their characteristic white patterns observed above black, sulfide-releasing muds in otherwise clear water. Similarly, such veils may be observed over decaying organic matter in flowthrough marine aquaria.

Measurements with microelectrodes in natural and laboratory systems (Jørgensen and Revsbech, 1983) have established that these veils are about 100 µm thick and are formed at the interface of the oxygen and sulfide zones. The veils create an unstirred boundary layer preventing mixing of oxygen and sulfide and thus also preventing chemical sulfide oxidation. The veils thus create a situation in which the *Thiovulum* cells are fed by diffusion of both substrates, which each penetrate over a distance of 50 µm into the veil. In oxygen-rich water the veils take the shape of small spheres which are made anaerobic in the center by the rapid oxygen utilization of the cells, which thus create the gradient required for optimum growth. Jørgensen and Revsbech (1983) provide further fascinating evidence showing that the chemotactic behavior of *Thiovulum* is extremely sensitive to environmental influences and is an important instrument, by "concerted action" of many cells, in the creation of the precarious niche in which *Thiovulum* lives.

Enrichment

Unpublished work by van Niel, Wijler, and Lascelles (van Niel, 1955) led to the development of a simple enrichment method, described by la Rivière (1963, 1965). The method has been successfully used in Pacific Grove (California), in Delft (The Netherlands), and also in Woods Hole (Massachusetts) (Wirsen and Jannasch, 1978).

Enrichment of *Thiovulum* (Wirsen and Jannasch, 1978)

A layer of decaying seaweed (Ulva) mixed with some marine mud is placed on the bottom of a jar of 1–10 liters filled with seawater, and the thickness of the compressed algal layer is kept to less than half the height of the jar (Fig. 6A). A continuous, slow flow of seawater is introduced near the surface of the sediment, and the jar is allowed to overflow. The layer of Ulva via sulfate reduction acts as a source of H_2S while the flowing seawater provides a continuous supply of O_2. By means of chemotaxis, the cells of Thiovulum seek out the regions of optimal concentration, where growth takes place in characteristic veils. The flow of seawater has also the essential functions of supplying the sediment with SO_4^{2-} as a source of H_2S and of flushing out contaminating organisms that are not chemotactic; as a rule the Thiovulum veils are surrounded by clear water.

When fresh *Ulva* is used, one should wait ca. 2 weeks before starting the seawater flow; a thick film of bacteria usually has developed at the surface at that time. After the flow of seawater is started, growth of *Beggiatoa* and/or *Thiothrix* may be observed in the upper part of the jar. In that case, the flow rate should be increased somewhat; the filamentous bacteria move to lower regions and eventually to the bottom while *Thiovulum* appears in the top layer usually 2–3 weeks after the start of the experiment. This indicates that the optimum sulfide concentration for *Thiovulum* is definitely lower than that for *Beggiatoa* and *Thiotrix*. When the flow rate is further increased, the veils of *Thiovulum* move further downwards.

At all times the culture should be kept in the dark, and relatively low temperatures (15°C) appear to be favor-

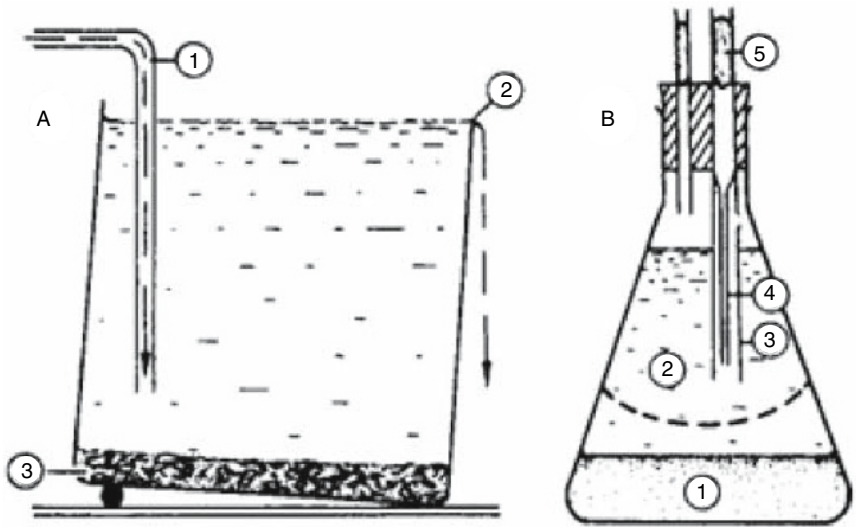

Fig. 6. Culture vessels for enrichment of *Thiovulum:* (A) by Wijler's method and (B) for stationary cultivation of *Thiovulum.* (A): 1, inflow of seawater; 2, overflow; and 3, layer of decaying *Ulva.* (B): 1, sulfide-containing agar layer; 2, seawater; 3, protective tube for localized aeration; 4, Pasteur pipette; and 5, cotton plug. The broken line indicates the zone of growth of *Thiovulum.*

able. The layer of *Ulva* can be replaced by decaying marine animals like starfishes and sea urchins; a layer of fishmeal has also given positive results.

Wirsen and Jannasch (1978) found that an initial addition of neutralized Na_2S led to an earlier appearance of *Thiovulum* veils and to larger enriched populations.

Enrichment cultures of *Thiovulum* can be used as a source of crude cell material for several weeks until the H_2S-generating power of the sediment is exhausted. Lateral illumination with a flashlight greatly facilitates observation and harvesting of the *Thiovulum* veils.

Purification of Crude Cell Material

Besides filtration, methods based upon the chemotaxis of *Thiovulum* have been used, singly or in combination. la Rivière (1963, 1965) used the following method:

Purification of *Thiovulum* (la Rivière, 1963, 1965)

A total of 50–100 ml of a cell suspension carefully harvested by pipetting from an enrichment culture is rapidly filtered through a thin layer of cotton or of cheesecloth into a 100-ml glass cylinder. After 5–10 min, the cells settle chemotactically near the bottom, from where they are transferred by means of a pipette in as small a volume as possible into a test tube containing 15 ml sterile, aerobic seawater, cooled to about 15°C, in which they again form a veil near the bottom in 5–15 min. Repeated transfers in a similar manner to fresh tubes with sterile seawater lead to highly purified cell suspensions, as the initial filtration removes debris, protozoa, and other larger organisms while subsequent "washings" decrease the number of smaller contaminants. Plating on media for Thiobacillus and for heterotrophs permits following the effectiveness of the purification steps.

The success of the method depends entirely on the degree of initial contamination of the raw material and the capacity of the cells to survive successive purification steps. In experiments in Pacific Grove, "washing" could be performed 6–10 times in succession, leading to suspensions that were consistently free from contaminants. However, similar pure suspensions were not obtained in experiments in The Netherlands (la Rivière, 1965) or in Woods Hole (Wirsen and Jannsch, 1978), which is probably caused by differences in vigor between the enriched populations and in properties of the seawater used, such as temperature, degree of pollution, and microbial contamination.

Wirsen and Jannasch (1978) used the following modifications of the method described above:

1. Repeated chemotactic "washing" by pipetting or decantation in sterile aerobic seawater without an initial filtration step; this could be done only when freshly formed veils, relatively free from larger organisms, were available in the enrichments.

2. Chemotactic "washing" in deoxygenated sterile seawater, in which case the cells migrate to the top layer.

3. Concentration and washing of the cells by means of a membrane filter with a porosity of 8 μm. Initial cell suspensions are concentrated to about 2 ml by suction, whereupon fresh sterile seawater is added, followed again by concentration by suction, *Thiovulum* cells being retained by the filter while contaminants are passed through it. Three to five such "washings" are possible.

Application of these methods combined with subsequent cultivation procedures provided Wirsen and Jannasch (1978) with highly purified cell suspensions suitable for electron microscopy and for the performance of some important physiological experiments. The various treatments, however, could not be repeated a sufficient number of times to obtain suspensions that were entirely free from contaminants.

Cultivation of Purified *Thiovulum* Populations

Stationary Cultivation of Thiovulum Suspensions free from Contaminants (La Rivière, 1963, 1965). In a 500-ml Erlenmeyer flask, 250 ml of the following sterile agar medium is sterilized at 120°C for 10 min: 250 ml seawater, 2% agar (Difco), 0.01% NH_4Cl, 0.01% KH_2PO_4. Just prior to solidification of the agar, 2.5 ml of a separately heat-sterilized solution of 1% Na_2CO_3 in seawater is added, followed by 8 ml of sterile seawater previously saturated by gaseous H_2S. The pH does not need adjustment; it should be around 8.0. After setting of the agar, 250 ml of seawater are added and the flask is closed with a steam-sterilized stopper allowing for local aeration by means of a Pasteur pipette surrounded by a vertical glass tube which is open at the lower end (Fig. 6B). In this way, aeration is restricted to the inside of the protective glass tube, the dissolved oxygen slowly diffusing downwards to the bulk of the seawater layer. Thus, a gradient between the tube and the agar block is established which can be easily demonstrated with a redox dye; e.g., thionine. Without aeration, the dye is in its reduced form throughout the liquid; with conventional aeration without protection tube, the turbulence distributes the oxygen uniformly and the dye is in its oxidized form throughout the liquid. With localized aeration we obtain a sharp boundary between a "reduced" and an "oxidized" zone, which can be maintained for weeks.

The flask is placed at a temperature of 10–15°C and kept under constant aeration with cotton-filtered air. After equilibration overnight, the flask is ready for inoculation with purified cell material, and soon the individual cells of the inoculum can be seen to settle in one plane somewhere between the agar surface and the aeration tube.

Within days, the cells increase in number until a sharply defined web is formed at about 1 cm above the agar surface in an otherwise clear liquid. On prolonged incubation, the web rises slowly because of increasing O_2 demand; later on the web moves downward as H_2S becomes exhausted. By this time, signs of decay become apparent: White strands consisting of dead cells adhering to each other hang down from the sides of the flask. The life of the culture lasts for about 3 weeks.

This procedure has been successfully used only in Pacific Grove, where purification of the inoculum could be pursued to the point where all contamination had been eliminated. It was also used—with some modification—by Pringsheim and Kowallik (1964) in their study of H_2S oxidation by *Beggiatoa*.

It should be pointed out that the method is unsuitable when impurities are present, as *Thiovulum* is rapidly overgrown in any closed stationary system. It should further be realized that even when successful the method yields only very small amounts of cell material.

Cultivation in Open, Flow-through Systems. Such systems are based upon the same principle that underlies the enrichment culture method. Besides the use of sterilized, aerated seawater fed into the culture vessel by controlled pumping, different sources for input of H_2S have been applied. These include periodical addition of H_2S or portions of saturated solutions of H_2S once or twice daily (la Rivière, 1963, 1965). Wirsen and Jannasch (1978) developed several reliable devices in which continuous H_2S provision was assured from different sources:

1. Decaying *Ulva* kept separately from the culture vessel by a nylon membrane of 0.45-µm porosity.
2. A pure culture of *Desulfovibrio aestuarii* separated from the culture vessel in the same way, H_2S generation being kept up by periodic addition (every 2–4 weeks) of fresh sodium sulfate/lactate medium. This system (Fig. 7) provided the best results, permitting the maintenance of active Thiovulum populations for 220 days without reinoculation; during this time cells were frequently harvested, leading to rejuvenation of the veils.

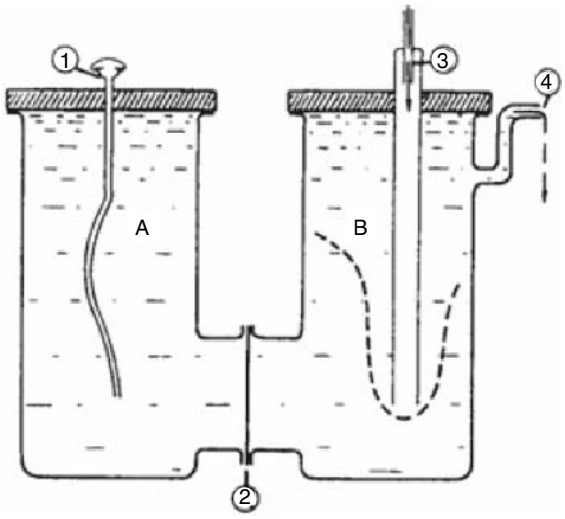

Fig. 7. Double culture vessel for the maintenance of purified cell suspensions of *Thiovulum* sp. (after Jannasch and Mateles, 1974; and Wirsen and Jannasch, 1978). (A) Culture vessel with *Desulfovibrio estuarii*. (B) Culture vessel for *Thiovulum*. 1, lactate supply; 2, semipermeable membrane; 3, inflow of air-saturated seawater; 4, overflow. The broken line indicates the zone of growth of *Thiovulum*.

3. A neutralized solution of Na_2S in sterile seawater separated from the culture vessel by a dialysis membrane.
4. A coil of silicone tubing, permeable to H_2S, through which a gas mixture of N_2 and H_2S (1%) was kept circulating. The coil was placed on the bottom of the culture vessel.

The same authors, furthermore, used closed-flow systems based upon recirculation rather than open systems with overflow. In the closed system, no *Thiovulum* cells are lost, but contaminants are not flushed away; hence they are only useful for specific short-term experiments.

Finally, it should be pointed out that none of the authors who studied *Thiovulum* has been successful in using solid media. Also H_2S could not be replaced by thiosulfate, nor could nitrate be substituted for O_2.

State of Present Knowledge on *Thiovulum*

Besides the properties mentioned earlier, further characteristics of the organism have been determined by study of cell material derived from enrichments and from mass cultivation of purified material.

Thiovulum is Gram-negative and catalase-negative (la Rivière, 1965); the cells die quickly at high O_2 concentrations, as can be easily seen when they are trapped at the edges of a slide preparation. They are also immediately killed by anaerobic conditions. Its internal structure

has been studied by electron microscopy by Fauré-Fremiet and Rouiller (1958), de Boer et al. (1961), Remsen and Watson (1972), and Wirsen and Jannasch (1978). Among its most striking features are Fauré-Fremiet's polar fibrillar organelle, the thin cell wall, and the slime excretion, which plays a role in structuring and maintaining the veils in which, nevertheless, the cells are in continuous motion. A discussion of the earlier results is presented by Starr and Skerman (1965).

Wirsen and Jannasch (1978) performed uptake experiments with CO_2 and some organic compounds labeled with $^{14}CO_2$ on highly purified cell suspensions, which permitted correction for uptake by contaminants. They showed substantial CO_2 uptake in *Thiovulum* which was optimal at H_2S concentrations of 1 mM in initially air-saturated seawater. No significant carbon uptake was registered for casamino acids, acetate, glutamate, mannitol, and some vitamins. These results provide strong evidence for the chemolithotrophic nature of the *Thiovulum* strains examined.

CHAPTER 14.2

The Genus *Propionigenium*

BERNHARD SCHINK

The genus *Propionigenium* consists so far of two species, *P. modestum* and *P. maris*. *Propionigenium modestum* comprises four strains of physiologically and morphologically similar isolates from various origins (Schink and Pfennig, 1982). This genus was created to house strictly anaerobic bacteria that are able to grow by decarboxylation of succinate to propionate. Enrichment cultures, which were set up originally to enrich for syntrophic succinate degraders from marine and freshwater sediments, developed unexpectedly fast growth of small, coccoid bacteria that did not depend on cooperation with hydrogen-scavenging partners and formed propionate as the sole organic fermentation product. Pure cultures could be obtained only with enrichment cultures from marine sources; the freshwater enrichments grew much slower, and pure cultures were finally isolated when the sodium chloride concentration of the medium was enhanced to 100–150 mM. This finding gave the first hint of sodium dependence of this new type of energy conservation. A further species, *P. maris*, was created later to comprise bacteria similar to *P. modestum* which, however, are metabolically much more versatile and are able to ferment, beyond succinate, also carbohydrates, amino acids, and other organic acids (Janssen and Liesack, 1995).

Succinate is formed in large amounts in the rumen of cows and sheep, but the animal host cannot take up this valuable fermentation product (Wolin, 1979). Conversion of succinate to propionate is therefore an important function of the rumen microbiota, and succinate decarboxylation appears to be a rather common capacity of several propionate-forming fermenting bacteria, e.g., *Selenomonas* (Scheifinger and Wolin, 1973), *Veillonella* (Yousten and Delwiche, 1961), or certain *Propionibacterium* spp. (Yousten and Delwiche, 1961). Initially these conversions were regarded as "cometabolic" activities, which did not provide any advantage to the bacteria. Many years later, it was shown that the methylmalonyl-CoA decarboxylase of *Veillonella alcalescens* is a membrane-bound enzyme that couples the decarboxylation reaction with the transfer of sodium ions across the cytoplasmic membrane (Hilpert and Dimroth, 1982). The sodium gradient thus established helps to provide energy for transport of dicarboxylic acids across the membranes, but it does not allow growth of these bacteria with succinate. It was quite a surprise, therefore, when a bacterium was isolated from sediments that can run its entire energy metabolism for growth on this decarboxylation reaction. This unusual capacity explains why these isolates were placed in a new taxonomic unit, apart from other propionate-forming bacteria.

Today several other bacteria able to grow by conversion of succinate to propionate are known. Among these are Gram-negative mesophiles and also thermophiles (Denger and Schink, 1990; C. Guangsheng and A. Stams, unpublished observations). The coupling between sodium-extruding decarboxylation and ATP synthesis varies to some extent between these isolates, and the direct sodium coupling between a methylmalonyl CoA decarboxylase and a sodium-dependent ATPase as found in *Propionigenium modestum* (see below) is not the only solution to this problem. Later we could show that also *Veillonella parvula* (Mays et al., 1982; Delwiche et al., 1985) harnesses energy from succinate decarboxylation leading to enhanced growth yields in the presence of other substrates, but it cannot convert succinate decarboxylation directly into ATP formation and thus is unable to grow with succinate as sole substrate (Denger and Schink, 1992).

Habitats

Propionigenium modestum was originally isolated from a black, anoxic, marine sediment sample taken from the Canal Grande in Venice, Italy, where it made up 100 cells/ml of sediment (Schink and Pfennig, 1982). Similar strains were isolated later from many other marine habitats and also from human saliva. Enrichments from freshwater sediments sometimes produced cells of similar morphology as *P. modestum* and could be cultivated only in media with enhanced (100–

150 mM) sodium chloride concentrations. Later enrichment experiments with freshwater sediments from many different sites in Germany, Italy and the United States yielded different, vibrioid, Gram-negative bacteria (Denger and Schink, 1990). Also *P. maris* was isolated from marine sediments (Janssen and Liesack, 1995). No isolates able to grow with succinate as the sole energy source have yet been obtained from rumen ecosystems.

It has to be assumed that anoxic marine sediments are the typical habitats of these bacteria. Their energy metabolism is based on sodium ions as coupling ions in energy conservation. With this ability, they are well adapted to a marine environment. Several marine bacteria have been found to use sodium ions as energy couplers in various functions, e.g., respiration (Skulachev, 1985; Dibrov et al., 1986b) or motility (Brown et al., 1983; Dibrov et al., 1986a).

Propionigenium maris-like bacteria were isolated also from burrows of bromophenol-producing marine infauna, where they obviously are involved in reductive debromination of bromophenols (Watson et al., 2000). They probably used organic excretions of the infauna as electron donor for this reductive reaction.

Isolation

Medium for Isolation and Cultivation

A strictly anoxic, sulfide-reduced mineral medium with 20 mM succinate as the sole organic carbon and energy source, and incubation at 27–30°C, has proved to be highly selective for the enrichment of *P. modestum* if marine sediment samples of about 5-ml volume are used as the inoculum. The carbonate-buffered standard medium used for enrichment and isolation is described below (Widdel and Pfennig, 1981; Schink and Pfennig, 1982).

Bicarbonate-Buffered Standard Medium

KH_2PO_4	0.2 g
NH_4Cl	0.5 g
NaCl	20.0 g
$MgCl_2 \cdot 6H_2O$	3.0 g
KCl	0.5 g
$CaCl_2 \cdot 2H_2O$	0.15 g

Dissolve ingredients in 1 liter of distilled water. Autoclave the complete mineral medium in a vessel equipped with a filter inlet to allow flushing of the headspace with sterile oxygen-free gas and use screw cap inlets for addition of thermally unstable additives after autoclaving. Connect silicon tubing from the bottom of the vessel to a dispensing tap (if possible with a protecting bell) for sterile dispensing of the medium (do not use latex tubing; it releases compounds that are toxic to many anaerobes). A stirring bar is also required. After autoclaving, connect the vessel with the still hot medium to a line of oxygen-free nitrogen: carbon dioxide mixture (90% N_2:10% CO_2) at low pressure (<100 mbar). Flush the headspace and cool the medium under this atmosphere to room temperature, perhaps with the help of a cooling water bath.

The mineral medium is amended with the following additions from stock solutions that have been sterilized separately (amounts per liter of medium): a) 30 ml of 1 M $NaHCO_3$ solution (autoclaved in a *tightly closed* screw cap bottle with about 30% headspace. The bottle should be autoclaved in a further protecting vessel, e.g., a polypropylene beaker, to avoid spills of carbonate if the bottle breaks in the autoclave); b) 2 ml of 0.5 M $Na_2S \cdot 9H_2O$ solution (autoclaved separately under oxygen-free gas atmosphere as above); c) 1 ml of trace element solution, e.g., SL 10 (Widdel et al., 1983); d) 0.5 ml of 10-fold concentrated, filter-sterilized vitamin solution (Pfennig, 1978); and e) adequate amounts of sterile 1 M HCl or 1 M Na_2CO_3 to adjust the pH to 7.1–7.3.

The complete medium is dispensed into either screw-cap bottles or screw-cap tubes which are filled to the top, leaving a lentil-sized air bubble for pressure equilibration. Enrichment cultures usually produce gas in the first enrichment stages and are better cultivated in half-filled 50- to 100-ml serum bottles under a headspace of nitrogen: carbon dioxide mixture (90% N_2:10% CO_2). Not all strains require this vitamin mixture.

For mass cultivation of *P. modestum* strain GraSucc2 in fermentors, a phosphate-buffered medium is easier to handle. The following medium has been applied successfully (Hilpert et al., 1984).

Phosphate-Buffered Medium

Distilled water	940 ml
KH_2PO_4	4.2 g
NH_4Cl	0.5 g
NaCl	20.0 g
$MgCl_2 \cdot 6H_2O$	3.0 g
$CaCl_2 \cdot 2H_2O$	0.15 g

Add sulfide, trace elements, and vitamins as above, as well as 60 ml of a neutralized 1 M sodium succinate solution, and adjust the pH to 7.0 before inoculation.

Isolation of Pure Cultures

After two to three transfers in liquid medium, gas should no longer be formed by the enrichment cultures, and a dominant population of short, coccoid rods should be established. These bacteria can be isolated in anoxic agar deep dilution series (Pfennig, 1978) or in roll tubes (Balch et al., 1979). Streaking Petri dishes in an anoxic glove box has not yet been tried with these bacteria. Preparation of pure cultures requires two subsequent dilution series; purity should be checked after growth in selective mineral

medium and in complex medium, e.g., AC medium (Difco Laboratories, Ann Arbor, MI, USA). AC medium prepared according to the original recipe appears to inhibit several sediment bacteria. Therefore, a 1:10 or 1:5 diluted variation (in seawater as well as in freshwater medium, with adjusted agar concentration) of this medium should be used to ensure that the cultures are pure.

Propionigenium maris requires yeast extract (0.1% [w/v]) for growth in pure culture. Addition of yeast extract is not recommended in the liquid enrichment cultures but is needed in the purification step.

Identification and Further Properties

In phase contrast microscopy, cells of *P. modestum* appear as short, coccoid rods (0.5–0.6 × 0.5–2.0 μm), often in short chains (Fig. 1). They are Gram negative and do not form spores. The G+C content of the DNA is in the range of 32–36 mol%.

Propionigenium modestum is strictly anaerobic and does not withstand increased oxygen tensions. The optimum temperature for growth is 30–33°C, and under these conditions, doubling times of 2.5–4.5/h are obtained, depending on whether yeast extract (0.1% [w/v]) is provided as source for assimilatory metabolism. Yeast extract is not required and does not support the energy metabolism, but it enhances the growth yields by about 35%.

In addition to succinate, fumarate and pyruvate also support growth and are fermented stoichiometrically to acetate and propionate. No sugars, alcohols, or any other organic substrates are utilized. No cytochromes have been detected, which is consistent with the absence of electron transport phosphorylation. The growth yields with fumarate and pyruvate are small (3.8 and 6.2 g/mol of fumarate and pyruvate, respectively).

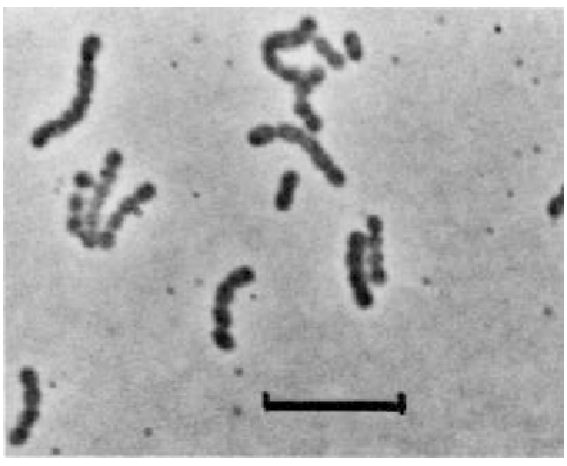

Fig. 1. Phase contrast photomicrograph of cells of *Propionigenium modestum* strain GraSucc2 (type strain) after growth with 20 mM succinate. Bar = 5 μm.

Also *P. maris* forms coccoid to ovoid cells or short rod-like cells of similar size as *P. modestum* cells. It is metabolically much more versatile than *P. modestum* but depends on yeast extract as an obligate medium constituent. In the presence of yeast extract, it ferments succinate, fumarate, pyruvate, citrate, 3-hydroxybutyrate, glucose, fructose, maltose, aspartate, lysine, threonine, glutamate and cysteine; the typical organic fermentation products include formate, acetate, propionate and butyrate. Succinate is fermented to propionate, carbohydrates are fermented to formate, acetate, ethanol and lactate. Hydrogen is produced from carbohydrates and yeast extract, ammonia from amino acids, and sulfide from cysteine. Sulfate, sulfur, thiosulfate and nitrate are not reduced; catalase is not present, and indole is formed from L-tryptophan. *Propionigenium maris* requires anoxic growth conditions. The temperature optimum is at 34–37°C and the pH optimum, at 6.9–7.7. Growth requires at least 5 g/liter of NaCl, at maximum 55 g/liter of NaCl. Cytochromes were not detected. The DNA base ratio is 40 mol% G+C.

Early 16S rRNA gene sequence analyses revealed that *P. maris* and *P. modestum* are closely related and form a distinct lineage within a phylogenetically coherent group characterized by *Fusobacterium nucleatum* and other *Fusobacterium* species, together with *Clostridium rectum*, *Leptotrichia buccalis* and *Sebaldella termitidis* (Both et al., 1991; Janssen and Liesack, 1995). This group has been elevated to the rank of a phylum, *Fusobacteria*, embracing besides *Propionigenium* the genera *Fusobacterium*, *Ilyobacter*, *Leptothrichia*, *Sebaldella*, *Streptobacillus* and *Sneathia* (Garrity et al., 2002).

The biochemical basis of energy conservation with succinate as sole substrate has been studied in detail with *P. modestum* (Hilpert et al., 1984). Succinate exchanges in the cell with propionyl-CoA to form succinyl-CoA and free propionate, which leaves the cell. Succinyl-CoA is rearranged to methylmalonyl-CoA and is decarboxylated by a membrane-bound decarboxylase that couples this reaction with the transport of sodium ions across the cytoplasmic membrane. The sodium ion gradient thus established drives ATP synthesis via a membrane-bound, sodium-dependent ATP synthase.

This unusual coupling of decarboxylation and ATP synthesis was the first case of an energy metabolism that was based entirely on sodium as coupling ions and which did not involve classical

substrate-linked phosphorylation or electron transport phosphorylation steps. Today we know of several more cases of bacteria whose total energy metabolism is based on decarboxylation reactions (Dimroth and Schink, 1998). The biochemical basis for energy conservation may be quite different in each case: e.g., anaerobic bacteria that ferment oxalate to formate and carbon dioxide employ a decarboxylase enzyme which is soluble in the cytoplasm and does not act as an ion pump, and energy conservation occurs via substrate import and product export by an antiporter system (Anantharam et al., 1989).

The ATPase of *P. modestum* has been characterized in more detail (Laubinger and Dimroth, 1987; Laubinger and Dimroth, 1988; Dimroth, 2000). It is composed of an F_1 and an F_0 moiety, both of which have subunits comparable to those of a classical bacterial proton ATPase. The enzyme of *P. modestum* can also pump protons across the membrane, but only if the sodium concentration is very low (<0.1 mM). Under physiological conditions, ATP synthesis is driven entirely by sodium ions. The Na^+ translocating ATP synthase of *P. modestum* became a model system for the study of ion translocation in ATPase enzymes in general. The specificity for Na^+ translocation is localized in the F_0 unit, as could be shown elegantly in transport experiments with hybrid ATPases composed of F_1 units from *Escherichia coli* and F_0 units of *P. modestum* (Laubinger et al., 1990). The specificity for sodium ions could be changed by site-directed mutagenesis (Kaim and Dimroth, 1995; Wehrle et al., 2002). The enzyme has been cloned and formed an active complex after homologous recombination in *E. coli* (Kaim and Dimroth, 1993). Detailed analysis of the rotation process by which ATP is synthesized by this enzyme has shown that voltage is the determining factor, together with the chemiosmotic effect of Na^+ (Kaim and Dimroth, 1998). Today, understanding of the ATP synthesis apparatus of *P. modestum* is very detailed (Dimroth, 2000) and at the same level as the corresponding proton-pumping enzyme of *E. coli*. It has become one of the two favorite ATPase systems studied in depth to understand the coupling of F_1 rotation in the F_0 stator system, and it may be the most promising one to finally elucidate the quantitative relationship between ion transport and ATP formation.

Energy conservation by decarboxylation is of special interest because the free energy change of such reactions is small and yields only about 20–25 kJ/mol. If such reactions drive ATP synthesis (the free energy expense is 70–75 kJ/mol of ATP; Thauer et al., 1977), several decarboxylation reactions have to be coupled with one ATP synthesis reaction. Although the exact stoichiometries of sodium ion translocation by the methylmalonyl-CoA decarboxylase and the ATP synthase have not yet been determined, it is obvious from these free energy calculations that at least three decarboxylations are necessary to allow synthesis of one ATP. This calculation agrees well with the cell yield obtained with *P. modestum* (2.0–2.5 g/mol of succinate). Whole energy metabolism based on a decarboxylation reaction is the most "modest" form of energy conservation, i.e., it produces the lowest amount of energy that can be converted into ATP by a living cell in pure culture (Thauer and Morris, 1984). Partners in syntrophic cocultures active in methanogenic degradation of, e.g., fatty acids, have to operate in the same range of energy yields (see the chapter Syntrophism among Prokaryotes in Volume 2).

Applications

So far there is no commercial application for the *Propionigenium* species. The fact that their unique energy conservation mechanism can also be reversed and allows carboxylation reactions without the direct involvement of ATP (Dimroth and Hilpert, 1984) can possibly render such systems interesting for new ways of biochemical syntheses. The debrominating activity of *P. maris* (Watson et al., 2000) might be of interest in the cleanup of halogenated contaminants in marine ecosystems.

Acknowledgments

The author is greatly indebted to P. Dimroth, A. Kröger, N. Pfennig, and R. K. Thauer for many inspiring discussions about decarboxylation energetics and to P. Janssen and K. Denger for their dedicated work on these bacteria in his laboratory.

CHAPTER 14.3

The Genus *Zoogloea*

PATRICK R. DUGAN, DAPHNE L. STONER AND HARVEY M. PICKRUM

Bacteria of the genus *Zoogloea* have historically been considered members of the family Pseudomonadaceae but have been differentiated from other obligately aerobic, Gram-negative, nonsporeforming, rod-shaped bacteria that grow in aquatic habitats on the basis of their production of a characteristic gelatinous matrix. The "zoogloeal matrix" surrounds clumps of cells found in natural aquatic habitats or when grown in unshaken liquid culture in the laboratory (Butterfield, 1935; Butterfield et al., 1937; Wattie, 1943). The name *Zoogloea*, which was derived from the Greek word meaning animal glue, refers to the primary trait, the zoogloeal matrix, that is used to distinguish *Zoogloea* from other metabolically similar bacteria.

The two species of *Zoogloea*, *Z. ramigera* and *Z. filipendula*, have been isolated from sewage or from sewage-treatment systems that employ oxidative methods, i.e., activated sludge systems, trickling filters, or oxidation ponds (Butterfield et al., 1937; Butterfield and Wattie, 1941; McKinney and Horwood, 1952; McKinney and Weichlein, 1953). Both species produce branched, finger-like projections or outgrowths from the floc (i.e., clumps of cells that grow in an aggregated form that settles or "flocs" from aqueous suspension) when grown under quiescent culture conditions but have been differentiated from each other on the basis of cell size, biochemical reactions, and appearance of the zoogloeal matrix.

Characteristics of the Zoogloeal Matrix

The zoogloeal matrix is a capsular envelopment that surrounds several cells and commonly results in a flocculent growth habit in liquid media. That is, cell flocs settle from suspension, leaving a relatively clear supernatant. Unz and coworkers (Unz, 1974; Farrah and Unz, 1975; Unz and Farrah, 1976a) have convincingly demonstrated that floc formers of the *Zoogloea* type grow in an aggregated state and that the individual cells are entrapped within the zoogloeal matrix while cell division occurs. Floc formation of the zoogloeal type implies cell growth in an aggregated form (Friedman and Dugan, 1968b), whereas the term "flocculation" (Peter and Wuhrmann, 1971) has been defined as the aggregation of suspended bacterial cells after growth of cells has occurred, i.e., the "flocculation" of colloidal material. Biologically, the two processes are considerably different although the same physical and chemical laws apply to both.

Although there can be confusion relative to the distinction between zoogloea formation and flocculent growth, there is a consensus that microbial floc formation results from the presence of adherent extracellular fibrils (Busch and Stumm, 1968; Deinema and Zevenhuizen, 1971; Finstein, 1967; Friedman and Dugan, 1968b; Friedman et al., 1968, 1969; Tago and Aida, 1977). The presence of polysaccharide and the ability to flocculate have been demonstrated with mutants lacking polysaccharide and which do not exhibit flocculent growth; recombinant bacteria with restored polysaccharide production also simultaneously show restored floc formation (Easson et al., 1987a, 1987b). All floc-forming bacteria appear to posses extracellular fibrillar strands, but not all Gram-negative floc-forming bacteria produce the characteristic zoogloeal matrix, such as that for *Zoogloea ramigera* strain 115 seen in Figs. 1 and 2.

The polysaccharide of *Zoogloea* may remain as a loose slime layer in the vicinity of the cells, a well-defined capsule, or a zoogloeal matrix around the cells which synthesized it or it may be dispersed in the medium as a colloidal suspension or in solution. Increased viscosity of the surrounding medium may result from extensive polymer synthesis by the cells. The key feature in bioflocculation appears to be the synthesis of relatively insoluble extracellular polymer strands that remain within the vicinity of cells and do not disperse. The photographs shown in Figs. 3, 4, 5, 6 and 7 show the insoluble polysaccharide strands found around flocs of these bacteria. The polymer strands shown in Fig. 6 were photographed under ultraviolet illumination after the flocs were stained with the fluorescent dye Paper White-BP as previously reported (Dugan and Pickrum, 1973; Friedman et al., 1969).

The chemical composition and structure of the extracellular polysaccharides determine its physical and chemical properties. Polysaccharides in solution or suspension vary in water solubility,

This chapter was taken unchanged from the second edition.

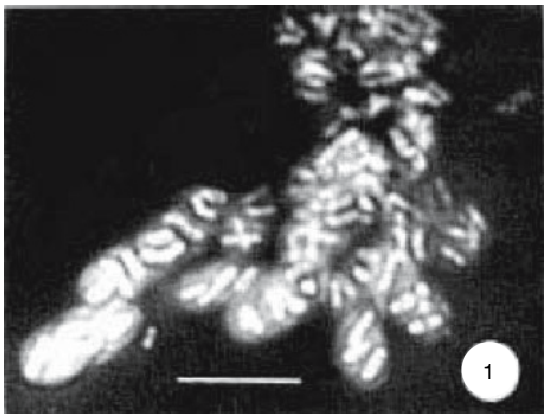

Fig. 1. Photomicrograph of *Zoogloea ramigera* strain 115 floc negatively stained by the Maneval method and photographed through the light microscope. The cells are shown embedded within the zoogleal matrix and with the characteristic finger-link projections. Bar = 10 μm.

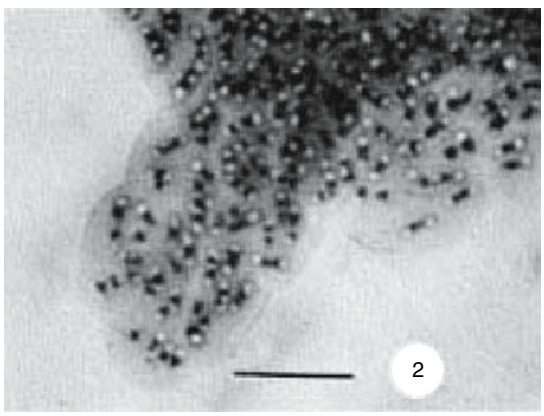

Fig. 2. Photomicrograph of *Zoogloea ramigera* 115 floc stained with 1% aqueous crystal violet. The gelatinous zoogloeal matrix in which cells are embedded is shown. The variable staining appearance is due to polybetahydroxy butyric acid (PHB) granules that accumulate in the cells. Bar = 10 μm.

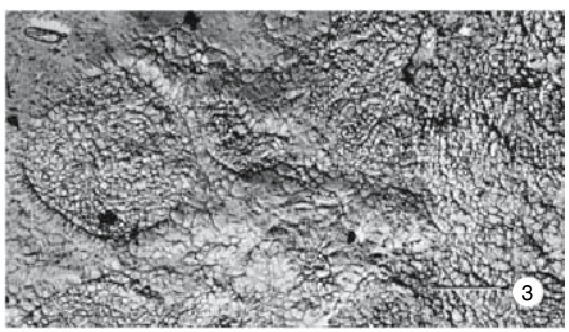

Fig. 3. Electron micrograph of a freeze-fractured specimen of *Zoogloea ramigera* 115. The fibrillar network of extracellular polysaccharide strands from which the zoogloeal matrix is formed is shown. In the living specimen, water is bound in the interstices of the network, which resembles a ball of chicken wire. Bar = 10 μm.

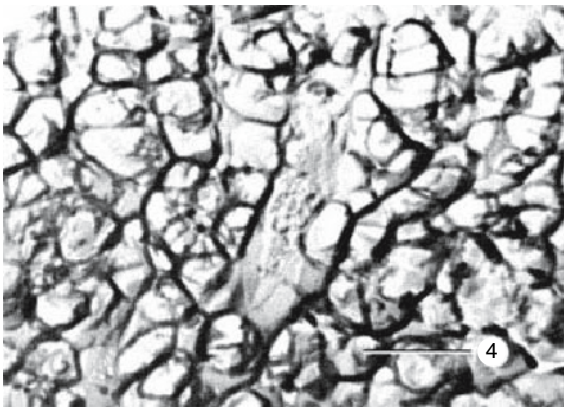

Fig. 4. Enlargement of the floc shown in Fig. 3. A cell embedded within the zoogloeal matrix is shown. Bar = 10 μm.

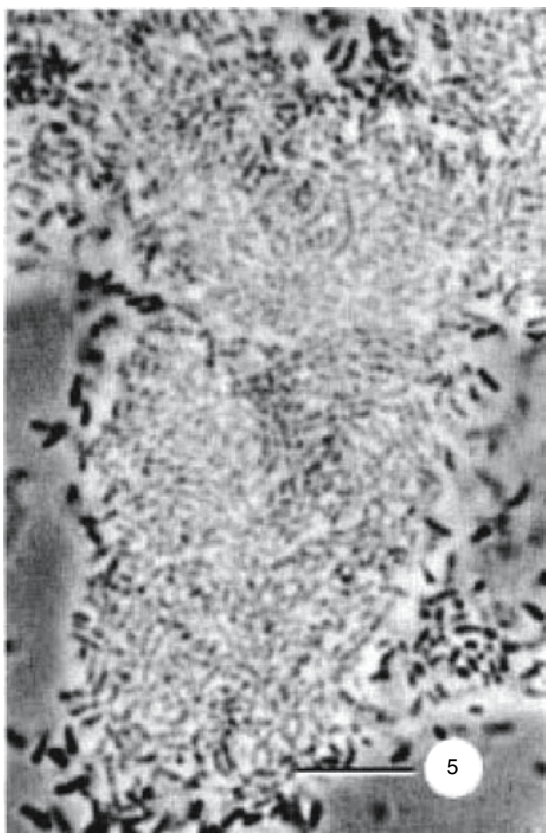

Fig. 5. Photomicrograph of a floc of the *Zoogloea* isolate designated CT-2 originally isolated by K. Crabtree. The floc was stained by a water-clear solution of the fluorescent dye Paper White-BP and photographed under phase-contrast optics. Some of the bacteria are in the focal plane whereas others are not. Bar = 10 μm.

rheological properties (e.g., viscosity, viscoelasticity), chemical and thermal stability, surfactant properties, the ability to bind water, etc. *Zoogloea* strains vary in the composition of the polysaccharide (Table 1), but information concerning the structure of some isolates is limited.

The polysaccharide of *Z. ramigera* 115 has been examined in detail. This weakly acidic polysaccharide is slightly soluble in water, is stable in a pH range of 3 to 10, and is not precipitated in the presence of salt (Stauffer et al., 1980). Stauffer et al. (1980) reported that the polysacchride of *Z. ramigera* 115 is stable to temperature cycling from –15° to 90°C. However, Norberg and Enfors (1982) reported that the first temperature cycle from 25° to 90°C did increase the viscosity of the polymer at the lower temperature. The polysaccharide of *Z. ramigera* 115 is highly viscous and lowers the surface tension of water. The polysaccharide exhibits Newtonian flow at lower concentrations and, as the concentration increases, the polymer becomes increasingly pseudoplastic and viscoelastic (Stauffer et al., 1980). Similar flow behavior was observed in relation to growth and polysaccharide production in a fermentor (Norberg and Enfors, 1982).

The polysaccharide of *Z. ramigera* 115 contains glucose, galactose, and pyruvic acid, the ratios of which may vary with culture conditions and growth phase of the culture (Norberg and Enfors, 1982; Franzen and Norberg, 1984; Ikeda et al., 1982). Growth on different sugar substrates did not alter the composition of sugars in

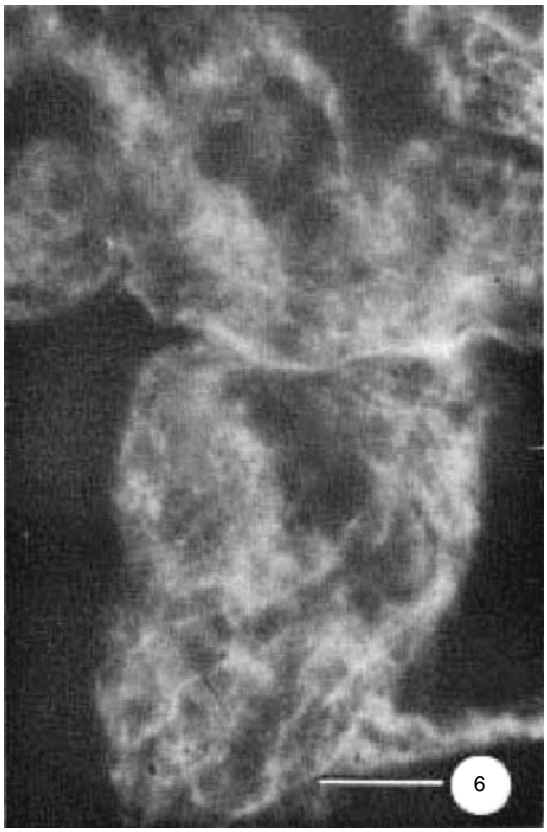

Fig. 6. Photomicrograph taken under ultraviolet (UV) illumination of the identical field shown in Fig. 5. Only material stained by the polysaccharide-specific fluorescent stain Paper White-BP can be seen under UV illumination. This procedure demonstrates that the cell floc shown in Fig. 5 was interspersed by a network of fibrous polysaccharide strands analogous to a "cobweb" which appears to hold the floc intact. Bar = 10 μm.

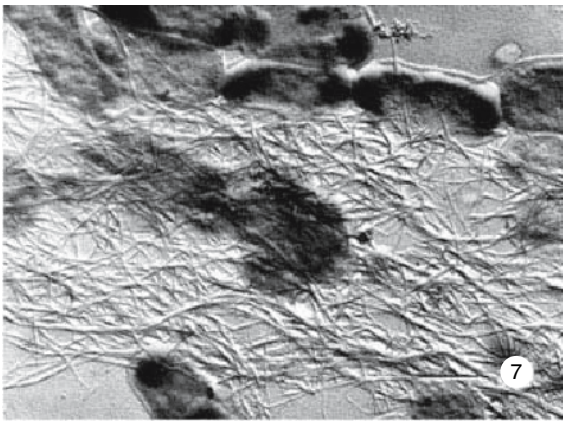

Fig. 7. Shadow-cast electron micrograph of *Zoogloea ramigera* isolate I-16-M after treatment with 1 N NaOH for 24 h at 28°C. Extracellular fibrillar strands and cell ghosts are shown. I-16-M produces flocs but no observable gelatinous zoogloeal matrix. Bar = 10 μm.

Table 1. Composition of purified extracellular polysaccharides of *Zoogloea*.

Strain	Composition	Reference
Z. ramigera 115	Glucose, galactose, pyruvic acid	Ikeda e al., 1982; Franzen and Norberg, 1984
Z. ramigera I-16-M	Glucose, galactose, mannose	Pickrum, 1972
Z. ramigera MP6	Glucosamine, methylpentose amine, hexose sugars, uronic acids	Farrah and Unz, 1976
Z. ramigera NRRL B-3669M	Glucose, galactose, mannose	Wallen and Davis, 1972
Zoogloea species NRRL B-3793	Rhamnose, mannose, galactose	Wallen and Davis, 1972
Zoogloea species C-1	Glucose, galactose, mannose, arabinose, rhamnose	Pickrum, 1972
Zoogloea species	Glucosamine, fucosamine	Tezuka, 1973
Z. filipendula P-8-4	Glucose, galactose, mannose	Pickrum, 1972
Zoogloea isolate P-95-5[a]	Glucose, galactose, mannose	Crabtree et al., 1965; Crabtree and McCoy, 1967

[a]The isolate is probably actually *Pseudomonas denitrificans*.

the polymers (Parsons and Dugan, 1971). A ratio of glucose:galactose of 2:1 with trace amounts of terminal pyruvylated glucose (Franzen and Norberg, 1984; Friedman et al., 1969; Parsons and Dugan, 1971; Sinskey et al., 1986) as well as a ratio of 11.0:3.1:1.5 for glucose:galactose:pyruvic acid (Ikeda et al., 1982) has been determined. Uronic acids, pentose, or amino sugars have not been detected in the polysaccharide of *Z. ramigera* 115 (Franzen and Norberg, 1984; Friedman et al., 1969; Ikeda et al., 1982). The polysaccharide of *Z. ramigera* 115 is a highly branched structure with β-1–4-linkages and a molecular weight of approximately 10^5 (Friedman et al., 1968, 1969; Ikeda et al., 1982). A structure with repeating units has been proposed (Ikeda et al., 1982), although there is conflicting evidence that the polysaccharide of *Z. ramigera* 115 has an irregular structure (Franzen and Norberg, 1984).

A variety of sugars have been identified as components of the polysaccharides of *Zoogloea* cultures (Table 1). Polymer from *Z. ramigera* MP6 contains the amino sugars, glucosamine, and possibly methyl-pentose amine, hexose sugars, and uronic acid (Farrah and Unz, 1976). Tezuka (1973) identified glucosamine and possibly fucosamine as components of the polymer of a *Zoogloea* culture isolated from activated sludge, but did not detect neutral sugars or uronic acids. Polymer of *Z. ramigera* NRRL B-3669M contains glucose, mannose, and galactose, while isolate NRRL B-3793 contained rhamnose, mannose, and possibly galactose (Wallen and Davis, 1972). *Z. filipendula* P-8–4 and *Z. ramigera* contain glucose, galactose, and mannose in the polysaccharide, while an unidentified *Zoogloea* species designated C-1 contained glucose, galactose, mannose, arabinose, and rhamnose (Pickrum, 1972). It is possible that those isolates that have been shown to produce extracellular polysaccharides with only glucose, galactose, and mannose are more closely related to *Pseudomonas dentrificans* than to the *Z. ramigera* 115 isolate (see Table 1). Research on *Zoogloea* isolates has increased significantly because of their potential use in applications for removal of hazardous metal contaminants from waste streams.

Habitats

Zoogloea species have been isolated from organically enriched oxygenated water, particularly domestic sewage and aerobic sewage-treatment systems, such as trickling filters, activated sludge tanks, or oxidation ponds (Amin and Ganapati, 1967; Dugan and Lundgren, 1960; Unz and Farrah, 1972). These are all continuous-flow systems that are rich in dissolved or particulate oxidizable organic materials, which provide for the enrichment of *Zoogloea* and closely related bacteria. Zoogloeal masses may also be found adhering to solid objects suspended or floating in lakes and ponds. For example, 19 of 36 Gram-negative bacteria isolated from Lake Erie formed flocs in the laboratory, and they all clustered with previously identified isolates of *Zoogloea* when subjected to a computer taxonomic program. Therefore, *Zoogloea* appears to be ubiquitous in aquatic environments.

Isolation

Zoogloeal masses obtained from organically rich natural aquatic systems, sewage treatment plants, wastewater, etc. may be used in isolation procedures to obtain pure cultures of *Zoogloea*. These organically rich sources may also be used to inoculate enrichment media from which strains of *Zoogloea* may be isolated. Both the zoogloeal matrix found around the characteristic isolates of *Zoogloea* and the nongelatinous fibrillar strands associated with the nonzoogloeal *Zoogloea* isolates are a deterrent to pure-culture isolation because other bacteria adhere to or become entangled within the floc. Successful isolation of *Zoogloea* has been achieved with methods employing ultrasonic methods to disrupt zoogloeal masses, micromanipulation to manually separate individual cells from the zooglea matrix, the inclusion of inhibitory agents in culture media to prevent the growth of unwanted microorganism and the use of carbon growth substrates which may enrich for *Zoogloea*. These methods are used in conjunction with conventional isolation precedures to obtain isolates of *Zoogloea*.

Enrichment

Several methods can be used to establish enrichments of zoogloeal bacteria. The simplest method is the incubation of raw sewage, sewage sludge, treated sewage effluent, etc. in containers at room temperature until a surface film or pellicle is formed (Amin and Ganapati, 1967). Alternatively, mineral salts solution overlaying a nutritive agar plug may be inoculated and incubated until a surface pellicle develops (Unz, 1984).

Mineral Salts Solution

> The overlay medium is prepared from stock solutions and adjusted to pH 8.5 with 0.5 N NaOH. The mineral salts solution contains:
>
> | | |
> |---|---|
> | $(NH_4)_2SO_4$ | 0.3 g |
> | NaCl | 5.85 g |
> | $CaCl_2 \cdot 2H_2O$ | 0.2 g |
> | K_2HPO_4 | 0.1 g |
> | $MgSO_4 \cdot 7H_2O$ | 0.14 g |

$FeSO_4 \cdot 7H_2O$	0.3 mg
$MnCl_2 \cdot 4H_2O$	6.3 mg
$CoSO_4 \cdot 7H_2O$	0.11 mg
H_3BO_4	0.6 mg
$ZnCl_2$	0.22 mg
$CuSO_4 \cdot 5H_2O$	0.08 mg
Distilled water	1 liter

Nutrient-Enriched Agar

The nutritive agar contains 20 g agar per liter of mineral salts solution. The carbon source is any one of the following added per liter of mineral salts.

Starch	2.4 g
m-Toluic acid	1.35 g (neutralized)
n-Butanol	1.5 ml
Lactic acid (85%)	1.35 g
Ethanol (95%)	1.5 ml
Glucose	2.4 g

After the addition of the carbon source, the pH is adjusted to 8.5 with 0.5 N NaOH.

Isolation

Isolations may be made from surfaces covered with zoogloeal masses and/or effluents taken from organically polluted water. Material on surfaces is scraped off and placed into 0.05% proteose peptone-yeast extract broth (PPYE). The gelatinous material is disrupted by ultrasound (20 kc output, Branson) in sterile PPYE, and samples are serially diluted and incubated in PPYE (28°C). After incubation for 3 days, the highest dilutions showing growth (10^{-7} to 10^{-10}) are streaked onto PPYE agar and tryptone-glucose extract agar (TGE, Difco). When sufficient growth has occurred, colonies of different morphological types are transferred to duplicate tubes of PPYE broth. Tubes are incubated with and without agitation. After incubation, tubes containing a pellicle (stationary) or a floc (shaken) are selected, and the entire isolation procedure is repeated until pure cultures are obtained. In general, isolations can be most readily achieved with the use of organically dilute media.

Micromanipulation may be used to separate bacterial cells from zoogloeal matrices in order to obtain pure cultures of *Zoogloea* (Unz and Dondero, 1967a). In this method, flocs or slimes from enrichment cultures are dispersed in liquid medium and observed at 100× magnification. To remove debris and microorganisms, fingered zoogloeal projections are transferred individually by micropipettes through successive drops of medium. Washed zoogloea are placed upon nutritive agar films coated on the underside of coverslips and individual cells dissected away from the zoogloeal matrix with microneedles. Slides are incubated and the developed microcolonies transferred with sterile micropipettes to broth medium. Alternatively, washed zoogloea may be collected and briefly sonicated prior to streaking on growth medium (Unz, 1984). Media appropriate for the above methods are casitone-yeast (CY) broth (see below), nutrient broth, and the respective agar media (Unz, 1984; Unz and Dondero, 1967a).

CY Medium

CY medium contains per liter of distilled water:

Casitone	5.0 g
Yeast autolysate	1.0 g

The addition of 0.001% crystal violet to isolation media, either broth or agar, has also been used successfully to inhibit many undesirable bacteria that tend to adhere to the flocs. Agar plates that contain crystal violet in the growth medium also have differential value. On these plates, the isolates listed in Table 1 can be identified as follows: *Z. ramigera* 115 decolorizes and degrades crystal violet and forms straw-colored colonies; isolate C-1 fails to develop colonies; and isolates I-16-M, P-8–4, and P-95–5 absorb the dye and produce violet colonies. Since isolate C-1 is different from the known *Zoogloea* isolates, the use of the crystal violet is considered to have value in the identification of *Zoogloea* species, but such use has not been well studied (Friedman and Dugan, 1968b; Dugan, 1975).

Aromatic compounds utilized for growth may be used for the isolation of some *Zoogloea* from environmental samples (Unz and Farrah, 1972). *Zooglea* isolates may be obtained from activated sludge using solid basal medium with 1% *m*-toluate as the carbon source by streaking sludge or other inocula directly on the media and incubating. Solid samples, i.e., soils and feces, may be suspended with equal volumes of sterile distilled water and then streaked onto media. Developed colonies are transferred to CY medium (see above), disrupted by agitation, and streaked for isolation on *m*-toluate medium. *Zoogloea* grown on *m*-toluate medium form large colonies with yellow-green coloration indicative of *meta* cleavage products. Colonies are usually difficult to remove from the surface of the plates. This procedure will not isolate *Zoogloea* that do not utilize *m*-toluate as a growth substrate.

Zoogloea colonies on agar plates have a glistening, viscous appearance (Fig. 8). Colonies are straw-colored on media containing yeast extract or protcose-peptone and white on mineral salts media supplemented with alanine and argenine as the carbon source. The color differences are also observed in liquid media. Colonies have a leathery consistency, and the entire colony can frequently be removed with an inoculating loop (Dugan and Lundgren, 1960; Friedman and Dugan, 1968b). This distinctive characteristic is probably related to the formation of extracellular polysaccharide. Growth of *Zoogloea* in shaken liquid culture is often flocculent but flocs

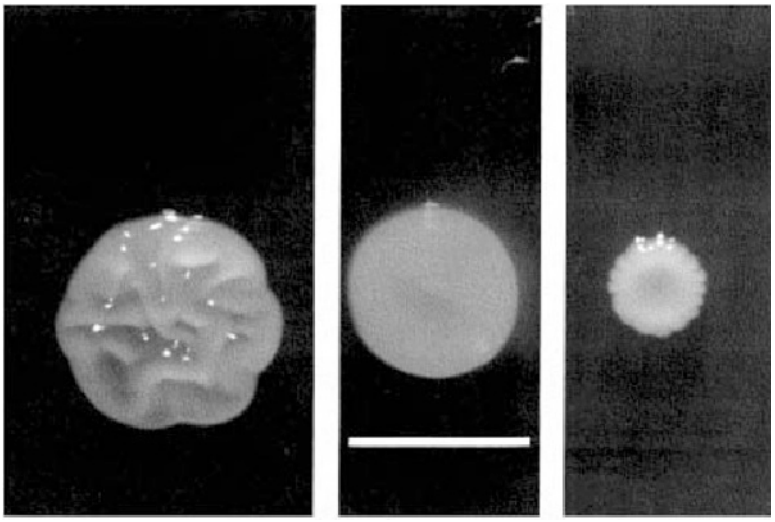

Fig. 8. Colonies of *Zoogloea ramigera* 115 vary in overall appearance and size. Variation is due to culture conditions and age of culture. Bar = 5 mm.

are tight and do not have a typical zoogloeal matrix.

Identification

As the name of the genus implies, *Zoogloea* species have been identified primarily on the basis of the presence of the characteristic extracellular, capsular, or zoogloeal matrix. However, matrix formation and its morphological appearance may be controlled nutritionally by the carbon and nitrogen sources, as well as by the carbon to nitrogen ratio and by the turbulence of the growth medium (Parsons and Dugan, 1971; Unz and Farrah, 1976b). Therefore, the presence or absence of a zoogloeal matrix is not a trait upon which identification can be reliably made. Although the presence of finger-like projections and a zoogloeal matrix is distinctive and a positive indicator, the absence of the zoogloeal matrix does not necessarily indicate that the isolate is not a *Zoogloea* species.

Isolates of *Zoogloea* are Gram-negative, polarly flagellated, rod-shaped bacteria that flocculate and accumulate poly-β-hydroxybutyrate (PHB) or polyalkanoic granules when cultivated in media that are rich in carbon. Cell size ranges from 0.5 to 1.3 μm in diameter and 1.0 to 3.6 μm in length. *Zoogloea* species are oxidative in metabolism and are able to utilize a variety of sugars, sugar alcohols, alcohols, amino acids, and proteins for growth. The inclusion of B vitamins, purines, pyrimidines, and nucleotides in culture media, although not required for growth, decreases the growth lag and increases biomass formation of cultures (Dugan and Lundgren, 1960; Friedman and Dugan, 1968b). The metabolic characteristics of the organisms are not sufficiently distinct to be the basis of identification for the genus *Zoogloea* (Crabtree and McCoy, 1967; Crabtree et al., 1965; Dugan, 1975; Dugan and Lundgren, 1960; Friedman and Dugan, 1968b; Ganapati et al., 1967; Unz, 1974; Unz and Dondero, 1967a, 1967b). However, the overall ability of *Zoogloea* species to oxidatively metabolize many sugars, sugar alcohols, and alcohols, with the formation of esters that often result in the typical fruity odor of esters in culture media, can be of use in restricting the options in identification (Joyce and Dugan, 1972). The strong capability of *Z. ramigera* 115 to form esters from a variety of organic acids and alcohols may be responsible for the addition of pyruvic acid to alcoholic groups on the extracellular zoogloeal polymer and may explain why some investigators were unable to observe pyruvate (Friedman et. al., 1969), whereas others observed traces (Norberg, 1984) and others identified a significant amount (Ikeda et al. 1982).

The taxonomy of the genus *Zoogloea* is uncertain with respect to differentiation from other genera within the family Pseudomonadaceae. Also uncertain is whether *Z. filipendula*, a species historically considered as a member of the genus *Zoogloea*, validly fits in the genus. The designation of the neotype strain of *Zoogloea ramigera* has also been questionable (Unz, 1984). Some *Zoogloea* isolates resemble species of the genera *Pseudomonas* (particularly *P. denitrificans*), *Gluconobacter*, and *Acetobacter. Zoogloea* differ from *Gluconobacter* and *Acetobacter* in the inability to grow at pH 4.5.

Antigenic relationships among some of the *Zoogloea* have been reported (Chorpenning et al., 1978). *Z. ramigera* 115 and I-16-M did not closely relate to *Z. filipendula* P-8–4 on a serologic basis. *Z. ramigera* 115 had greater antigenic relatedness to *Gluconobacter oxydans* subspe-

cies *suboxydans* (ATCC 621) than to either *Z. ramigera* I-16-M or *Z. filipendula* P-8-4. These data indicated that *Z. ramigera* 115 and I-16-M are distinctly different serovars, an observation which is also supported by the difference in composition of their extracellular polysaccharides.

The GC content of the DNA of *Zoogloea* ranged from 60.1 to 64.8 mol% (Pickrum, 1972; Unz, 1984). The data, although not conclusive, reinforce the view that several of the floc-forming isolates are similar organisms that are sufficiently distinctive to allow differentiation from other Gram-negative rods. However, at present there is no definitive description of either the genus *Zoogloea* or its species, other than the gelatinous matrix of finger-like projections, but this matrix is not always present.

Genetics

Because of the potential application of *Zoogloea* in several microbially based technologies, there is a need to isolate and identify genes for polysaccharide and PHB production, determine the biosynthetic pathways, and examine the enzymatic and genetic control mechanisms.

The exopolysaccharides of *Zoogloea* are involved with flocculation (Easson et al., 1987a, 1987b; Friedman et al., 1969) and adsorption of heavy metals (Dugan, 1987; Dugan and Pickrum, 1972; Ikeda et al., 1982). As with other polymers, the structure and physical and chemical properties of polysaccharides define its flocculation and adsorption characteristics. Therefore, manipulation of the structure of the polysaccharide is of importance in developing flocculants and bioadsorbents with desired characteristics that may be applicable to microbially based technologies for waste water treatment or metal reclamation. Genetic control of the biosynthesis of polysaccharides by microorganisms is a means by which the structure of the polymers may be manipulated and production of the polysaccharides increased.

Mutants generated by the insertion of the Tn5 transposon were used to examine the genetics of polysaccharide production in *Z. ramigera* I-16-M (Easson et al., 1987a, 1987b). There is an inherent instability in the chromosome in which DNA sequences spontaneously delete within the polysaccharide gene region, and this results in the loss of polysaccharide production. The frequency of chromosomal deletions within this gene region was enhanced by the presence of Tn5 transposon. Polysaccharide production was restored in the mutants by complementation with a gene library constructed with a broad-host-range cosmid vector. The restoration of polysaccharide production in a number of mutants by a single plasmid vector suggests that the genes for polysaccharide production may be clustered on the chromosome.

The genetics involved with PHB synthesis is of interest because of the potential use of PHB and other polydroxyalkanoates in the plastics industry. PHB metabolism in *Z. ramigera* I-16-M is a cyclic process (Tomita et al., 1983). The biosynthesis of PHB involves the condensation and reduction of acetyl CoA to form D(−)-3-hydroxybutyryl CoA followed by incorporation into PHB granules. Degradation of PHB granules proceeds via the production of D(−)-3-hydroxybutyrate oligomers and hydrolysis and oxidation to acetoacetate. The cycle is completed with the activation of acetoacetate to acetoacetyl CoA.

Studies examining the structure and function of enzymes in PHB synthesis (Davis et al., 1987a, 1987b; Fukui et al., 1976; Nishimura et al., 1978; Saito et al., 1977) and genetic experiments to determine the sequence and location of genes (Peoples et al., 1987) have focused on the enzyme β-ketothiolase, which mediates the first step in the biosynthesis of PHB, the condensation of two acetyl CoA units to form acetoacetyl CoA. A recombinant DNA clone designated LDBK1 expresses the complete thiolase gene sequence in *Escherichia coli* (Peoples et al., 1987). The encoded protein has thiolase enzyme activity and co-migrates with native enzyme in Western blotting and immunodetection experiments. The expression of thiolase-coding sequences is under transcriptional control of the *lac* promoter region contained in the ;glgtll expression vector that was used to generate the recombinant library of *Z. ramigera* DNA. The structural gene for the thiolase enzyme is 1,173 nucleotides long and codes for a protein of 391 amino acids. The calculated molecular weight and the predicted amino acid sequence of the gene product are in agreement with the molecular weight and amino acid sequence determined experimentally for the native thiolase. The high GC content of the complete sequence (66.2 mol%) is in agreement with values obtained for the *Z. ramigera* genome (64.5 mol%). The position of the active site peptide, a potential ribosome binding site, and start codons within the DNA sequence have all been identified.

The major DNA-dependent deoxyribonucleic acid polymerase from *Z. ramigera* isolate I-16-M has been partially purified and biochemically characterized (Pickrum, 1975). The polymerase activity was eluted as a single peak at 0.1 M potassium phosphate from a DEAE-cellulose column. The partially purified enzyme showed one major, one intermediate, and five minor protein bands after polyacrylamide gel electro-

phoresis. The DNA polymerase activity was detected in the acrylamide gels by an in situ assay and coincided with the major protein band. Nuclease activity could not be detected in the preparation after electrophoresis.

The DNA polymerase resembles the *Micrococcus luteus* enzyme in many characteristics, and its properties seem to place it as an intermediate between the polymerase I and polymerase II of *Escherichia coli* and *Bacillus subtilus* (Pickrum, 1975). It appears that the enzyme requires all four deoxynucleoside-5′-triphosphates, a divalent cation, 2-mercaptoethanol, and denatured DNA as a template-primer for maximal activity. Dithiothreitol is capable of replacing 2-mercaptoethanol in the reaction. The enzyme replicated, with varying efficiencies, the DNAs isolated from *Bacillus subtilus*, *Escherichia coli*, calf thymus, salmon, and soft fish roe. Treatment of DNA with pancreatic deoxyribonuclease improved its priming ability, the effectiveness of which depended on the extent of treatment with deoxyribonuclease.

The divalent metal ion requirement of the polymerase could be satisfied with either Mg^{2+} or Mn^{2+}. A slight but observable synthesis was obtained in the presence of 20 mM Co^{2+} or 10 mM Cd^{2+}. The enzyme was unstable in solutions of ionic strength below 0.2 M potassium phosphate or protein concentrations below 1 mg/ml. Enzyme solutions could be stabilized by the addition of glycerol or by increasing the salt or protein concentrations and storing at –20°C.

A synthesis-dependent exonuclease activity, interpreted as a 5′ to 3′ exonuclease, was found, at a low level, with the most purified DNA polymerase preparation; however, this activity was not characterized. Rates were stimulated in the presence of deoxynucleoside triphosphates. The most purified fraction contained no detectable endonuclease activity.

The polymerase enzyme is sensitive to the sulfhydryl-blocking reagents N-ethyl-maleimide, *para*-(chloro)mercuribenzoate, and *para*-(chloro) mercuriphenylsulfonic acid. Of these, *para*-(chloro) mercuribenzoate is the most effective sulfhydryl reagent.

Applications

Z. ramigera is important in inducing flocculation (Unz, 1974) and reducing biological oxygen demand (BOD) in sewage-waste water treatment (Butterfield, 1935; Joyce and Dugan, 1970). The metal-adsorbing characteristic of *Z. ramigera* has been investigated with application to the treatment of heavy metals and transuranic waste streams (Dugan, 1970, 1987; Dugan and Pickrum, 1973; Friedman and Dugan, 1986a; Kuhn and Pfister, 1989; Norberg and Persson, 1984). Production of PHB or other polyhydroxyalkanoates by *Zoogloea* may be useful for the development of copolymers for commercially useful biodegradable plastics.

Waste Water Treatment

An early and continued use of *Zoogloea* in a treatment process has been in the area of domestic waste water treatment. Although zoogloeal bacteria are not the only microorganisms responsible for a successful waste water treatment process, they are important for the degradation of organic carbon and for the flocculation required for settling. *Zoogloea* bacteria are highly active oxidizers of organic compounds which significantly reduce the biological oxygen demand (BOD) in waste water. Butterfield et al. (1937) reported that 50% of the BOD from sewage could be removed in 5 hours by the aerobic, Gram-negative, floc-forming bacteria indigenous to aerobic waste water system, and 68% could be removed in 3 hr by a natural mixed population of bacteria. *Zoogloea ramigera* converts excess carbon to PHB, extracellular polysaccharide, and esterified organic acids (Joyce and Dugan, 1970). It is the interaction of extracellular microbial polymer by adsorption and bridging that aggregates microorganisms and produces flocs (Busch and Stumm, 1968).

Poly-β-hydroxybutyrate Production

A potential use of *Zoogloea* involves the production of PHB, a highly polymerized lipid reserve material that is usually synthesized by the bacteria in response to nitrogen limitation in the presence of excess carbon source. The production, enzymology, and genetic control of PHB metabolism in *Zoogloea* is of interest because of the application of PHB and other polyhydroxyalkanoates in the biodegradable plastics industry. PHB produced by some *Alcaligenes* species is currently being marketed as a biodegradable plastic under the trade name Biopol (Holmes, 1985).

Biosorption of Metals

A developing technology is the use of *Zoogloea* to adsorb and concentrate metals and transuranic elements from contaminated waste streams. The significance of extracellular microbial polymers as agents for relatively nonspecific adsorption of dissolved or suspended organic, particulate, and ionic substances has been established with polysaccharides produced by Gram-negative floc-forming bacteria (Dugan, 1970;

Dugan et al., 1971; Friedman and Dugan, 1968a). The adsorptive characteristics of the whole cell or purified polymer can be exploited for commercial waste water treatment to remove heavy metal and transuranic ions and also may be useful in mineral separation processes, where the use of other flocculating agents of biological origin are currently being investigated.

Zoogloea biomass can remove a variety of metallic cations from solution (Dugan and Pickrum, 1973; Friedman and Dugan, 1968a; Norberg and Persson, 1984; Norberg and Rydin, 1984; Sag and Kutsai, 1989a, 1989b). The removal of aluminum, calcium, cobalt, iron, magnesium, manganese, nickel, and silicon from acidic mine water samples demonstrates the effective metal binding characteristic of *Zooglea* and *Zoogloea*-derived polymer that is applicable to the treatment of complex, relatively undefined aqueous metal containing systems (Dugan, 1987; Dugan and Pickrum, 1973). Presumably, microorganisms are partially responsible for the accumulation of metals within the solids generated by sewage treatment and the reduction in metal concentration in effluent supernatant as compared to the metal concentration of the influent and the supernatant from primary settling (Dugan et al., 1971).

Chemically, the purified polysaccharide isolated from *Z. ramigera* 115 interacts with monovalent cations to form soluble salts, binds but does not appear to form cross-linkages with divalent cations, and forms insoluble precipitates with trivalent cations (Ikeda et al., 1982; Stauffer et al., 1980). Successive removal of uranium, copper, and cadmium from solution by *Zoogloea* biomass indicates selective binding among cations in mixed solutions (Norberg and Persson, 1984).

With the potential use of *Zoogloea* for the treatment of metal-bearing waste waters demonstrated, a microbially based technology for the treatment of these wastes appears to be developing. *Z. ramigera* 115 cells, immobilized in calcium alginate beads, have been used in air-bubbled column reactors to remove mixtures of cadmium, copper, lead, manganese, strontium, and zinc from aqueous solutions (Kuhn and Pfister, 1989,1990). Although calcium alginate alone sorbed metals, the use of immobilized *Z. ramigera* 115 enhanced metal binding significantly. A batch method was used to study the removal of cadmium, copper, and uranium from solution using biomass of *Z. ramigera* 115 (Norberg and Persson, 1984). A bench-scale continuous process was demonstrated with *Zoogloea* biomass to adsorb copper from solution (Norberg and Rydin, 1984). Affecting adsorption was the concentration of biomass and copper in solution and the operating pH.

Important to the costs of a treatment process is the ability to recycle biomass for multiple treatment cycles. Acid treatment re-leases cadmium, copper, and uranium adsorbed to *Zoogloea* biomass, thus enabling multiple cycling for the complete removal of metals from solution (Norberg and Persson, 1984). In experiments with cadmium it was shown that the sorbed cadmium could be eluted by exposing the beads to nutrient solutions whereupon more cadmium could be sorbed (Kuhn and Pfister, 1989, 1990). Alternatively, the release of cadmium from calcium alginate immobilized *Z. ramigera* 115 was achieved by use of a 0.04% aqueous nitrilotriacetate solution (Kuhn and Pfister, 1989, 1990).

CHAPTER 14.4

Large Symbiotic Spirochetes: *Clevelandina*, *Cristispira*, *Diplocalyx*, *Hollandina* and *Pillotina*

LYNN MARGULIS AND GREGORY HINKLE

The genera *Cristispira*, *Clevelandina*, *Diplocalyx*, *Hollandina,* and *Pillotina* are morphologically complex, Gram-negative, motile, spirochetes (helical bacteria) in which the flagella are always entirely periplasmic (i.e., located between the inner "plasma" and the outer membrane typical of Gram-negative bacteria) (Fig. 1). (For a general discussion of the morphology of spirochetes, see Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta* in this Volume). All are obligate symbionts in the digestive system of mollusks or arthropods. These morphologically complex spirochetes have greater than 10 and sometimes as many as 300 flagella inserted at both ends of the cell and overlapping in the middle. If n is the number of flagella at one end of the cell and 2n the number of overlapping flagella in the middle of the cell, then the characteristic array is n:2n:n (e.g., 10:20:10 or 300:600:300). The coated membranes, distinctive cytoplasmic structures (including the sillon, a cell-length invagination or groove of the outer membrane in contact with the inner membrane), and relative proportions that distinguish these genera are depicted in Fig. 2, based on the morphometric analyses summarized in Table 1.

The habitats of these organisms are predictable (e.g., the crystalline style of bivalve mollusks for *Cristispira* and the intestine of dry wood-eating cockroaches and termites for the others). None has been grown axenically. As molecular biological data are not yet available, species have been determined morphologically. Five species of large, symbiotic spirochetes have been described in the modern bacteriological literature and reverified, revised, or named as: *Clevelandina reticulitermitidis*, *Cristispira pectinis*, *Diplocalyx calotermitidis*, *Hollandina pterotermitidis,* and *Pillotina calotermitidis*. (For genera description, including an explanation of the morphometric analysis of spirochetes, see Bermudes et al., 1988.)

Although often classified on the basis of size and light microscopic morphology in the family Spirochaetaceae (e.g., Bermudes et al., 1988), these spirochetes are ultrastructurally distinct from all other members of the Spirochaetaceae (see Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta* in this Volume). Therefore, we classify the large symbiotic spirochetes in the family Pillotinaceae. (This family was first suggested by Hollande and Gharagozlou, 1967, who used the incorrect Latin derivative "Pillotaceae.") The spirochetes most similar morphologically to any member of the Pillotinaceae are the tick-borne symbionts, e.g., *Borrelia persica*, (flagella formula 25:50:25) (Karimi et al., 1979); the free-living microbial mat spirochete *Mobilifilum chasei* (10:20:10) (Margulis et al., 1990a); and the pectinolytic rumen spirochete *Treponema saccharophilum* strain PB, which is reported to have approximately 32 flagella (whether 32:64:32 or 16:32:16 is not clear) (Paster and Canale-Parola, 1985). All these spirochetes are significantly smaller than any member of the Pillotinaceae. No free-living *Pillotina*-like spirochete has ever been reported—none, at least, larger than 0.5 μm in diameter bearing at least 30 flagella.

A summary of the characteristics of the large, symbiotic spirochetes is presented in Table 1. Although only five genera are in the formal taxonomic literature, hundreds of symbiotic spirochetes from a large number of animals have been reported. For a more extensive discourse on *Cristispira* species in a variety of mollusks, see Kuhn (1981) and Breznak (1984a). Large spirochetes in the hindguts of termites and wood-eating cockroaches are more thoroughly described by To et al. (1980).

Cristispira pectinis (Gross) was first described as the trypanosome *Trypanosoma balbiani* (a eukaryote) by Certes (1882). Thought to have a multicellular, chambered body, *Cristispira* was renamed by Gross (1910), the name *Cristispira* being derived from the unusually prominent flagellar bundle or "crest." The modern understanding of the organism comes from Noguchi (1921), who, detecting them in oysters (*Crassostrea*), clams (*Venus*), and mussels (*Modiola*), recognized *Cristispira* as a spirochete bacterium. This identification was confirmed when the crest

This chapter was taken unchanged from the second edition.

Sieburth.) *Pillotina* from *Reticulitermes flavipes.* (Courtesy of R. Bloodgood.) *Hollandina* from the Sonoran desert termite. (Courtesy of L. P. To.) *Clevelandina* from *Zootermopsis.* (Courtesy of J. Breznak and H. Pankratz.) *Diplocalyx* from the Madeiran termite. Numerous flagella are seen in cross-section in the region between the outer and the plasma membrane. (Bars = 0.5 μm.)

was shown to be a flagellar bundle by Ryter and Pillot (1965).

Leidy (1850) first described spiral-shaped microbes from termite intestines and called them *Spirillum undula*, later renaming them *Vibrio termites* (Leidy, 1881). Dobell (1912) recognized these organisms as spirochetes; he called the larger ones *Treponema termites* and the smaller ones *Treponema minor*. The larger spirochetes were transferred to the genus *Cristipira* by Hollande (1922). They were further described by Damon (1925), Duboscq and Grassé (1929), and Kirby (1941). In an early electron microscopic study, Grimstone (1967) described a large unnamed spirochete from the wood-eating cockroach *Cryptocercus punctulatus.* Electron microscopy and the use of glutaraldehyde as a fixative reinvigorated the study of the termite hindgut microbiota by providing a means of distinguishing morphologically the uncultivable symbiotic bacteria. After the genus *Pillotina* and the family Pillotinaceae were proposed by Hollande and Gharagozlou (1967) for large spirochetes from the Madeiran termite *Incisitermes praecox,* large insect gut spirochetes were informally called "pillotinas." The discovery of a separate spirochete morphotype from the termite *Incisitermes flavicollis* led Gharagozlou (1968) to establish the genus *Diplocalyx*. To et al. (1978) described a third genus, *Hollandina,* from the hindgut of the Sonoran desert termite *Pterotermes occidentis.*

Known informally from the micrographs of D. G. Chase, *Clevelandina* was fixed in the microbiological literature by Bermudes et al. (1988).

Habitat

Cristispira develops especially dense populations in and on the crystalline style of many marine (and a few freshwater) mollusks. Styles are noncellular, gelatinous, cellulase-containing rods that extend into the stomach of many bivalve mollusks. Their presence, appearance, and consistency differ from species to species and even from individual to individual. In actively feeding animals, the style is rotated by epithelial cilia and, much like a pestle, one end is pushed against the stomach wall. The rotation likely aids in the mixing of food particles and digestive enzymes within the mollusk stomach. Some styles dissolve and reform with a tidal rhythm; when the style dissolves, the *Cristispira* disappear. Other smaller bacteria, including *Spirillum ostrea* (Margulis et al., 1991), an unidentified Gram-negative rod, and a smaller spirochete, have also been found in mollusk styles (Kuhn, 1981). Though they do not have a style, gastropods (single-valve mollusks) have been reported to harbor *Cristispira* as well (Morton, 1952; Orton, 1922; Terasaki, 1960). A partial list of the distribution of *Cristispira* in marine mollusks is given in Table 2.

The four other genera of large spirochetes are insect symbionts; they swim freely in the

lumen of the distal portion of the intestine, actually a hypertrophied hindgut or paunch. The paunch, which has less oxygen relative to air (Breznak, 1984b), is easily identified and dissected in any of the wood-eating cockroaches or so-called "lower" termites. The geographical distribution of these spirochetes is listed in Table 3. Their abundance is greatest in insects that attack and ingest dry rather than damp or wet wood. As a rule, Pillotinaceae spirochetes are very abundant in both kalotermitid (dry wood) and rhinotermitid (subterranean) termites. In rhinotermitids they tend to be most abundant just posterior of the midgut/anterior hindgut junction. These spirochetes are apparently absent from the damp-wood-eating nasutitermitids and other "higher" termites. In "higher" termites, a bacterial or bacterial/fungal community rather than a protistan/bacterial community has evolved. (Spirochetes 0.5 μm in diameter with approximately 40–50 flagella have been reported in the hindgut of the higher termite *Nasutitermes exitiosus*; Czolij et al., 1985.) The presence of Pillotinaceae spirochetes is easily determined by light microscopy on the basis of habitat, size, flexibility, and motility, but genera and species are not identifiable without ultrastructural analysis.

Morphology

Given ecological information and high resolution ultrastructural analysis, a single transverse thin section suffices to identify one of these large symbiotic spirochetes to genus. Ultrastructural analysis requires morphometrics (Bermudes et al., 1988). Sixteen criteria are useful when sufficient information is available (Fig. 2b). Diameters (criterion 1) in oblong cells are measured at the narrowest and widest points enclosed by the membrane. In crenulated cells, measurements are made at the tips of the crenulations. The number of flagella (criterion 2) is reported as the number inserted at each end. The number of flagella observed ranges from zero (in sections taken beyond the most distal insertion) to twice the number of flagella inserted at one end, where, toward the center, flagella inserted at one end overlap with the flagella from the other end. The sillon or groove (criterion 3) is a contact or pronounced invagination running the length of the cell of the outer membrane toward the inner membrane (Fig. 2). This structure provides a reference point for the description of other structures. Crenulations (criterion 4) are conspicuous folds or ruffles in the outer membrane (Fig. 2); to date they are limited to the genus *Pillotina*. Criteria 5, 6, and 7 deal with the presence of coatings on the inner and outer membranes of the Gram-negative cell walls (i.e., the glycocalyx or sheath). Criterion 8 is the ratio of the diameter of the protoplasmic cylinder to the cell diameter. Criterion 9, the angle subtended by the flagella, is a measurement of the distribution of the flagella in the periplasm. Flagellar bundles (criterion 10) are deemed present if the angle made by lines C and D is less than 180° (Fig. 2a). Criteria 11, 12, and 13 are the length, amplitude, and wavelength of the spirochete (Fig. 2b). Cytoplasmic tubules (criterion 14) are small, hollow structures within the protoplasmic cylinder as observed by negative stain or transmission electron microscopy (Fig. 2 and 6). They vary from 15 to 25 nm in diameter. The polar organelle (synonym, polar membrane; criterion 15) is an electron-dense lamina located on the inside of the inner (plasma) membrane toward the distal ends of the cell (Fig. 2 and 5). Rosettes (criterion 16) are linearly aligned, peripheral structures of the protoplasmic cylinder (Fig. 5); they have only been seen in *Cristispira*.

The largest spirochete in the microbiological literature, *Cristispira* is usually the only spirochete seen in mollusk styles. Healthy termites, however, may contain from one to more than five different morphotypes of pillotina spirochetes difficult to distinguish from each other with a light microscope (Fig. 3, 7, 8, and 9). Length (from 12 to 100 μm), amplitude (from 1.5 to 6.0 μm), and wavelengths (from 6 to 20 μm) can thus only be represented in approximate terms. The combination of large diameter (0.4 to greater than 1.0 μm), great length, and long wavelength distinguishes pillotinas from the many other smaller, hindgut spirochetes (Figs. 7 and 8). Idealized drawings based on electron micrographs of transverse sections of all five genera are shown in Fig. 4.

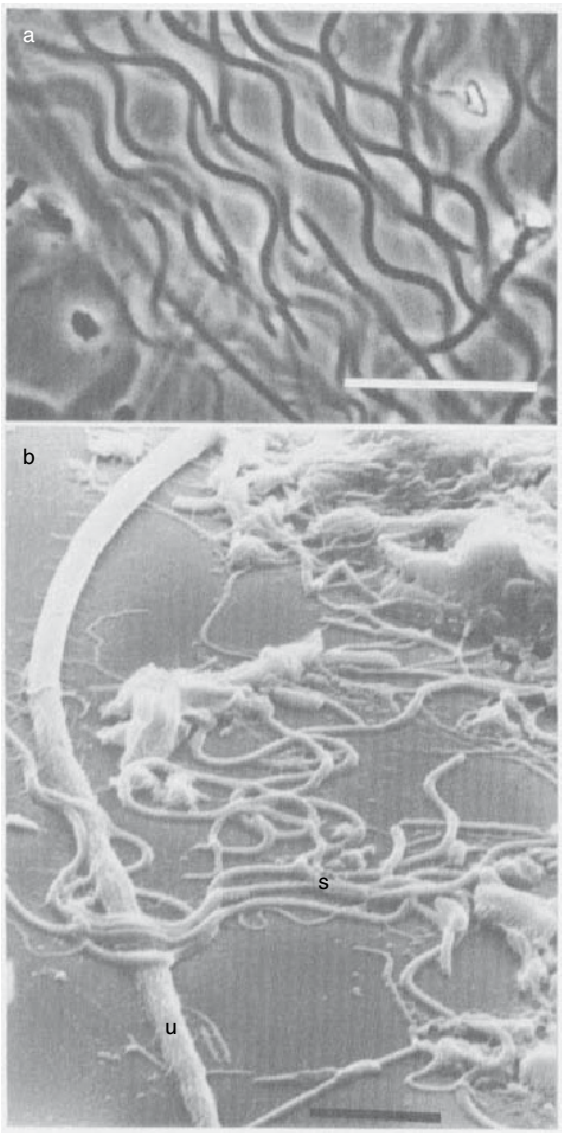

Fig. 3. (a) Live *Hollandina* spirochetes from *Pterotermes occidentis;* light micrograph. (b) *Hollandina pterotermitis* (S) and a huge, unidentified bacterium (U); scanning electron micrograph. (Bar = 5 μm.)

Cristispira

Cristispira cells can be greater than 3 μm in diameter and over 150 μm in length. The enormous number of periplasmic flagella (>100) gives *Cris-*

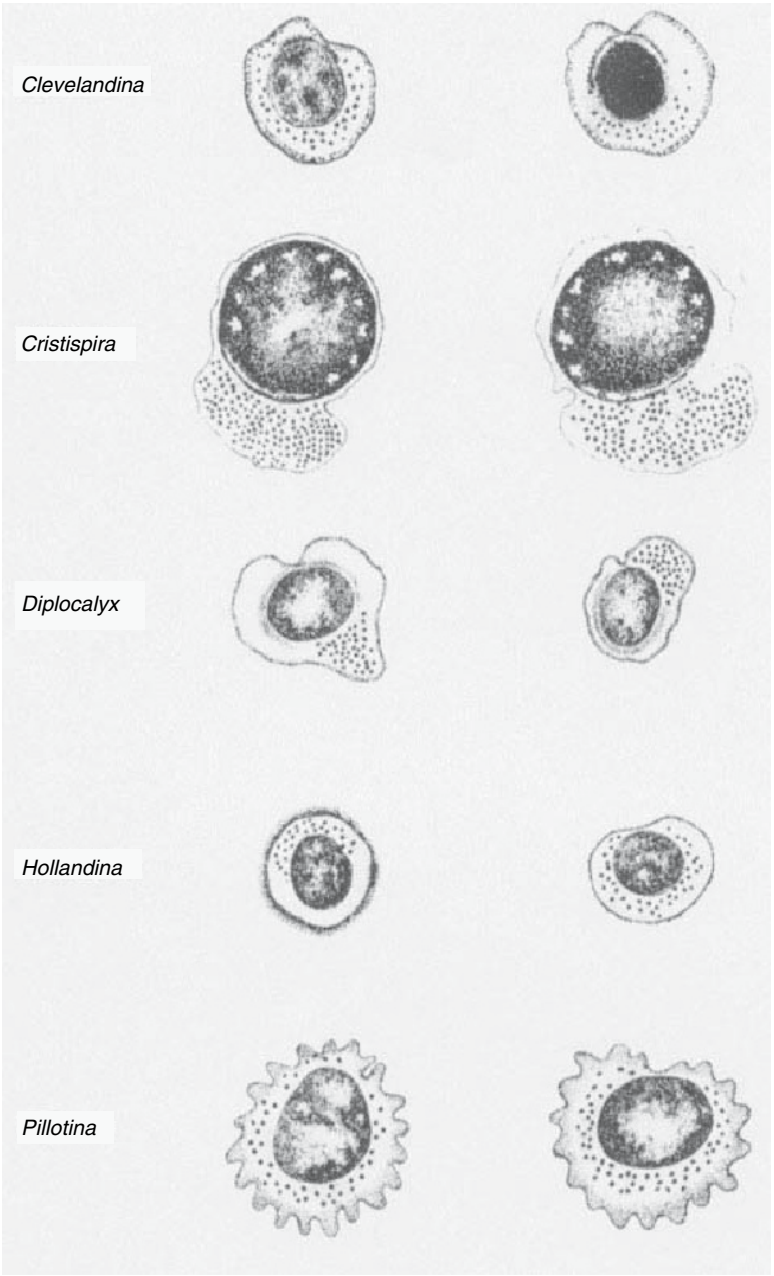

Fig. 4. Idealized drawings of transverse electron microscopic sections showing the range of morphotypes in the five genera of large, symbiotic spirochetes. Not drawn to scale. (Drawings by C. Lyons.)

tispira a figure-eight shape in cross-section, with the flagellar bundle often equal in size to the protoplasmic cylinder (Figs. 1 and 4). In highly motile *Cristispira*, the crest, which is merely the flagellar bundle, is difficult to discern. As the spirochetes lose vitality and speed, the crest swells and becomes more obvious. The periplasmic space in *Cristispira* tends to be minimal, but expands to much greater diameter where subtended by the periplasmic flagella.

Rosettes line the periphery of *Cristispira* along its length except where flagella insert (Fig. 5). Although the electron-luminous spheres making up the rosettes generally measure about 100 nm in diameter, the number of component spheres varies from 2 to as many as 9, such that the ultrastructure of the rosettes is not constant. "Chambers" or ovoid inclusions in light micrographs correspond to these rosettes; they have no known function.

The polar organelle, a structure first described in spirilla and subsequently found in other types of flagellated bacteria, is clearly present in *Cristispira* and lies conspicuously beneath the flagellar bundle (Figs. 2 and 5a). The proximity of the polar organelle to flagella insertions suggests a role in motility generation. Nothing is known directly about the reaction of *Cristispira* to gaseous oxygen, though if cytochrome oxidase were present at the polar organelle in *Cristispira* (as it is in

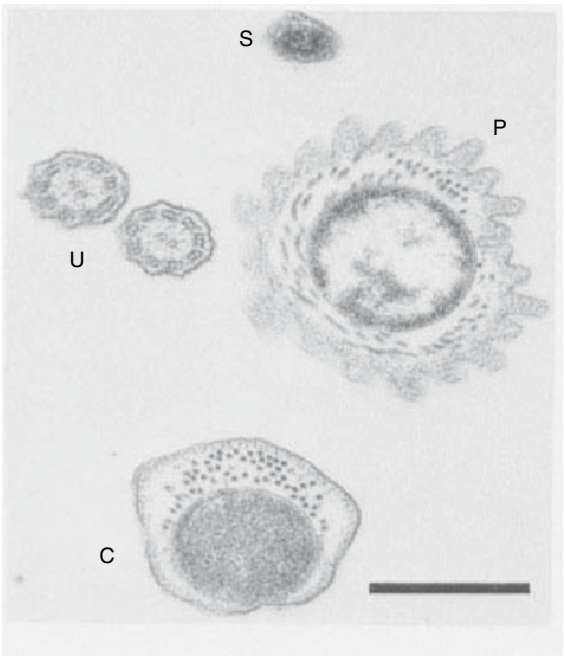

Fig. 9. *Clevelandina* (C), *Pillotina* (P), and an unidentified spirochete (S) coexisting with undulipodia (U) in the hindgut of *Reticulitermes hesperus.* Bar = 0.5 μm.

Sphaerotilus natans; Tauschel, 1985), this would suggest that the metabolism of this spirochete is aerobic or microaerophilic. The type species for the genus is *Cristispira pectinis* (Gross, 1910).

Clevelandina

Clevelandina spirochetes are symbiotic in the paunch of subterranean termites and therefore may be anaerobes. The cells are generally oblong in cross-section, are 0.4 to 0.8 μm in diameter and have 30 to 50 periplasmic flagella (Fig. 1, 4, and 9). The angle subtended by the flagella tends to be greater than 180°, and the inner coat (calyx) is correspondingly reduced. The cells are characterized by a thick inner coat (layer) of the outer membrane which tends to be chambered and an outer coat of the inner membrane which is present except where the circumference is covered by flagella. A sillon, the contact between the inner and outer membrane that extends longitudinally, is present and crenulations are lacking. The type species is *Clevelandina reticulitermitidis* from the California termite *Reticulitermes tibialis* (Bermudes et al., 1988).

Diplocalyx

The *Diplocalyx* spirochetes are symbionts in hindguts of dry wood-eating termites; they are probably either anaerobes or microaerophiles. The cells are helical and 0.7 to 0.9 μm in diameter. In *Diplocalyx* the 40 to 60 periplasmic flagella are tightly bundled between the inner and outer membranes (Figs. 1 and 4). A prominent sillon varies in position in different morphotypes relative to the flagellar bundle. A thick outer coat of the inner membrane, forming a calyx (cup), is present except under the flagellar bundle and sillon. Crenulations of the outer membrane are absent. Cytoplasmic tubules, about 21 nm in diameter (Fig. 6b), and polar organelles have been seen in some sections. The type species is *Diplocalyx calotermitidis* from the Mediterranean termite *Incisitermes flavicollis* (Gharagozlou, 1968).

Hollandina

Hollandina spirochetes, found in wood-eating cockroaches and termites, are probably anaerobes or microaerophiles. They are smooth, rounded to oblong, and helical when observed in transverse section; they are 0.4 to 1.0 μm in diameter (Figs. 1 and 4). *Hollandina* spirochetes generally have a thick coating on the outer surface of the outer membrane. Crenulations of the outer membrane are lacking. Cells have from 15 to 70 flagella dispersed in the periplasmic space. A sillon is absent or relatively inconspicuous. Polar organelles and cytoplasmic tubules have been observed in some sections. The type species

is *Hollandina pterotermitides* from the Sonoran desert termite *Pterotermes occidentis* (Bermudes et al. 1988).

Pillotina

Pillotina spirochetes are symbionts in the guts of wood-eating cockroaches and termites and are probably anaerobes or microaerophiles. They have helical cells 0.6 to 1.5 μm in diameter with prominent crenulations in the outer membrane (Figs. 1, 4, 6a, 7, 8, and 9). A stellate profile with approximately 30 to 70 flagella distributed throughout the periplasmic space is distinctive for the genus. The inner coat of the outer membrane is consistently prominent; an outer coat of the outer membrane is present in some populations. A deep and narrow crenulation forms the sillon. The type species is *Pillotina calotermitidis* from the Madeiran termite *Incisitermes praecox* (Hollande and Gharagozlou, 1967).

Cytoplasmic Tubules

Hollow tubules, called microtubules by Gharagozlou (1968; Fig. 6a) although they are somewhat smaller in diameter than the standard 25-nm microtubules of eukaryotes (Margulis et al., 1978, 1981; To, 1978), have been seen in the protoplasmic cylinders of many termite spirochete genera, including those listed in Table 1. In large spirochetes of the dry-wood-eating termites *Incisitermes schwarzi* and *Pterotermes occidentis,* the presence of a tubulin-like protein was detected by antitubulin immunofluorescence and by co-migration with authentic brain tubulin in acrylamide gel electrophoresis (Bermudes et al., 1987; Margulis et al., 1978). Tubulin proteins, which comprise eukaryotic cilia, flagella (undulipodia), and the mitotic apparatus, are ubiquitous in eukaryotes. This is the only known evidence of tubulin-like proteins in prokaryotes. An evolutionary relationship between the cytoplasmic tubules of these spirochetes and eukaryotic microtubules has been suggested (Margulis, 1981). Cytoplasmic tubules have not been reported in any *Cristispira* strains.

Distribution of Morphotypes

The geographical distribution of *Cristispira* (Table 2) and of large spirochetes from insect hindguts (Table 3) was summarized earlier. In any given termite, distinctive spirochete morphotypes are consistently and reliably found. Many undescribed spirochete morphotypes, especially smaller ones, are present in termite and cockroach hindguts, often in impressive numbers (Fig. 7). More than 25 species of kalotermitids and rhinotermitids have been examined, and they nearly all harbor some type of pillotina spirochete. Since more than 350 species of dry-wood termites (Krishna, 1961) and 158 species of subterranean termites are known (Wilson, 1971) and fewer than 30 termite species have been examined with the electron microscope, many more complex spirochetes likely await discovery.

Isolation

Collection and Examination of Symbiotic Spirochetes

Large spirochetes are easily observed live in wet mounts. Styles can be readily dissected from fresh mollusks and crushed with a coverslip for direct observations of *Cristispira*. Intestines are removed with forceps from termites or wood-eating cockroaches. The microorganisms are very densely packed and so are usually diluted with Trager's solution (1934) before observation. They may be maintained for observation for up to 2 hours (*Cristispira*) or 24 hours (some hindgut spirochetes), using petrolatum- or paraffin-sealed microscope slides. The style or gut, its microcosm intact, is prepared for electron microscopy by fixation with glutaraldehyde (Margulis et al., 1991; To, 1978) or observed directly.

Collection of *Cristispira*

To observe live *Cristispira*, the host mollusk must be freshly harvested since styles degenerate within a few hours after removal from their natural estuarine habitat. Oysters maintained in the laboratory quickly lose their spirochetes. *Cristispira* tend to be either plentiful or absent in any given style and when present tend to align longitudinally in the style matrix. The environmental conditions indicative of the presence and abundance of *Cristispira* in a mollusk are poorly understood. Mollusks of the same species sharing the same environment will not all contain *Cristispira*. The aeration of the general environment seems to have no correlation with the presence of *Cristispira*. Mollusks in well-aerated surf and mollusks buried deep in black, anaerobic muds both contain *Cristispira*. *Cristispira* can be collected the year round.

Maintenance of Motile *Pillotina* Cells

In spite of many efforts, no medium has yet been devised that permits the in vitro growth of any of these large, symbiotic spirochetes. The following medium, however, did maintain motile ter-

mite spirochetes in mixed culture for at least 72 and up to 120 hours:

> Sweet E broth (Holdeman and Moore, 1972) is adjusted to a pH of 6.8, rendered anaerobic by gassing with 80% Ar, 10% CO_2, and 10% H_2, and anaerobically sterilized in Hungate anaerobic tubes containing 1.5% agar. By the syringe method, fetal bovine serum and cocarboxylase are added to a final concentration of 5.0% and 0.05%, respectively. Hindgut contents from a surface-sterilized termite are inoculated into the medium.

The obvious sensitivity of the spirochetes to air bubbles on the slides and in the medium suggests that these organisms are microaerophiles or anaerobes.

Identification

Large symbiotic spirochetes may be identified by light microscopy to at least the family Pillotinaceae and in some cases to genus given identification of their animal hosts. For classification to species, ultrastructural identification is required. The use of molecular sequence analysis, in particular 16S ribosomal RNA sequence comparison, has not been applied to any large symbiotic spirochetes so the phylogenetic relation of these spirochetes with other spirochetes or any bacteria is unknown.

Symbiotic Relationships with Other Organisms

Cristispira

The crystalline styles of oysters digest cellulose in the absence of *Cristispira* symbionts. With respect to cellulose digestion in oysters, styles with spirochetes do not differ from styles without spirochetes (Margulis et al., 1991). Therefore, the role, if any, the spirochete plays in oyster digestion is unknown.

Termite Spirochetes

Termite spirochetes are always found in association with dense populations of hypermastigote and polymastigote protists, as well as with other bacteria. They are present in the hindguts of healthy, dry-wood, and subterranean termite hosts of all insect stages and castes: larvae, pseudergates, alates, and soldiers. The termite communities include some 10^5–10^6 protists per ml of fluid gut: lophomonads, trichonymphids, devescovinids, monocercomonads, and oxymonads. They also regularly contain 10^9–10^{11} bacteria per ml of hindgut fluid, including *Arthromitus* (Margulis et al., 1990b) and other Gram-negative rods of many kinds (To and Margulis, 1978; To et al., 1980; Figs. 7, 8, and 9). Live spirochetes are observed in many sorts of relationships with each other and with members of the community: 1) free in the lumen of the intestine (Grimstone, 1967; Margulis et al., 1979; Fig. 3, 7, and 9); 2) attached casually to the surfaces of protists, especially devescovinids and dinenymphids (Bloodgood and Fitzharris, 1976); 3) attached to other bacteria (Margulis and Schaadt, 1976); 4) attached to each other and translating in moving bundles (Margulis and Schaadt, 1976; To et al., 1978); 5) attached to debris and beating in synchrony without translation (Margulis and Schaadt, 1976); 6) attached in regular tufts to the surfaces of mastigotes (these populations of spirochetes may beat in synchrony and thus move their mastigote hosts, thereby forming motility symbioses; Cleveland and Grimstone, 1964; To et al., 1978); or 7) entirely engulfed within the cytoplasm of protists (Margulis et al., 1979, 1981; Fig. 8). Apparently, these spirochetes have sticky surfaces that facilitate attachment to each other and to other microbes. The hindgut spirochetes, along with other members of the hindgut microbial community, are actively transferred to newly hatched larvae and from insect to insect by proctodeal (mouth-to-anus or anus-to-anus) contact. If unprotected or exposed to oxygen, the spirochetes die in a few minutes.

The spirochetes are probably not essential for cellulose digestion because the community and the host can survive their absence, at least for some weeks. The spirochetes appear to depend on the protists in the hindgut community; the spirochetes do not survive more than a few days after the protists are removed by chemical or heat treatment of the termite hosts (Grosovsky and Margulis, 1982). None of the large symbiotic spirochetes seem to have any practical importance.

CHAPTER 14.5

Streptobacillus moniliformis

JAMES R. GREENWOOD AND SYDNEY M. HARVEY

Introduction

The genus *Streptobacillus* is presently represented by one species, *Streptobacillus moniliformis*, the etiologic agent of rat-bite fever and Haverill fever. *S. moniliformis* has also been known as *Haverhillia multiformis, Actinomyces muris*, *Actinobacillus muris*, and *Haverhillia moniliformis.* Although the genus *Streptobacillus* was described in the 1920s, taxonomically it continues to be a genus of uncertain affiliation. Previously this genus was placed in the families Parvobacteriaceae (Tribe Haemophileae) and Bacteroidaceae. Since the 8th edition of *Bergy's Manual, Streptobacillus* has been described as a genus of "uncertain affiliation." It was recently suggested (Savage, 1989) that *S. moniliformis* is more similar to some of the Mycoplasmatales. This suggestion is based on the low GC content of the DNA (24–26 mol%), serum or blood requirements for growth, cholesterol incorporation into the cell membrane, animal parasitism, and production of L-phase organisms. Further clarification of the taxonomic position of this genus awaits genetic studies, such as DNA-RNA hybridizations.

Habitats

S. moniliformis is found in the nasopharynx of laboratory and wild rats, with some studies reporting as many as 50–100% of wild rats carrying it as a commensal organism and excreting it in their urine (McHugh et al., 1985). It is reported to have caused tendon sheath infections in turkeys, cervical abscesses in guinea pigs, epizootics in laboratory mice, and lesions in laboratory rats with bronchopneumonia. Humans become involved in the transmission cycle through rat bites or from the bites of squirrels, weasels, and such rat-eating carnivores as dogs, cats, and pigs. Rat bite fever has also been reported following the handling of dead rats. Haverhill fever may result from the ingestion of milk to which rats have had access.

Selective Enrichment

S. moniliformis is both fastidious and slow growing; consequently it is frequently overgrown by normal flora. Because it is an uncommon human pathogen, little work has been done to develop a selective culture medium. Recently, however, colistin nalidixic acid agar (CNA) was used in conjunction with other media to isolate Gram-negative *S. moniliformis* from a 2-month old with a fatal infection following a bite by a wild rat (Sens et al., 1989). CNA is inhibitory for many other Gram-negative bacteria and the use of this medium or a modification combining colistin, nalidixic acid and serum might provide a new approach to isolation of *S. moniliformis* from nonsterile body sites.

Isolation

S. moniliformis growth media should be supplemented with blood, serum, or ascitic fluid. Because L-phase variants might be present in clinical samples, media formulations must also take the specialized growth requirements of these forms into account. The bacterial phase has been isolated on media with either a meat infusion or tryptose base enriched with 20% horse serum or 15% sterile defibrinated rabbit blood. L-phase variants are more easily observed in culture when grown on the clear, serum-containing agar. Agar plates should be incubated in a humid environment with increased CO_2, such as that obtained in a candle jar, or in a humidified CO_2 incubator. Plates should be incubated at temperatures of 35–37°C. *S. moniliformis* colonies are greyish, are round, and have a butyrous consistency. They generally have a discrete edge and reach approximately 1–2 mm after incubation for 3 days. The L-phase

This chapter was taken unchanged from the second edition.

colonies exhibit a typical mycoplasma-type "fried egg" appearance and are considerably smaller than bacterial colonies.

When blood cultures are required to diagnose *S. moniliformis* endocarditis, thioglycolate broth appears adequate to support growth. However, it appears important not to use broth that contains sodium polyanethol sulformate, as this has been reported to be inhibiting at levels as low as 0.0125% (Lambe et al., 1973).

Identification

Table 1 lists the salient features of *S. moniliformis*. Because of the fastidious nature of these organisms, the literature frequently reports numerous discrepant biochemical features probably resulting from the use of different basal media. The most comprehensive studies on biochemical reactions of this genus are presently based on the studies of Aluotto et al. (1970) and Cohen et al. (1968).

Perhaps the most reliable and accessible method of testing carbohydrate fermentation is to inoculate a 24-h broth culture of *S. moniliformis* into a cystine trypticase agar (CTA) base that contains one drop of rabbit serum and 1% carbohydrate in final concentration. These tubes are incubated at 35°C and reactions read at 1, 2, 7, and 14 days. Inoculated tubes should be compared to control tubes consisting of CTA with added carbohydrate and serum. For detection of other biochemical features, the work of Cohen et al. (1968) should be consulted. Fatty acid profiles have also been used to rapidly identify *S. moniliformis* during an outbreak of Haverhill fever (Rowenbotham, 1983). In this work, strains were grown in serum broth for 24 h, and the cultures were used to prepare fatty acid methyl esters. *S. moniliformis* strains had consistent peaks of palmitic, linoleic, oleic, and stearic acid.

[a]d = Different biotypes.

The microscopic morphology of *S. moniliformis* may vary depending on the media used, cultural conditions, and age of culture. Generally, cells appear as elongated Gram-negative rods, frequently in chains and filaments with occasional thickenings along the filaments giving rise to a necklace appearance ("moniliformis" means necklace-shaped). *S. moniliformis* is nonencapsulated, nonmotile, and facultatively anaerobic.

Preservation of Cultures

Cultures of *S. moniliformis* can be lyophilized for effective storage. They can also be subcultured in broth, but transfer to fresh broth medium is required as frequently as every 24 h to maintain viability. Refrigerated agar plate cultures can survive up to 15 days.

Applications

Animal research personnel are at risk from developing rat bite fever when working with laboratory rats. From 1958 to 1983, of 13 cases of rat bite fever reported in the United States, six of the cases were associated with bites of laboratory rats (Anderson et al., 1983). This is in keeping with the high rate of colonization by *S. moniliformis* in these animals. Studies on the mechanism of pathogenicity, virulence, and host range have not been reported.

CHAPTER 14.6

The Genus *Toxothrix*

PETER HIRSCH

The first description of a bacterium that produced twisted bundles of thin filaments which contained oxidized iron was given by Cholodny (1924). He called this organism *Leptothrix trichogenes*, the filament-producing *Leptothrix*. The flexible bacterium was observed in a water basin next to the river Dnjepr near Kiev, Russia. Its cells (diameter approximately 0.5 μm) were connected to form a trichome of up to 400 μm in length. A peculiar movement was observed: the U-shaped trichome glided with its rounded part forward; both ends of the trichome left bundles of twisted filaments of polymer as parallel "railroad tracks." Occasionally, parts of the bundles appeared to be drawn out in a fan-shaped fashion (Figs. 1a, 2).

Although this first description was very accurate, as we know now, later scientists failed to notice the presence and importance of the flexible, gliding bacterium (trichome); they only observed the often rigid, brittle, iron-encrusted bundles of filaments. Consequently, these filaments were interpreted to be alive, to comprise the organism. It appears strange that the producer of these structures did not attract greater interest.

The explanation for the failure to recognize the true nature of *Toxothrix* came from Krul, Hirsch, and Staley (1970), who employed a partially immersed, phase-contrast microscope to study the formation of such filament bundles in an iron spring in Michigan. The bacterial trichome was observed to consist of up to 40 rods, each of 0.5–0.75 × 3–6 μm, with a total length of up to 240 μm. The forward movement of the often U-shaped trichome consisted of symmetrical rotation of both trichome ends, which thereby left a track on their attachment surface that consisted of twisted polymer fibers. Occasionally, the torque on the rounded center part of the U was released by an upward twist followed by a downward "printing" of polymer onto the surface of the glass slide. Later these polymer fibers became encrusted with iron oxide. Attempts to study the flexible filaments in the laboratory resulted in an explosive lysis that occurred within a few minutes after the living preparation had been made (Fig. 1b). Thus the absence of trichomes in samples of many earlier observers could be explained (Krul, Hirsch, and Staley, 1970).

The fact that the bundle of twisted fibers was different from the "true" sheaths produced by other *Leptothrix* spp. caused Molisch (1925) to name this organism *Toxothrix ferruginea* (*toxon,* Greek noun, a bow). Later, Beger and Bringmann (1953) changed the name partially back into *Toxothrix trichogenes*, a more proper name (Hirsch and Zavarzin, 1974).

This chapter was taken unchanged from the second edition.

Habitats

The organism is not at all common in nature, although in specific habitats it has been found with a worldwide distribution. Most observers have seen *Toxothrix trichogenes* in fairly cold iron springs under conditions of reduced oxygen tension and slightly acidic pH (Table 1). The highest water temperature at which *Toxothrix* has ever been reported to grow is 15.5°C; thus this bacterium is obviously a psychrotroph. Concentrations of ferric iron were, when measured, low: 1–2.7 mg/liter Fe^{2+}. Many authors do not mention, in their reports, the occurence of the gliding *Toxothrix* trichomes, and thus the organism itself could have been absent when the more persistent, iron-encrusted filament bundles were seen and the parameters measured.

If one studies the variety of other bacteria present with *Toxothrix trichogenes*, one discovers that *Gallionella ferruginea* usually accompanies it. *Leptothrix* spp., *Siderocapsa* spp. or *Sphaerotilus*, *Naumanniella* spp., and *Ochrobium tectum* also occur, but if present they appear in smaller numbers. The natural habitat of *Gallionella* seems to be very similar to that of *Toxothrix*. But while the former grows best in nutrient-poor environments, the *Toxothrix* trichomes seem to prefer a higher concentration of organic matter. Also, *Toxothrix* grows best under microaerophilic conditions (Table 1).

Occurrence of *Toxothrix* in lakes or ponds has rarely been reported. Gorlenko, Dubinina, and Kusnezov (1977) found this organism in a 7- to 8-m depth in a Karelian mesotrophic lake and state that, if meromictic lakes were studied, *Toxothrix* could be found in one out of three such lakes.

Enrichment Suggestions

Toxothrix trichogenes has not been obtained in pure culture to date. However, natural *Toxothrix* samples—especially from cold iron springs with low pH—can be kept in the laboratory for sev-

Fig. 1. *Toxothrix trichogenes* growing on a slide submerged in an iron-spring basin. The flexible trichomes with dense granules. (a) Typical U-shape of gliding cells. (b) A trichome has fragmented. Bar = 10 µm.

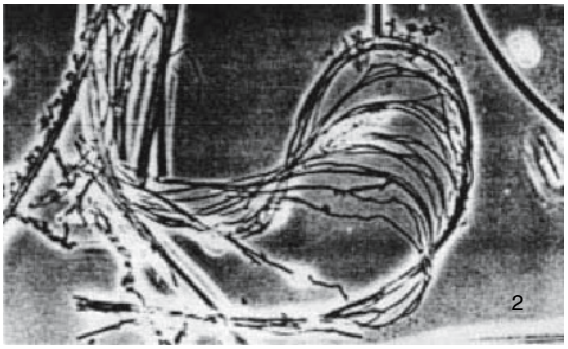

Fig. 2. *Toxothrix* polymer filaments (twisted bundle, fanshape) with iron encrustations. There are also sheaths of *Leptothrix* sp. and *Gallionella* bands. Preparation from the same site as in Fig. 1.

eral months, provided they contain some sediment with organic matter and are kept cold (5°C) and dark.

Microscopic examination of such stored samples often results in rapid lysis of the trichomes, a behavior also observed in some other gliding bacteria. The reason for the rapid lysis is not entirely clear. It could not be caused by a temperature that is too high, since lysis will occur below temperatures of some natural habitats. Light intensity and lack of oxygen could also be ruled out for the same reasons. *Toxothrix* trichomes may be extremely sensitive to pressure. Therefore, the cover slip of a preparation for microscopy should be carefully supported by small fragments of cover slip glass. It may also be quite harmful to these organisms to be streaked out, for the same reasons.

Future enrichments should be made with natural samples that contain many actively gliding trichomes; the number of twisted rope structures is quite irrelevant. The liquid medium should probably have a pH of 5.5–6.5, a constant iron supply of not more than 1–2 mg/liter Fe^{2+}, and an oxygen concentration of about 1 mg/liter. The incubation should be performed in the dark and at 5–10°C.

Identification

In the absence of iron-encrusted, excreted filament bundles, *Toxothrix trichogenes* could be mistaken for other gliding bacteria such as *Herpetosiphon* spp. The genus *Haliscomenobacter* (= *Streptothrix*), described from polluted environments (see The Genus *Haliscomenobacter* in this Volume), also shows some morphological similarities to *Toxothrix*. It is quite possible that gliding bacteria without such filamentous sheaths that have been observed in various freshwater, marine, or polluted habitats could have been *Toxothrix* spp. The absence, in *Toxothrix* trichomes, of constrictions at the cross-wall sites is quite characteristic. Their mode of gliding (in the

form of a U) separated them from the equally colorless, filamentous, and gliding *Achroonema* spp., which normally remain fairly straight.

Fragmentation of *Toxothrix* trichomes into short rods is more common in some habitats than in others and indicates the possibility of there being more than one *Toxothrix* species. Even before fragmentation, one recognizes many dense (electron-dense) granules in the *Toxothrix* trichomes. These may be polyphosphate granules (volutin). After fragmentation, each rod-shaped cell usually has two such granules, one at either end.

CHAPTER 14.7

The Genus *Gallionella*

HANS H. HANERT

The bacteria of the genus *Gallionella* belong to the so-called "iron bacteria," which achieved their theoretical importance after Winogradsky (1888, 1922) postulated his conception of chemolithotrophy for these organisms. These bacteria also have practical significance since they clog drains, water pipes, and wells with deposits of iron oxide compounds. In connection with freshwater supply problems and the rapid growth of agriculture, hydrotechnicians and land-reclamation (underground drainage) specialists have become increasingly interested in bacterial iron oxidation as a common source of interference with wells and drainage systems (Ford, 1978; Hanert, 1974b; Khrutskaya, 1970; Martin et al., 1978). Iron bacteria are also interesting for ecological and biogeochemical reasons. Like algae, iron bacteria may develop in their natural habitats in such masses that the idea of their participation in the sedimentary formation of iron ore is plausible, as was recognized in the first description of the iron bacterium *Gallionella ferruginea* (Ehrenberg, 1836).

Iron bacteria are reputed to be difficult to work with. The general opinion of microbiologists is that it is difficult to cultivate these organisms in the laboratory and that there are difficulties in isolating and identifying them. Therefore, it is one of the main purposes of this contribution to show that this poor reputation is unjustified. It will be demonstrated that cultivation and handling of the treated bacteria are in no way more difficult than for other microorganisms, if attention is paid to only a few fundamental peculiarities, such as "sessility" and "gradient growth." Disregard of these factors may be one of the most common practical reasons for failure to locate these organisms in natural habitats, for failure to cultivate them successfully, for misinterpretation of presumed developmental stages, and for discouragement which can often be observed when students are starting in this field. Therefore, the following text is narrowly restricted to methods and practical advice—without any theoretical discussion on the controversial life cycle, taxonomic position, and physiology, which are described in the literature cited.

This chapter was taken unchanged from the second edition.

Habitats

Chemistry of the Habitats

Gallionella ferruginea characteristically occurs most abundantly in very pure, iron-bearing waters that contain only traces of organic material. Habitats with the best prospects for a successful search are ferruginous mineral springs, water works, wells, and drainages, especially underground drainages in regions near the groundwater table. Swamp ditches and lakes are unusual habitats that contain *Gallionella* in large quantities only at places where pure, ferrous waters infiltrate. Occurrence is not restricted to fresh waters or to low-temperature habitats, as commonly assumed; *Gallionella* has been convincingly found in salt water, marine bays, and thermal springs with temperatures up to 47°C (Hanert, 1973b, 1981a; Sharpley, 1961; Volkova, 1939; Vouk, 1960).

Common to all of the various *Gallionella* localities investigated are sharply limited physicochemical conditions characterized by a low redox potential in an Eh range of +200 to +320 mV (rH_2 values generally vary from 19 to 21) and a slightly acidic environment caused by the solution of considerable amounts of CO_2. Adding the data determined by Volkova (1939) in slightly alkaline mineral waters, the pH environmental limits range from 6.0 to 7.6, which excludes growth in acid habitats. Occurrence of *Gallionella* in acid mine waters as described by Walsh and Mitchell (1969, 1970) may be a result of confusing *Gallionella* with *Metallogenium* and/or nonbiological structures.

These Eh and pH limits characterize *Gallionella* as a very good example of a gradient organism that develops under neither strongly reducing conditions nor in a highly oxidizing zone, but in a level between the two extremes with redox conditions about 200–300 mV lower than typical surface waters. This region in which *Gallionella* grows characterizes the lowest zone of Eh-pH environmental limits of iron bacteria

established by Baas-Becking et al. 1956, in which there are usually only low concentrations of oxygen.

Comparison with geochemical-stability field data for ferrous iron, published by Garrels and Christ (1965) and Hem (1972), shows that the *Gallionella* Eh-pH milieu, in all the cases that have been measured, lies significantly within the zone in which ferrous ions are stable. This stability appears to be the essential factor in the environmental conditions for the existence of *Gallionella,* much more important than the factors of temperature and oxygen content, to which *Gallionella* manifests greater adaptability than generally thought. The marked psychrophily and the microaerophily generally ascribed to *Gallionella* seem to be only secondary effects that depend on the fact that bivalent iron is most stable under these conditions (Hanert, 1975). Thus, it is easy to understand why *Gallionella* also occurs in O_2-saturated waters, for example, in aerated, iron-removal treatment plants in water works or in thermal springs, when the only essential condition, stability of bivalent iron in the presence of oxygen, is fulfilled. These observations do not invalidate the most common values of physicochemical factors measured in *Gallionella* habitats, which are 0.1–1 mg/liter O_2, 8–16°C, 5–25 mg/liter Fe(II), around 20 or more mg/liter CO_2, and a very slight content of organic material, not above 12 mg/liter $KMnO_4$ (Hanert, 1975).

Growth Measurement and Analysis of Iron-Oxidation Structures by In Situ Exposure

The red-brown deposits at *Gallionella* sites consist primarily of the typical spiral bands of dead matter excreted from the terminal *Gallionella* cells. These deposits may be extremely pure. However, their *Gallionella*-nature may be very difficult to recognize when the deposits have been altered by additional chemical iron-oxidation processes. False conclusions may then be drawn about the nature of the iron-oxide precipitation. A direct measurement of *Gallionella* growth is indispensable for analyzing such structures, as well as for determining whether or not *Gallionella* is actually growing on the site.

There are three proven methods of in situ exposure for light microscopy and for transmission and scanning electron microscopy: (1) The exposure of cover slips or slides for several hours or days, singly or in multiple vertical alignment, in plastic clamp fittings. This method, a modification of the on-growth method of Naumann (1919) and Cholodny (1924), allows the localization of the zones in which *Gallionella* develops in still waters, the densitometric and photometric registration of the total iron oxidation (Hanert, 1981a) and, by determining stalk production, the quantification of the momentary *Gallionella* development (Hanert, 1973a). (2) The exposure of Formvar-coated, platinum or gold, electron-microscope grids (copper grids are inappropriate due to the frequent presence of H_2S). With these procedures, the fine structure of the bands, as well as of the terminal *Gallionella* cells on the sessilely excreted intact stalks, may be observed. The latter is not included when suspension preparations of the stalk fragments are used (Hanert, 1970; Hirsch and Pankratz, 1970). (3) Exposure of round glass slides for scanning electron microscopy and electron probe microanalysis (FeKα). This procedure is especially important because it allows tiny globular particles (0.04–0.3 μm in diameter) to be chemically and physically analyzed (Hanert, 1981a). Until now, they were thought to be mycoplasma-like developmental stages and buds of *Gallionella,* but they have been shown to be pure Fe(III)-oxide particles.

The advantages of these three procedures, which all make use of the sessile way of life, are obvious when one considers that the failure to find the characteristic apical cells in natural habitats (van Iterson, 1958) was the starting point for the studies that aimed at proving the mycoplasma-like and *Metallogenium*-like viable nature of *Gallionella* stalks (Balashova, 1967b, 1969, 1974; van Iterson, 1958; Zavarzin, 1961). The three procedures described above may also be applied to pure cultures of *Gallionella.*

Isolation

Physiological Basis for Isolation

Although chemolithotrophy has not as yet been generally recognized for *Gallionella,* it must be emphasized that all of the successful cultures were able to develop only in mineral media with iron(II) as energy source. This is true for Lieske's first cultures (1911) containing metallic iron as well as for the excellent culturing procedures of Kucera and Wolfe (1957) that use ferrous sulfide as a source of reduced iron. Culture procedures that used organic media containing serum, as suggested by Balashova (1969), have remained unsuccessful. Classic *Gallionella* organisms with stalks and apical cells as well as developmental stages producing such forms have not been obtained. It thus seems evident that *Gallionella* is truly a chemolithotrophic bacterium and that ferrous-containing mineral media are best for cultivation and isolation.

Isolation Principles and Procedures

Two isolation procedures have proven useful. Both use mineral Wolfe's FeS medium (see below) as a selective isolation medium for *Gallionella,* in which neither sheathed nor capsulated iron bacteria will grow.

One procedure is a test-tube dilution method in which a final concentration of one colony per culture is reached. The ability to stick to the vessel walls is used to separate *Gallionella* from the contaminants (Engel and Hanert, 1967; Hanert, 1968; Hanert 1981b).

Isolation of *Gallionella* by Dilution and Serial Transfer (Engel and Hanert, 1967; Hanert, 1968)

> One Gallionella colony is withdrawn with a capillary pipette from the wall of a test tube containing an enrichment culture, suspended homogeneously in 10 ml of Wolfe's medium without FeS, diluted to 10^{-5} (maximally 10^{-6}, one colony of 1 mm in diameter consists of about 100,000 apical cells), and then inoculated into test tubes with Wolfe's FeS medium (30–50 parallel cultures starting with a 10^{-4} dilution).
>
> After 1 week of culture, a one-colony culture is treated, in essentially the same way as above, to obtain a pure culture. The colony, which is attached to the wall of the test tube, is carefully rinsed using a pipette with approximately 200 ml of fresh, sterile medium without FeS, after first disposing of the FeS sediment (1 ml) and the mineral medium (9 ml). Then the colony is transferred five times into test tubes containing 10 ml of sterile medium (without FeS) and washed with gentle shaking to rid the colony of clinging contaminations. The washed colony is then suspended into sterile medium (10 ml) and again inoculated into test tubes containing Wolfe's FeS medium at dilutions of maximally 10^{-6} (again 30–50 parallel cultures). Five to ten serial transfers are necessary to achieve pure culture in this manner. Although this procedure requires up to 10 weeks, it is a very certain method of continually reducing the number of contaminants and obtaining a pure culture (Hanert, 1975).

The second isolation technique requires much less time and leads, according to the authors, to a pure culture in 7 out of 10 cases. It is based on the observation that some strains of *Gallionella,* in contrast to most contaminants, are resistant to 0.5% formalin.

Isolation of *Gallionella* by Formalin Resistance (Nunley and Krieg, 1968)

> Five-tenths milliliter of formalin (40% formaldehyde solution) was added to a dilution bottle of Wolfe's medium containing 10 ml of ferrous sulfide agar and 100 ml of fluid medium. Samples of *Gallionella* from its natural source were centrifuged at $3000 \times g$ for 3 minutes. One to five milliliters of sediment was transferred to the Wolfe's medium with formalin. The medium was incubated at 25°C for 1–2 days. One-milliliter aliquots of the culture were transferred to fresh Wolfe's medium without formalin. Cultures were incubated at 25°C for 2–3 weeks. Tests for culture purity were performed using the third serial transfer after the formalin treatment.

Purity is checked by use of a variety of heterotrophic and autotrophic test media, for example, yeast extract bouillon, nutrient agar, *Nitrosomonas* medium, *Ferrobacillus* medium, and *Thiobacillus* agar. The length of observation is up to 4 weeks.

Micro- and Macrocultures and Axenic Maintenance

There are no principal difficulties in cultivating *Gallionella* in containers ranging from small chambers to 12-liter fermentors. The difficulties of culture that have been reported in almost all publications on *Gallionella* generally are due to overlooking interactions in the medium among the following factors: phosphate, ferrous and ferric iron, oxygen, pH, and redox potential. The most important growth-inhibiting chemical processes in the medium are: (1) iron phosphate precipitation caused by too high a concentration of phosphate; (2) chemical autoxidation of ferrous iron caused by too high a concentration of oxygen or by the redox potential being too high; and (3) the pH becoming more acidic when elevated O_2 concentration causes hydrolysis of ferric iron. All three processes eventually reduce the Fe(II) content of the mineral medium of the FeS cultures below the lower limit of 5 ppm. In order to retain the required Fe(II) concentration, it is absolutely necessary to have the following initial conditions in the medium: oxygen content 1 ± 0.2% (0.42 ppm), pH 6.0 (values from CO_2 bubbling, border values between 5.5 and 6.3), Eh +330 mV to +350 mV (Eh border values from –55 to +395 mV), phosphate (as K_2HPO_4) 0.05 g/liter. These conditions were established in optimum growth zones of 3-liter Erlenmeyer flasks and confirmed in test tube cultures (Hanert, 1975). They lead, following interactions between mineral medium and FeS-sediment, to an iron(II) concentration of 10–20 ppm which guarantees good growth of *Gallionella.* The conditions of gassing must be varied according to the volume in each vessel, so that common standardized instructions may not be given for all sizes of flasks. Identical for all cultures, though, is the production and storage of ferrous sulfide as well as the production of modified mineral Wolfe's medium. During the first process, essential mistakes may be made that inhibit the growth of *Gallionella.*

Preparation and Storage of Ferrous Sulfide

> For preparation of ferrous sulfide, two precipitation reactions with equal molar quantities are possible. FeS can be produced by reacting either 78 g ferrous ammonium sulfate "$(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$" with 44 g sodium sulfide ($Na_2S \cdot 9H_2O$) or 140 g ferrous sulfate ($FeSO_4 \cdot 7H_2O$) with 120 g sodium sulfide in deionized water (50°C; ferrous salts are added in solid form while stirring). The resulting FeS precipitate must be washed extensively using deionized water (decanting of the supernatant and its replacement with deionized water at 50°C), removing Na^+, NH_4^+, and, above all, S^{2-} ions until the precipitate reacts neutrally (pH measurement in FeS, not in the supernatant).

Washing of FeS while continually checking pH is indispensable, since hydrolysis of any residual sulfide ions ($S^{2-} + H_2O \rightarrow HS^- + OH^-$) raises the pH to 7.7 directly over the FeS sediment. The elevated pH prevents bivalent iron from dissolving and *Gallionella* development does not begin (Gebauer, 1978). Because of this indirect effect of sulfide on the development of *Gallionella,* sodium sulfide, used to manufacture FeS, is added in slightly less than the equimolar amount. The separation of the adsorbed sulfide ions from the FeS precipitate during the washing procedure is a slow process and takes approximately 5 days (5–9 washings at intervals of at least 4 h). Delayed FeS sedimentation caused by formation of FeS-hydrosol can easily be eliminated by including a few drops of a saturated $FeCl_3$ solution or by once washing with tap water. After this cautious washing, FeS precipitate can be stored without oxidation in glass-stoppered bottles that are completely filled.

Modified Mineral Wolfe's Medium

> The modified mineral medium contains per liter distilled water: 1 g NH_4Cl, 0.2 g $MgSO_4 \cdot H_2O$, 0.1 g $CaCl_2 \cdot 2H_2O$, and only 0.05 g $K_2HPO_4 \cdot 3H_2O$ (one-tenth of the original concentration).

With the strongly reduced concentration of phosphate, it is no longer necessary to separately autoclave the individual components (no earth alkali phosphates are formed during autoclaving). Low phosphate concentration also prevents iron phosphate precipitate in the culture medium. Such precipitation would result in a total growth inhibition of *Gallionella* due to lack of dissolved iron(II).

Microculture Slide Chambers for In Vivo Studies on Cell Division, Cell Rotation, and Stalk Twisting

> In constructing a chamber, one cover glass (20 × 50 mm) is mounted on each slide (26 × 76 mm). The cover glass is maintained at 0.05 or 0.1 mm above the slide by initially inserting a 0.05- or 0.1-mm flat bar and then sealing the two sides with sealing wax. The bar is removed, the third side (bottom of the chamber) is then sealed, and the slide is held erect for filling. First, a tiny drop of FeS is inserted (by capillary pipette) and then mineral medium is added so that the chamber is two-thirds full, whereby the final ratio of FeS:medium is 1:10. The chamber is then inoculated and the fourth side is sealed. Microaerobic conditions are produced by replacing the air with CO_2 or with a mixture of 94% N_2–5% CO_2–1% O_2. *Gallionella* growth (stalk production) starts immediately after the chamber is closed (Hanert, 1974a).

Procedure for Maintenance of Axenic Cultures of *Gallionella*

> The following procedure has proven useful in maintaining pure cultures of *Gallionella*.
>
> Thirty-four test tube cultures are set up with the dilutions 10^{1-} (4 cultures; inoculum 150,000–300,000 cells), 10^{2-} (5 cultures), 10^{3-} (15 cultures), and 10^{4-} (10 cultures; inoculum 150–300 cells). For this purpose, the cotton-plugged test tubes are aseptically filled with 9 ml autoclaved mineral medium. Then, 22.8 cm^3 of cotton-filtered CO_2 is bubbled through each tube using a 1-ml pipette (length of bubbling approximately 5 s; the pH of the medium is now 4.5–4.8). One milliliter of sterile FeS precipitate is then slowly added with a pipette.
>
> Six hours after the addition of FeS, the inoculation follows subsequent to dissolving 5–10 ppm bicarbonatic Fe(II) in the medium; meanwhile, the tubes are stored in jars at 17°C under an atmosphere of 94% N_2–5% CO_2–1% O_2. In preparing the initial suspension for inoculation (10^0 dilution), two colonies with a diameter of 2 mm (or one colony with a diameter of 4 mm) are suspended in 10 ml of sterile medium using a vortex mixer. Dilution series and inoculation are repeated as described above. The cultures are then incubated in preserving jars at 17°C in an atmosphere of 94% N_2–5% CO_2–1% O_2. This gas mixture can also be used for bubbling through the cultures (135 cm^3 for each test tube). The best *Gallionella* growth is usually at a dilution of 10^{3-} and is macroscopically visible after 3–5 days. Enrichment cultures may be obtained in the same manner, using a drop of natural *Gallionella* sediment for inoculation. Cultures are transferred every 4 weeks.

Preservation of *Gallionella* culture material in viable form for at least 13 weeks has been reported by Nunley and Krieg (1968) using the following procedure.

Culture Preservation by Freezing (Nunley and Krieg, 1968)

> The organisms were centrifuged at 3000 × *g* for 3 minutes, resuspended in the fluid portion of fresh Wolfe's medium containing 15% glycerol, and stored in 1-ml quantities in a low-temperature cabinet at –80°C. Survival was tested by transfer to Wolfe's medium at weekly intervals; in every case, the organisms were viable, forming a distinct mat of growth on the submerged ferrous sulfide agar after 7–10 days.

Batch Cultures in Erlenmeyer Flasks for Physicochemical Studies in the Optimal *Gallionella* Growth Zone

> In order to obtain the described physicochemical growth conditions, FeS (100 ml of FeS precipitate or 100 ml of 1.5% FeS agar) is added to the sterile culture medium (2 liters) in 2-liter Erlenmeyer flasks (silicon stoppers with glass tubes for bubbling) and then bubbled with 94% N_2–5% CO_2–1% O_2 up to pH 6 (gassing takes approximately 90 min). Then, pH, O_2, and Eh values are checked electrometrically and the medium is additionally gassed with N_2 and CO_2 to adjust to the required conditions (see above). The inoculation is with a suspension containing 10–15 *Gallionella* colonies (2 mm in diameter) into 10 ml of mineral medium. *Gallionella* growth becomes macroscopically visible after a lag phase of 4–6 days, during which the redox potential of the culture medium is lowered 300–400 mV by the bacteria (Hanert, 1975).

Fermentor Cultures in Mineral Ferrous Bicarbonate Medium

> A clear $Fe(HCO_3)_2$ medium is made by adding 200 ml of FeS precipitate to 10 liters of modified Wolfe's medium, and CO_2 is bubbled through for approximately 24 h until a Fe(II) concentration of 50 ppm (pH 4.6) is reached. After FeS sedimentation, 4.5 liters of the supernatant, combined with 4.5 liters of modified Wolfe's medium

"without Fe(II)," is filtered into the autoclaved fermentor through a membrane-filter apparatus containing coarse prefilter (10-µm pore size) followed by a Sartorius membrane filter (0.2-µm pore size) using a gas mixture of 94% N_2–5% CO_2–1% O_2 under 2 atm pressure. This filtration results in 9 liters of culture volume with 25 ppm ferrous iron. For measurement, control, and eventual readjustment of the physicochemical conditions with N_2 or CO_2 gas, the solution is left in the fermentor vessel for 24 h. The conditions are so reductive that no autoxidation of the ferrous iron occurs (culture temperature, 17°C). Inoculation is with 10–15 colonies (4 mm in diameter), suspended in 10 ml of medium. In contrast to normal fermentation cultures, the medium should be only moderately stirred (25 rpm) and gassed (1 bubble/2 s).

Gallionella growth becomes macroscopically visible after 2 days (white flakes on the walls of the vessel; after 5 days, the entire Fe(II) in the culture medium has been oxidized. *Gallionella* grows on all the inner surfaces of the culture vessel without gradient formation. This procedure seems suitable for the development of *Gallionella* fermentor cultures with a continuous flow of culture solution, during which it is particularly important to prevent contamination of the culture (changing of redox potential during *Gallionella* growth; Hanert, 1975).

Identification

The characteristic, spirally twisted, stalk structure formed by rotation of the apical cell makes *Gallionella* very easy to identify. It is uncertain, though, whether the genus consists of one or more species. This question has repeatedly been discussed at length (Beger and Bringmann, 1953; Pringsheim, 1949; van Iterson, 1958; among others). These authors have pointed out—and rightly so—that in almost all cases the differentiation into species has been based only on differences visible under light microscopy in the bands of *Gallionella* collected in nature.

Studies on quantification of the iron content of the bands of pure cultures of *Gallionella ferruginea* (Hanert, 1975) have shown that, due to additional chemical-physical iron oxidation on the surface of the bands, these surfaces may vary greatly in morphology. Six stalk types have been differentiated. Thus, the differentiation into species on the basis of light-microscopic band differences is definitely unreliable.

The genus is presently differentiated into two species, *Gallionella ferruginea* (stalk consists of 40 filaments or more) and *Gallionella filamenta* (stalk consists of only 3–8 filaments), based on the electron-microscopic band differentiation of Balashova (1967a, 1968). But this differentiation is only a morphological definition in another dimension; it does not exclude the possibility that "filamenta" is only an underfed "ferruginea." It seems conceivable that the presumption of Pringsheim (1949), which we favor, is accurate—the genus may consist of only a single species *(Gallionella ferruginea)* and all the other described species are only ecological growth forms of this one. The proof of this presumption by the results of additional physiological investigations would show that this bacterium—unique in its physiology and stalk excretion—is not nearly as complex as *Gallionella* literature may give the impression.

CHAPTER 14.8

The Genera *Caulococcus* and *Kusnezovia*

JEAN M. SCHMIDT AND GEORGI A. ZAVARZIN

Perfil'ev and Gabe (1965) observed bacteria of the genera *Caulococcus* and *Kusnezovia*, along with *Metallogenium* and *Siderococcus,* as manganese- and, to a lesser extent, iron-depositing or -oxidizing organisms of mud and sandy de-posits. The use of capillary devices that permit microscopic observation (peloscopes) has permitted some observations of structure and colonial morphologies. Their morphologies suggest that these organisms might be related to *Acholeplasma, Metallogenium,* or *Siderococcus,* but lack of axenic cultures has prevented thorough study of their physiology and composition; understanding of the nature of these rather rare bacteria is quite meager.

Habitats

Caulococcus has been found in samples of mud and sandy deposits as observed with microcapillary techniques (Kutuzova et al., 1972; Perfil'ev and Gabe, 1961; Perfil'ev et al., 1965). It was originally found in Lake Khepo-Yarvi (Karelian Isthmus), "especially in ore deposits," and was "frequently observed in the upper layers of bottom mud deposits, above the reducing horizon," or in the bottom water (periphyton) over the mud (fine mineral or sandy) surface (Perfil'ev et al., 1965).

Kusnezovia was observed, using the peloscope technique, only "in mud samples from Lake Ukshezero, Karelian ASSR" (Perfil'ev et al., 1965), and in secondary profiles in zones of manganese oxidation of mud samples stored in the laboratory.

As described by Perfil'ev and Gabe (1965), in capillary peloscope samples from many ore-bearing lakes, for all those "with a black-orange microzone, the blackish-brown horizon of the microzone in the peloscope canals showed a mass-development of *Metallogenium,* rarely *Caulococcus*, and sometimes *Kusnezovia*, the biogenic deposits of which consist mostly of manganese oxides."

Isolation

Neither *Caulococcus* nor *Kusnezovia* has been isolated in pure culture. Distinctive morphologies, particularly those of microcolonies using microcapillary techniques, have been used to define these two groups (Perfil'ev et al., 1965).

Organisms could be maintained in the isolated samples of mud (Perfil'ev et al., 1965): a sample of water (approximately $^1/_3$) and mud ($^2/_3$) from the natural habitat was mixed thoroughly and incubated in a 200-ml beaker at room temperature for months. Peloscopes were placed across the upper 3 cm of the mud. Development of manganese- and iron-depositing organisms was observed to occur in sharp, horizontal microzones (a few millimeters in width) in the upper layers of mud following the reduction of metal oxides in the bottom layers.

Identification

In the absence of axenic cultures and information on cultural traits, colonial morphology is used, along with the characteristic manganese deposition, for tentative recognition of these kinds of bacteria. To observe cell morphology, Perfil'ev and Gabe (1965) dissolved manganese deposits with 0.2–1.0% oxalic acid, washed them with distilled water, and stained them with a carbol solution of gentian violet. All steps were monitored with the light microscope. The bacteria appeared as minute bodies without sharp contours and appeared to reproduce by budding. They were embedded in a matrix or connected with thin filaments. For identification, the original illustrations of Perfil'ev et al. (1965) should be consulted. Some other characteristics are given in Table 1.

Colonial morphology is variable. Three sorts of microcolony morphologies have been described for *Caulococcus manganifer*. The most commonly observed microcolonies occur as dense, irregular clusters, the surfaces of which appear ribbed. The central portion of the microcolony is more heavily mineralized than the periphery, due to manganese deposition. The mineralized colonies are blackish brown in color.

This chapter was taken unchanged from the second edition.

Table 1. Characteristics of *Caulococcus* and *Kusnezovia* spp.

Trait	*Caulococcus manganifer*	*Kusnezovia polymorpha*
Coccoid cell diameter (μm)	0.5	0.5–1.5
Connecting filament diameter (μm)	0.1	0.1–0.2
Mode of reproduction	Budding (?)	Budding (?)
Motility	Present	Not observed
Gram reaction	Not reported	Not reported
Zoogleal accumulations	Present	Not observed
Oxygen relationship	Microaerophilic	Microaerophilic (presumed)
Occurrence	Rare, in iron-manganese ore from several lakes (Karelian Isthmus, ASSR)	Extremely rare, found in only one lake (Ukshezero, Karelia)

Occasionally, colonies have radial arms (termed "radial lobate" colonies); the rarest colonial form in *Caulococcus* microaccretions is the trichospherical colony with very fine, radiating processes.

Kusnezovia polymorpha microcolonies (polymorphous cenobia) also occur in a variety of forms: filamentous sprouts, open lily-of-the-valley leaves, or goblets with a toothed margin, with the wider portion of the microcolony pointing downward in the peloscope canals. Candelabra-like and clavate, filamentous cenobia structures attached to the peloscope wall, with an appearance analogous to *Cladonia* (a bryophyte), have also been attributed to *Kusnezovia*. Removal of manganese from these deposits revealed the cocci, connected by thread (Perfil'ev et al., 1965).

These organisms will require further attention in order to distinguish them from other quite similar manganese depositers, such as *Metallogenium.* In fact, we strongly suspect that these genera, particularly *Caulococcus*, are merely growth forms of *Metallogenium* in a certain habitat. The description of *Siderococcus* (see The Genus *Siderocapsa* (and Other Iron- and Maganese-Oxidizing Eubacteria in this Volume) should be consulted, since these iron-depositing organisms are very probably members of the same group, although they are not presently classified as such.

CHAPTER 14.9

The Genus *Brachyarcus*

PETER HIRSCH

Light-microscopic investigation of the microorganisms in the hypolimnion of many lakes shows the presence of a highly diverse population of bacteria. Here, most of the recognizable forms have never been cultured and many of them have not even been described morphologically. Among these bacteria are rod-shaped organisms that are bent in an arc by asymmetric, polar cell growth and that frequently assume the shape of a pretzel. Cell division in the center and separation result in two arcs that face each other. Additional cell divisions and the presence of masses of polymer lead to even numbers of arcs facing each other in a symmetric, mirror-image way (Fig. 1).

Phase-contrast light microscopy, using slides coated with water agar to improve resolution, reveals the presence of gas vesicles in most of these organisms. The wide distribution and often the high cell numbers of such arc-shaped bacteria warrant attempts to cultivate and study them, but such attempts have been unsuccessful. Skuja (1964) found similar bacteria in a Lappish lake, and he described them as *Brachyarcus thiophilus*. The species name was used to suggest a possible sulfur metabolism, since the cells occasionally possessed intracellular structures resembling sulfur globules.

Since *Brachyarcus* spp. have never been cultivated, not even in enrichments, their possible identification presents some problems. In fact, a rodlike, arc-shaped cell shape is quite common among other bacteria. But the cell arrangement after division, the presence of gas vesicles, the absence of photosynthetic pigments, and the frequent observation of these bacteria among other "thiophilic" organisms may indeed allow a recognition sufficient for a descriptive treatment here, as has been done in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Hirsch, 1974).

This chapter was taken unchanged from the second edition.

Habitats

The original observations were made by Skuja (1964) on a hypolimnion water sample collected April, 1953, at a depth of 12–13.5 m in Lake Vuolep Njakajaure, Swedish Lappland (408 m above sea level). The water sample had a temperature of 2°C; the lake was ice-covered. Together with *Brachyarcus thiophilus*, large numbers of other "thiobiontic" bacteria were found, many of which contained sulfur storage globules but none of which has ever been cultured (for nomenclature, see Skuja, 1964), e.g., *Macromonas bipunctata*, *M. mobilis*, *Gigantomonas cucullata, G. capitata, Thiovulumspora, Hyalobotrys hypolimnicus.* Also present in this sample were some photosynthetic bacteria *(Thiocystis violacea, Pelochromatium roseum consortium)* and sulfate reducers *(Microspira desulfuricans).*

Similar crescent-shaped organisms have been found by other authors (Table 1) in various lakes or ponds. Bacteria of such cell arrangement and/or shape were also found in soil (Nikitin, 1971, 1973; *"Renobacter vacuolatum"*) or even in reindeer rumen (Tarakanov, 1972). The latter bacteria were $0.4–0.5 \times 1.1–1.2$ μm and occurred in the above-described cell-plate arrangements. Their shape, however, was more that of a vibrio than that of an arc.

Isolation

Although isolation has not yet been successful, the data on occurrence in Table 1 allow us to speculate on possible enrichment techniques. In Wintergreen Lake, temperatures in the *Brachyarcus* layers during the time of observation varied between 11° and 20°C, with the maximum cell density of *Brachyarcus* spp. at 13°C (depth, 5 m). In the other sites—as far as data are available—temperatures ranged from 5° to 12.5°C. These observations indicate that *Brachyarcus* is psychrophilic.

In all cases observed, the organism occurred under anaerobic conditions. A pH of 7.5 and a phosphate concentration below 2.56 mg/liter would be additional parameters. No information is available on the carbon nutrition, although one could guess that *Brachyarcus* (being nonphotosynthetic) would have a chemoorganotrophic metabolism. Their presence in strata that contain methane (Wintergreen Lake) or reducible sulfate (Lake Vuolep Njakajaure) points to preference for a low redox potential in the environment. Storage of intracellular sulfur globules indicates participation in the sulfate reduction or sulfide oxidation processes.

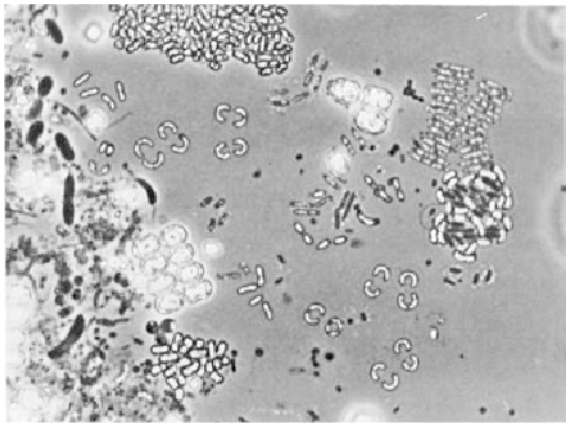

Fig. 1. Arc-shaped cell families of a *Brachyarcus* sp. from Wintergreen Lake (Michigan), collected from 4 m. Magnification × 1,280.

Identification

Brachyarcus Skuja 1964, 19, is a genus of colorless rod-shaped bacteria of approximately 1.0 × 1.5–2.5 µm that usually contain few to many gas vesicles (Fig. 1). Occasionally, globules resembling sulfur were observed by Skuja (1964), but these have not been reported by other authors nor have they been seen by this author. The cells are bent like a bow or arc, almost to a circle or even a pretzel shape. Upon division, a 3-shape is initially assumed until two semi-circles lie opposite each other, embedded in a thick polymer capsule with diffuse edges (Fig. 1). Families of two to 16 synchronously dividing cells are common; they often form cell plates, which may be free floating or grow attached to a surface. Three-dimensional, free-floating families of polymer-embedded cells of up to 100-µm family size or larger have been observed. The type species is *Brachyarcus thiophilus* Skuja 1964, 20, so named for the "thiophilic" environment in which it has been found.

Table 1. Occurrence of *Brachyarcus*-like bacteria.

Location	Date	Depth (m)	Temperature (°C)	Remarks	Reference
Lake Vuolep, Njakajaure (Lappland)	April 1953	12–13.5	2		Skuja, 1964

Wintergreen Lake (Michigan)	23 July 1970	4	16.5	O_2, 0.22 mg/liter; pH, 7.74	P. Hirsch, unpubl.
	22 July 1975	3.5–6.0	20–11	Anaerobic; pH, 7.8–7.3; DOC, 9–7 mg/liter; POC, 2–5 mg/liter; methane, 60–320 µM/liter × 10^{-3}; PO_4^{3-}, 0.23–2.56 mg/liter; max. distribution at 5 m (= 13°C)	P. Hirsch, unpubl. (M. Klug, R. Wetzel, unpubl.)
Lake Blunkersee (Holstein)	16 Sept. 1975	8	12.5	Anaerobic; sulfide +	P. Hirsch, unpubl.
Lake Plußsee (Holstein)	17 June 1967	27	5.5	Anaerobic	P. Hirsch, unpubl.
Forest Pond, Augusta (Michigan)	15 Oct. 1968	0.25–0.51	15.5	Anaerobic; sulfide (+)	P. Hirsch, unpubl.
	17 Nov. 1968	0.55–0.65	6	Anaerobic; sulfide +	P. Hirsch, unpubl.
Arco Lake (Minnesota)	Sept. 1972	6.5–9		Anaerobic ?	Walsby, 1974
	May, June 1973	6.5–9			Walsby, 1974

Identification is still largely on the basis of morphology. Cells or cell aggregates of similar shape are formed by the purple bacterium, *Rhodocyclus* (Rhodospirillaceae), or by the green bacteria, *Chlorobium vibrioforme* and *Pelodictyon luteolum* (Gorlenko, Dubinina, and Kuznetsov, 1977; Pfennig, 1978). The former two bacteria lack gas vesicles while *P. luteolum* does contain them. Since *Brachyarcus* has been described (Skuja, 1964) and has subsequently been found to be colorless (see Table 1), differentiation from these photosynthetic bacteria should be possible.

Morphological similarity with a colorless, gas-vacuolated soil bacterium called *Renobacter vacuolatum* (Nikitin, 1971, 448; 1973) also holds true for the size (0.7–1.0 × 1.6–1.8 μm). However, this bacterium appears to grow out, before cell division, to an S-shape rather than a 3-shape or pretzel. Similarity also exists with *Microcyclus* spp. Electron micrographs of the nonvacuolated *Microcyclus marinus* (Raj, 1977) or the gas-vacuolated strains of *M. aquaticus* (Van Ert and Staley, 1971) show cells that appear to be more vibrioid; in pure culture, the characteristic orderly arrangement in symmetric cell plates, as seen in *Brachyarcus* (in nature), is not seen in the genus *Microcyclus.* Furthermore, both of the *M. aquaticus* strains that were studied in greater detail had temperature optima of 37° and 30°C, respectively, and neither strain grew anaerobically. *Brachyarcus thiophilus* can be expected to be an anaerobic psychrophile.

Acknowledgments. Information on *Brachyarcus* kindly supplied by H. Skuja in 1968 is gratefully acknowledged. M. Klug and R. Wetzel (Kellogg Biological Station, Michigan State University) supplied data on Wintergreen Lake for 22 July 1975.

CHAPTER 14.10

The Genus *Pelosigma*

PETER HIRSCH

The Danish scientist E. Warming observed, during a walk along Kallebo Beach in 1874, a reddish discoloration of mud and decaying algae. His microscopic investigation of a sample started the now-famous study of "bacteria living on Denmark's coasts" (Warming, 1875). One of the organisms he found in "stinking mud at the height of decay" at several locations was a highly unusual, flat and striated, motile "bacterium" (which he called *Spiromonas cohnii*) that resembled a flagellate *Spiromonas* previously described from Switzerland. Although Warming himself was not quite sure of what he saw, his drawings are remarkably accurate illustrations of bacteria that can still be found in hypolimnia and on anaerobic sediment surfaces.

About 40 years later, these organisms were observed again and described as the bacterial genus *Pelosigma* (Lauterborn, 1913, 1915). Lauterborn clearly stated that a bacterium could not belong to a flagellate genus, but otherwise his observations confirmed the findings of Warming. Another 40 years later, a study on Swedish lakes revealed *Pelosigma* organisms in many different locations (Skuja, 1956). But now the old theory that this organism was a flagellate—at least in part—was revived. Skuja was convinced that he had found another example of a flagellate/bacterium symbiosis, and he produced detailed drawings of various stages of such consortia. Nevertheless, the genus name *Pelosigma* was retained for the consortium for both the flagellate and the bacterium organisms.

Detailed microscopic investigations of aquatic microorganisms and the study of several lakes and ponds in the United States and northern Germany revealed the presence of *Pelosigma* spp. in many locations, often in large numbers (P. Hirsch, unpublished observation). These studies allowed a preliminary description and interpretation for the eight edition of *Bergey's Manual of Determinative Bacteriology* (Hirsch, 1974). Since then, many additional samples have been found to contain *Pelosigma* spp., and evidence is mounting that these are, indeed, bacteria living in sigmoid, bundle-shaped aggregates just as originally drawn by Warming (1875) and described by Lauterborn (1913, 1915). Unfortunately, all attempts to cultivate these organisms so far have failed. Suggestions for enrichment cultures can be made, however, on the basis of the observed occurrence.

Habitats

The original description (Warming, 1875) does not contain many details on the natural habitat. It is not even clear whether *Spiromonas* (= *Pelosigma*) *cohnii* was found in mud of salt water, brackish water, or fresh water. However, the location "Limfjord" suggests brackish water, and the purpose of the article by Warming was to describe bacteria living at the coasts. Warming listed four locations for *S. cohnii* and stressed its occurrence in mud that was most active in the decaying process. He stated also that *S. cohnii,* like other bacteria discussed later in his paper, did not contain granules such as those of the organism now known as *Chromatium okenii*. His description of these granules makes it quite likely that he meant sulfur globules. Although obviously an anaerobe, *S. cohnii* thus did live in a sulfide-rich environment but did not store elementary sulfur.

The habitat of *Pelosigma* (= *Spiromonas*) *palustre* (Lauterborn, 1913) was likewise poorly described: fresh water; in the decaying sediment especially in ponds with characean algae.

The observations of Skuja (1956) could be added to the habitat description, if one accepts the interpretation that his *Pelosigma* organisms indeed were identical with those seen by Warming and Lauterborn. Skuja found *Pelosigma* spp. in Swedish lakes (Hönsan, Lushavet, Munkbosjön, Tjärnatjärn), usually at depths ranging from 10 to 14 m. Although he did not describe these environments chemically or physically, some information can be obtained from the list of accompanying bacteria. Skuja mentioned *Peloploca* spp. *(P. pulchra, P. fibrata, P. taeniata), Macromonas mobilis, Achroonema* sp.,

This chapter was taken unchanged from the second edition.

Table 1. Occurrence and morphological characteristics of *Pelosigma* spp. and some data on their environment.

[a]Not determined.
Data from P. Hirsch, unpublished observations.

Pelonema tenue, Achromatium oxaliferum, *Gigantomonas cucullata, Ochrobium tectum, Beggiatoa arachnoidea*, *Leukobium maior, Pelochromatium roseum,* and *Thiocystis violace* (nomenclature sensu Skuja, 1956). These bacteria are generally known to be anaerobic or microaerophilic, hypolimnetic organisms, many of which are found in sulfide-rich environments. Thus, we can expect the presence of low sulfide concentrations in an otherwise mostly anaerobic and dark environment.

More information comes from recent observations on *Pelosigma* habitats (Table 1; P. Hirsch, unpublished). The presence of *Pelosigma* spp. appears to be correlated with anaerobic conditions and, generally, temperatures below 11 °C. Like *Brachyarcus* spp., often found in the same location, *Pelosigma* spp. can be expected to be psychrophilic. It should be pointed out, however, that *Pelosigma* spp. have been found occasionally at higher temperatures.

The presence, in Wintergreen Lake (Michigan), of sulfide together with measurable concentrations of dissolved methane during *Pelosigma* occurrence points to a need of these organisms for a low redox potential.

Isolation

From the data given by Warming (1875), by Lauterborn (1915), by Skuja (1956), and in Table 1, an enrichment procedure could be conceived. It would consist of inoculating an anaerobic medium of pH 7.5 that contains organic matter (such as organic acids, amino acids, etc.), a mixed vitamin solution and, perhaps, a low concentration of sulfide (10^{-4} M or less). The sample for inoculation should be drawn anaerobically, and it should be kept at temperatures below 10°C. Incubation would be in the dark at 5–10°C.

Identification

All *Pelosigma* spp. observed were more or less flat, band-shaped aggregates of slender, long, and S-shaped bacterial rods. The aggregates appear to be formed preferentially by four cells or by multiples of four. At least one end of the aggregates appears to be more pointed. If a flagellar structure is present, it is located at the more pointed end. The overall length of the aggregates (9–25′30′ μm) is not the length of the individual, component rod, since uneven elongation and cross-division occur. The maximum width of aggregates is 5–11 μm and depends on the number of rods in the aggregate (Fig. 1).

At present, there are two species recognized (Hirsch, 1974): *Pelosigma cohnii* (Warming) Lauterborn 1913, 100 (synonym: *Spiromonas cohnii* Warming 1875, 370) and *P. palustre* Lauterborn 1915, 418. Both species show great morphological similarity but differ in size. Aggregates of *P. cohnii* are 1.2–4 μm wide and 9–20 μm long, while those of *P. palustre* are 8–10 μm wide and 20–25 μm long. The aggregates of *P. cohnii* are usually pointed at both ends

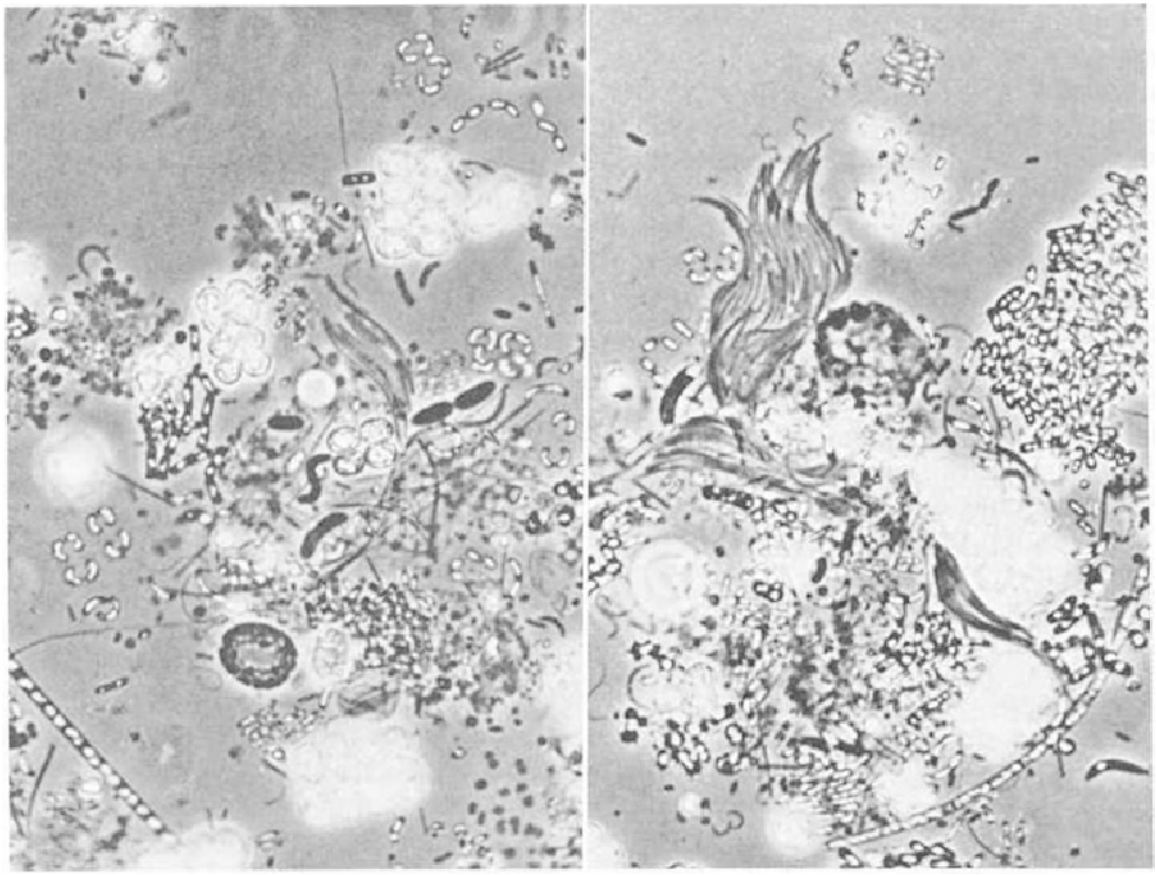

Fig. 1. A mixed bacterial flora with *Pelosigma* palustre cell aggregates from Wintergreen Lake (Michigan), collected from 4.5 m on 5 August 1970. × 1,280.

(and often flagellated on both ends), they are actively motile, and the individual cells measure approximately 0.4 µm in diameter (from the drawings of Warming, 1875). The aggregates of *P. palustre* normally show only one pointed end; they are much less actively motile, and flagella have not been seen. They occur in freshwater habitats.

The *Pelosigma* aggregates found by Skuja (1956) were thought to surround a colorless flagellate which multiplied by longitudinal fission. One to eight (usually four) colorless, S-shaped rods were kept by the flagellate "subpellicularly" with the ends sometimes sticking out. The aggregate (consortium) of bacteria and flagellate was described as "*Pelosigma cohnii*"; the overall sizes were 1–7 × 11–27 µm. The bacterial component was 0.3–0.4 × 7–15 (20) µm in size, colorless, without any granules, and sometimes yellowish pigmented. Cross-division was not synchronous with the longitudinal fission of the monad. The consortium did not have two flagella; the aggregates seen by Warming were likewise not supposed to have front and rear flagella—despite the fact that Warming (1875) mentions these and has actually drawn three double-flagellated aggregates (Table VII, Fig. 4a, 4c by Warming). The consortium was thought to be "oligothiophilic" and possibly involved in the decomposition of cellulose and/or hemicelluloses.

The aggregates described in Table 1 (Fig. 1) were, in general, 19.5 µm long and either 5–6 or 10–11 µm wide; thus, they resembled *P. palustre*. One sample (Wintergreen Lake, 4.5 m, August 1970) had much larger aggregates with thinner cells. None of the numerous aggregates seen contained anything that could have resembled a flagellate. Only two cases of flagellation and motility were seen; in both cases, the flagellum had the appearance of bacterial flagella, with a permanent, constant wavelength. Therefore, the author believes that such visible flagella constitute tufts of several prokaryotic flagella, attached polarly to each individual bacterium and combined to form the visible structure. Another argument against a eukaryotic flagellum would be the absence of two flagella from the "dividing" cell pole (as would be formed during longitudinal fission of a eukaryotic flagellate).

Instead, the *one* "flagellum" (tuft) is located on the nondividing cell pole. Occasional bipolar flagellation (as has been observed by Warming) would be expected to occur in polarly flagellated bacteria. The transparent area in between the aggregate's bacteria is probably filled with an extracellular, common polymer. It is also possible that there exist, in nature, *Pelosigma*-like consortia of S-shaped bacteria with colorless flagellates. Only observation of laboratory cultures and directly embedded and sectioned natural material could solve this problem. For the time being, it may be advisable to restrict the name *Pelosigma* to the bacteria that are agreed upon by all observers.

Acknowledgments. This work was supported and encouraged by G. Lauff, Director, Kellogg Biological Station of Michigan State University. Data on Wintergreen Lake and kind hospitality were provided by M. Klug and R. Wetzel during part of this work. The author is also grateful to D. E. Caldwell for information on Little Lake (Wisconsin) and to J. Overbeck (Plön) for information and help with Lake Plußsee. Kellogg Biological Station Publication No. 402.

CHAPTER 14.11

The Genus *Siderocapsa* (and Other Iron- and Manganese-Oxidizing Eubacteria)

HANS H. HANERT

This chapter discusses those species of *Siderocapsa* and members of the family Siderocapsaceae (Pribram, 1929) whose morphology, ecology, and, to some extent, culture physiology have been so exactly described that, in spite of disagreement concerning their taxonomic position, there can be no doubt of their existence and great ecological significance. The discussion concentrates on such existing and ecologically significant representatives of this family in order to preserve the practical orientation of this Handbook. Information on many genera and species whose position is uncertain has been drawn together in *Bergey's Manual of Determinative Bacteriology,* eighth edition (Buchanan and Gibbons, 1974; contributor G. A. Zavarzin) and seventh edition (Breed et al., 1957; contributor R. S. Breed in cooperation with H. Beger) and by Dorff (1934). A comparison of the genera and species treated in these references provides a bird's-eye view of this entire group of organisms.

The family Siderocapsaceae is defined as unicellular, nonfilamentous or nonstalkforming, iron and/or manganese bacteria that are able to deposit these metal oxides under natural conditions, on or in capsules or on extracellular mucoid material excreted by these bacteria. This definition is taxonomically rather imperfect, but for practical purposes it is quite adequate. That the validity of this family, in particular of the species of the genus *Siderocapsa*, has often been questioned is to be ascribed exclusively to the present taxonomic inadequacy of the definition. Such questions have been raised most recently by Dubinina and Zhdanov (1975); but a final clarification of the taxonomic question will not be possible until the complete developmental cycle of these bacteria in their natural habitat has been clearly described. Culture experiments are doubtless very helpful here, but they cannot provide a final clarification of the taxonomic question as long as the natural development of the organisms remains unknown.

Merely because there have been controversial questions of taxonomy it does not follow that these bacteria do not exist. Their existence and great ecological significance have become firmly established in the last decades through the discovery of their mass development in the hypolimnion of many lakes.

Habitats

Occurrence and Natural Mass Development

Siderocapsaceae are widely distributed in nature (see Table 1). They are found in all habitats which contain iron and manganese. They were first found in meadow and swamp ditches and mesosaprobic flowing streams, as well as in stagnant waters (Dorff, 1934; Drake, 1965; Galinsky and Hanert, 1979a; Hardman and Henrici, 1939; Molisch, 1910; Naumann, 1921). The organisms occur in these habitats as epiphytes on submerged water plants or on growths of exposed slides, or they are free-living and neustonic in metallic, glossy, iron oxide films on the water. A second important source of these organisms is deep wells, pipes, and waterworks, as described by Beger (1949) and by Hässelbarth and Lüdemann (1967). Greatest development of Siderocapsaceae has been found in the hypolimnion of lakes, often near growths of *Metallogenium.* At present, five species of the genus *Siderocapsa* (see Table 1) have been shown to be planktonic, not sessile, and so are not susceptible to slide growth (Kalbe, 1965; Redinger, 1931; Skuja, 1948, 1956; Wawrik, 1956).

The occurrence of Siderocapsaceae is not limited to typical freshwater habitats. As the investigations by Ten (1967, 1968, 1969) have shown, the family Siderocapsaceae *(Naumanniella polymorpha)* occurs in brown forest soils and iron-manganese crusts on soil-forming rocks as well. A marine *Siderocapsa* has been found in the iron bay of Palaea Kameni in Santorini, Greece (Hanert, 1981).

In all habitats, the most characteristic feature of *Siderocapsa* is its capacity to form

This chapter was taken unchanged from the second edition.

Table 1. Spectrum of Siderocapsaceae habitats and environmental parameters.

Habitats	Organisms	Environment	Physicochemical basic conditions inferred from natural occurrence or culture experiments
Iron-rich meadow and swamp ditches, flat pools (often stagnant) and mesosaprobic flowing streams	*Siderocapsa*		
	S. treubii	Typically epiphytic (attached to submerged roots and leaves of water plants; also on growth on slides; mesosaprobic waters)	Aerobic, organotrophic, pH 6.2–8.7
	S. major	Neustonic and epiphytic	As above
	S. monoica	Epiphytic	Aerobic tending to microaerobic, organotrophic
	Siderocystis		
	S. vulgaris	Ongrowth in the upper water layer	Aerobic, organotrophic, pH 6–7
	S. confervarum	Forming large iron aggregates on algae	Aerobic, organotrophic, pH 6–7
Wells, pipes, and waterworks	*Siderocapsa*		
	S. botryoides		
	Naumanniella		
	N. pygmaea	All found in cool waters of pipes and deep wells by Beger (1949)	Microaerobic, psychrophilic, organotrophic
	N. elliptica		
	N. minor		
	N. catenata		
	Siderobacter		
	S. gracilis		
	S. brevis		
	S. latus		
Lakes (planktonic forms)	*Siderocapsa*		
	S. anulata	Epilimnetic (water surface up to 6 m)	Aerobic, pH around 8.0, organotrophic
	S. coronata	Generally neustic, mass development at time of vernal thaw, also found at depths of 17–20 m	Aerobic to microaerobic, organotrophic
	S. arlbergensis	Epilimnetic in alpine pools with mass development at time of thaw	Aerobic, organotrophic, ferous iron up to 4 ppm, pH 4.5–8.5
	S. eusphaera	Generally hypolimnetic in larger meso and eutrophic lakes, at depths of 6–30 m, mass development	Microaerobic to aerobic, organotrophic
	S. geminata	Generally hypolimnetic, epilimnetic occurrence during vernal and autumnal circulation, at depths of 0–26 m, mass development in lakes	Microaerobic to aerobic, organotrophic
	Metallogenium		
	M. personatum	Hypolimnetic with mass development in the chemocline zone, where O_2 disappears, at an iron and manganese content of 1–5 ppm	Microaerobic, organotrophic
Soils, bottom deposits of water bodies, mud, iron manganese crusts on soil-forming rocks	*Siderocapsa* sp. (Ten, 1967)	Different soil types	Aerobic to microaerobic, organotrophic
	Naumanniella		
	N. polymorpha	Iron-manganese crusts and brown forest soils	Aerobic to microaerobic, possibly mixotrophic by manganese oxidation
	*Sidero*coccus		
	S. limoniticus	Mud horizons and bottom deposits of fresh waters	Microaerobic, neutral pH

large masses of iron and/or manganese oxide. This mass development of Siderocapsaceae, like that of the classical stalk- and threadforming iron bacteria, is often visible to the naked eye. Such readily visible deposits usually develop during vernal and autumnal circulation or during vernal thaw in alpine lakes and pools; deposits have been reported from all planktonic lake Siderocapsaceae, as well as from some epiphytic *Siderocapsa species* (Sokolova, 1959). A yearly cycle of Siderocapsaceae development with vernal and autumnal maxima in swamp ditches has been demonstrated and quantified for *Siderocystis vulgaris* (Galinsky and Hanert, 1979b). Detailed measurements which give some impression of Siderocapsaceae mass development in nature were taken by Dubinina, Gorlenko, and Suleimanov (1973) in the meromictic lake Gek-Gel', using the membrane-filter method (filters stained with erythrosine and treated with potassium ferricyanide and hydrochloric acid). These determinations counted up to 60,000 cells/ml at a depth of 27–29.5 m in the zone of massive development of *Siderocapsa eusphaera* (distinct narrow zone below *Metallogenium* growth zone) and also demonstrated the gradient growth of this organism (see also Sorokin, 1968).

Aspects of Siderocapsaceae Physiology Deduced from Environmental Variables

The old idea that Siderocapsaceae are aerobic iron bacteria arose from their initial discovery in epiphytic, neustonic, and surface film habitats. More recent discoveries of Siderocapsaceae in deep wells, and especially in the hypolimnion of lakes, have forced the revision of this idea. *Siderocapsa treubii*, *Siderocapsa major*, and *Siderocapsa monoica* (which are probably only growth forms of one species—Drake, 1965; Hardman and Henrici, 1939) as well as *Siderocystis vulgaris, Siderocystis confervarum, Naumanniella neustonica,* and possibly *Siderocapsa anulata* (see Table 1) appear to be the only markedly aerobic species. All the other Siderocapsaceae (*Siderococcus limoniticus, Naumanniella polymorpha,* and the lake *Siderocapsa* species) tend to be microaerophilic. The oxygen content of the mass growth zone in lakes is at the level where oxygen disappears (narrow water layer at the chemocline: $O_2 < 1$ ppm, $rH_2 < 19$, Fe^{2+} 1–2 ppm, Mn^{2+} 1–5 ppm; Dubinina, Gorlenko, and Suleimanov, 1973). These natural mass growth conditions established for *Siderocapsa eusphaera* are very similar to those for *Siderocapsa geminata* (Schmidt, 1976), which also grows under extremely microaerobic conditions (see later, Fig. 2a–f). Generalizing, and including the macroscopic observations concerning the onset of a mass development of lake *Siderocapsa* described by the first observers (see Table 1), it seems that optimal Siderocapsaceae growth takes place at the beginning of a change from extremely reduced to oxidized conditions in a neutral-to-light alkaline environment.

A more essential difference between classical stalk- or threadforming bacteria and capsular iron bacteria appears to be the latter's obvious growth dependence on organic material. It appears to be no accident that Siderocapsaceae have not yet been found in iron springs or mineral water very poor in organic substances (with the exception of certain results concerning very unsure forms obtained by Beger, 1949). From this standpoint, classifying Siderocapsaceae as a chemolithotrophic bacterial group (Buchanan and Gibbons, 1974) appears less justified and a physiologically indeterminate classification would correspond better to the facts and would avoid invalid inferences. Until now, only *Naumanniella olymorpha* cultivated by Ten (1968, 1969) in Beijerinck's $MnCO_3$ medium appeared to have a certain probable capacity for mixotrophic growth by manganese oxidation.

For the other capsular iron or manganese bacteria, the natural conditions of the habitat suggest that the highest probability is organotrophic nutrition, possibly of the sort first postulated by Aschan (1907) (utilizing the organic portion of iron humates or other iron organic substances and precipitating ferric iron in or on the capsules).

Isolation

Enrichment

Table 2 lists suitable enrichment procedures for Siderocapsaceae. In particular, the procedures with natural water are extraordinarily simple, straightforward, and characteristic for the speedy enrichment of iron bacteria in general. In habitat-water samples maintained in cold storage or at room temperature without any stirring, a rapid growth of iron bacteria begins within a few days (often overnight). The growth can be recognized mostly by the formation of yellow to black-brown (iron and/or manganese oxides) flocs which sediment slowly. The Siderocapsaceae in general are no exception; nor, for example, is *Siderocapsa geminata*, observed in the hypolimnion of the "Pluβsee" (Plön, Germany) and investigated by Schmidt (1976), among others. Our own

Table 2. Procedures for Siderocapsaceae enrichment in natural waters and synthetic media.

A. Procedures using natural waters:	Procedure suitability and incubation time:
1. Maintenance of sample flasks (totally or $^2/_3$ filled) at 4°C and room temperature without any stirring. Flask size: up to 1 liter. Modifications: addition of 1 mg $MnCO_3$/liter or 1 mg $FeCO_3$/liter.	These procedures with natural waters seem suitable for the majority of all known Siderocapsaceae
2. Test tubes filled with sample water underlayed by 1 ml natural sediment. Modification as above.	
3. 30- to 40-liter aquarium cultures adding 0.07 g yeast extract/liter and 1 mg $FeCO_3$/liter or 1 mg $MnCO_3$/liter (divided in 5 portions added in intervals of 2 days).	Incubation time: up to 3 weeks
B. Procedures with synthetic liquid media (frequently used with 0.1% agar):	
1. Yeast extract-$MnSO_4$ medium; Pringsheim (1949)—medium in modification of Tyler and Marshall (1967) and application according to Dubinina and Zhdanov (1975). Composition (%): yeast extract, 0.005; $MnSO_4$, 0.002; distilled water, 1 liter—in place of manganese, to the bottom of the test tubes iron oxalate or ferrous sulfide were added.	
2. Peptone-$MnCO_3$ medium; manganese-peptone media have been frequently used, see Schweisfurth, 1972. Composition according to Schmidt (1976) with addition of glucose (%): peptone, 0.00002; $MnCO_3$, 0.00002; glucose, 0.00002; distilled water, 1 liter.	Growth usually within 2–3 days
3. Yeast and beef extract-manganese-iron medium (according to Mulder and van Veen, 1963). Composition (%): $MnCO_3$, 0.2; $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$, 0.015; Difco yeast extract, 0.0075; beef extract, 0.1; cyanocobalamin, 0.005 mg/liter; Na-citrate-2-hydrate, 0.015; distilled water, 1 liter.	
4. Starch-$MnCO_3$ medium (Zavarzin, 1964—medium modified according to Dubinina, 1970). Composition (%): starch, 0.1; $MnCO_3$, 0.5 (freshly prepared); distilled water, 1 liter.	
C. Procedures with solid media for isolation: Media as B 1–4 with 1–1.5% agar in petri dishes.	Growth within 2 days; iron and/or manganese oxidation within 7 days

samples from the same site behaved in the same way and led within a week to an intensive development of *Siderocapsa geminata* in the sample flasks.

A second suitable enrichment method involves the use of 30- to 40-liter aquaria cultures with habitat water after the addition of 0.007% yeast extract and 0.0001% $FeCO_3$ or $MnCO_3$. At first, within 2 days after the culture start and before the addition of yeast extract and $FeCO_3$, thread-forming bacteria develop. Then, 7 days after the addition of $FeCO_3$ and yeast extract and the start of desulfurication, an intensive development of Siderocapsaceae takes place at the end of the desulfurication phase. The Siderocapsaceae form an ochreous layer, 2–3 mm thick, on the water surface. This method makes enrichment possible by more closely simulating natural conditions, particularly with *Siderocapsa treubii* and *Naumanniella neustonica,* which both form dense nests of bacterial cells. The first enrichment of a *Siderocapsa* strain, as carried out by the discoverer of this organism group, is fundamentally similar; *Siderocapsa treubii* was cultivated as an epiphytic growth on water plants in aquaria with the addition of 0.1% $MnCl_2$ (Molisch, 1910). Test tubes with sample water underlayed with natural sample mud were successfully used for the enrichment of *Siderococcus limoniticus* and showed growth 3–4 days after the beginning of the culture (Dorff, 1934). The enrichment of *Siderocystis confervarum,* an organism which grows in direct contact with filamentous algae, also uses natural sample water.

In Table 2, section B, four synthetic media are presented which have proven to be particularly suitable for cultivating Siderocapsaceae. Yeast extract is particularly suitable as an organic carbon and nitrogen substrate, as is pep-tone and beef extract in weak concentration; iron and manganese are best given as carbonate or sulfate salts. On the basis of the presently available facts, in particular the culture experiments by Dubinina and Zhdanov (1975) and Schmidt (1976), as well as indications from the older literature (summarized by Schweisfurth, 1972), Siderocapsaceae can be regarded as organisms that grow well in weak concentrations of organic media, when cultivated in a neutral environment under aerobic to microaerobic conditions. Growth without oxygen appears to be impossible. Table 3 provides a bird's-eye

Table 3. Enriched or presumably isolated Siderocapsaceae.

Organism	Enrichment or isolation procedure[a]
Siderocapsa	
S. treubii	Enriched: method A3 (Moldau-water resp. tap water + 0.1% $MnCl_2$ as epiphytic growth; Molisch, 1910). Enriched: method A3 (swamp-ditch water + 0.007% yeast extract + 0.0001% $FeCO_3$; growing as neustic form in the water surface layer).
S. eusphaera	Enriched: method B1; presumably isolated: on medium B1 with 1% agar by Dubinina and Zhdanov (1975).
S. geminata	Enriched: method A1; presumably isolated: on media B1-4 by Schmidt (1976).
Naumanniella	
N. neustonica	Enriched: method A3 (swamp-ditch water + 0.007% yeast extract + 0.0001% $FeCO_2$; growing as neustic form in the water surface layer).
N. polymorpha	Presumably isolated: on Beijerinck's medium (K_2HPO_4, 0.05%; NH_4Cl, 0.05%; $MnCO_3$ or $Mn(HCO_3)_2$, 1%; agar, 2%); further on Aristovskaya's (1965) medium (ulminofulvate complex) and on iron ammonium salt of citric acid by Ten (1968, 1969).
Ferribacterium	
F. duplex	Enriched: modified method A2 underlayed with peat and iron bars, Brussoff (1916); presumably isolated: in iron ammonium citrate medium, Brussoff (1916).
Siderocystis	
S. vulgaris	Enriched: method A1 in 3-liter Erlenmeyer flasks $^3/_4$ filled with swamp-ditch water; growing as rust-spot ongrowth on the flask walls at room temperature, H. H. Hanert (unpublished observations).
S. confervarum	Enriched: method A1 in 100-ml flasks filled to the top with swamp-ditch water and some algae threads, cultivated at room temperature and near a window (daylight).
Siderococcus	
S. limoniticus	Enriched: method A2, coupled with slide and capillary ongrowth, Dorff, 1934; Zavarzin, 1972; Kutuzova, 1974.
S. communis	Enriched: in ferrous ammonium citrate, Dorff, 1934.

[a]See Table 2 for methods.

view of all Siderocapsaceae that have been enriched so far.

Isolation

The isolation of Siderocapsaceae is much more a problem of identification than the application of particular isolation techniques. As Dubinina and her co-workers indicated for *Siderocapsa eusphaera* (1973, 1975), Schmidt for *Siderocapsa geminata* (1976), and Ten for *Naumanniella polymorpha* (1968, 1969), pure cultures of these organisms could be conventionally produced without difficulty in liquid and solid media, using serial solution or plating techniques, respectively (Table 3).

The main problem in isolating Siderocapsaceae is the question of relating the isolated organism with the Siderocapsaceae organism of the inoculated material from the natural environment. The isolated strains of *Naumanniella polymorpha, Siderocapsa eusphaera*, and *Siderocapsa geminata* show—as described by the authors—an extreme polymorphism and a quite complex cycle of development, whereas it has not yet been possible to demonstrate corresponding changes directly in the natural environment immediately from an individual object. This is one of the reasons why the task of identifying Siderocapsaceae has such crucial importance at the moment and why isolation work cannot lead to really secure results so long as the individual developmental cycle remains unexplained.

Identification

Initial Identification

Siderocapsaceae are defined purely morphologically, without physiological features, and the morphological definition provided by the people who first described them refers to their morphology in their natural environment or in habitat water cultures. This fact is the starting point from which all identification work has to proceed. The second important point to make is that the first morphological descriptions of the organisms corresponded to the then present state of microscopic technology; the descriptions used only light-microscopic photographs or drawings and the natural ultramorphology and ultrastructure remained unknown. *Siderocapsa anulata* is the only Siderocapsaceae which, at the time of its discovery, was described by means of an electron microscope (Kalbe et al., 1965) so that a clear picture of its morphology was produced which was completely adequate for purposes of identification.

The description which defines the morphology of the Siderocapsaceae contains three components: the bacterial cell, the capsule or excreted gelatinous material, and iron and/or manganese compounds deposited in or on the excreted

material. The capacity to form capsule-like material has been recently shown for *Siderococcus limoniticus* (Kutuzova, 1974), which had previously been regarded as a non-capsule-forming Siderocapsaceae, so that this component appears to be common to all Siderocapsaceae. For the identification of Siderocapsaceae, the analysis of natural ultramorphology of these three components is of crucial importance, and thus, in virtue of new ideas concerning the pleomorphic development of these organisms, the analysis of the individual natural development must be added as a further new component.

Identification by Analysis of the Natural Ultramorphology and Development

The methods that are indispensable for a clear identification, which must be carried out with all Siderocapsaceae whose existence has been made certain by repeated finds, and ecological descriptions are summarized in Table 4. They relate to the visualization of the bacterial cell, the differentiation of cell and capsule or slime material, the ultramorphology of the capsular material, the specific evidence for the presence of iron and manganese, the ultramorphology of the iron deposits, and the analysis of the individual development under natural conditions.

Light Microscopy, Staining, and Differentiation of the Bacterial Cell. In phase contrast microscopy, the central cells can only be distinguished from the surrounding capsule which contains metal oxide by their differing light reflection. This appearance can also be created by the shape of the capsule, and cell and capsule staining are indispensable. Carbolfuchsin and fluorescence staining have been found suitable for cell staining. Erythrosine staining has been applied just as successfully by other authors. In combination with the Prussian blue

Table 4. Procedures necessary for identification of Siderocapsaceae.

Procedure	Methods for realization
1. Exact light-microscopic visualization of the bacterial cell and surrounding iron capsule	a. Phase-contrast observation: Yellowish iron capsule with light-refrangible central bacterial cell. b. Direct microscopic control of capsular ferric iron dissolution by adding 5% HCl to the edge of the cover glass (suspension preparations), immediately followed by carbolfuchsin staining of the central cell under microscope. c. Carbolfuchsin-Prussian blue double-staining (air-dried preparations): Prussian blue solution (70 ml 0.1% HCl + 30 drops 2% $K_4[Fe(CN)_6]\cdot 3H_2O$); 10 min (cuvette); washing with water (cuvette); 10 min into nonheated Ziehl-Neelsen carbolfuchsin (cuvette). d. Benzidine staining for manganese reaction: Material on slides or filters is first wetted with benzene, and 2 or 3 drops of 0.5% benzidine hydrochloride in 50% acetic acid are applied to the wet surface. After 1–2 s, the benzidine is removed with filter paper (Dubinina, Gorlenko, and Suleimanov, 1973). e. Flourescence staining of the bacterial cell: air-dried preparations covered with a filtered FITC solution for 5 min (0.1 N Na_2CO_3 + 0.1 $NaHCO_3$ in 3:2 proportion + 3.5 mg FITC per 10 ml)—washing with the same buffer. Very suitable for visualization of bacterial cells in rust-spot-forming bacteria.
2. Scanning electron microscopy and electron probe microanalysis	a. Stereoscan: Necessary for detection of the slimy nature of the capsule as well as the globular ferrihydrite particles in rust spots. Preparation in the usual way, placing a drop of material directly onto the specimen stub or using ongrowth method (specimens metal-coated). Figs. 1 (without 1h), 2a–d, and 2h–k. b. Electron-probe microanalysis for proof concerning iron or manganese incorporation of the capsules using X-ray analysis (area- or point-scanning). Figs. 1h, 2e, f, and l.
3. Transmission electron microscopy	Realization in the usual way using formvar-coated grids (ongrowth method for sessile Siderocapsaceae; see also Kutuzova, 1974, 1975; Kutuzova, Gabe, and Kravkina, 1972); cell observation is better when capsular iron or manganese is removed by dissolving.
4. Direct microscopic observation of developmental cell cycle in micro-chambers or reverse light microscope	The possibility of pleomorphic development of Siderocapsaceae members makes it necessary to compare cell development in chambers filled with habitat water or culture media for identifying growing cells with the natural originals. This should be possible by directly proving stalk excretion from the apical cell in the way done for *Gallionella* (Hanert, 1974) or by using the reverse microscope (Schmidt, 1976, cell cycle of *Siderocapsa geminata*; see also Dubinina and Zhdanov, 1975, cell cycle of *Arthrobacter siderocapsulatus*).

reaction for iron and the benzidine hydrochloride reaction for manganese, a differentiating double staining of the cell and metal-containing capsule is possible. Fluorescein isothiocyanate (FITC) fluorescence staining is especially suitable for the visualization and differentiation of the bacterial cells from iron/manganese oxides in rust-spot-forming bacteria, since the inorganic deposits are not stained (Hanert, 1981). A specific staining of the capsular polysaccharides has not yet been carried out, so that the capsule until now has only been made recognizable by staining the iron or manganese which it contains.

Ultramorphology of the Capsule and Excreted Gelatinous Material. In all the Siderocapsaceae material which has been sampled in the natural environment or in habitat water cultures, the capsules showed a very characteristic slime-thread ultramorphology and structure, which can be recognized best with scanning electron microscopy. The capsules are slimy but, nevertheless, form casings which the bacteria vacate, leaving a noticeable hole when they depart. The bacteria produce this gelatinous thread slime, cover themselves with it—at this stage the bacteria cannot be recognized with a scanning electron microscope—and break through the capsule after a certain time. Even though this process cannot be observed in vivo, the electron microscope pictures allow scarcely any other inference. (See Fig. 1a–c, *Siderocapsa treubii*; Fig. 1d–f, *Siderocapsa* sp.; Fig. 2a–d, *Siderocapsa geminata* from flocs.) On the basis of this characteristic ultramorphology, it seems reasonable to think that the slime capsule might be a very characteristic feature of genuine Siderocapsaceae. It should be noted that the gelatinous slime of the Siderocapsaceae also resembles ultramorphologically those thread slimes which we have observed without the formation of capsules in *Metallogenium* habitat water cultures (Fig. 2g–k, *Metallogenium* flocs).

Table 5. Siderocapsaceae which have clearly been shown to exist by repeated finds.

Organisms	Morphological features and characteristic ecology
Siderocystis	
S. confervarum	Large ovoid iron precipitations on *Conferva*-algae; iron-containing swamp ditches.
S. vulgaris	Forming rust spots up to 1 mm in diameter on exposed glass slides (Fig. 1j); iron-containing swamp ditches.
Naumanniella	Slim rods with a thin, sharply limited iron capsule in the form of a torus (marginal thickening); single and in short chains.
N. neustonica	Rod-shaped cells, including the torus, 1.8–3.3 by 4.9–10 μm; surface of iron-bearing well and swamp water.
N. polymorpha	Ellipsoid rods of 0.7–1.0 × 1.0–2.0 μm that form coccoid cells by budding and fission; thin capsules; manganese- not ferrous iron-oxidizing; colony-forming in manganese carbonate or manganese acetate agar; brown forest soils and rock crusts.
Siderococcus limoniticus	Cocci (0.2–0.5 μm in diameter) without capsules (recently, capsule-like formations in which iron-oxide deposition takes place have been found by Kutuzova, 1974); in mud horizons and zone growth in culture.
Siderocapsa	Coccus resp. ovoid or short rods, single or in groups in a very thick, slimy iron capsule.
S. treubii	(Including the intermediary form of *S. major* and *S. monoica* found by Hardman and Henrici, 1939 and Drake, 1965.) Coccoid cells of 0.6–1.6 μm in diameter and small rods 0.4–1.0 × 2 μm; single or in groups; most frequently of 6–8 up to 30 cells and more in mucoid capsules averaging about 2 μm by 4.5 μm with round, elliptical, or irregular outer edge surrounded by thick, rust-brown deposits of iron (light microscopic photographs by Hardman and Henrici, 1939).
S. anulata	Single coccus (0.2–0.5 μm in diameter) surrounded by sharply limited ferric iron ring (1.2–1.9 μm), excellent electron microscopic photographs by Kalbe, Keil, and Theile, 1965; planktonic and epilimnetic.
S. coronata	Two to eight cocci (maximal 1.2 μm) in one capsule (up to 24 μm in diameter); aggregating to coenobia of up to 90 capsules and a length of 400 μm (described and pictured by drawings; Redinger, 1931); in alpine lakes.
S. arlbergensis	Cocci (0.4–1.0 μm) normally in pairs in capsules (diameter 6–15 μm); coenobia similar to *S. coronata*, but single capsules not fusing; light-microscopic photographs by Wawrik, 1956; planktonic and neustic in alpine pools.
S. eusphaera	Coccoid to ovoid (1–2 μm) cells up to 60 in large capsules (regular spheres up to 50 μm in diameter); capsules occur singly (drawings by Skuja, 1948); planktonic and hypolimnetic in large lakes.
S. geminata	Ovoid cells (0.5 × 0.8 μm) usually in pairs in round capsules (7–11 μm in diameter); capsules occur singly (drawings by Skuja, 1956); planktonic and hypolimnetic in lakes.

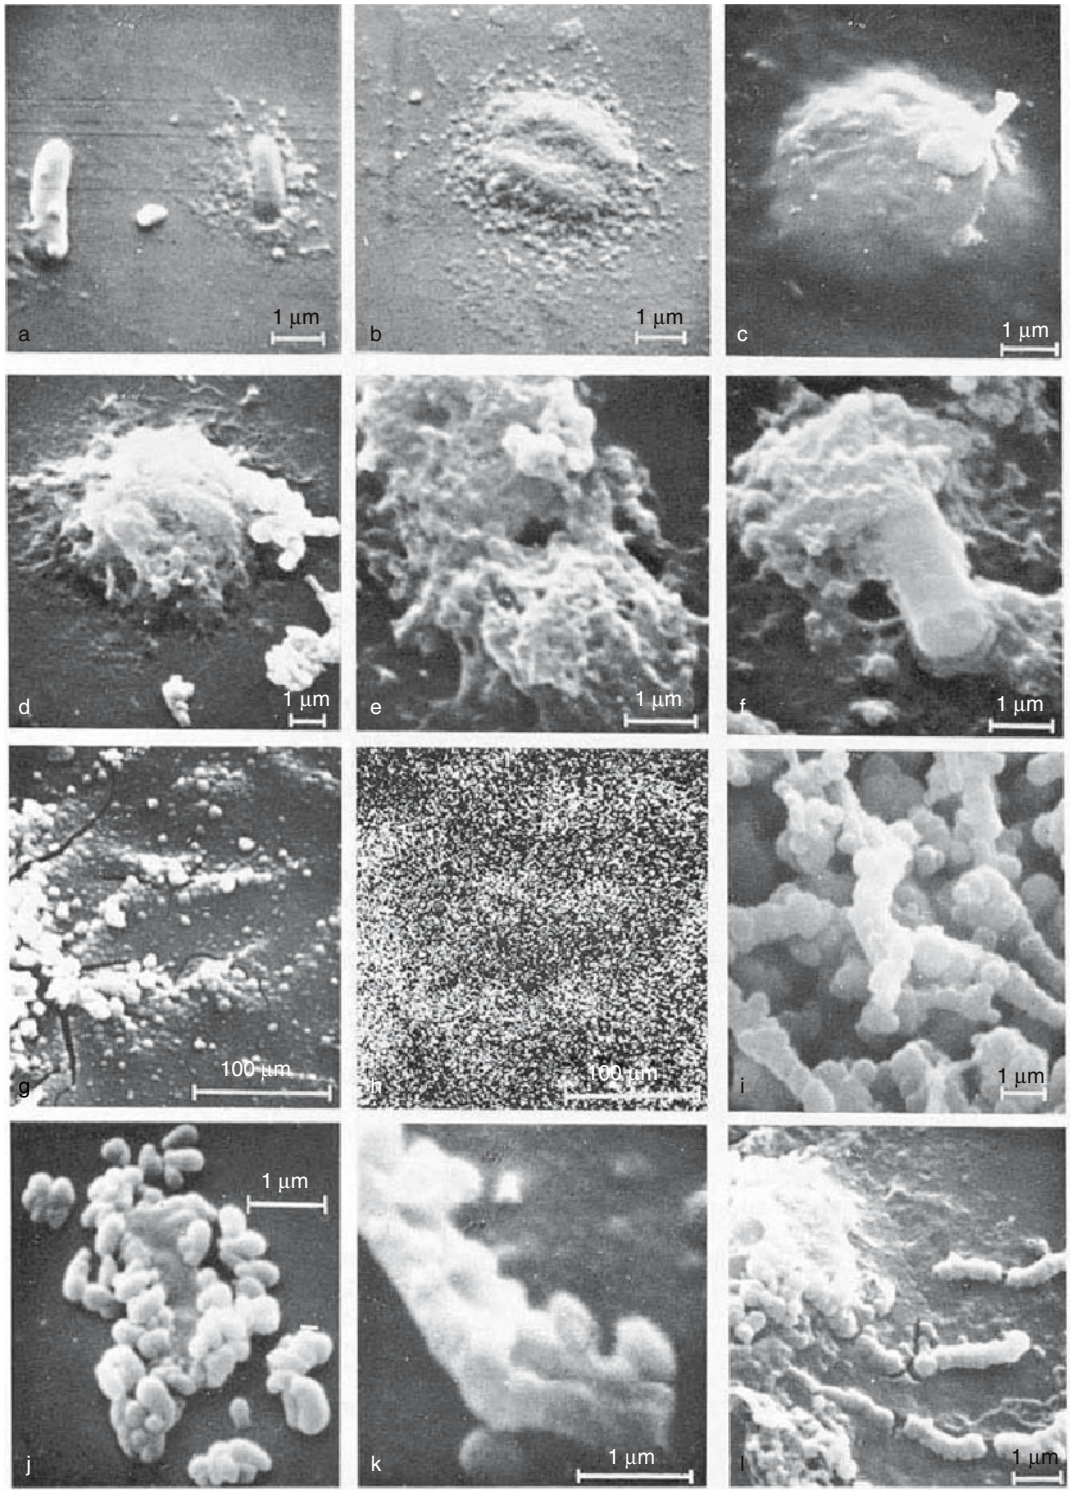

Fig. 1. Identification and differentiation of Siderocapsaceae cells, capsules, and ferrihydrite particles. (a–c) *Siderocapsa treubii*, in situ growth on slide in aquarium-natural water culture: (a) single cells at the initial phase of capsule formation; (b) two cells coated with slime and iron particles; (c) slime capsule completely coating the cell. (d–f) *Siderocapsa* sp. from the Siderocapsaceae zone in the marine iron bay of Palaea Kameni, in situ growth on slide, Hanert, 1981: (d) thread-slime capsule; (e) capsule with two holes; (f) cell half-coated with thread-slime capsular material. (g–i) Globular, chain-forming ferrihydrite particles on the slime surface of the rust-spot bacteria (formed in the marine bay): (g and i) ferrihydrite particles; (h) FeKα picture to (g). (j) Single cell of *Siderocystis vulgaris* surrounded by ferrihydrite particles. (k) Single cell of the marine rust-spot-former surrounded by ferrihydrite particles. (l) Slime capsule of the marine *Siderocapsa* sp. coated with ferrihydrite particles.

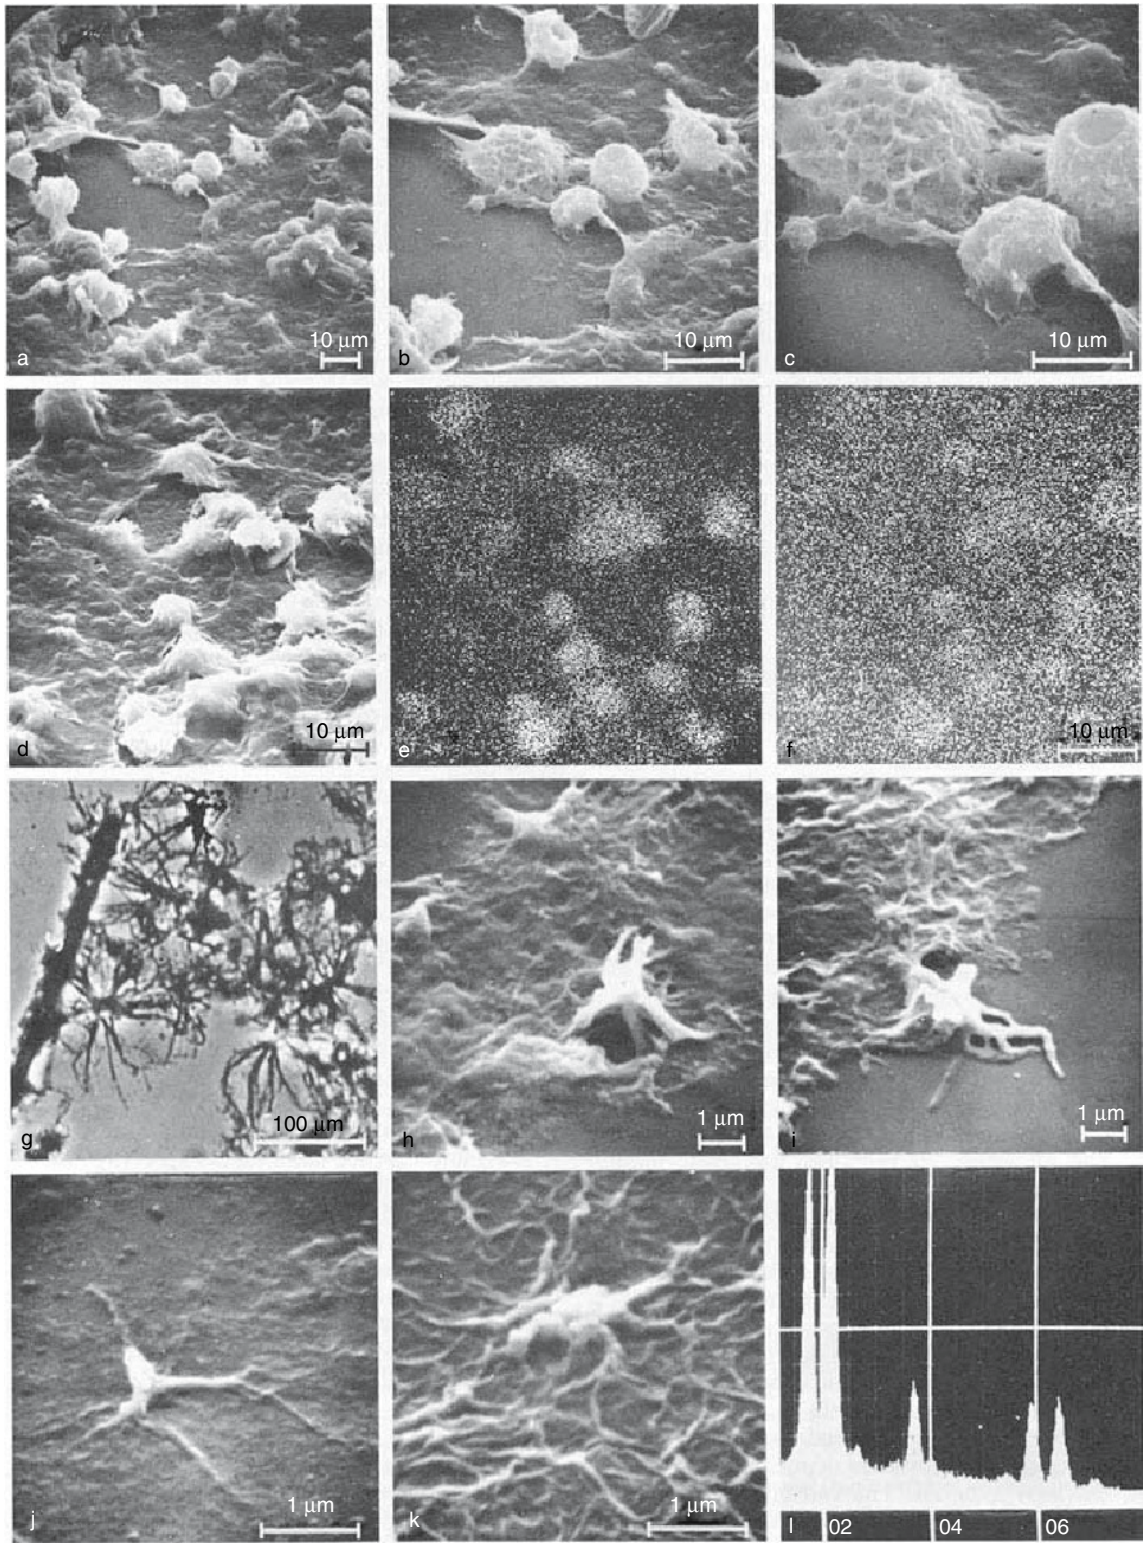

Fig. 2. Iron/manganese capsules and slimes of *Siderocapsa geminata* and *Metallogenium personatum,* (a–f) *Siderocapsa geminata*, flocs grown in Pluβsee sample flasks, three-quarters filled at a depth of 26 m in the natural habitat and maintained in cold storage at 4°C, where the *S. geminata* flocs formed in clear, natural habitat water: (a–d) capsules closed or with a hole; (e) MnKα (f) FeKα picture to (d), proving simultaneous presence of manganese and iron, the latter at a much lower level. (g–l) *Metallogenium personatum,* flocs grown in habitat water-sample flasks from 4°C at a depth of 27 m, Pluβsee: (g) light microscopic; (h–k) young *Metallogenium* organisms and thread-slime structure; (l) simultaneous manganese (MnKα, 5894keV) and iron (FeKα, 6398keV) evidence in the center of *Metallogenium* (k).

Ultramorphology of Deposited Iron Particles and Element-Specific, X-Ray Determination of the Presence of Iron/Manganese in the Capsules in Combination with Postulated Developmental Stages. There has been intensive discussion concerning the existence of tiny mycoplasma-like developmental and budding stages in certain iron and manganese bacteria, for example, in *Gallionella* (Balashova, 1969), in *Metallogenium* (Dubinina, 1970), and also in Siderocapsaceae (*Sidero*c*occus limoniticus,* Kutuzova, 1974; Kutuzova, et al., 1974; *Naumanniella polymorpha,* Ten, 1968, 1969; *Siderocapsa geminata*, Schmidt, 1976). Evidence which has previously been presented in favor of this hypothesis has largely been pictures obtained by transmission electron microscopy which, however, show only tiny dense particles.

Relevant here are observations on rust-spot-forming bacteria (rust spots in the Palaea Kameni Bay, Hanert, 1981; *Siderocystis vulgaris* rust spots, Galinsky and Hanert, 1979a). The iron oxides in these rust spots consist of tiny, spherical ferric iron particles which are often chainlike in form; these particles correspond to the iron bodies which have been analyzed as ferrihydrite by Tschukrov (1974). These particles consist exclusively of iron, which can easily be demonstrated by X-ray analysis (point-scanning) and dissolving in acids.

Another useful aid in structural analysis in this field is area-scanning electron microscopy in combination with element-specific scanning. The existence of both iron and manganese incorporation in the capsules can be indicated simultaneously (see Fig. 2d–f for *Siderocapsa geminata* and Fig. 2l for *Metallogenium*).

The methodological possibilities for analyzing natural individual development in vivo are represented in Table 4.

In summary, it should be emphasized that an adequate number of identification and culture methods are available for the investigation of Siderocapsaceae, which can be applied to those genera and species (Table 5) whose existence has been made certain. One of these forms is *Siderocystis confervarum,* which forms large, round, iron oxide aggregates on algae and can be found in profusion in iron-bearing swamp ditches in the vicinity of Braunschweig. The application of the methods described here to this bacterium has resulted in the surprising discovery that this organism lives not only on the surface of the algae but also within it. This bacterium might have a lytic function for this algae, similar to those lytic bacteria which colonize on the hyphae of fungi in natural habitats (e.g., *Phytophthora cinnamomi;* Nesbitt, Malajczuk, and Glenn, 1978).

Acknowledgments. I wish to thank the following organization and persons: The "Deutsche Forschungsgemeinschaft" for financial support; Ilona Koschik, Detlef Herz, and Bernd Hoppe for technical assistance in environmental measurements and preparation of cultures, stains, and photographs.

CHAPTER 14.12

The Genus *Fusobacterium*

TOR HOFSTAD

The genus *Fusobacterium* includes several species of obligately anaerobic, nonsporeforming, motile or nonmotile, Gram-negative rods. Some are slender, spindle-shaped bacilli, while others are pleomorphic rods with parallel sides and rounded ends. Their habitat is the mucous membranes of humans and animals.

During the last decade of the nineteenth century, several authors, among them Miller (1898), Plaut (1894), and Vincent (1896, 1899, 1904), observed spindle-shaped, or fusiform, bacilli in material from both the diseased and the healthy human mouth. Veillon and Zuber (1998), Lewkowicz (1901), and Ellermann (1904) were the first to cultivate fusiform bacilli. Loeffler, in 1884, observed pleomorphic rods in diphtheritic lesions of calves and doves. The same organism, identifiable with the *F. necrophorum* of today, was cultured by Bang (1890–1891) from necrotic lesions of a number of domestic animals and by Schmorl (1891) from an epizootic in rabbits.

The more pleomorphic fusobacteria without tapering ends have been described under different generic names. Examples are *Bacteroides*, *Sphaerophorus, Bacterium, Necrobacterium, Pseudobacterium, Bacillus*, *Actinomyces*, *Corynebacterium*, *Ristella,* and *Zuberella.*

The family name Bacteroidaceae was first used by Pribram (1929) for strictly anaerobic rods. Ten years earlier, Castellani and Chalmers (1919) proposed that the genus *Bacteroides* should only contain obligately anaerobic bacilli that did not form spores. Eggerth and Gagnon (1933) and Weiss and Rettger (1937) excluded the Gram-positive rods from the genus. The generic name *Fusobacterium* was proposed by Knorr (1923) for obligately Gram-negative bacilli that were fusiform. Prévot (1938), who argued that the generic name *Fusobacterium* (and also the names Bacteroidaceae and *Bacteroides*) was invalid, used the term *Sphaerophorus* for the nonmotile, pleomorphic fusobacteria, and the term *Fusiformis* for the fusobacteria that had tapered ends. The seventh edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957) divided the family Bacteroidaceae into three genera: *Bacteroides*, defined as rods with rounded ends; *Fusobacterium*, defined as rods with tapering ends; and *Sphaerophorus,* defined as rods with rounded ends that showed a marked pleomorphism and where filaments were common.

Cell morphology, therefore, had so far been the main criterion for the classification of the nonsporeforming, anaerobic rods. Physiological studies (Beerens et al., 1962; Werner, 1972a; Werner et al., 1971) and studies of DNA base ratios (Sebald, 1962) showed that there was insufficient evidence to separate the genera *Fusobacterium* and *Sphaerophorus.* In the eight edition of *Bergey's Manual* (Moore and Holdeman, 1974a) the genus *Fusobacterium* was restricted to anaerobic, nonsporeforming, Gram-negative rods which form butyric acid as a major endproduct from peptone or glucose (without isobutyric and isovaleric acids). Further, *Leptotrichia* (see The Genus *Leptotrichia* in the second edition) was reestablished as a genus for the saccharolytic fusiform bacilli producing lactic acid as the only major fermentation product.

Up to now, 12 human species of *Fusobacterium* have been adequately described (Table 1). The GC content of these species ranges from 26 to 34 mol%. In addition, *F. prausnitzii*, which has a GC content of 52–57 mol%, has been included in the genus. The species isolated most frequently from humans and animals are *F. nucleatum* and *F. necrophorum*, respectively. *F. simiae* is a new species which has been isolated from the mouth of the stumptailed macaque (*Macaca arctoides*) (Slots and Potts, 1982).

Habitats

As Normal Microbiota of Humans and Animals

All *Fusobacterium* species are parasites of humans and animals. Anaerobic Gram-negative rods with the same morphological and biochemical properties as *Fusobacterium* species have also been isolated from the hindgut of the

This chapter was taken unchanged from the second edition.

Table 1. The main human sources of *Fusobacterium* isolates.

Species	Normal flora: Mouth	Normal flora: Gastrointestinal tract	Clinical specimens
F. nucleatum	+		+
F. necrophorum		+	+
F. alocis	+		
F. gonidiaformans		+	+
F. mortiferum		+	+
F. naviforme	+		+
F. necrogenes		+	
F. periodonticum	+		
F. prausnitzii		+	
F. russii		+	
F. sulci	+		
F. ulcerans			+
F. varium		+	+

cockroach *Eublaberus posticus* (Foglesong et al., 1984) and the gastrointestinal tract of the grass carp *Ctenopharyngodon idella* (Trust et al., 1979).

The main human habitats of the different *Fusobacterium* species are listed in Table 1.

F. nucleatum is a constant member of the oral microflora of adults, but has also been isolated from the oral cavity of predentate children (Hurst, 1957; McCarthy et al., 1965). The principal habitat of *F. alocis* and *F. sulci* is the human gingival sulcus. The incidence of *F. periodonticum* in the human oral cavity is unknown. Occasionally, *F. naviforme* has been found in the mouth or the upper respiratory tract (Holdeman et al., 1977). The isolation of *F. necrophorum* from pleuropulmonary infections suggests that this organism is also able to live as a parasite on the mucous membranes of the oral cavity and upper respiratory tract of humans. The number of fusobacteria per milliliter of saliva has been estimated to be 5.6×10^4 (Richardson and Jones, 1958). In different surveys, fusobacteria have been found to make up from 0.4 to 7% of the cultivable dental plaque flora (Hardie and Bowden, 1974). There are, however, great individual variations. In patients with different forms of periodontitis, *F. nucleatum* is a predominant member of the subgingival plaque flora (Williams et al., 1976; Moore et al., 1982, 1983). Hadi and Russel (1969) reported a mean viable count of *F. nucleatum* per gram wet weight of gingival plaque material from patients with advanced chronic periodontal disease and acute ulcerative gingivitis of 3.3×10^7 and 9.3×10^7, respectively. In subjects with healthy gingivae, the corresponding figure was 5.7×10^6.

Fusobacterium makes up a small part of the fecal microflora of man, with individual variation ranging from about 7% to less than 1% of the cultivable fecalflora (Finegold et al., 1974; Finegold et al., 1975; Holdeman et al., 1976; Moore and Holdeman, 1974b; van Houte and Gibbons, 1966). The most prevalent species seem to be *F. prausnitzii*, *F. russii*, and *F. mortiferum*. Both the number of fusobacteria in feces and the relative frequency of the different species are influenced by the diet (Finegold et al., 1974; Maier et al., 1974; Peach et al., 1974). Thus, Japanese on a traditional diet rich in carbohydrate have a relatively high number of *F. necrophorum* in feces (Ohtani, 1970a; Ueno et al., 1974).

The occurrence of fusobacteria on the mucous membranes of the genitourinary tract is virtually unknown. Fusobacteria were not present in the normal microflora of the cervix of 30 healthy females examined by Gorbach et al. (1973), and Hite et al. (1947) found no fusobacteria in the healthy vaginas of pregnant women. Fusobacteria, particularly *F. necrophorum*, were, however, present in the vagina of pregnant women with trichomoniasis and in the postpartum uterus of such women. Spaulding and Rettger (1937) found *F. nucleatum* in the normal vagina but not in the vagina of pregnant women. Davis and Pilot (1922) and Brams et al. (1923) isolated fusiform bacilli (and spirochetes) from the clitoris region in females and from preputial secretions of 50 out of 100 men.

The habitat of *F. ulcerans* is unknown. The organism has been isolated from tropical ulcers (Adriaans and Drasar, 1987) and from a few specimens of mud (Adriaans and Shah, 1988). Tropical ulcer is a form of skin ulceration predominantly affecting children and is most commonly in the tropics (Robinson and Hay, 1985).

F. necrophorum is a normal inhabitant of the alimentary tract of cattle, horses, sheep, and pigs. Fuller and Lev (1964), in a study of the Gram-negative bacteria of the pig alimentary tract, found *F. necrophorum* to be present from the age of 43 days. Aalbæk (1972) isolated the organism from the colon of pigs in numbers up to 10^3 per gram of wet material, but in considerably higher number in the ileus, cecum, and colon of pigs with experimental enteritis. *F. necrophorum* has also been found in infections and in feces of other animals, such as mules (Nolechek, 1918), goats (Jensen, 1913), reindeer (Horne, 1898–1899), antelope (Mettam and Carmichael, 1933), macropods (Bang, 1890–1891; Samuel, 1983), wildebeest (Grainer, 1983), dogs (Jensen, 1913), rabbits (Cameron and Williams, 1926; Schmorl, 1891), rats (Lewis and Rettger, 1940), chickens (Jensen, 1913), and apes (Dack et al., 1935; Dack et al., 1937). It has also been reported in buffaloes, cats, guinea pigs, mice, snakes, tortoises, and fowl (Simon and Stovell, 1969; Weinberg et al., 1937).

Less is known about the presence in animals of the other *Fusobacterium* species. Fusiform bacilli, probably *F. nucleatum*, have been isolated from the alimentary tract of pigs (Aalbæk, 1977) and mice (Syed, 1972), and from the oral cavity and the throat of monkeys (Krygier et al., 1973; Pratt, 1927; Slanetz and Rettger, 1933), dogs (Slanetz and Rettger, 1933), cats (Prèvot et al., 1951), rabbits (Pratt, 1927; Slanetz and Rettger, 1933), and guinea pigs (Pratt, 1927; Spaulding and Rettger, 1937). Terada et al. (1976) isolated *F. necrogenes* and *F. mortiferum* from pig feces, and *F. perfoetens* has been found in piglet feces (van Assche and Wilssens, 1977). *F. necrogenes* is a member of the cecal flora of poultry (Holdeman et al., 1977). *F. russii* is a member of the normal oral flora of cats (Love et al., 1987) and has been mentioned as being part of the normal microflora of mice and pigs, as well as of the rumen flora of cattle (Smith, 1975).

As Pathogens of Humans and Animals

Next to members of the "*Bacteroides fragilis* group" and the black-pigmented bacteroides, *F. nucleatum* is the Gram-negative anaerobic organism most often encountered in human infections. Also, *F. necrophorum* is clearly pathogenic in humans. Before the advent of antibiotics and other antimicrobial drugs, this organism was frequently isolated from suppurative infections of the oral cavity and the upper respiratory tract and from pleuropulmonary infections. Reviewing the literature concerning anaerobic pleuropulmonary infections, Finegold (1977) found that *F. necrophorum* accounted for 24% of all anaerobic bacteria isolated from 358 cases. Today the organism is less commonly isolated from human infections. *F. nucleatum* is usually found associated with other anaerobic and/or facultative organisms. On a percentage basis, *F. nucleatum* and *F. necrophorum* have been isolated in pure culture from pyogenic infections more frequently than have other anaerobic bacteria (Beerens and Tahon-Castel, 1965; Werner and Pulverer, 1971; Bartlett et al., 1974). However, when in mixture with other organisms the recovery of fastidious strains of *F. nucleatum* and *F. necrophorum* may fail. Other species of *Fusobacterium* are occasionally isolated from clinical specimens, and nearly always in mixed culture.

Pathogenic fusobacteria are in particular isolated from inflammatory processes accompanied by necrosis and ulceration. They are most frequently found in head and neck infections, pleuropulmonary infections, abscesses of the brain and the liver, and in infections following human and animal bites. *Fusobacterium* species are also recovered from subcutaneous and soft-tissue abscesses, obstetrical and gynecological infections, and abdominal abscesses. Because of variations in nomenclature and anaerobic culture technique, the incidence of *Fusobacterium* infections is difficult to determine from the literature. In a series of 15,844 clinical specimens submitted over 12 years (1973–1985) to the microbiological laboratories in two military hospitals, *Fusobacterium* species accounted for 4% of all anaerobic isolates (Brook, 1988). *F. nucleatum* was the most common Fusobacterium species (47% of all *Fusobacterium* species). The incidence of fusobacteria was somewhat higher in a 10-year series of anaerobic isolates from hospital patients (Sutter et al., 1985). *F. nucleatum* and *F. necrophorum* may also be encountered in blood cultures, particularly when the upper respiratory and the female genital tract are the portals of entry (Felner and Dowell, 1971; Henry et al., 1983). *Fusobacterium* species may be a cause of chorioamnionitis (Altshuler and Hyde, 1985). *F. nucleatum* is invariably present in Plaut-Vincent's angina (fusospirochetal angina) and in acute necrotizing ulcerative gingivitis.

F. necrophorum is the cause of human necrobacillosis. This is a rare, but life-threatening septicemia which predominantly affects healthy young adults. The infection is characterized by sore throat, followed by rigor and the formation of abscesses, usually involving the lung (Lemierre, 1936; Moore-Gillon et al., 1984).

F. necrophorum is an animal pathogen that is frequently isolated from necrotic and gangrenous lesions in cattle, sheep, and pigs and less frequently from other animals. Carnivorous animals appear to be resistant. The most common manifestations of diseases associated with *F. necrophorum* are liver abscess (hepatic necrobacillosis) and footrot.

Liver abscesses are especially encountered in heavily fattened cattle. Ninety % or more of such abscesses contain *F. necrophorum* as the only organism or in combination with other organisms (Hussein and Shigidi, 1974; Kanoe et al., 1976; Newsom, 1938; Simon and Stovell, 1971; Berg and Scanlan, 1982). The disease is associated with inflammation of the forestomach, presumably caused by irritating substances produced by fermentation of the high-caloric feed or by foreign bodies (Jensen and Mackay, 1965). *F. necrophorum* present in the stomach contents is thought to gain entry to the vascular system through the injured mucosa. Liver abscesses have thus been produced experimentally in cattle and sheep by intraportal injections of viable cells of a bovine isolate of *F. necrophorum* (Jensen et al., 1954). Hepatic necrobacillosis in feedlot cattle may present an economic problem in meat-producing countries (Langworth, 1977; Panel report, 1973). Footrot is frequently encountered in sheep and cattle. The disease

affects the epidermal tissues of the interdigital skin and hoof and leads to separation of the hoof from the soft tissues. Lameness and morbidity from infection lead to a reduction in productivity and economic losses. Footrot in sheep is caused by *Bacteroides nodosus* in combination with *Fusobacterium necrophorum*. *B. nodosus* is the principal causative agent transmitting the disease from one animal to another (Beveridge, 1941), whereas *F. necrophorum* is essential for the later inflammatory destruction of tissue (Egerton et al., 1969; Roberts and Egerton, 1969). Injury to the foot and damp soil are predisposing factors (Graham and Egerton, 1968). Effective protection against ovine footrot is achieved through immunization with killed, fimbriated *B. nodosus* cells (Egerton and Roberts, 1971; Stewart et al., 1982).

The primary cause of epizootic footrot in cattle has not been found. *F. necrophorum* is present in the lesions as a concurrent pathogen or a secondary invader. Typical lesions have been produced in cattle by the intradigital or intradermal inoculation of *F. necrophorum* alone or in combination with black-pigmented bacteroides (Berg and Loan, 1975; Clark et al., 1985).

Another disease associated with *F. necrophorum* is calf "diphtheria," which is necrotic laryngitis that occurs in calves up to 2 years of age. *F. necrophorum* is also involved in several other suppurative or gangrenous processes in domestic animals, such as interdigital dermatitis and heel abscess in sheep (Parsonson et al., 1967; Roberts et al., 1968), neonatal bacteremias in calves and lambs, necrotic enteritis of pigs, necrotic rhinitis of growing pigs, and oral infections in several animals.

Necrobacillosis has long been known as a serious cause of death of macropods, mainly in zoological collections, but also in wild habitats. The body sites most commonly affected are the face, the stomach wall, and the hind limbs. There is good evidence that *F. necrophorum* is the main etiological agent of the disease, but other organisms, especially *Bacteroides* species, are often also present in the lesions in high numbers (Oliphant et al., 1984; Samuel, 1983). *Fusobacterium* species are the predominant species of the mixed flora in soft tissue infections of cats caused by contamination from the oral flora (Love et al., 1980).

Virulence Determinants

The natural infections have verified the infectivity and invasiveness in animals of *F. necrophorum* and in man of *F. nucleatum* and *F. necrophorum*. Experimental investigations in animals have shown that synergistic mechanisms may be of importance in the pathogenesis of mixed infections involving fusobacteria (Brook and Walker, 1986; Hamp and Mergenhagen, 1963; Hill et al., 1974; Kaufman et al., 1972; Onderdonk et al., 1976; Roberts, 1967a, b).

Our current knowledge of virulence determinants is cursory. Fimbriation has been seen in *F. necrophorum* (Shinjo and Kiyoyma, 1986), but not in *F. nucleatum* or other *Fusobacterium* species. Encapsulation has been observed in *F. nucleatum* and *F. necrophorum* (Brook, 1986; Emery, 1988).

F. necrophorum isolates from cattle and sheep have been assigned to biovars A and B, and to an intermediate type, AB, on the basis of cultural characteristics (Fievez, 1963). A and AB biovars are frequently isolated from lesions, are highly virulent in mice, are hemolytic, and produce a hemagglutinin. B biovars are of low virulence in mice and nonhemolytic. The agglutinin is associated with the cell vall, has a subunit molecular weight of 19,000, and is heat labile (Nagai et al., 1984). Certain strains of *F. necrophorum* produce a leukocidin which is also destructive for erythrocytes and a variety of cultivated cells (Coyle-Dennis and Lauerman, 1978; Fales et al., 1977; Garcia et al., 1975a; Ishii et al., 1988; Roberts, 1967a, b; Scanlan et al., 1982). The toxin is possibly a phospholipase (Abe et al., 1979). High amounts of leukocidin are produced by A and AB biovars of *F. necrophorum*, indicating a correlation between toxin production and virulence. (Coyle-Dennis and Lauerman, 1979; Emery and Vaughan, 1986; Scanlan et al., 1982).

A hemagglutinin is also produced by *F. nucleatum* (Dehazya and Coles, 1980; Falkler and Hawley, 1977). *F. nucleatum* and *F. necrophorum*, as well as other *Fusobacterium* species, posses a cell wall lipopolysaccharide with the characteristics of an endotoxin (Garcia et al., 1975; Hofstad and Kristoffersen, 1971; Sveen et al., 1977; Warner et al., 1975).

Physiology

Fusobacterium species are not particularly demanding with regard to a low oxidation-reduction potential. The maximum E_h value permitting growth varies, depending on the species, the size of inoculum, and the medium. Stock strains of *F. nucleatum* were able to grow in an oxygen tension of up to 6% (Loesche, 1969). Fusobacteria are, however, fairly readily killed by exposure to air. This is possibly due to their susceptibility to hydrogen peroxide and is especially noticeable when thioglycolate or cysteine HC1 is incorporated into media that are exposed to air before inoculation and incubation.

Fusobacteria grow readily on ordinary solid media, such as Brucella blood agar and brain heart infusion agar, and in fluid media with a

base of peptone and yeast extract. Proteose peptone, tryptone, and trypticase have better growth-promoting effects than casamino acids (Gharbia and Shah, 1988a).

Energy is obtained from peptides and amino acids, which are fermented to give a mixture of butyric and acetic acids. Peptides represent the most important energy source (Gharbia et al., 1989). Lysine is likely catabolized by the 3-keto, 5-aminohexanoate pathway (Barker et al., 1982). Glutamate may be degraded through different pathways (Gharbia, 1987). *F. necrophorum* has an absolute need for protein-containing polypeptides (Wahren and Holme, 1973). Most *Fusobacterium* species convert threonine to proprionate. Lactate is converted to proprionate by *F. necrophorum*.

All the *Fusobacterium* species are either nonfermentative or only weakly fermentative. All species examined are able to utilize glucose, which is incorporated into cellular components (Robrish et al., 1987; Gharbia and Shah, 1988a). The accumulation of glucose is dependent upon energy supplied by fermentation of amino acids (Robrish et al., 1987). A low terminal pH (seldom lower than pH 5.5) in glucose-containing media indicates that, in at least a few species, some glucose is fermented.

Glutamate dehydrogenase is produced by all *Fusobacterium* species. The activity at different pH values and the electrophoretic mobility of the enzyme differ between species or groups of species (Gharbia and Shah, 1988b). Possibly all fusobacteria produce deoxyribonuclease (Porschen and Sonntag, 1974). *F. necrophorum* is able to deconjugate bile salts (Shimada et al., 1969).

The fusobacteria are susceptible to many of the commonly used antibiotics, including penicillins and cephalosporins. They are, however, resistant or relatively resistant to vancomycin, neomycin, and erythromycin. *F. nucleatum* may produce beta-lactamase. *F. varium* and *F. mortiferum* are resistant to rifampicin (rifampin). The growth of these two organisms is not inhibited by bile, to which other species of *Fusobacterium* are susceptible. Along with several other Gram-negative bacteria, the fusobacteria will grow in the presence of low concentrations of various dyes.

Isolation

Sampling

Fusobacterium nucleatum is best isolated from saliva or centrifuged salivary deposits or from the crevice or pocket that exists between the gingiva and the tooth surface. Sampling from the crevice area is performed by the use of sterile filter paper points (absorbent dental points), which are gently inserted into the crevice. Saliva or salivary deposits may be inoculated into the medium either directly or after being resuspended in a reducing diluent, such as the serum-containing diluent of Bowden and Hardie (1971), or in prereduced anaerobically sterilized (PRAS) one-fourth-strength Ringer solution (Sutter et al., 1985). The inoculated tapering end of the paper point is streaked on a small area of the solid medium, and further spreading of the deposited material is carried out by a wire loop. Because of their presence in small numbers, isolation of other *Fusobacterium* species from their natural habitat in man can be difficult. Detailed directions for collection, transport, and processing of fecal specimens have been given by Sutter et al. (1985). It is essential that the specimens are thoroughly homogenized and adequately diluted in a reducing diluent before inoculation. This applies also to the isolation of *F. necrophorum* from the intestinal tract of animals.

Isolation Under Nonselective Conditions

When present in clinical specimens, *Fusobacterium nucleatum* and *F. necrophorum* and the less commonly isolated *Fusobacterium* species are usually recovered on solid nonselective media. If the colonies are carefully inspected, the Gram stain is properly used and subculturing is performed promptly, isolation is usually straight forward.

Nonselective isolation of fusobacteria from their natural habitats on the mucous membranes in man and animals is laborious and time-consuming. Such isolation attempts should be avoided in those instances where isolation on selective media is possible. However, isolation under nonselective conditions seems to be the most reliable method for examination and quantitation of viable cells in normal flora specimens. For this purpose the roll tube method (Holdeman et al., 1977; Moore, 1966) or the use of a glove box (Aranki et al., 1969) is to be recommended. By inoculating roll tubes with 1 ml each of 10^8, 10^9, and 10^{10} dilutions of homogenized feces, bacterial species—including fusobacteria—present in numbers as low as 3×10^{10} per gram of fecal dry matter (0.06% of the fecal bacterial population) were counted (Moore and Holdeman, 1974).

Selective Isolation

Media formulations have been developed and evaluated for selective isolation of fusobacteria

from human (Baird-Parker, 1957; Morgenstein et al., 1981; Ohtani, 1970b; Omata and Disraely, 1956; Sutter et al., 1971; Walker et al., 1979) and animal (Fales and Teresa, 1972a) sources.

The following medium of Morgenstein et al., (1981) is recommended for the isolation of *Fusobacterium* species from their natural habitats and from clinical specimens.

Fusobacterium Egg Yolk Agar (FEA) Medium (Morgenstein et al., 1981; Sutter et al., 1985)

Brucella agar base	37 g
Disodium phosphate	5 g
Monopotassium phosphate	1 g
Magnesium sulfate	0.1 g
Hemin solution (5 mg/ml)	1 ml
Polysorbate 80	1 ml
Neomycin solution (100 mg/ml)	1 ml
Distilled water	1,000 ml
Vancomycin solution (7.5 mg/ml)	0.67 ml
Josamycin (Yamanouchi Pharmaceuticals)	3 mg
Egg yolk emulsion (Difco)	50 ml
(or Egg yolk emulsion) (Oxoid)	74 ml

The vancomycin, the josamycin and the egg yolk emulsion are added to the medium after adjustment of pH to 7.6, dissolving by boiling, autoclaving at 121°C for 15 min, and cooling to 50°C.

The FEA medium is selective because of its content of antibiotics. Addition of egg yolk makes it differential for *F. necrophorum*, which is lipase positive. All species of *Fusobacterium* grow on the medium with only minimal inhibition. The typical colonial morphology is translucent to white, convex, round, and entire colonies. *Leptotrichia* grows with white, raised, and granular colonies, and *Veillonella* forms small and translucent colonies. The growth of a majority of facultative Gram-negative organisms is inhibited. Gram-positive organisms do not grow on the medium.

The CVE medium of Walker et al. (1979) may be used in addition to the FEA medium for isolation of *F. nucleatum* from the oral cavity.

Crystal Violet Erythromycin Agar (CVE) Medium (Walker et al., 1979)

Trypticase	10 g
Yeast extract	5 g
Sodium chloride	5 g
Glucose	2 g
Tryptophane	0.2 g
Agar	15 g
Crystal violet	5 mg
Distilled water	1,000 ml
Sterile defibrinated sheep blood	50 ml
Erythromycin (dissolved in small volume of 95% ethanol)	4 mg

The blood and the erythromycin are added to the medium after adjustment of the pH to 7.0–7.2, autoclaving at 121°C for 20 min, and cooling to 50°C.

The selectivity of the CVE medium depends on its content of erythromycin and crystal violet. Strains of *F. nucleatum* exhibit one of two different colony types on CVE. Some strains form transparent, smooth, round, blue colonies having an entire edge with a darker blue center. Other strains form transparent, rounded or irregular, blue colonies with a speckled internal appearance. Several species of Gram-positive and Gram-negative organisms grow on the medium, but with a colonial morphology distinguishable from those of *F. nucleatum*.

The medium of Sutter et al. (1971) is selective for *F. varium* and *F. mortiferum* and can be used for isolation of these species from feces or from other sources. The selectivity of this medium depends on the addition of rifampin to standard blood agar.

Rifampin Blood Agar (Sutter et al., 1971; Sutter et al., 1985)

A total of 50 µg/ml of rifampin is added to Brucella blood agar just before the plates are poured. Rifampin stock solution: 0.1 g of rifampin is dissolved in 20 ml of absolute ethyl alcohol, and 80 ml of sterile distilled water is added. This gives a final concentration of 1,000 µg/ml. The solution can be stored at 4°C for up to 2 months.

F. varium and *F. mortiferum* grow freely on this medium, while the growth of *Bacteroides* and most other organisms present in human feces in high numbers is inhibited.

A medium selective for the isolation of *F. necrophorum* from bovine liver abscesses was reported by Fales and Teresa (1972a). The medium is based on the trypticase and egg yolk medium of McClung and Toabe (1947) and contains crystal violet and phenethyl alcohol as selective agents.

Isolation Medium for Fusobacterium necrophorum (Fales and Teresa, 1972a)

To 415.0 ml of distilled water add the following:

Trypticase	16.0 g
Biosate	4.0 g
Thiotone	2.0 g
Glucose	0.5 g
$MgSO_4$ (5% solution)	0.1 ml
Na_2HPO_4	2.5 g
Agar	8.3 g

Adjust to pH 7.3.

After autoclaving, the basal medium is cooled to 50°C, and 1.35 ml (0.27% vol/vol) of phenethyl alcohol is added. One egg yolk mixed with an equal volume of a 0.9% sterile saline solution (total volume, approximately 45.0 ml) and blended with the basal medium and then 11.5 mg of crystal violet dissolved in 25.0 ml of sterile distilled water are added. Finally, the volume is adjusted to 500 ml with sterile distilled water.

Small colonies of *Proteus* species appearing on the medium are easily distinguished from the

Table 2. Differential characteristics of *Fusobacterium* species encountered in clinical specimens.

Characteristic	*F. nucleatum*	*F. necrophorum*	*F. gonidiaformans*	*F. naviforme*	*F. mortiferum*	*F. russi*	*F. varium*

larger colonies (1.5–1.7 mm in diameter after 48 h of incubation) of *F. necrophorum*.

As previously mentioned, the various selective media designed for isolation of *Fusobacterium* species allow other organisms to grow to a varying extent. In order to gain experience with these media it is important, therefore, to check the different colony types by Gram-staining.

Axenic Cultivation and Maintenance

Fusobacterium strains can be maintained by weekly serial subcultures on blood agar. Viable cells can be stored at –70°C in Greave's solution. Stock cultures can also be prepared in skim milk (Sutter et al., 1985).

Greave's Solution

Bovine serum albumin	50 g
Sodium glutamate	50 g
Glycerol	100 g
Distilled water	1,000 ml

Batch cultivation is best performed in a nutrient broth with a tryptone base, which is supplemented with yeast extract (0.3%), glucose (0.25%), and cysteine HC1 (0.1%), or in the selective media bases. If narrow-necked, well-filled containers are used, PRAS media are usually not necessary.

F. necrophorum has been grown in continuous culture with glucose as the growth-limiting factor (Wahren et al., 1971). Maximal cell yields (3.5 mg/ml dry weight) were achieved at dilution rates between 0.19 h^{-1} and 0.40 h^{-1}, at a pH of 6.8, and at temperatures of 33–36°C.

Identification

All *Fusobacterium* species are susceptible to colistin and kanamycin, are resistant to vancomycin, and produce butyric acid without isobutyric or isovaleric acids. In the clinical diagnostic laboratory identification is based on both cell and colony morphology and on biochemical properties. Chemotaxonomic methods, such as DNA-DNA hybridization, lipid analysis, electrophoretic mobility of glutamate dehydrogenase, outer membrane protein patterns, and peptidoglycan composition, are useful for taxonomical purposes.

Morphology

Fusobacterium nucleatum has a characteristic cell morphology that makes presumptive identification relatively easy. The cells are Gram-negative, slender, spindle-shaped bacilli with sharply pointed ends, often appearing in pairs and end-to-end. Most cells are 5–10 μm long, but both shorter and longer rod forms may be seen. *F. periodonticum* has a similar cell morphology. This organism has, however, not been isolated from clinical specimens. The fusiform cells of *Capnocytophaga* species are generally smaller than those of *F. nucleatum*. Those of *Leptotrichia buccalis* are thicker and usually larger (distinguishing characters are given in Table 1 of The Genus *Leptotrichia* in the second edition). The cells of *F. necrophorum* are pleomorphic, are often curved, and may have spherical enlargements. Free coccoid bodies and, especially, filaments are common. *F. naviforme* strains may have boat-shaped cells. Gonidial forms may be seen in old cultures of *F. gonidiaformans*. The other *Fusobacterium* species have no distinctive cellular morphology.

Colonies of *F. nucleatum* on blood agar are low convex, glistening, and slightly irregular in form. Those of *F. necrophorum* are circular, rough, and often β-hemolytic. The other *Fusobacterium* species form smooth, small-to-punctiform colonies on blood agar after incubation for two days.

Biochemical Properties

Differential characteristics of the most common *Fusobacterium* species are shown in Table 2. In addition, *F. periodonticum* hydrolyzes hippurate; nitrate is reduced by *F. ulcerans*; and the pH may be slightly lowered in cultures of *Fusobacterium* species grown in carbohydrate-containing media, but also in cultures grown without added carbohydrate. This makes the interpretation of fermentation reactions difficult.

Commercial multitest systems for identification of bacteria are generally associated with a percentage of misidentifications, which may be either system or laboratory dependent. Experience is limited with respect to identifications of *Fusobacterium* species.

DNA probes for identification of *Fusobacterium* species are not available. The fluorescent antibody technique has been used for identification of fusobacteria in clinical specimens from man (Griffin, 1970; Stauffer et al., 1975) and for *F. necrophorum* in bovine liver abscesses (Fales and Teresa, 1972b). Simon (1975) has described a hemagglutination inhibition test for rapid identification of *F. necrophorum*.

CHAPTER 14.13

Prokaryotic Symbionts of Amoebae and Flagellates

KWANG W. JEON*

Amoebae and flagellates have long been known to be associated with both extracellular and intracellular symbionts (Hall, 1969; Kirby, 1941a; Lee et al., 1985). The presence of prokaryotic symbionts on and in flagellates and in some amoebae, as observed by light microscopy, was reported by several authors during the late 1800s and the early part of this century, as was comprehensively reviewed by Kirby (1941a). Symbiont-bearing flagellates were chiefly found in termite guts, and only a few free-living flagellates were found to have adhering symbionts. Hall (1969) extensively reviewed the literature on symbionts of protozoa published since 1941. Both in flagellates and amoebae, the suspected presence of some of the small bacterial symbionts had to be confirmed later by more sophisticated methods such as electron microscopy and specific staining.

Amoebae and flagellates represent two very diverse groups of protozoa and it is not possible to cover all known prokaryotic symbionts in depth. In this chapter, we shall simply list known symbionts described in the above two reviews in a tabular form (Tables 1 and 2) and then consider newly found symbionts or results of recent studies on earlier symbionts in some detail. The significance of symbiotic relationships remains obscure in most cases and in only a few instances has the host-symbiont relationship been studied in detail. Some disagreements remain about whether the term "symbiosis" should be limited to associations where definite benefits have been proven to exist or not. In this chapter, we shall use the broader definition of symbiosis to include parasitism, commensalism, and mutualism, as did Kirby (1941a) and Hall (1969). Thus, the list of prokaryotic symbionts will include those whose relationships to their hosts are not known or may not be mutually beneficial.

The heightened interest in cellular symbiosis in recent years has been stimulated, in part, by the notion that eukaryotic cell organelles such as mitochondria, chloroplasts, and microtubules may have originated from endosymbionts, i.e., the Serial Endosymbiosis Theory (Sagan, 1967; Margulis, 1970, 1981; Taylor, 1974; papers in Lee and Fredrick, 1987). Some authors have felt that the role of endosymbiosis in the origin of eukaryotic cell organelles has not yet been clearly established (Gray and Doolittle, 1982), but the theory is gaining wider support in view of recent results on the close relationship between the ribosomal RNAs of prokaryotes and those of chloroplasts and mitochondria (e.g., Watson et al., 1987). It should be noted that an opposing view has existed, according to which such organelles evolved as a result of autogenous intracellular differentiation without involving symbionts (Cavalier-Smith, 1975; Raff and Mahler, 1972; Uzzell and Spolsky, 1974, 1981).

Meanwhile, it is interesting to note that *Pelomyxa palustris*, which does not have mitochondria (Daniels et al., 1965; Leiner and Wohlfeil, 1953) contains several types of intracellular symbionts (Daniels, 1973), and the suggestion has been made that such symbionts may carry out metabolic functions in place of mitochondria (Chapman-Andresen, 1971). Bacteria present in *P. palustris* have been found to be methanogenic (van Bruggen et al., 1983, 1985; see also The Methanogenic Bacteria) and may function as electron sinks related to energy production, comparable to mitochondrial function in aerobic eukaryotic cells.

In the case of amoeba-bacteria symbiosis, the D strain of *Amoeba proteus* became spontaneously infected with a large number (60,000–150,000 bacteria per amoeba) of rod-shaped Gram-negative bacteria (Jeon and Lorch, 1967). Initially, the bacteria were harmful and brought about damaging effects to their hosts, called xD amoebae, such as reduced cell size, slower cell growth, increased membrane fragility, sensitivity to starvation, and a poor clonability. When introduced into symbiont-free D amoebae, the bacteria multiplied and killed their new hosts within a few host cell generations. However, adverse effects of infection gradually diminished over a period of about 1 year, and the bacteria became

*This chapter was originally planned to appear in volume 1, but due to technical reasons it has been placed here to ensure inclusion.

less virulent, bacteria-bearing xD amoebae growing well with near-normal growth rates. Also, some of the newly infected D amoebae survived, indicating a reduced virulence as compared to earlier infection.

Within a few years, host amoebae became dependent on their endosymbionts (Jeon, 1972). Thus, xD amoebae lost viability when they were deprived of endosymbionts either by nuclear transplantation (Jeon and Jeon, 1976), by treatment with antibiotics (Jeon and Hah, 1977), or by raising the culture temperature (Jeon and Ahn, 1978). Aposymbiotic xD amoebae could be resuscitated only by reintroducing live X-bacterial symbionts (Lorch and Jeon, 1980). Newly infected amoebae became dependent on their symbionts after about 200 cell generations or 18 months. The reason for the hosts' dependence is not known, but preliminary evidence suggests that a symbiont-synthesized protein may be required for the survival of hosts. When xD amoebae are grown in the presence of chloramphenicol (100–700μg/ml) or rifampicin (125μg/ml), the synthesis of a unique 29-kDa polypeptide by endosymbionts is instantly suppressed and xD amoebae die much sooner than do symbiont-free D amoebae (Kim and Jeon, 1986, 1987a). The symbiont's gene coding for the xD-specific protein has been cloned (Park and Jeon, 1988) and its nucleotides sequenced (Park and Jeon, 1989). The symbiotic bacteria were found to accumulate host actin selectively (Kim and Jeon, 1987b), as studied using a monoclonal antibody against the amoeba actin. Thus, in this example, the transition of spontaneously infecting parasites to required cell components was observed while it occurred (Jeon, 1980, 1983, 1986, 1987). While the host's dependence on symbionts developed over 200 host cell generations, some physiological characters changed after a few host cell divisions (Lorch and Jeon, 1981, 1982).

In *Blastocrithidia culicis* and *Crithidia oncopelti,* symbiotic bacteria were found to supply their hosts with lysine (Gill and Vogel, 1962, 1963), hemin (Guttman and Eisenman, 1965; Chang and Trager, 1974; Newton, 1956, 1957), and other nutritional factors. An aposymbiotic host, produced by growing symbiont-bearing cells in the presence of chloramphenicol, required exogenous hemin for growth. The ectosymbiotic spirochetes on *Myxotricha* were found to help their host move by their coordinated undulation while the host's flagella functioned only to steer its movement (Cleveland and Grimstone, 1964). Flagella of prokaryotic symbionts attached to *Cryptotermes* were also found to help propel the host cell (Tamm, 1978b).

These are a few examples in which protozoan hosts and prokaryotic symbionts have developed an intimate relationship, and symbiont integration and host-symbiont interactions have been experimentally studied.

Habitats

General

The host-symbiont relationship appears to be somewhat specific for both ecto- and endosymbionts, since certain symbionts are almost always found associated with given hosts (Hall, 1969; Kirby, 1941a). However, the mechanism for specific recognition of the host by symbionts is not known. For ectosymbionts, their only requirement for continuing symbiotic association with their hosts would be to stay attached to their host-cell surfaces. Some symbionts cover the whole surface of their host, while others are limited to certain areas of the host's body (Kirby, 1941a). In some cases, specialized attachment sites such as brackets and underlying network of fibrous strands are present, as in *Myxotricha* (Fig. 1A; Cleveland and Grimstone, 1964). On the basis of extensive electron-microscopic observations, Cleveland and Grimstone reconstructed the attachment complexes as shown in Fig. 1B. Tamm (1978a) also found membrane specialization where two kinds of bacteria, rod-shaped and filamentous, were attached to *Crytptotermes cavifrons.* Thus, the attachment of ectosymbionts is not haphazard but appears to be helped by structural adaptations on the part of host cells.

For endosymbionts, their habitat in the cytoplasm of host cells can be considered to be an extreme environment comparable to hot springs and salt lakes (Moulder, 1979), although most symbionts live within symbiont-containing vesicles and the membranes protect them from direct exposure to the host cytoplasm. These symbiont-containing vesicles have been called "symbiosomes" (Fig. 2; Roth et al., 1988). It appears that endosymbionts have adapted in various ways to overcome adverse effects of the harsh environment, e.g., the possession of rigid cell walls to withstand digestive action of the hosts' hydrolytic enzymes (Drozanski and Chmielewski, 1979; Han and Jeon, 1980) or prevention of lysosomal fusion with symbiosome membranes, thus avoiding exposure to hosts' digestive enzymes (Ahn and Jeon, 1979; Armstrong and Hart, 1971; Jeon, 1983).

Amoebae

In amoebae, all known bacterial symbionts are intracellular. This is understandable since amoebae do not have a firm cortex and ectosymbionts

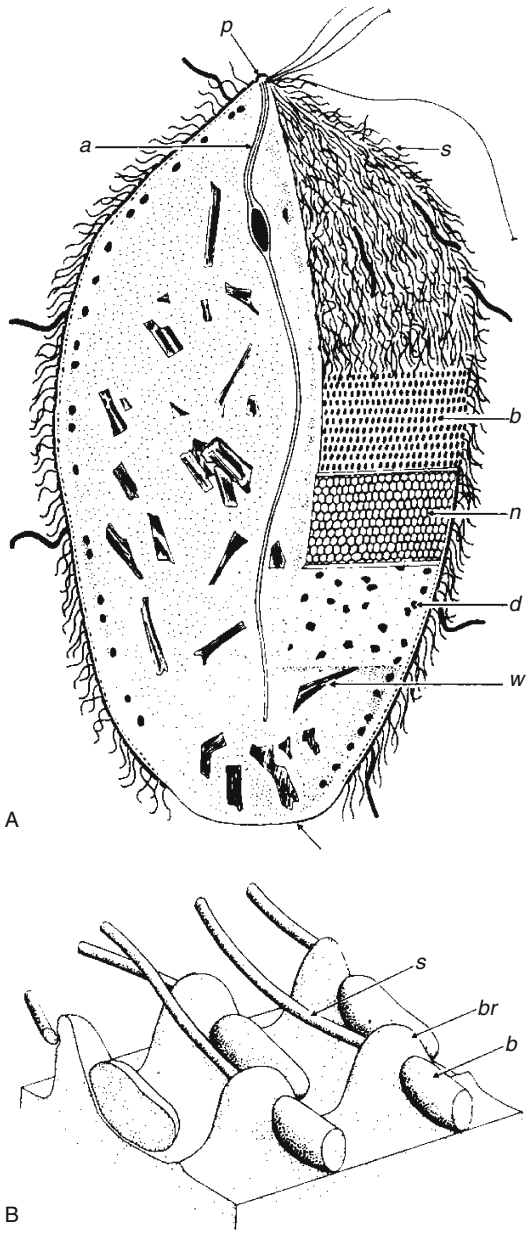

Fig. 1. A diagram of *Myxotricha paradoxa* showing the attachment of ectosymbionts on the cell surface (A) and a reconstruction of a small area of the cell surface showing the attachment complex (B). An optical section is shown on the left and surface structures are shown on the right. b, bacteria; br, brackets; n, fibrous network; s, spirochetes. (From Cleveland and Grimstone, 1964.)

cannot permanently attach to them as do flagellates. Several different bacterial types have been reported in the cytoplasm of amoebae, mostly enclosed in symbiosomes singly or in groups (Fig. 3). Roth and Daniels (1961) were among the first to confirm by electron microscopy the bacterial nature of previously reported bacteria-like particles (0.5×2μm) in vacuoles of *Amoeba proteus* (Cohen, 1957). These symbionts could not be eliminated by starvation or penicillin treatment. Chapman-Andresen and Hayward (1963) found rod-shaped bacteria (0.5 × 3–5μm) in a strain of *A. proteus* (about 4000 bacteria per cell), that could not be detected by light microscopy. Drozanski (1963a) reported Gram-negative rods (0.6–0.8 × 1.3–2.1μm) that caused a fatal infection in *Acanthamoeba castellanii.* These bacteria first multiplied in food vacuoles and later in the cytoplasm. Other reports followed that confirmed the presence of a large number of bacteria in various strains of amoebae (Jeon and Lorch, 1967; Wolstenholme and Plaut, 1964). In one strain of *Pelomyxa palustris*, Daniels et al. (1966; Daniels and Breyer, 1967) found rod-shaped bacteria (0.3 × 3μm) within individual vesicles characteristically surrounding the nuclei, while another type of bacteria of similar size was located in other parts of the cytoplasm. In *Acanthamoeba* (Drozanski, 1963a; Hall and Voelz, 1985; Proca-Ciobanu et al., 1975), symbionts are found throughout the cytoplasm. In the large, free-living *Amoeba,* all symbionts were enclosed in symbiosomes located in all parts of the cell (Jeon and Lorch, 1967; Wolstenholme and Plaut, 1964). So far, no endonuclear symbionts have been found in amoebae. Many unsuccessful attempts have been made to grow symbiotic bacteria in vitro (Drozanski, 1963b; Jeon and Lorch, 1967; K. Jeon, unpublished observations), and none of the reported bacterial symbionts of amoebae has been grown outside living cells.

The fact that symbionts of amoebae cannot be cultured outside amoebae indicates the symbionts' dependence on their hosts, but in many cases the dependence does not appear to be species-specific. Thus, bacteria isolated from

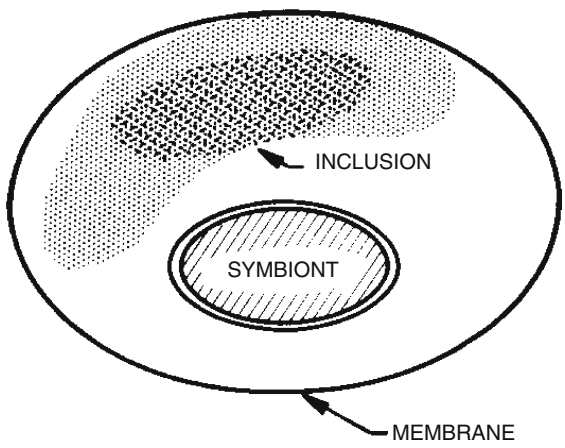

Fig. 2. A schematic diagram of a symbiosome to show its components. Each line represents a membrane and the intrasymbiosome space is shown to contain inclusions. (From Roth et al., 1988.)

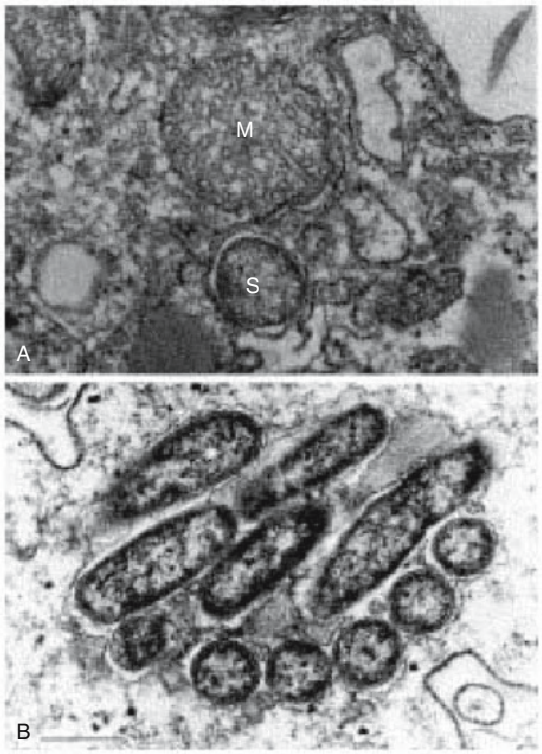

Fig. 3. Electron micrographs of symbiosomes in amoebae. (A) A small symbiosome with a single round symbiont (S) called a "DNA-containing body" and (B) a larger symbiosome with several rod-shaped symbionts. (A) A mitochondrion (M) with tubular cristae is shown for comparison. (B) The interbacterial space is filled with inclusions containing fibrous matter. Bar = 0.5 µm. (Fig. 3B from Jeon, 1987.)

infected *Acanthamoeba castellanii* were able to infect trophic forms of *Hartmannella rhysodes*, *Schzopyrenus resselli*, *Didasculus thorntoni*, and other unidentified amoebae of *Limax* type (Drozanski, 1963b). Jeon and Jeon (1982) found that X-bacteria isolated from xD amoebae *(Amoeba proteus)* cross-infected an unrelated species of giant amoeba, *Chaos carolinensis*.

Flagellates

Unlike amoebae, all of whose symbionts are intracellular, flagellates have symbionts in various parts of the cells, some as ectosymbionts and others in the nucleus, in the endoplasmic reticulum, in chloroplasts, or free in the cytoplasm. Most of the prokaryotic symbionts of flagellates were first found as ectosymbionts by light microscopy early in the 20th century (Table 2), and the hosts were mostly flagellates living in termite guts. Some suspected prokaryotic endosymbionts were reported in those flagellates, but confirmation of the bacterial nature of such endosymbionts had to await electron-microscopic observation and advanced biochemical tests. Thus, definitive reports of the presence of endosymbionts in flagellates started to appear in the late 1950s. For example, Roth (1959) found rod-like bacteria within the nucleus of *Peranema*, several hundred per nucleus, while others reported endocytoplasmic symbionts in *Volvox* (Kochert and Olson, 1970). Since then many other flagellates have been found to harbor endosymbiotic bacteria. Gromov (1977) described the presence of Gram-negative bacteria in the surface cortical region of *Trichonympha turkestanica* and suggested that the symbiotic bacteria play a role in the host flagella operation. Gerola (1978) reported inclusion bodies of several bacteria-like elements in *Euglena* cells from an alpine water pool rich in organic residues; the endosymbionts were free in the host cytoplasm, but there was no sign of cytoplasmic reaction around the symbionts detectable by electron microscopy. Endosymbiotic bacteria living inside the endoplasmic reticulum were reported in *Ochromonas monicis* isolated from a saline pool (Doddema and van der Veer, 1983), and these authors thought that the symbionts enabled their hosts to survive in vitamin-poor water. Sousa-Silva and Franca (1985) studied the ultrastructure of two species of dinoflagellates, *Gyrodinium instriatum* and *Glenodinium foliaceum*, harboring bacterial symbionts, some of which were in the nucleus while others were in the cytoplasm, and the third group appeared to live in both.

Chesnick and Cox (1986) presented a summary of results from 17 studies reporting the presence of endosymbiotic bacteria in algal species. In most cases, bacterial symbionts were usually found in small vesicles. However, in the marine alga *Penicillus*, bacteria were contained in one large central vacuole, with occasional presence found in the tip cytoplasm (Turner and Friedmann, 1974). Wilcox (1986) found small bacteria-like symbionts within chloroplasts of the dinoflagellate, *Woloszynskia pascheri*, and suggested that the bacteria may have been in a symbiotic relationship for some time, although no supporting evidence was presented. The author also consider it possible that the "symbionts" may represent regions where chloroplasts' nucleic acids are packaged in membranes. Different species of *Giardia* have been found to have mycoplasma-like organisms attached on the surface of trophozoites while harboring intracellular bacteria in trophozoites and cysts (Feely et al., 1988).

While the roles of many symbionts are not clear, the presence of symbionts has some effects on the structure and physiology of their hosts. Freymuller and Camargo (1981) compared the ultrastructure of symbiont-bearing and sym-

biont-free species of trypanosomatids and found some differences. For example, paraxial rods of flagella or intraflagellar structures were present only in symbiont-free species, while branching of mitochondria was found exclusively in symbiont-bearing species. Endonuclear symbionts of *Peranema trichophorum* appeared to cause structural changes in their hosts, such as fragmented karyosome and granulation of DNA and RNA within the nucleus (Radchenko, 1983). McLaughlin et al. 1983 found differences in lectin agglutinability between symbiont-bearing and aposymbiotic strains of *Crithidia* and *Blastocrithidia.* Later, it was found that aposymbiotic hosts failed to incorporate detectable amounts of fucose into a major surface glycopeptide (McLaughlin and Cain, 1985a). These authors attributed the differences in lectin agglutinability to different carbohydrate compositions of the flagellates' surfaces. In contrast, McLaughlin and Cain (1985b) failed to detect differences in the incorporation of labeled leucine and methionine between symbiont-bearing and aposymbiotic strains of these hemoflagellates. Krylov et al. 1985 detected many differences between symbiont-bearing (Sym^+) and symbiont-free (Sym^-) strains of *Crithidia oncopelti* and proposed that the two strains be named as different species; observed differences included cell size, flagellum length, colony shape and size, rate of movement, electrophoretic mobility of malate dehydrogenases, growth rate at 32°C, oxygen consumption, and sensitivity to antibiotics. In most other cases, however, host-symbiont relationships have not been clarified.

There have been some reports for the presence of blue-green algae as endosymbionts in various species of dinoflagellates (reviewed by Gaines and Elbrachter, 1987; Steidinger and Baden, 1984). Some of the symbiotic algae appeared to have nutritional importance to their hosts and others were thought to produce toxins.

Isolation

Since all the known endosymbiotic prokaryotes of flagellates and amoebae are obligatory symbionts and do not grow in vitro, the only sure source for their isolation would be symbiont-bearing hosts. Even for facultative ectosymbionts of flagellates that may live free from their hosts at one time or another, their natural host is the best source. *Amoeba proteus* cells are grown in dilute salt solution (Goldstein and Ko, 1976; Jeon and Jeon, 1975). Since these amoebae are strictly phagocytic, they have to be fed live prey organisms, commonly used food organisms for mass culture being *Tetrahymena* cultured axenically in a rich, complex medium containing various vitamins and mineral additives with proteose peptone and liver extract as the main ingredients (Goldstein and Ko, 1976). Amoebae are fed with washed *Tetrahymena* daily or every other day, depending on the desired growth rate. *Acanthamoeba* are cultured axenically in a medium containing proteose peptone, yeast extract, and glucose (Drozanski, 1984). Various media have been used to culture hemoflagellates and other flagellates as hosts of bacterial endosymbionts (e.g., Chang and Trager, 1974).

Bacterial endosymbionts have been isolated in mass from a few species of amoebae and flagellates. No reports are found for mass isolation of ectosymbionts from flagellates. For example, symbiotic bacteria have been isolated from xD amoebae *Amoeba proteus* (Ahn and Jeon, 1982; Han and Jeon, 1980) and *Acanthamoeb castellanii* (Drozanski et al., 1984). In the first example (Han and Jeon, 1980), symbionts were collected by Ficoll gradient centrifugation from lysed amoebae. Later, the method was modified to apply filtration through nylon screens to remove larger pieces of cell debris first (Ahn and Jeon, 1982). Pure bacteria were collected after centrifugation on a sucrose-step gradient. In either procedure, the recovery of symbionts could be greater than 90%. Symbiotic bacteria from *A. castellanii* were obtained by centrifugation from lysed amoebae (Drozanski et al., 1984).

Chang (1975) isolated endosymbionts of hemoflagellates by a sequential treatment of host flagellates by hypotonic shock, complement-dependent immune lysis, and needle passage. Host flagellate cells were incubated in Trager buffer (Trager, 1959) containing guinea-pig serum and rabbit antiserum against flagellates, followed by DNase digestion and differential centrifugation. The final fraction was free of contamination, and the recovery of symbionts was about 20%.

Identification

Since symbionts of amoebae and flagellates cannot be cultured in vitro, the traditional methods of identifying and classifying them (e.g., *Bergey's Manual*, see Buchanan and Gibbons, 1974) cannot be used. Thus, these symbionts have been simply identified as fusiform, rod-shaped, round, or filamentous on the basis of their external morphology based on light or electron-microscopic observations. Most of the bacterial endosymbionts have been reported to be Gram negative, either as a result of Gram staining or by electron microscopic examination for the presence of characteristic surface membranes. More specialized methods are available to

identify bacterial species, such as serological tests, bacteriophage typing, and DNA and rRNA sequencing. In particular, the use of specific oligodeoxynucleotide probes, which can be applied in identifying single microbial cells (Giovannoni et al., 1988), should be helpful in dealing with endosymbionts that cannot be grown in vitro. It is also desirable to culture isolated symbionts in vitro for their definitive identification based on their metabolic, physiological, and biochemical characteristics.

Concluding Remarks

This short survey reiterates that many prokaryotic organisms live on and in a wide variety of flagellates and amoebae as symbionts. Their presence is known to bring about various structural, physiological, and biochemical changes in the host. However, many questions still remain unanswered regarding the host-symbiont relationship. For example, it is not clear in many instances how the host and symbionts recognize each other and establish a specific association, how endosymbionts escape digestion by their host, how the symbiont population is controlled, and how the host and symbionts benefit or suffer from their association. Studies of prokaryotic symbionts in flagellates and amoebae have lagged behind those in ciliates (see Prokaryotic Symbionts of Ciliates), where identification and culture of symbionts in vitro and the clarification of the genetic interaction between the host's and symbionts' genomes have been well established. It is hoped that similar advancement will be achieved soon with symbionts in flagellates and amoebae.

Acknowledgments. I thank Drs. L. E. Roth and W. S. Riggsby for their helpful comments on the manuscript. The research work from my laboratory described in this chapter was supported by a grant from the National Science Foundation.
