Preface

Each of the first two editions of *The Prokaryotes* took a bold step. The first edition, published in 1981, set out to be an encyclopedic, synoptic account of the world of the prokaryotes—a collection of monographic descriptions of the genera of bacteria. The Archaea had not yet been formalized as a group. For the second edition in 1992, the editors made the decision to organize the chapters on the basis of the molecular phylogeny championed by Carl Woese, which increasingly provided a rational, evolutionary basis for the taxonomy of the prokaryotes. In addition, the archaea had by then been recognized as a phylogenetically separate and distinguishable group of the prokaryotes. The two volumes of the first edition had by then expanded to four. The third edition was arguably the boldest step of all. We decided that the material would only be presented electronically. The advantages were obvious and persuasive. There would be essentially unlimited space. There would be no restrictions on the use of color illustrations. Film and animated descriptions could be made available. The text would be hyperlinked to external sources. Publication of chapters would be seriati—the edition would no longer have to delay publication until the last tardy author had submitted his or her chapter. Updates and modifications could be made continuously. And, most attractively, a library could place its subscribed copy on its server and make it available easily and cheaply to all in its community. One hundred and seventy chapters have thus far been presented in 16 releases over a six-year period. The virtues and advantages of the online edition have been borne out. But we failed to predict the affection that many have for holding a bound, print version of a book in their hands. Thus, this print version of the third edition shall accompany the online version.

We are now four years into the 21st century. Indulge us then while we comment on the challenges, problems and opportunities for microbiology that confront us.

Moselio Schaechter has referred to the present era of microbiology as its third golden age—the era of "integrative microbiology." Essentially all microbiologists now speak a common language. So that the boundaries that previously separated subdisciplines from each other have faded: physiology has become indistinguishable from pathogenesis; ecologists and molecular geneticists speak to each other; biochemistry is spoken by all; and—mirabile dictu!—molecular biologists are collaborating with taxonomists.

But before these molecular dissections of complex processes can be effective there must be a clear view of the organism being studied. And it is our goal that these chapters in *The Prokaryotes* provide that opportunity.

There is also yet a larger issue. Microbiology is now confronted with the need to understand increasingly complex processes. And the modus operandi that has served us so successfully for 150 years—that of the pure culture studied under standard laboratory conditions—is inadequate. We are now challenged to solve problems of multimembered populations interacting with each other and with their environment under constantly variable conditions. Carl Woese has pointed out a useful and important distinction between empirical, methodological reductionism and fundamentalist reductionism. The former has served us well; the latter stands in the way of our further understanding of complex, interacting systems. But no matter what kind of synoptic systems analysis emerges as our way of understanding host–parasite relations, ecology, or multicellular behavior, the understanding of the organism as such is sine qua non. And in that context, we are pleased to present to you the third edition of *The Prokaryotes*.

Martin Dworkin
Editor-in-Chief

Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These four volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors many of the strategies and tools as well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the "organism approach" has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of the *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and

prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the "nitrosome," a unique nitrogen-fixing organelle. Study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become "dog-eared" and worn as students seek basic information for the hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, i.e., from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator these volumes should generate excitement.

Happy hunting!

Preface **v**
Foreword by Ralph S. Wolfe **vii**
Contributors **xxix**

Volume 1

1. ***Essays in Prokaryotic Biology***

1.1 How We Do, Don't and Should Look at Bacteria and Bacteriology 3
CARL R. WOESE

1.2 Databases 24
WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER and ERKO STACKEBRANDT

1.3 Defining Taxonomic Ranks 29
ERKO STACKEBRANDT

1.4 Prokaryote Characterization and Identification 58
HANS G. TRÜPER and KARL-HEINZ SCHLEIFER

1.5 Principles of Enrichment, Isolation, Cultivation, and Preservation of Prokaryotes 80
JÖRG OVERMANN

1.6 Prokaryotes and Their Habitats 137
HANS G. SCHLEGEL and HOLGER W. JANNASCH

1.7 Morphological and Physiological Diversity 185
STEPHEN H. ZINDER and MARTIN DWORKIN

1.8 Cell-Cell Interactions 221
DALE KAISER

1.9 Prokaryotic Genomics 246
B. W. WREN

1.10 Genomics and Metabolism in *Escherichia coli* 261
MARGRETHE HAUGGE SERRES and MONICA RILEY

1.11 Origin of Life: RNA World versus Autocatalytic Anabolism 275
GÜNTER WÄCHTERSHÄUSER

1.12 Biotechnology and Applied Microbiology 284
EUGENE ROSENBERG

1.13 The Structure and Function of Microbial Communities 299
DAVID A. STAHL, MEREDITH HULLAR and SEANA DAVIDSON

2. Symbiotic Associations

2.1 Cyanobacterial-Plant Symbioses 331
DAVID G. ADAMS, BIRGITTA BERGMAN, S. A. NIERZWICKI-BAUER, A. N. RAI and ARTHUR SCHÜßLER

2.2 Symbiotic Associations Between Ciliates and Prokaryotes 364
HANS-DIETER GÖRTZ

2.3 Bacteriocyte-Associated Endosymbionts of Insects 403
PAUL BAUMANN, NANCY A. MORAN and LINDA BAUMANN

2.4 Symbiotic Associations Between Termites and Prokaryotes 439
ANDREAS BRUNE

2.5 Marine Chemosynthetic Symbioses 475
COLLEEN M. CAVANAUGH, ZOE P. MCKINESS, IRENE L.G. NEWTON and FRANK J. STEWART

3. Biotechnology and Applied Microbiology

3.1 Organic Acid and Solvent Production 511
PALMER ROGERS, JIANN-SHIN CHEN and MARY JO ZIDWICK

3.2 Amino Acid Production 756
HIDEHIKO KUMAGAI

3.3 Microbial Exopolysaccharides 766
TIMOTHY HARRAH, BRUCE PANILAITIS and DAVID KAPLAN

3.4 Bacterial Enzymes 777
WIM J. QUAX

3.5 Bacteria in Food and Beverage Production 797
MICHAEL P. DOYLE and JIANGHONG MENG

3.6 Bacterial Pharmaceutical Products 812
ARNOLD L. DEMAIN and GIANCARLO LANCINI

3.7 Biosurfactants 834
EUGENE ROSENBERG

3.8 Bioremediation 850
RONALD L. CRAWFORD

3.9 Biodeterioration 864
JI-DONG GU and RALPH MITCHELL

3.10 Microbial Biofilms 904
DIRK DE BEER and PAUL STOODLEY

Index 939

Volume 2

1. Ecophysiological and Biochemical Aspects

1.1 Planktonic Versus Sessile Life of Prokaryotes 3
KEVIN C. MARSHALL

1.2 Bacterial Adhesion 16
ITZHAK OFEK, NATHAN SHARON and SOMAN N. ABRAHAM

1.3 The Phototrophic Way of Life 32
JÖRG OVERMANN and FERRAN GARCIA-PICHEL

1.4 The Anaerobic Way of Life 86
RUTH A. SCHMITZ, ROLF DANIEL, UWE DEPPENMEIER and GERHARD GOTTSCHALK

1.5 Bacterial Behavior 102
JUDITH ARMITAGE

1.6 Prokaryotic Life Cycles 140
MARTIN DWORKIN

1.7 Life at High Temperatures 167
RAINER JAENICKE and REINHARD STERNER

1.8 Life at Low Temperatures 210
SIEGFRIED SCHERER and KLAUS NEUHAUS

1.9 Life at High Salt Concentrations 263
AHARON OREN

1.10 Alkaliphilic Prokaryotes 283
TERRY ANN KRULWICH

1.11 Syntrophism among Prokaryotes 309
BERNHARD SCHINK and ALFONS J.M. STAMS

1.12 Quorum Sensing 336
BONNIE L. BASSLER and MELISSA B. MILLER

1.13 Acetogenic Prokaryotes 354
HAROLD L. DRAKE, KIRSTEN KÜSEL and CAROLA MATTHIES

1.14 Virulence Strategies of Plant Pathogenic Bacteria 421
BARBARA N. KUNKEL and ZHONGYING CHEN

1.15 The Chemolithotrophic Prokaryotes 441
DONOVAN P. KELLY and ANNE P. WOOD

1.16 Oxidation of Inorganic Nitrogen Compounds as an Energy Source 457
EBERHARD BOCK and MICHAEL WAGNER

1.17 The H_2-Metabolizing Prokaryotes 496
EDWARD SCHWARTZ and BÄRBEL FRIEDRICH

1.18 Hydrocarbon-Oxidizing Bacteria 564
EUGENE ROSENBERG

1.19 Cellulose-Decomposing Bacteria and Their Enzyme Systems 578
EDWARD A. BAYER, YUVAL SHOHAM and RAPHAEL LAMED

1.20 Aerobic Methylotrophic Prokaryotes 618
MARY E. LIDSTROM

1.21 Dissimilatory Fe(III)- and Mn(IV)-Reducing Prokaryotes 635
DEREK LOVLEY

1.22 Dissimilatory Sulfate- and Sulfur-Reducing Prokaryotes 659
RALF RABUS, THEO A. HANSEN and FRIEDRICH WIDDEL

1.23 The Denitrifying Prokaryotes 769
JAMES P. SHAPLEIGH

1.24 Dinitrogen-Fixing Prokaryotes 793
ESPERANZA MARTINEZ-ROMERO

1.25 Root and Stem Nodule Bacteria of Legumes 818
MICHAEL J. SADOWSKY and P. H. GRAHAM

1.26 Magnetotactic Bacteria 842
STEFAN SPRING and DENNIS A. BAZYLINSKI

1.27 Luminous Bacteria 863
PAUL V. DUNLAP and KUMIKO KITA-TSUKAMOTO

1.28 Bacterial Toxins 893
VEGA MASIGNANI, MARIAGRAZIA PIZZA and RINO RAPPUOLI

1.29 The Metabolic Pathways of Biodegradation 956
LAWRENCE P. WACKETT

1.30 Haloalkaliphilic Sulfur-Oxidizing Bacteria 969
DIMITRY YU. SOROKIN, HORIA BANCIU, LESLEY A. ROBERTSON and J. GIJS KUENEN

1.31 The Colorless Sulfur Bacteria 985
LESLEY A. ROBERTSON and J. GIJS KUENEN

1.32 Bacterial Stress Response 1012
ELIORA Z. RON

1.33 Anaerobic Biodegradation of Hydrocarbons Including Methane 1028
FRIEDRICH WIDDEL, ANTJE BOETIUS and RALF RABUS

1.34 Physiology and Biochemistry of the Methane-Producing Archaea 1050
REINER HEDDERICH and WILLIAM B. WHITMAN

LUC DEVRIESE, MARGO BAELE and PATRICK BUTAYE

1.2.6 Enterococcus 175
DONALD J. LEBLANC

1.2.7 The Genus *Lactococcus* 205
MICHAEL TEUBER and ARNOLD GEIS

1.2.8 The Genera *Pediococcus* and *Tetragenococcus* 229
WILHELM H. HOLZAPFEL, CHARLES M. A. P. FRANZ, WOLFGANG LUDWIG, WERNER BACK and LEON M. T. DICKS

1.2.9 Genera *Leuconostoc*, *Oenococcus* and *Weissella* 267
JOHANNA BJÖRKROTH and WILHELM H. HOLZAPFEL

1.2.10 The Genera *Lactobacillus* and *Carnobacterium* 320
WALTER P. HAMMES and CHRISTIAN HERTEL

1.2.11 *Listeria monocytogenes* and the Genus *Listeria* 404
NADIA KHELEF, MARC LECUIT, CARMEN BUCHRIESER, DIDIER CABANES, OLIVIER DUSSURGET and PASCALE COSSART

1.2.12 The Genus *Brochothrix* 477
ERKO STACKEBRANDT and DOROTHY JONES

1.2.13 The Genus *Erysipelothrix* 492
ERKO STACKEBRANDT, ANNETTE C. REBOLI and W. EDMUND FARRAR

1.2.14 The Genus *Gemella* 511
MATTHEW D. COLLINS

1.2.15 The Genus *Kurthia* 519
ERKO STACKEBRANDT, RONALD M. KEDDIE and DOROTHY JONES

1.2.16 The Genus *Bacillus*—Nonmedical 530
RALPH A. SLEPECKY and H. ERNEST HEMPHILL

1.2.17 The Genus *Bacillus*—Insect Pathogens 563
DONALD P. STAHLY, ROBERT E. ANDREWS and ALLAN A. YOUSTEN

1.2.18 The Genus *Bacillus*—Medical 609
W. EDMUND FARRAR and ANNETTE C. REBOLI

1.2.19 Genera Related to the Genus *Bacillus*—*Sporolactobacillus*, *Sporosarcina*, *Planococcus*, *Filibacter* and *Caryophanon* 631
DIETER CLAUS, DAGMAR FRITZE and MILOSLAV KOCUR

1.2.20 An Introduction to the Family Clostridiaceae 654
JÜRGEN WIEGEL, RALPH TANNER and FRED A. RAINEY

1.2.21 Neurotoxigenic Clostridia 679
CESARE MONTECUCCO, ORNELLA ROSSETTO and MICHEL R. POPOFF

1.2.22 The Enterotoxic Clostridia 698
BRUCE A. MCCLANE, FRANCISCO A. UZAI,
MARIANO E. FERNANDEZ MIYAKAWA, DAVID LYERLY and
TRACY WILKINS

1.2.23 *Clostridium perfringens* and Histotoxic Disease 753
JULIAN I. ROOD

1.2.24 The Genera *Desulfitobacterium* and *Desulfosporosinus*: Taxonomy 771
STEFAN SPRING and FRANK ROSENZWEIG

1.2.25 The Genus *Desulfotomaculum* 787
FRIEDRICH WIDDEL

1.2.26 The Anaerobic Gram-Positive Cocci 795
TAKAYUKI EZAKI, NA (MICHAEL) LI and YOSHIAKI KAWAMURA

1.2.27 The Order Haloanaerobiales 809
AHARON OREN

1.2.28 The Genus *Eubacterium* and Related Genera 823
WILLIAM G. WADE

1.2.29 The Genus *Mycoplasma* and Related Genera (Class Mollicutes) 836
SHMUEL RAZIN

1.2.30 The Phytopathogenic Spiroplasmas 905
JACQUELINE FLETCHER, ULRICH MELCHER and ASTRI WAYADANDE

1.3 Firmicutes with Atypical Cell Walls

1.3.1 The Family Heliobacteriaceae 951
MICHAEL T. MADIGAN

1.3.2 *Pectinatus*, *Megasphaera* and *Zymophilus* 965
AULI HAIKARA and ILKKA HELANDER

1.3.3 The Genus *Selenomonas* 982
ROBERT B. HESPELL, BRUCE J. PASTER and FLOYD E. DEWHIRST

1.3.4 The Genus *Sporomusa* 991
JOHN A. BREZNAK

1.3.5 The Family Lachnospiraceae, Including the Genera *Butyrivibrio*, *Lachnospira* and *Roseburia* 1002
MICHAEL COTTA and ROBERT FORSTER

3.1.1 The Phototrophic Alpha-Proteobacteria 41
JOHANNES F. IMHOFF

3.1.2 The Genera *Prosthecomicrobium* and *Ancalomicrobium* 65
GARY E. OERTLI, CHERYL JENKINS, NAOMI WARD, FREDERICK A. RAINEY, ERKO STACKEBRANDT and JAMES T. STALEY

3.1.3 Dimorphic Prosthecate Bacteria: The Genera *Caulobacter*, *Asticcacaulis*, *Hyphomicrobium*, *Pedomicrobium*, *Hyphomonas* and *Thiodendron* 72
JEANNE S. POINDEXTER

3.1.4 The Genus *Agrobacterium* 91
ANN G. MATTHYSSE

3.1.5 The Genus *Azospirillum* 115
ANTON HARTMANN and JOSE IVO BALDANI

3.1.6 The Genus *Herbaspirillum* 141
MICHAEL SCHMID, JOSE IVO BALDANI and ANTON HARTMANN

3.1.7 The Genus *Beijerinckia* 151
JAN HENDRICK BECKING

3.1.8 The Family Acetobacteraceae: The Genera *Acetobacter*, *Acidomonas*, *Asaia*, *Gluconacetobacter*, *Gluconobacter*, and *Kozakia* 163
KAREL KERSTERS, PUSPITA LISDIYANTI, KAZUO KOMAGATA and JEAN SWINGS

3.1.9 The Genus *Zymomonas* 201
HERMANN SAHM, STEPHANIE BRINGER-MEYER and GEORG A. SPRENGER

3.1.10 The Manganese-Oxidizing Bacteria 222
KENNETH H. NEALSON

3.1.11 The Genus *Paracoccus* 232
DONOVAN P. KELLY, FREDERICK A. RAINEY and ANN P. WOOD

3.1.12 The Genus *Phenylobacterium* 250
JÜRGEN EBERSPÄCHER and FRANZ LINGENS

3.1.13 *Methylobacterium* 257
PETER N. GREEN

3.1.14 The Methanotrophs—The Families Methylococcaceae and Methylocystaceae 266
JOHN P. BOWMAN

3.1.15 The Genus *Xanthobacter* 290
JÜRGEN WIEGEL

3.1.16 The Genus *Brucella* 315
EDGARDO MORENO and IGNACIO MORIYÓN

3.1.17 Introduction to the Rickettsiales and Other Intracellular Prokaryotes 457
DAVID N. FREDRICKS

3.1.18 The Genus *Bartonella* 467
MICHAEL F. MINNICK and BURT E. ANDERSON

3.1.19 The Order Rickettsiales 493
XUE-JIE YU and DAVID H. WALKER

3.1.20 The Genus *Coxiella* 529
ROBERT A. HEINZEN and JAMES E. SAMUEL

3.1.21 The Genus *Wolbachia* 547
MARKUS RIEGLER and SCOTT L. O'NEILL

3.1.22 Aerobic Phototrophic Proteobacteria 562
VLADIMIR V. YURKOV

3.1.23 The Genus *Seliberia* 585
JEAN M. SCHMIDT and JAMES R. SWAFFORD

3.2. Beta Subclass

3.2.1 The Phototrophic Betaproteobacteria 593
JOHANNES F. IMHOFF

3.2.2 The *Neisseria* 602
DANIEL C. STEIN

3.2.3 The Genus *Bordetella* 648
ALISON WEISS

3.2.4 *Achromobacter*, *Alcaligenes* and Related Genera 675
HANS-JÜRGEN BUSSE and ANDREAS STOLZ

3.2.5 The Genus *Spirillum* 701
NOEL R. KRIEG

3.2.6 The Genus *Aquaspirillum* 710
BRUNO POT, MONIQUE GILLIS and JOZEF DE LEY

3.2.7 *Comamonas* 723
ANNE WILLEMS and PAUL DE VOS

3.2.8 The Genera *Chromobacterium* and *Janthinobacterium* 737
MONIQUE GILLIS and JOZEF DE LEY

3.2.9 The Genera *Phyllobacterium* and *Ochrobactrum* 747
JEAN SWINGS, BART LAMBERT, KAREL KERSTERS and BARRY HOLMES

3.2.10 The Genus *Derxia* 751
JAN HENDRICK BECKING

3.2.11 The Genera *Leptothrix* and *Sphaerotilus* 758
STEFAN SPRING

3.2.12 The Lithoautotrophic Ammonia-Oxidizing Bacteria 778
HANS-PETER KOOPS, ULRIKE PURKHOLD, ANDREAS POMMERENING-RÖSER, GABRIELE TIMMERMANN and MICHAEL WAGNER

3.2.13 The Genus *Thiobacillus* 812
LESLEY A. ROBERTSON and J. GIJS KUENEN

3.2.14 The Genera *Simonsiella* and *Alysiella* 828
BRIAN P. HEDLUND and DAISY A. KUHN

3.2.15 *Eikenella corrodens* and Closely Related Bacteria 840
EDWARD J. BOTTONE and PAUL A. GRANATO

3.2.16 The Genus *Burkholderia* 848
DONALD E. WOODS and PAMELA A. SOKOL

3.2.17 The Nitrite-Oxidizing Bacteria 861
AHARON ABELIOVICH

3.2.18 The Genera *Azoarcus*, *Azovibrio*, *Azospira* and *Azonexus* 873
BARBARA REINHOLD-HUREK and THOMAS HUREK

Index 893

Volume 6

3. Proteobacteria

3.3. Gamma Subclass

3.3.1 New Members of the Family Enterobacteriaceae 5
J. MICHAEL JANDA

3.3.2 Phylogenetic Relationships of Bacteria with Special Reference to Endosymbionts and Enteric Species 41
M. PILAR FRANCINO, SCOTT R. SANTOS and HOWARD OCHMAN

3.3.3 The Genus *Escherichia* 60
RODNEY A. WELCH

3.3.4 The Genus *Edwardsiella* 72
SHARON L. ABBOTT and J. MICHAEL JANDA

3.3.5 The Genus *Citrobacter* 90
DIANA BORENSHTEIN and DAVID B. SCHAUER

3.3.6 The Genus *Shigella* 99
YVES GERMANI and PHILIPPE J. SANSONETTI

3.3.7 The Genus *Salmonella* 123
CRAIG D. ELLERMEIER and JAMES M. SLAUCH

3.3.8 The Genus *Klebsiella* 159
SYLVAIN BRISSE, FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.9 The Genus *Enterobacter* 197
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.10 The Genus *Hafnia* 215
MEGAN E. MCBEE and DAVID B. SCHAUER

3.3.11 The Genus *Serratia* 219
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.12 The Genera *Proteus*, *Providencia*, and *Morganella* 245
JIM MANOS and ROBERT BELAS

3.3.13 *Y. enterocolitica* and *Y. pseudotuberculosis* 270
ELISABETH CARNIEL, INGO AUTENRIETH, GUY CORNELIS, HIROSHI FUKUSHIMA, FRANÇOISE GUINET, RALPH ISBERG, JEANNETTE PHAM, MICHAEL PRENTICE, MICHEL SIMONET, MIKAEL SKURNIK and GEORGES WAUTERS

3.3.14 *Yersinia pestis* and Bubonic Plague 399
ROBERT BRUBAKER

3.3.15 *Erwinia* and Related Genera 443
CLARENCE I. KADO

3.3.16 The Genera *Photorhabdus* and *Xenorhabdus* 451
NOEL BOEMARE and RAYMOND AKHURST

3.3.17 The Family Vibrionaceae 495
J. J. FARMER, III

3.3.18 The Genera *Vibrio* and *Photobacterium* 508
J. J. FARMER, III and F. W. HICKMAN-BRENNER

3.3.19 The Genera *Aeromonas* and *Plesiomonas* 564
J. J. FARMER, III, M. J. ARDUINO and F. W. HICKMAN-BRENNER

3.3.20 The Genus *Alteromonas* and Related Proteobacteria 597
VALERY V. MIKHAILOV, LYUDMILA A. ROMANENKO and ELENA P. IVANOVA

3.3.21 Nonmedical: *Pseudomonas* 646
EDWARD R. B. MOORE, BRIAN J. TINDALL, VITOR A. P. MARTINS DOS SANTOS, DIETMAR H. PIEPER, JUAN-LUIS RAMOS and NORBERTO J. PALLERONI

3.3.22 *Pseudomonas aeruginosa* 704
TIMOTHY L. YAHR and MATTHEW R. PARSEK

3.3.23 Phytopathogenic Pseudomonads and Related Plant-Associated Pseudomonads 714
MILTON N. SCHROTH, DONALD C. HILDEBRAND and NICKOLAS PANOPOULOS

3.3.24 *Xylophilus* 741
ANNE WILLEMS and MONIQUE GILLIS

3.3.25 The Genus *Acinetobacter* 746
KEVIN TOWNER

3.3.26 The Family Azotobacteraceae 759
JAN HENDRICK BECKING

3.3.27 The Genera *Beggiatoa* and *Thioploca* 784
ANDREAS TESKE and DOUGLAS C. NELSON

3.3.28 The Family Halomonadaceae 811
DAVID R. ARAHAL and ANTONIO VENTOSA

3.3.29 The Genus *Deleya* 836
KAREL KERSTERS

3.3.30 The Genus *Frateuria* 844
JEAN SWINGS

3.3.31 The Chromatiaceae 846
JOHANNES F. IMHOFF

3.3.32 The Family Ectothiorhodospiraceae 874
JOHANNES F. IMHOFF

3.3.33 *Oceanospirillum* and Related Genera 887
JOSÉ M. GONZÁLEZ and WILLIAM B. WHITMAN

3.3.34 *Serpens flexibilis*: An Unusually Flexible Bacterium 916
ROBERT B. HESPELL

3.3.35 The Genus *Psychrobacter* 920
JOHN P. BOWMAN

3.3.36 The Genus *Leucothrix* 931
THOMAS D. BROCK

3.3.37 The Genus *Lysobacter* 939
HANS REICHENBACH

3.3.38 The Genus *Moraxella* 958
JOHN P. HAYS

3.3.39 *Legionella* Species and Legionnaire's Disease 988
PAUL H. EDELSTEIN and NICHOLAS P. CIANCIOTTO

3.3.40 The Genus *Haemophilus* 1034
DORAN L. FINK and JOSEPH W. ST. GEME, III

3.3.41 The Genus *Pasteurella* 1062
HENRIK CHRISTENSEN and MAGNE BISGAARD

3.3.42 The Genus *Cardiobacterium* 1091
SYDNEY M. HARVEY and JAMES R. GREENWOOD

3.3.43 The Genus *Actinobacillus* 1094
JANET I. MACINNES and EDWARD T. LALLY

3.3.44 The Genus *Francisella* 1119
FRANCIS NANO and KAREN ELKINS

3.3.45 Ecophysiology of the Genus *Shewanella* 1133
KENNETH H. NEALSON and JAMES SCOTT

3.3.46 The Genus *Nevskia* 1152
HERIBERT CYPIONKA, HANS-DIETRICH BABENZIEN, FRANK OLIVER GLÖCKNER and RUDOLF AMANN

3.3.47 The Genus *Thiomargarita* 1156
HEIDE N. SCHULZ

Index 1165

Volume 7

3. Proteobacteria

3.4 Delta Subclass

3.4.1 The Genus *Pelobacter* 5
BERNHARD SCHINK

3.4.2 The Genus *Bdellovibrio* 12
EDOUARD JURKEVITCH

3.4.3 The Myxobacteria 31
LAWRENCE J. SHIMKETS, MARTIN DWORKIN and HANS REICHENBACH

3.5. Epsilon Subclass

3.5.1 The Genus *Campylobacter* 119
TRUDY M. WASSENAAR and DIANE G. NEWELL

3.5.2 The Genus *Helicobacter* 139
JAY V. SOLNICK, JANI L. O'ROURKE, PETER VAN DAMME and ADRIAN LEE

3.5.3 The Genus *Wolinella* 178
JÖRG SIMON, ROLAND GROSS, OLIVER KLIMMEK and ACHIM KRÖGER

4. Spirochetes

4.1 Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta* 195
SUSAN LESCHINE, BRUCE J. PASTER and ERCOLE CANALE-PAROLA

4.2 The Genus *Treponema* 211
STEVEN J. NORRIS, BRUCE J. PASTER, ANNETTE MOTER and ULF B. GÖBEL

4.3 The Genus *Borrelia* 235
MELISSA J. CAIMANO

4.4 The Genus *Leptospira* 294
BEN ADLER and SOLLY FAINE

4.5 Termite Gut Spirochetes 318
JOHN A. BREZNAK and JARED R. LEADBETTER

4.6 The Genus *Brachyspira* 330
THADDEUS B. STANTON

5. Chlorobiaceae

5.1 The Family Chlorobiaceae 359
JÖRG OVERMANN

6. Bacteroides and Cytophaga Group

6.1 The Medically Important *Bacteroides* spp. in Health and Disease 381
C. JEFFREY SMITH, EDSON R. ROCHA and BRUCE J. PASTER

6.2 The Genus *Porphyromonas* 428
FRANK C. GIBSON and CAROLINE ATTARDO GENCO

6.3 An Introduction to the Family Flavobacteriaceae 455
JEAN-FRANÇOIS BERNARDET and YASUYOSHI NAKAGAWA

6.4 The Genus *Flavobacterium* 481
JEAN-FRANÇOIS BERNARDET and JOHN P. BOWMAN

6.5 The Genera *Bergeyella* and *Weeksella* 532
CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE

6.6 The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella* 539
BARRY HOLMES

6.7 The Order Cytophagales 549
HANS REICHENBACH

6.8 The Genus *Saprospira* 591
HANS REICHENBACH

6.9 The Genus *Haliscomenobacter* 602
EPPE GERKE MULDER and MARIA H. DEINEMA

6.10 *Sphingomonas* and Related Genera 605
DAVID L. BALKWILL, J. K. FREDRICKSON and M. F. ROMINE

6.11 The Genera *Empedobacter* and Myroides 630
CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE

6.12 The Genera *Chryseobacterium* and *Elizabethkingia* 638
JEAN-FRANÇOIS BERNARDET, CELIA J. HUGO and BRITA BRUUN

6.13 The Marine Clade of the Family Flavobacteriaceae: The Genera Aequorivita, Arenibacter, Cellulophaga, Croceibacter, Formosa, Gelidibacter, Gillisia, Maribacter, Mesonia, Muricauda, Polaribacter, Psychroflexus, Psychroserpens, Robiginitalea, Salegentibacter, Tenacibaculum, Ulvibacter, Vitellibacter and Zobellia 677
JOHN P. BOWMAN

6.14 Capnophilic Bird Pathogens in the Family Flavobacteriaceae: Riemerella, Ornithobacterium and Coenonia 695
PETER VAN DAMME, H. M. HAFEZ and K. H. HINZ

6.15 The Genus *Capnocytophaga* 709
E. R. LEADBETTER

6.16 The Genera *Rhodothermus*, *Thermonema*, *Hymenobacter* and *Salinibacter* 712
AHARON OREN

7. Chlamydia

7.1 The Genus *Chlamydia*—Medical 741
MURAT V. KALAYOGLU and GERALD I. BYRNE

8. Planctomyces and Related Bacteria

8.1 The Order Planctomycetales, Including the Genera *Planctomyces*, *Pirellula*, *Gemmata and Isosphaera* and the Candidatus Genera *Brocadia*, *Kuenenia* and *Scalindua* 757
NAOMI WARD, JAMES T. STALEY, JOHN A. FUERST, STEPHEN GIOVANNONI, HEINZ SCHLESNER and ERKO STACKEBRANDT

9. Thermus

9.1 The Genus *Thermus* and Relatives 797
MILTON S. DA COSTA, FREDERICK A. RAINEY and M. FERNANDA NOBRE

10. Chloroflexaceae and Related Bacteria

10.1 The Family Chloroflexaceae 815
SATOSHI HANADA and BEVERLY K. PIERSON

10.2 The Genus *Thermoleophilum* 843
JEROME J. PERRY

10.3 The Genus *Thermomicrobium* 849
JEROME J. PERRY

10.4 The Genus *Herpetosiphon* 854
NATUSCHKA LEE and HANS REICHENBACH

11. Verrucomicrobium

11.1 The Phylum Verrucomicrobia: A Phylogenetically Heterogeneous Bacterial Group 881
HEINZ SCHLESNER, CHERYL JENKINS and JAMES T. STALEY

12. Thermotogales

12.1 Thermotogales 899
ROBERT HUBER and MICHAEL HANNIG

13. Aquificales

13.1 Aquificales 925
ROBERT HUBER and WOLFGANG EDER

14. Phylogenetically Unaffiliated Bacteria

14.1 Morphologically Conspicuous Sulfur-Oxidizing Eubacteria 941
JAN W. M. LA RIVIÈRE and KARIN SCHMIDT

14.2 The Genus *Propionigenium* 955
BERNHARD SCHINK

14.3 The Genus *Zoogloea* 960
PATRICK R. DUGAN, DAPHNE L. STONER and HARVEY M. PICKRUM

14.4 Large Symbiotic Spirochetes: *Clevelandina*, *Cristispira*, *Diplocalyx*, *Hollandina* and *Pillotina* 971
LYNN MARGULIS and GREGORY HINKLE

14.5 *Streptobacillus moniliformis* 983
JAMES R. GREENWOOD and SYDNEY M. HARVEY

14.6 The Genus *Toxothrix* 986
PETER HIRSCH

14.7 The Genus *Gallionella* 990
HANS H. HANERT

14.8 The Genera *Caulococcus* and *Kusnezovia* 996
JEAN M. SCHMIDT and GEORGI A. ZAVARZIN

14.9 The Genus *Brachyarcus* 998
PETER HIRSCH

14.10 The Genus *Pelosigma* 1001
PETER HIRSCH

14.11 The Genus *Siderocapsa* (and Other Iron- and Maganese-Oxidizing Eubacteria) 1005
HANS H. HANERT

14.12 The Genus *Fusobacterium* 1016
TOR HOFSTAD

14.13 Prokaryotic Symbionts of Amoebae and Flagellates 1028
KWANG W. JEON

Delta Subclass

Prokaryotes (2006) 7:5–11
DOI: 10.1007/0-387-30747-8_1

CHAPTER 3.4.1

The Genus *Pelobacter*

BERNHARD SCHINK

The genus *Pelobacter* was proposed as a taxonomic entity consisting of strictly anaerobic, Gram-negative, nonspore-forming, rod-shaped bacteria that use only a very limited number of substrates. The members of the genus are all unable to ferment sugars and therefore cannot be grouped with any other genus in the family Bacteroidaceae (Krieg and Holt, 1984). The genus comprises five different species, *P. acidigallici* (Schink and Pfennig, 1982), *P. venetianus* (Schink and Stieb, 1983), *P. carbinolicus* (Schink, 1984), *P. propionicus* (Schink, 1984), and *P. acetylenicus* (Schink, 1985), which all are based on 3–5 described strains.

Comparisons of the various *Pelobacter* species by DNA-DNA hybridization experiments revealed that the genus is rather inhomogenous; therefore, a reorganization may perhaps be necessary in the future (J. P. Touzel and B. Schink, unpublished observations). Whereas the species *P. venetianus*, *P. carbinolicus*, and *P. acetylenicus* form a homogenous cluster, *P. acidigallici* and *P. propionicus* appear to be only distantly related to the others. These findings are consistent to some extent with the fermentation patterns of these species (see below). Comparison of three *Pelobacter* species with other anaerobes on the basis of 16S rRNA structure analysis supports this view. Whereas *P. venetianus* and *P. carbinolicus* exhibit a rather high similarity, with an S_{AB} of 0.70, *P. acidigallici* is related to both at an S_{AB} of only 0.53 (Stackebrandt et al., 1989). It is interesting to note that these three Pelobacter strains did not show any resemblance to other fermenting Gram-negative strict anaerobes; instead, they appeared to be highly related to several strains of sulfur-reducing anaerobes, namely, *Desulfuromonas succinoxidans*, *D. acetexigens*, and *D. acetoxidans*, to which they are even more closely related than *P. acidigallici* is to the other two *Pelobacter* species. Since *Pelobacter* species and the obligately sulfur-respiring bacteria are quite diverse metabolically and the latter are supposed to have derived directly from phototrophic ancestors, it has been suggested that the genus *Pelobacter* represents a group of fermenting bacteria that developed a fermentative metabolism as a "secondary" evolutionary event and that they are separate from the first fermentative bacteria (Stackebrandt et al., 1989).

Habitat

All *Pelobacter* strains have been isolated so far from marine or freshwater sediments. The name *Pelobacter* was based on this origin (Greek *pelos* meaning mud, sediment). Enrichments from sewage sludges led to similar isolates as well. Viable counts using the characteristic substrates gallic acid, acetoin, polyethylene glycol, and acetylene showed that there were approximately 100 cells/ml of each of the *Pelobacter* species in sediment and up to 2,500 cells/ml in sewage sludge. Since their substrate ranges are comparably small, their ecological niche in such sediments can be understood rather well in most cases. *P. acidigallici* is restricted to the utilization of trihydroxybenzenoids, which are probably its only energy source in its natural habitat. *P. venetianus*, *P. carbinolicus*, *P. propionicus*, and *P. acetylenicus* were enriched and isolated with polyethylene glycol, 2,3-butanediol, and acetylene, respectively, but the ecological importance of these substrates in the respective environments is questionable. Since all these species can also ferment ethanol, either in syntrophic cooperation with hydrogen scavengers or in pure culture, it appears more probable that degradation of this important fermentation intermediate is their predominant function in these environments. *P. carbinolicus* has been identified as the dominant ethanol-degrading bacterium in digesting industrial sewage sludge (Dubourguier et al., 1986), and high numbers (10^6–10^7 cells/ml) of syntrophically ethanol-oxidizing anaerobes were detected also in other sewage sludges (Schink et al., 1985) and in freshwater creek sediments (Eichler and Schink, 1985). *Pelobacter* has to compete for ethanol with certain homoacetogenic bacteria, e.g., *Clostridium aceticum* (Wieringa, 1940) or *Acetobacterium carbinolicum* (Eichler and Schink, 1984), which appear to be at least as successful in freshwater sediments (Schink et al., 1985), especially if the sediment is slightly acidic (Schink et al., 1985) or the temperature is low (Conrad et al., 1989). The ecological importance of ethanol fermentation to propionate by *P. propionicus* has been elucidated by enumerations and by tracer experiments (Schink et al., 1985). These studies revealed that up to 20% of the total ethanol turnover can go through propionate and that bacteria forming propionate from ethanol contribute significantly to the total ethanol-metabolizing microbial community.

It has to be concluded that bacteria of the metabolic types represented by the various *Pelo-*

This chapter was taken unchanged from the second edition.

bacter species make up a significant part of the anaerobic microbial population in sediments and sewage sludge. No *Pelobacter*-like bacteria have so far been isolated from the rumen. The numerically predominant, syntrophically ethanol-oxidizing *Pelobacter* species represent new isolates of the metabolic type of the S-strain in the mixed culture "*Methanobacillus omelianskii*" (Bryant et al., 1967). These *Pelobocter* species have become accessible to pure culture growth in our laboratory by the use of unusual substrates that all can be converted easily into acetaldehyde, the key intermediate in the energy metabolism of these bacteria (see next section).

Isolation

Growth Media

All *Pelobacter* strains have been enriched and isolated in a carbonate-buffered, sulfide-reduced mineral medium that contained only one organic energy and carbon source. Since they grow with substrates that yield 2-carbon intermediates exclusively, they have to form pyruvate and sugars via reductive carboxylation of acetyl coenzyme A and need carbon dioxide for this reaction. Use of a bicarbonate-buffered medium is therefore recommended for enrichment, isolation, and maintenance. Three different versions of this medium are described below for the isolation of *Pelobacter* from freshwater, estuarine, and marine sediment, respectively (after Widdel and Pfennig, 1981; Schink and Pfennig, 1982):

Pelobacter Growth Media

Dissolve in 1 liter of distilled water:

Autoclave the complete mineral medium in a vessel equipped with 1) a filter inlet to allow flushing of the headspace with sterile oxygen-free gas; 2) screw-cap inlets for addition of thermally unstable additives after autoclaving; 3) a silicon tubing connection from the bottom of the vessel out to a dispensing tap (if possible with a protecting bell) for sterile dispensing of the medium (do not use latex tubing; it releases compounds which are highly toxic to many anaerobes); and 4) a stirring bar.

After autoclaving, connect the vessel with the still-hot medium to a line of oxygen-free nitrogen/carbon dioxide mixture (90%: 10%) at low pressure (<100 mbar), flush the headspace and cool it under this atmosphere to room temperature, perhaps with the help of a cooling water bath.

The mineral medium is amended with the following additions from stock solutions that have been sterilized separately (amounts/l of medium): a) 30 ml of 1 M $NaHCO_3$ solution (autoclaved in a *tightly closed* screw-cap bottle with about 30% headspace; the bottle should be autoclaved inside another protective vessel, e.g., a polypropylene beaker, to avoid spills of carbonates if the bottle breaks in the autoclave); b) 2 ml of 0.5 M $Na_2S9{\cdot}H_2O$ solution (autoclaved separately under oxygen-free gas atmosphere as above); c) 1 ml of trace element solution, e.g., SL 10 (Widdel et al., 1983); d) 0.5 ml of 10-fold concentrated, filter-sterilized vitamin solution (Pfennig, 1978); and e) adequate amounts of sterile 1 M HC1 or 1 M $Na_2\ CO_3$ to adjust the pH to 7.1–7.3.

The complete medium is dispensed into either screw-cap bottles or screw-cap tubes which are filled completely to the top, leaving a lentil-sized air bubble for pressure equilibration. Enrichment cultures usually produce gas in the first enrichment stages and are better cultivated in half-filled serum bottles (50–100 ml volume) under a headspace of nitrogen: carbon dioxide mixture (90%:10%).

This mineral medium is amended with the respective organic substrates for enrichment and cultivation of pure cultures. The vitamin mixture is not really needed by all strains.

Selective Enrichment

All enrichment cultures were set up in our laboratory at 27–30°C in 50-ml fluid cultures inoculated with about 5 ml of sediment or sludge. Smaller inocula may also lead to isolation of the same bacteria, but this has not been evaluated in our lab. *P. acidigallici* can be selectively enriched with either one of its growth substrates (see Table 1) at 5–10 mM concentration. For enrichment of *P. venetianus*, either polyethylene glycol (mol wt 106–20,000; 0.1% w/v) or methoxyethanol (10 mM; Tanaka and Pfennig, 1988) is recommended. In this medium, 10 mM 2,3-butanediol enriches for *P. carbinolicus* from marine sediments and for *P. propionicus* from freshwater sediments. *P. acetylenicus* is successfully enriched with mineral medium under the above-mentioned nitrogen: carbon dioxide atmosphere containing 5–10% acetylene in addition.

Isolation

After 3–4 transfers in liquid medium, a homogeneous microbial population should have become established in liquid enrichment cultures. Purification of *Pelobacter* species is most easily done by serial dilution in agar deep cultures ("agar shakes"; Pfennig, 1978). Roll tubes have not been used and are not necessary since these bacteria neither consume nor produce insoluble gaseous compounds. *P. acetylenicus* can be easily purified with 10 mM acetoin as substrate. Other procedures (streaking on agar plates in an anoxic glove box or on agar surfaces in flat agar bottles) have not been tried yet, but there is no reason why such methods would not be successful as well, if the solid media are incubated under a nitrogen/carbon dioxide atmosphere.

Preservation

Liquid cultures were maintained in our laboratory in 50-ml bottles at 4°C for 4–12 weeks

Table 1. Properties of the five *Pelobacter* species.

[a]Growth is possible only at very low concentration (<1 mM) or in continuous culture.
[b]Growth is possible only in the presence of a hydrogen-scavenging anaerobe, e.g., a methanogenic bacterium.
[c]Growth is possible only in the presence of small amounts of acetate for cell carbon synthesis.
Symbols: +, growth; –, no growth.

between transfers. Longer storage intervals may be possible as well. Long-term preservation is easily accomplished by storage of dense cell suspensions in glass capillaries kept in liquid nitrogen.

Identification

Morphological and Cytological Properties

Cells of all *Pelobacter* species are Gram-negative, short rods that do not form spores (Fig. 1). The cell ends are usually rounded; however, *P. acetylenicus* cells can be slightly pointed (Fig. 1e). The cell sizes vary from 0.5 to 1.0 μm in width and from 1.2 to 6.0 μm in length. More exact cell sizes of the different type strains are listed in Table 1. The temperature optima for growth are in the range of 28–35°C; the pH optima are 6.5–7.5. On the basis of the GC content of the DNA, two clusters can be defined; the one (*P. acidigallici*, *P. venetianus*, *P. carbinolicus)* has a GC value at 50–53 mol%, the other one *(P. acetylenicus*, *P. propionicus)* at 57–58 mol%. It should be noted that this clustering does not agree with the subgroupings based on DNA and RNA homologies (see "Introduction," this chapter) or with physiological similarities.

Cytochromes have been found only in *P. propionicus*. A *b*-type cytochrome was detected at a very low level (Schink et al., 1987), but there is no evidence that this cytochrome plays any role in ATP-generating electron transport (see below).

Physiological Properties and Biochemistry

Table 1 presents a listing of all substrates used by the various *Pelobacter* species described so far. It is obvious from this table that *Pelobacter acidigallici* differs in its substrate spectrum from all other *Pelobacter* species. It utilizes only trihydroxybenzenoids for growth, and it ferments them to acetate as sole fermentation product. With this, it resembles *Eubacterium oxidoreducens* (Krumholz and Bryant, 1986) to some extent, but does not depend on formate as an external co-substrate for degradation of these compounds. Growth experiments with increased substrate concentrations have revealed that the pathway of gallic acid fermentation leads via pyrogallol and phloroglucinol (Samain et al., 1986) and has nothing in common with the pathway of anaerobic benzoate degradation (Evans, 1977). Obviously, three hydroxyl groups in alternating position at the ring polarize the π-electron system sufficiently to permit selective reduction to dihydrophloroglucinol and ring opening by a thiolytic or hydrolytic mechanism. The isomerization of pyrogallol to phloroglucinol has recently been characterized as a unique transhydroxylase reaction involving a tetrahydroxybenzene as co-substrate (Brune and Schink, 1990). The third trihydroxybenzene isomer, hydroxyhy-

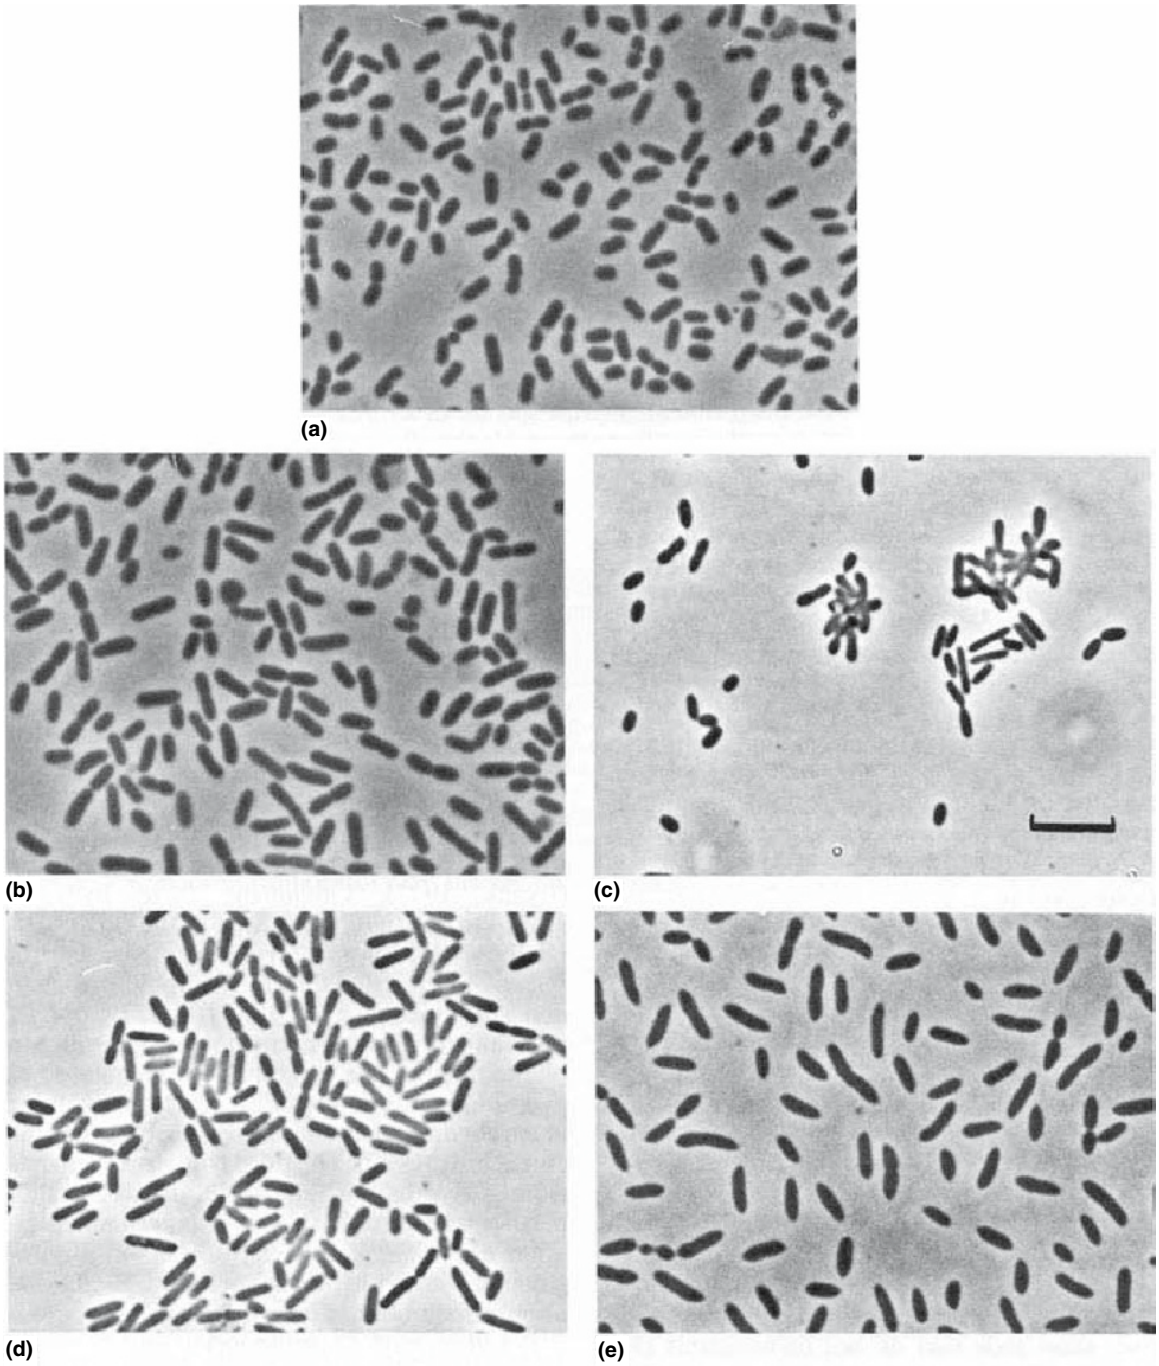

Fig. 1. Phase contrast photomicrographs of cells of *Pelobacter* species. Bar = 5 µm for all figures. (a) *P. acidigallici*; (b) *P. venetianus*; (c) *P. carbinolicus*; (d) *P. acetylenicus*; (e) *P. propionicus*.

droquinone, is not metabolized by these bacteria, but it is fermented by other new anaerobic bacteria, also via phloroglucinol (A. Brune, S. Schnell and B. Schink, unpublished observations).

P. venetianus, *P. carbinolicus*, and *P. acetylenicus* have been enriched and isolated with polyethylene glycol, 2,3-butanediol, or acetylene, respectively. They can all grow with acetoin, some also with ethylene glycol or ethanolamine. All these substrates are converted to acetaldehyde, which is further dismutated to acetate and ethanol as final products. ATP is formed exclusively by substrate level phosphorylation via the acetate kinase reaction. The higher homologs of

ethylene glycol, 1,2-propanediol and 1,2-butanediol, are dismutated to propanol and propionate or butanol and butyrate, respectively, provided that the medium contains some acetate (2–3 mM) for synthesis of cell material. Glycerol undergoes a similar dismutation to 3-hydroxypropionate and 1,3-propanediol. It is interesting to note that glycerol fermentation also requires the presence of acetate and that this substrate cannot itself be assimilated.

In the presence of hydrogen-scavenging anaerobes, e.g., homoacetogens or methanogens, *Pelobacter* oxidizes primary aliphatic alcohols to the corresponding acids; with propanol and butanol, acetate is again required for cell matter synthesis. This syntrophic oxidation of ethanol via "interspecies hydrogen transfer" was first observed with the S-strain isolated from the syntrophic mixed culture "*Methanobacillus omelianskii*" (Bryant et al., 1967), which was lost many years ago. *Pelobacter* strains are the only representatives of this type of metabolism that are available today in pure cultures. Pure and mixed culture experiments have been carried out recently to understand the energetics and kinetics of interspecies hydrogen transfer in model cultures of *P. acetylenicus* and hydrogen-scavenging homoacetogenic and methanogenic partners (Seitz et al., 1988; Seitz et al., in preparation).

The biochemistry of polyethylene glycol degradation is not yet understood, neither in *P. venetianus* nor in other polyethylene glycol-degrading anaerobes (Dwyer and Tiedje, 1986; Wagener and Schink, 1988). *P. venetianus* degrades all polymers from the dimer up to a molecular weight of 40,000. Growth experiments in batch and continuous culture have shown that ethylene glycol can also support growth if it is provided at limiting amounts and that acetaldehyde is the first free intermediate in both polymer and monomer degradation (Strass and Schink, 1986). Perhaps the polymer is attacked by a diol dehydratase-like reaction that transforms the terminal ether linkage into an unstable half-acetal linkage yielding acetaldehyde as product. Unfortunately, the cleavage reaction is very difficult to demonstrate in cell-free extracts, and a B_{12} compound of atypical structure appears to be involved (E. Schramm and B. Schink, unpublished observations). This cleavage reaction occurs inside the cells, and it is not clear how high-molecular-weight polyethylene glycols are able to cross the cytoplasmic membrane at sufficiently high transport rates.

Anaerobic degradation of polyethylene glycols is of major ecological concern because many industrially produced nonionic surfactants contain polyethylene glycols as hydrophilic moieties that may be subject to anaerobic degradation in anoxic sediments and sludge (Wagener and Schink, 1987, 1988).

P. carbinolicus is related to *P. venetianus* and has basically the same biochemistry and physiology. It degrades ethylene glycol rather than polyethylene glycols, and it was originally enriched and isolated with acetoin or 2,3-butanediol as substrate. 2,3-Butanediol is oxidized to acetoin, which undergoes oxidative cleavage to acetyl CoA and acetaldehyde by a dichlorophenol indophenol-dependent enzyme analogous to pyruvate dehydrogenase (Oppermann et al., 1988). The physiological electron acceptor of this enzyme is not yet known. Acetaldehyde is either oxidized by a benzyl viologen-dependent enzyme to acetyl CoA or, depending on the electron balance, reduced to ethanol.

P. acetylenicus is the first strict anaerobe known to ferment an unsaturated hydrocarbon in pure culture. Again, the first intermediate of acetylene fermentation is acetaldehyde, which is further dismutated to acetate and ethanol. The enzyme that hydrates acetylene to acetaldehyde could not be demonstrated in a cell-free assay system; perhaps unusual cofactors are also involved in this reaction. A report on an acetylene-hydratase enzyme in cell-free extracts of an aerobic *Rhodococcus* species (deBont and Peck, 1980) could not be reproduced in our hands either. The function of such an acetylene-hydrating enzyme in an anoxic environment is hard to understand since acetylene is probably not an important substrate in such environments. Perhaps its main role is hydration of other possibly toxic compounds, such as nitriles or cyanides, but there is no experimental evidence so far for such activities.

P. propionicus differs from the other *Pelobacter* species by producing propionate as one of its main fermentation products. Degradation of acetoin, 2,3-butanediol, and ethanol probably follows the same routes via acetaldehyde and acetyl CoA, as outlined above for the other species. The biochemistry of propionate formation from these C-2 compounds has been studied in detail (Schink et al., 1987). The key reaction is catalyzed by pyruvate synthase (pyruvate ferredoxin oxidoreductase), which operates here in the opposite direction to that predicted by its chemical equilibrium. The equilibrium is shifted by the exergonic propionate-forming reaction chain via methylmalonyl CoA; this chain is not coupled to ATP-yielding electron transport phosphorylation in these bacteria. This reaction in *P. propionicus* and other bacteria with similar biochemical capacities (Stams et al., 1984; Samain et al., 1982) is probably responsible for the formation of C-3 compounds from C-2 compounds in significant amounts in anoxic sediments and sludges (Goldberg and Cooney, 1981; Schink et al., 1985).

Applications

All *Pelobacter* strains discussed in this chapter may act as important syntrophic oxidants of primary aliphatic alcohols in sediments and sludges, where they have been found to be predominant (Dubourgier et al., 1986). Of technological interest may be the capacity of *P. venetianus* and similar isolates to degrade polyethylene glycols and to attack nonionic surfactants based on these compounds. These surfactants are of growing interest in the industrial manufacture of detergents, soaps, emulsifiers, etc. Aerobic degradation of polyethylene glycol-containing surfactant wastes creates enormous problems of foam formation in conventional activated-sludge sewage treatment and in natural waters. Anaerobic degradation of most of these compounds to methane can easily be achieved in packed column reactors, in which *P. venetianus*-like anaerobes ferment the polyethylene glycol moieties to substrates for the methanogenic microbial community (Wagener and Schink, 1987).

P. propionicus produces acetate and propionate from the substrates listed in Table 1. Propanol is fermented together with acetate exclusively to propionate. This fermentation may be of interest for biological production of propionate at high purity.

Acknowledgments. The author wishes to thank N. Pfennig and H. G. Trüper for their help on all questions concerning bacterial taxonomy and in the establishment of this new genus. The assistance of Martin Bomar in compiling the phase contrast photomicrographs shown in Fig. 1 is highly appreciated.

CHAPTER 3.4.2

The Genus *Bdellovibrio*

EDOUARD JURKEVITCH

Introduction

Bdellovibrio spp. are Gram negative, motile, and uniflagellated bacteria. What characterizes this bacterial genus as unique is its predatory behavior: Bdellovibrios attack other Gram negative cells, penetrate their periplasm, multiply in their cytoplasm, and finally burst their cell envelopes to start anew (Figure 1). Although many predator bacteria may lyse other bacteria, and many "micropredators" have been described, these *Bdellovibrio*-like organisms can grow without bacterial prey and do not divide inside the periplasm (Varon and Shilo, 1978).

Bdellovibrio research began with their serendipitous discovery by Stolp and Petzold (1962). The physiology, ecology, taxonomy, interactions with prey, and cell cycle of *Bdellovibrio* were established in the 1960's and 70's mainly by the groups of Shilo and Varon, Stolp and Starr, Rittenberg, Hespell, Diedrich, Ruby, Tudor, Thomashow, and more recently Williams.

Bdellovibrios can be described as predators, or parasites, or symbionts (Starr, 1975). In this review, the terms predator-prey and parasite-host will be used interchangeably.

Bdellovibrios are found in wet, aerobic environments. As described in other sections, their importance in shaping or influencing bacterial community dynamics and structure is still unknown. Similarly, the way these predators interact with potential prey, their survival mechanisms, and their preferred habitats in natural settings or man-made biotops are poorly understood.

Particularly fascinating is the two-phased cell cycle of bdellovibrios, which are dimorphic. During the "attack phase," small cells (0.5 to 1.5 μm long, 0.5 μm in diameter, Figure 2) swim at speeds up to one hundred body lengths·sec^{-1} (Stolp, 1967) to find prey. Prey-encounter is apparently by random collision, as evidence of chemotaxis has not been detected. After encountering and attaching to a substrate cell, a predatory cell penetrates the periplasm, shedding its long-sheathed flagellum in the process. The "growth phase" can then be initiated. The invaded bacterium usually rounds into the ensemble predator-prey, called a bdelloplast (Figure 3). Within this confined space *Bdellovibrio* engages in restricted development, turning the short cell into an unseptated filament at the expense of the host's cytoplasm (Figure 4). After a lag phase of about 45 min, DNA begins to replicate within the bdelloplast and proceeds for a couple of hours along with cell growth, and then the filament divides by multiple fission into progeny attack cells, the number determined by the size of the host. Progeny bursts from the ghost cell, ready for another attack cycle. Within the bdelloplast, the bdellovibrio cell is protected from photooxidation (Friedberg, 1977) and phage attack (Varon and Seijffers, 1975) and shows increased resistance to pollutants (Varon and Shilo, 1981). Host-independent mutants growing axenically can be isolated. The cell cycle can be extended to include the development of a cyst-like stage called a bdellocyst, which, however, has been seen in only two strains.

Basic biological questions such as predator-prey interactions, host recognition, regulation of a simple developmental program, and cell-cell signaling can be addressed by using this two-membered model. We shall deal with each of these issues in the linked sections.

Taxonomy

The taxomony of *Bdellovibrio* is still fragmentary. Historically, microorganisms that have been assigned to the genus *Bdellovibrio* exhibit characteristic features: flagellum-driven high motility, attachment and penetration through the outer membrane of Gram-negative hosts, intraperiplasmic growth, cell multiplication at the expense of host cytoplasm, lysis of prey, and finally release of *progeny*. Their wide habitat and heterogeneity can be interpreted in terms of development of a common lifestyle by convergent evolution or increased heterogeneity by divergent evolution from a common very ancient ancestor (Varon and Shilo, 1978).

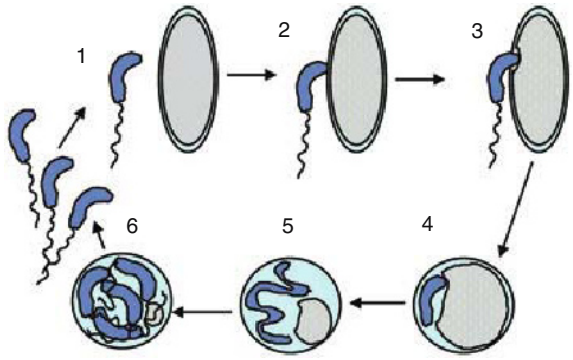

Fig. 1. The life cycle of *Bdellovibrio*. 1. Attack-phase cells; 2. Attachment to the prey's outer membrane; 3. Penetration; 4. Initiation of growth; 5. Intraperiplasmic growth; 6. Differentiation into attack cells and lysis of the prey envelope.

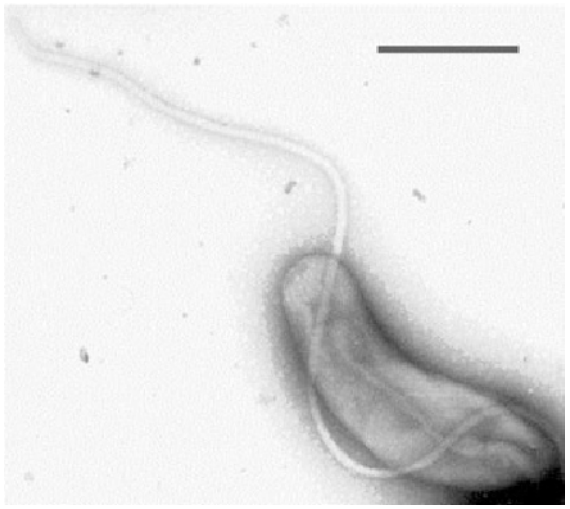

Fig. 2. A *Bdellovibrio* cell in the attack phase. The flagellum is wrapped around the cell. Bar: 0.5 µm.

The genus has been placed within the Proteobacteria (Ribosomal Database Project), myxobacteria and sulfate-reducing bacteria being their closest relatives. Based on G+C content, DNA/DNA (Table 1) and DNA/rRNA homology, and enzyme migration patterns, the genus was divided into three species: *B. bacteriovorus*, *B. stolpii* and *B. starrii* (Siedler et al., 1972). *Bdellovibrio* strain W, one of the two bdellocyst-forming isolates (Hoeniger et al., 1972), and the marine isolates were left undefined. The ion requirements of these halophilic isolates have been described (Taylor et al., 1974; Marbach and Shilo, 1978). Based on the similarities in host ranges, Taylor et al. (1974) subdivided the 13 analyzed isolates into three groups. Mole %G+C of three isolates from one group was similar (38.5–38.8) and much lower than that of any of the terrestrial isolates, whereas G+C content of

Strain W	2030	43.7					100	32
N 6804 (ICPB 3294)	2040	37.4						100

one isolate from another group was 43.5%. Marbach et al. (1976) separated halophilic bdellovibrios into 10 groups, based on prey range. However, no such grouping was found by Torrella et al. (1978) or by Schoeffield et al. (1991), and host range was shown to depend on the experimental conditions, thereby raising questions about the usefulness of this parameter as a taxonomic criterion. Bacteriophages of bdellovibrios (bdellophages) have been isolated (Sagi and Levisohn, 1976; Althauser et al., 1972; Varon and Levisohn, 1972; Hashimoto et al., 1970) and in some instances used to define taxomic groups of bdellovibrios (Althauser et al., 1972; Varon, 1974).

16S rRNA

Resolution of the phylogeny of *Bdellovibrio* has been increased by the analysis of the 16S rRNA molecule. Donze et al. (1991) analyzed 11 terrestrial strains and one marine isolate using partial sequences of the *16S rDNA* gene. Their results confirmed the placement of Bdellovibrio within the Proteobacteria and showed *Bdellovibrio* strains were related more closely to each other than to other bacteria, supporting the claim of common ancestry. The heterogeneity of the genus *Bdellovibrio* could be divided into two groups, *B. bacteriovorus* strains forming one and *B. stolpii*, *B. starrii* and the marine isolate the other (Figure 5). However, the large phenotypic and molecular (%G+C content, DNA/DNA reassociation) differences between the marine and terrestrial isolates, the scant molecular information available on the diversity of marine strains, and the heterogeneity observed within the species *B. bacteriovorus* call for further studies.

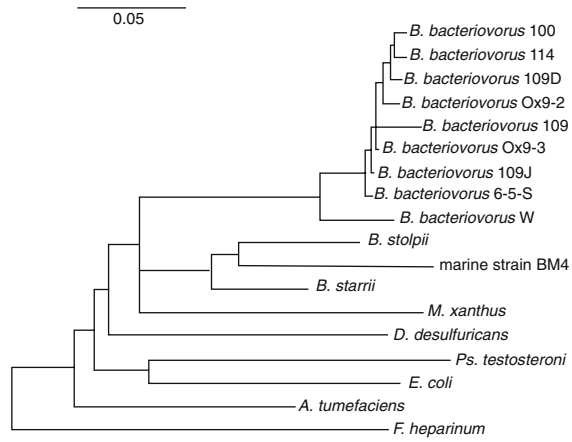

Fig. 5. Phylogenetic tree for 12 strains of *Bdellovibrio* based on the analysis of the 16S rRNA gene. Bar: fractional difference in nucleotide sequence. (From Donze et al., 1991.)

Serological Classification

Immunological approaches have been shown to offer a level of sensitivity high enough to resolve taxonomic groups of bdellovibrios (Schoeffield et al., 1991; Schelling et al., 1983; Kramer et al., 1977). Using techniques such as immunodiffusion, immunoelectrophoresis, agglutination, and indirect immunofluorescence, halophilic and nonhalophilic bdellovibrios can be separated into several serologically distinct subgroups: the terrestrial subgroups, sharing a common antigen (Schelling et al., 1983; Kramer et al., 1977); the halophilic isolates (Schoeffield et al., 1991), each identified by at least one common antigen; and the aquatic, salt-loving strains, sharing a common antigen with terrestrial strain W (Schoeffield et al., 1991). Thus, such immunology-based tools can help determine taxonomy.

Habitat and Ecology

Bdellovibrios have been isolated from a wide range of water systems: estuaries (brackish water), sea coasts and oceans, rivers, sewage, fish ponds, runoff (irrigation water), and man-made water supplies. Also, organisms have been found in the gills of crabs, in sediments, on submerged surfaces, in soils, in rice paddies, and in the rhizosphere of plants. Table 2 presents a summary of biotops in which *Bdellovibrio* were detected. Interestingly, the concentration of recovered *Bdellovibrio* in rivers correlated with water pollution. Whereas no predators could be detected

in pure well waters (Varon and Shilo, 1978), *Bdellovibrio* counts increased from 10 to 3500 PFU·mL^{-1} (plaque-forming units) at the source and near an urbanized section of the river, respectively (Lambina et al., 1974). Although a higher total bacterial load in the sample may promote *Bdellovibrio* growth, the predator has been shown sensitive to environmental pollutants such as heavy metals, detergents, and pesticides (Varon and Shilo, 1978). Bdellovibrios are aerobic, multiplying under oxic conditions, but they are able to survive anoxic periods as attack-phase cells or as bdelloplasts (Schoeffield et al., 1991). Furthermore, halo-tolerant predators have been shown to grow under microaerobic conditions. Spells of low oxygen tension occur in soils and in water, and the parasite seems to be adapted to these conditions. The range of possible niches for bdellovibrios to survive and be active, therefore, may not be restricted to permanently aerobic biotas.

Another environment in which bdellovibrios have been found is biofilms on surfaces. In the continuous space between the solid phases of biofilms, dissolved chemicals, suspended particles, and cells move freely (Wanner, 1989). It is therefore plausible that bdellovibrios due to their small size, high motility, and mode of multiplication may strongly influence the bacterial composition of their associated biofilms. Recently, an isolate that effectively reduces the level of biofilm *E. coli* cells on stainless steel has been reported (Fratamico and Cooke, 1996). In some instances, biofilms seem to offer better conditions for the multiplication and survival of bdellovibrios as they have been found in the fabric of natural marine biofilms but not always recovered from the surrounding water (Kelley et al., 1997; Kelley et al., 1992; Williams et al., 1995). In these specific econiches, bdellovibrios might become entrapped in the gel-matrix of biofilms, benefiting from higher concentrations of prey cells that ensure survival, a greater multiplication rate, and also physical protection. Surface-associated bdellovibrios were shown to survive various environmental insults but free-living cells died rapidly (Markelova et al., 1998).

A high density of prey has often been shown to be necessary for *Bdellovibrio* survival. Various authors have reported that prey concentrations of at least 10^5 to 10^6 CFU·g^{-1} soil or mL^{-1} are required for *Bdellovibrio* survival (Keya and Alexander, 1975; Uematsu, 1980). Calculations based on the Lotka-Volterra predator-prey model (Varon and Zeigler, 1978) indicate that at least 3×10^6 prey cells are needed to give bdellovibrios a 50% chance of survival. From this type of calculation, the general conclusion was that *Bdellovibrio* can survive only in special ecological niches. However, low-level, steady-state bdellovibrio populations were sustained for long periods in continuous cultures at low host density (10^4 cells·mL^{-1}).

As seen above, biofilms can potentially provide a richer habitat for bdellovibrios. Biofilms may provide an environment more conducive to bdellovibrio development in low microbial density biotas, the predator expanding beyond that realm during bacterial population surges. Notably, the calculated minimal prey levels usually relate to bdellovibrio predation upon a defined bacterial species in pure culture. Because bdellovibrios are usually not stringently host-range specific, the concentration of substrate cells in natural settings may well be high enough to sustain bdellovibrio populations. Moreover, only a fraction (>1 to a few percent) of the bacterial cells contained in environmental samples are typically amenable to cultivation. This fact has to be considered (Amann et al., 1995), as did Rice et al. (1998), who quantified the number of bdellovibrio-susceptible bacteria in an estuarine environment. Seventy to 85% of recovered bacteria were found susceptible to bdellovibrios isolated from the same sampling sites. Assuming that almost 10% of the bacteria in samples were retrieved on culture, the authors calculated that the susceptible populations were sufficient to ensure survival of the predators. Therefore, *Bdellovibrio* spp. may have a modulatory role in nature (Rice et al., 1998), eradication being prevented by natural oscillations in a predator-prey system (Varon, 1979).

Survival of bdellovibrios in nature has been the subject of conjecture because cell composition in bdellovibrios is known to change rapidly in starving conditions, and bacterial suspensions quickly lose viability (Marbach et al., 1976; Hespell et al., 1974), signifying that a free swimming cell must find a prey rapidly. However, bdellovibrios were shown to survive longer periods in nutrient-poor environments (Fry and Staples, 1976; Daniel, 1969), possibly due to population heterogeneity (Varon and Shilo, 1978) or better resilience of bdelloplasts (certainly as bdellocysts, although the number of strains able to develop this morphology seems to be small). The molecular responses to starvation are unknown.

Isolation

The peculiar cell cycle of *Bdellovibrio* dictates its method of isolation, whether from sewage, plant parts, submerged surfaces, or water samples. Basically, bdellovibrios and phages are isolated in a similar manner. The sample, or serial dilutions of it, is mixed with a potential prey bacterium in melted soft agar and poured onto an agar

plate containing a diluted growth medium. The bacterial predator forms plaques that have to be differentiated from those formed by protozoa or bacteriophages.

Relatively low levels of bdellovibrios are usually retrieved from environmental sources that contain much higher levels of unsusceptible bacteria and "blurring" through overgrowth results, which can interfere with the detection of bdellovibrio plaques. Moreover, bdellovibrio growth can be hindered by bacteria-excreted compounds as well as by bacteriophages. A number of protocols have been developed based on the physical separation of *Bdellovibrio* cells from the rest of the bacterial population, with the purpose of obtaining enriched fractions of the predator while reducing contaminating protozoa, bacteria, or viruses.

The number of bdellovibrio plaques detected in any environmental sample depends on the host bacterium chosen, the processing of the sample, and the isolation protocol. *Bdellovibrio* shows variation in host range, and no single bacterial species can potentially support the growth of all isolates. This problem is compounded by the lack of information on the structure and diversity of *Bdellovibrio* populations. However, *Vibrio parahaemolyticus* was shown to be an effective host for the retrieval of *Bdellovibrio* from estuarine environments (Schoeffield and Williams, 1990). *Pseudomonas* spp., *Aquaspirillum serpens*, a number of phytopathogens such as *Erwinia carotovora* sspp. *carotovora*, *E. amylovora*, *Xanthomonas oryzae* and *P. syringae* have been used to isolate soil and water bdellovibrios (Stolp and Starr, 1963; Scherff, 1973; Uematsu, 1980; Epton et al., 1989; Elsherif and Grosman, 1996).

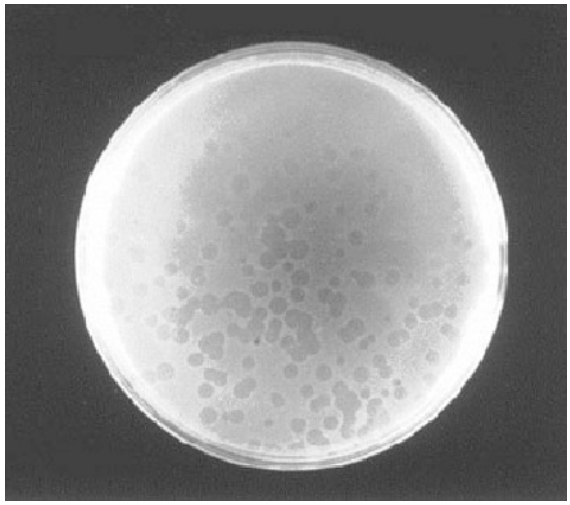

Fig. 6. Lytic plaques of *Bdellovibrio* on *Pseudomonas corrugata*.

Direct Isolation of *Bdellovibrio* from Environmental Samples

The most common approach is based on the use of one or more filtration steps with or without differential centrifugation of the sample analyzed. The compositions of the agar and soft agar can also vary. *Bdellovibrio* plaque development is favored in low-nutrient media, resulting in a higher plaque yield (Staples and Fry, 1973), but growth of contaminating bacteria is inhibited in plain agar medium (Uematsu, 1980).

Based on Stolp (1981): A water sample or 50-g soil in 500 mL of sterile buffer is shaken vigorously for 1 h, then centrifuged for 5 min at 2000g to remove gross particles. The supernatant is passed through a series of membrane filters of decreasing pore size (3.0, 1.2, 0.8 and 0.45 μm). Filtrates from the last two steps are serially diluted, and 100-μL aliquots are mixed with approximately 109 cells of the prey bacterium in molten soft top agar. The mixture is poured onto an agar plate and incubated at 28–32°C. Rapidly developing lytic regions visible after 24 h are the result of bacteriophage multiplication. These plaques are usually small and do not grow further. They should be marked to differentiate them from the slower growing bdellovibrios. Plaques becoming visible within two to three days and showing further expansion for a few more days are potentially bdellovibrios (Figure 6). Small and highly motile *Bdellovibrio* cells can be detected by examination of crushed plaque material in wet-mounts with a phase-contrast microscope.

Because only a fraction of the bdellovibrios is detected using this method, a number of variations have been proposed that increase the efficiency of recovery, thereby enabling more accurate quantification. From Uematsu (1980): Samples are collected, filtered through a 1.2-μm membrane filter, mixed with a phage-resistant host in molten top plain agar and plated on bottom plain agar. From Varon and Shilo (1970): The sample is centrifuged at 800 g for 5 min or passed through filter paper to remove coarse particles, then the bacteria are concentrated by centrifugation at 27,000 g for 20 min. The supernatant, which contains free bacteriophages, is discarded. The pellet is resuspended in a few mL and passed through a 1.2-μm membrane filter. Serial dilutions of the filtrate are then mixed with the prey in molten agar and plated on solid DN.

Sixty to 70% of bdellovibrios may be recovered with less than 1% of prey cells passing through the filter, as compared with 0.1% recovery with sequential filtration.

A second method, using a Ficoll gradient for purifying bdellovibrios from mixed samples, was also proposed by Varon and Shilo (1970): Samples are prepared as above but instead of being filtered, the resuspended pellet is layered on top of a 14-mL linear Ficoll gradient of 1 to 15% (Mw = 400,000) in DN, in 1.5 × 9.5 cm centrifugation tubes. The tubes are centrifuged horizontally in the cold at 1,620 g. The upper 3 mL contains 80 to 90% of the *Bdellovibrio* with less than 2% contamination, whereas the other bacteria concentrate lower along the gradient.

Low-nutrient media:

DN: (Diluted Nutrient, Seidler and Starr, 1969a) 0.08% Difco Nutrient Broth is supplemented with $CaCl_2 \cdot 2H_2O$, 2 mM, and $MgCl_2 \cdot 6H_2O$, 3 mM, after autoclaving, and pH is adjusted to 7.2 with 0.1 N NaOH.

YP (Yeast Extract Peptone, Stolp and Starr, 1963) contains 0.3% yeast extract, 0.06% peptone in 0.05 M Tris buffer, pH 7.5.

Plain agar (Uematsu, 1980): $MgCl_2 \cdot 6H_2O$, 20 mM; $CaCl_2 \cdot 2H_2O$, 30 mM, pH 6.5–8. Bottom agar: 1.2 to 1.5%. Top agar: 0.6%.

Plating: Aliquots of 4-mL molten top agar are kept at 42°C in a water bath prior to mixing with prey and sample suspensions.

Isolation of Marine Bdellovibrios

Halophilic or halotolerant bdellovibrios have been isolated from marine environments such as estuaries, sediments, coastal waters, open sea and submerged surfaces (Williams et al., 1995; Williams and Falkler, 1984; Williams, 1988; Taylor et al., 1974; Marbach and Shilo, 1978). The chemical composition of sea water has to be considered for isolating marine bdellovibrios. These organisms have a different G+C content than the terrestrial strains (Taylor et al., 1974) and their requirements for Na^+, K^+, and Ca^{2+} dictate the use of adapted media for their isolation (Marbach and Shilo, 1978). Marine bacteria such as *Vibrio parahaemolyticus* P-5 can be used as prospective hosts. Moreover, the relative low abundance of *Bdellovibrio* in these biotas may require concentration of large sample volumes.

From Marbach et al. (1976): Both direct and enrichment approaches can be used. If needed, the water samples are concentrated by centrifugation (10,000 g, 30 min) or collected on a 0.1-μm membrane. The concentrate is then mixed with a potential host bacterium in soft agar and poured on bottom agar. Alternatively, 5 mL of the sample is added to 3.3 mL of molten top agar having 0.7 mL of the prey suspension for a final agar concentration of 0.65%. The mixture is then poured onto large Petri dishes and incubated at 25°C (Schoeffield and Williams, 1990).

The medium used for isolating marine strains of *Bdellovibrio* should contain at least 25% sea water or appropriate salts.

Polypeptone (Pp 20) medium (Williams et al., 1982): Filtered ocean water, 1 L; Polypeptone, 1 g; agar, 15 g for bottom agar and 6.5 g for top agar; pH 7.7–7.8.

Synthetic marine salt solution (Marbach and Shilo, 1978): NaCl, 500 mM; KCl, 10 mM; $MgSO_4$, 25 mM; $MgCl_2$, 25 mM; $CaCl_2$, 10 mM.

Specific Enrichment for *Bdellovibrio*

Stolp (1968) devised a method yielding large numbers of *Bdellovibrio* plaques, thereby greatly facilitating the isolation of the predator on a specific host bacterium whenever quantification is not needed. This approach has been applied to obtain bdellovibrios lytic to *Rhizobium* and *Agrobacterium* (Parker and Grove, 1970), *Legionella* (Richardson, 1990) and *Azospirillum brasilense* from 2-years-stored air-dried soils (Germida, 1987).

Based on Stolp, modified by Ruby (1991): One-hundred milliliter aliquots of a dense suspension of the prospective prey bacterium (10^{10} cells·mL^{-1}) are prepared in DN medium or HM buffer in Erlenmeyer flasks. The sample (soil, 100 mg; sewage, 0.5 mL; river water, 1 mL) is added and the flasks are incubated on a rotary shaker. The suspension is examined daily over 2 to 4 days for lysis (reduction in optical density) and for the presence of small, highly motile presumptive bdellovibrio cells or bdelloplasts by phase contrast microscopy. If no bdellovibrios are apparent, the incubation can be prolonged or a 1-mL aliquot can be transferred into a fresh suspension of substrate bacterium. When bdellovibrios are detected, the enrichment culture is centrifuged for 5 min at 2000g (250g; Germida, 1987) and the supernatant filtered through a 0.45-μm membrane. Serial dilutions are plated on the prospective prey bacterium. Developing plaques are checked microscopically for bdellovibrios.

HM buffer: Hydroxyethyl piperazine-N′-2-ethanesulfonic acid, 25 mM, adjusted to pH 7.6 with NaOH and supplemented with $CaCl_2 \cdot 2H_2O$, 1 mM, and $MgCl_2 \cdot 6H_2O$, 1 mM.

Isolation of Host-Independent-Saprophytic *Bdellovibrio* Mutants

Wild-type bdellovibrios isolated from natural habitats are obligate parasites. However, host-independent (H-I) mutants can be recovered from all wild-type strains at a low frequency of 10^{-5} to 10^{-8} (Cotter and Thomashow, 1992a; Varon and Seijffers, 1975; Seidler and Starr,

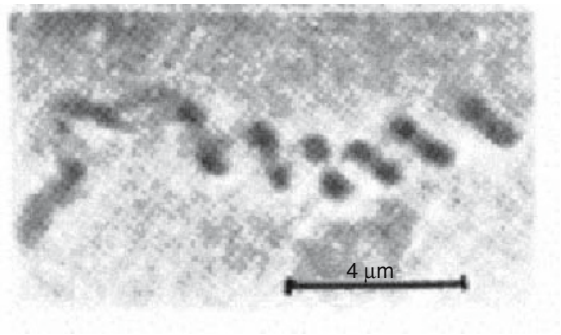

Fig. 7. Growth phase of a host-independent mutant of *B. bacteriovorus* 10^9D growing in enriched nutrient broth (From Eksztejn and Varon, 1977.)

1969b; Stolp and Starr, 1963). This suggests that the H-I phenotype results from a single mutational event. Although these axenic mutants are able to lyse substrate cells, they do so less efficiently than their wild-type counterparts (Cotter and Thomashow, 1992b; Varon and Seijffers, 1975; Stolp and Starr, 1963), and they tend to lose this ability completely after numerous transfers, seemingly the result of a second mutational event (Cotter and Thomashow, 1992b; Gray and Ruby, 1991). Host-independence may have pleiotropic effects as only partial phenotypic complementation can be achieved (Cotter and Thomashow, 1992b) and the mutants, contrary to the colorless wild-type cells, produce pigments protective against photooxidative damage (Friedberg, 1977).

The axenic mutants show strong proteolytic activities and are oxidase positive; most are catalase positive and possess a cytochrome *a* and *c* component (Seidler and Starr, 1969b; Diedrich et al., 1970; Stolp and Starr, 1963). Strikingly, the cell cycle of H-I mutants still shows the dimorphic pattern of filamentous growth, division, and differentiation (Figure 7; Seidler and Starr, 1969a). This observation has triggered many investigations of the possible involvement of prey-derived signals in the initiation or completion of the specific growth phases of the parasite.

From Shilo and Bruff (1965): A *Bdellovibrio* suspension (10^9 cells·mL^{-1}) is filtered through a 0.45-µm membrane. The filtrate is transferred to nutrient broth (NB) or DN broth (containing 10^8 heat-killed host cells) and incubated at 30°C with vigorous shaking. For growth on plates, solid NB or PY (peptone, 10 g; yeast extract, 3 g, pH 6.8) is supplemented with 1% autoclaved culture supernatant fluid of the same bdellovibrio strain grown in NB. In that case, a large (10^4 cells per plate) inoculum is required.

Although more exacting, the method described by Seidler and Starr (1969b) was successful with all isolates tested, contrary to the protocol of Shilo and Bruff (1965), which did not always yield axenic mutants:

1. Selection of Sm^r *Bdellovibrio*. The host-dependent (H-D) strain is grown in DN broth on a Sm^r host. After 24 h, streptomycin is added (50 µg·mL^{-1}) and the culture is incubated for another 12 h. Next, the H-D strain is heavily (15%, v/v) inoculated in DN broth with the Sm^r host in the presence of streptomycin. When a lysate is obtained, it is washed from the antibiotic by centrifugation, resuspended in DN broth, and filtered through a 0.45-µm membrane.

2. A Sm^s host suspension is inoculated with the filtrate. Five to 10 mL of the resulting lysate are transferred to the selection medium (DN or PY broth amended with 10^9 cells·mL^{-1} heat-killed prey cells and with streptomycin) and incubated for 3 to 6 days. Cultures are transferred twice in PY broth with a heavy inoculum (15 to 25%) and the H-I isolates can then be plated on solid PY.

Preparation of Pure Cultures

Pure cultures of *Bdellovibrio* are obtained in the manner of bacteriophages. A single plaque of the original isolation event is lifted, resuspended in HM buffer or in dilute medium, passed through a 0.45-µm filter, and serially diluted. Plating of the dilutions on the original host results in growth of plaques. The procedure is performed at least three times.

Identification

Bdellovibrios are best identified by morphological features along with the particular growth requirements of the bacteria, i.e. a cell cycle featuring an obligate, intraperiplasmic, developmentally separated stage inside the substrate bacterium, leading to the generation of progeny cells. The physiology of both host and parasite is intimately linked to the interaction between the two and is dealt with separately. No molecular markers have been developed to date that enable the detection and identification of bdellovibrios in samples without relying on isolation, cultivation, and morphological identification.

Morphology and Ultrastructure

After isolation, plaques have to be detected before filtrates can be examined under phase contrast for small, highly motile cells, swimming at a speed of up to 100 body-lengths per second (Stolp, 1967). Electron microscopy of subsequent lysates reveals small, vibrioid or rod-shaped bacteria. The size of bdellovibrio can

vary between 0.25 and 0.40 μm in width and 1 and 2 μm in length (Ruby, 1991), but smaller cells (0.2 μm, width; 0.8 μm, length) have been reported (Pan et al., 1997). The cell is propelled by a long (up to 30 μm), thick-sheathed polar flagellum. The sheath is an extension of the outer membrane but is of different biochemical composition (Thomashow and Rittenberg, 1985). To date and under the proper conditions, only two isolates have been shown to enter the bdellocyst stage.

The *Bdellovibrio* Cell Cycle

Chemotaxis Attack-phase bdellovibrios in liquid culture have been shown to lose viability rapidly (Hespell et al., 1973). Therefore, the steps leading to attachment and penetration within the host cell are crucial. No chemotactic responses towards potential hosts, their exudates, or their lysates have been detected (Straley and Conti, 1977; LaMarre et al., 1977). However, positive and negative chemotaxis was measured for numerous compounds including organic and amino acids, sugars and inorganic ions, but very different responses were obtained with different *Bdellovibrio* strains (Straley et al., 1979). All the tested strains showed aerotaxis. Because nonhalophilic and halophilic bdellovibrios have been shown not to grow or to grow less, respectively, in microaerobic conditions (Schoeffield et al., 1996), aerotaxis lets the cells find optimal niches. Similarly, the chemotactic responses may drive the predator towards ecological niches rich in prey (LaMarre et al., 1977) or may help the cells find compounds that alleviate starvation in the extracellular environment (Varon and Shilo, 1978).

Because there is no active "marauding," the process of finding prey appears to be based on random collisions and therefore on the concentration of both predator and prey cells. At low prey density (10^4 cells·mL^{-1}), a high initial predator : prey ratio (1 : 250) is necessary to obtain significant predation (Varon and Zeigler, 1978).

In pelagic habitats, many bacteria are attached to particles, and clusters of bacteria continuously form and disperse around patches centered on the lysis of a large cell or protozoal excretion (Caldwell, 1977; Blackburn et al, 1998). Chemotaxis towards organic compounds may indicate bacteria-rich niches and therefore be helpful in bringing bdellovibrios in proximity to potential prey.

Attachment Attachment to substrate cells is affected by many factors such as the composition and the pH of the medium, oxygen tension, and temperature (Varon and Shilo, 1968). It is reversible within the first minutes of an encounter, but agitation is unable to separate attached bdellovibrios after 20 to 30 min (Varon and Shilo, 1968). Reversible attachment to non-hosts as well as to inorganic surfaces has been reported (Varon and Shilo, 1978). Although completely different in their mechanisms, two-stage attachment processes (the first reversible, the second irreversible) are required in many bacteria-host systems: *Agrobacterium tumefaciens* for DNA transfer into a plant cell; *Rhizobium* for cell invasion (Vande Broek and Vanderleyden, 1995) and colonization of plant surfaces (Romantschuk, 1992); and pathogenic *E. coli* for penetration into epithelial cells (Mulvey et al., 1998). Recognition sites on the surface of the bacterial prey of bdellovibrios are still uncharacterized. *B. bacteriovorus* 109D and *B. stolpii* UKi2 interacted differently with various components of the host cell's outer membrane. Whereas strain 109D specifically required core sugar of the host's lipopolysaccharide for irreversible attachment to occur, *B. stolpii* UKi2 seemed to require specific proteins to interact with its prey (Schelling and Conti, 1986).

Corroborating the involvement of specific moieties in the recognition process, detailed electron microscopy revealed that, upon attachment, the nonflagellated pole has strands believed to mediate the attachment of parasite to host protoplast, even before a pore is created. The parasite is subsequently anchored to the host protoplast (Figure 8; Abram et al., 1974).

Two extracellular components of bacterial cells have been shown to exert opposite effects on the attachment of bdellovibrios. Bacterial capsules did not hinder *B. bacteriovorus* 109J to infect *E. coli* cells (Koval and Bayer, 1997), but the proteinaceous S-layer of *Aquaspirillum ser-*

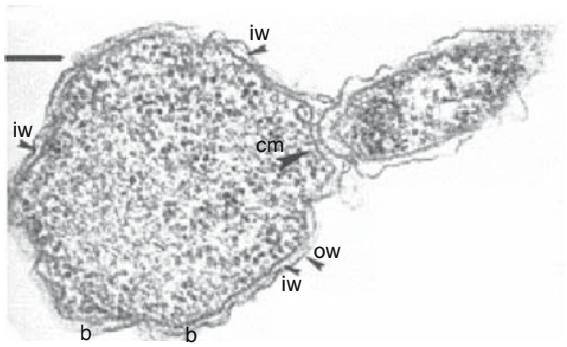

Fig. 8. Penetration of *B. bacteriovorus* 10^9 into an *E. coli* cell. The penetration pole is flattened against the host cytoplasmic membrane. b: bulges in the host membranes. cm: cytoplasmic membrane. iw: peptidoglycan layer. ow: outer membrane. The penetrating parasite shows constriction at the entry pore. (From Abram et al., 1974.)

pens, *A. sinuosum*, and *Aeromonas salmonicida* played a protective role, rendering the bacteria resistant to penetration by bdellovibrios (Koval and Hynes, 1991).

Penetration Penetration is completed within 5 to 20 min after attachment. It may involve mechanical "drilling" through the prey's membranes (Stolp, 1981), although enzymatic action is essential (Physiology). The inhibition of invasion by streptomycin (Varon and Shilo, 1968) supports the involvement of a tightly regulated response to initial attachment and production of enzymes. On the other hand, penicillin has no effect on invasion but inhibits intraperiplasmic multiplication (Varon et al., 1969). The driving force for entry may be generated by fluxes of water entering the infected host and causing a differential expansion of the host protoplast and cell wall, leading to their separation. The bdellovibrio cell, which is bound to the cytoplasmic membrane, is then passively pulled into the periplasm, shedding its flagellum in the process. During attack and penetration, the prey-cell's membrane-derived oligosaccharides are lost to the extracellular medium and are not used by the predator (Ruby and McCabe, 1988).

Intraperiplasmic Growth The invaded periplasm offers a protected environment for the predator to enter a new developmental stage characterized by elongation into a spiraling cell, DNA replication, and finally fragmentation of the filament by the formation of septa and the biosynthesis of one flagellum per progeny cell. The ghost host cell is then lysed by the action of lytic enzymes, and the progeny is released. The filamentous cell developing at the expense of the host's cytoplasmic content grows in proportion to the size of the prey (Kessel and Shilo, 1976) and exhibits a very efficient energy metabolism. Therefore, the number of progeny varies, from 5.7 per *E. coli* (Seidler and Starr, 1969b) to 20 to 30 cells in *Aquaspirillum serpens* (Stolp, 1967). In liquid culture, the initial cell cycle is completed within 2 to 4 h, depending on the age of the bdellovibrios (Varon et al., 1969). The signals leading to initiation of growth within the periplasm, cell elongation, division, and differentiation into attack phase cells have been sought, but a consistent picture of their mode of action has not been obtained.

Bdellocysts Under special growth conditions, bdellovibrios enter a cyst-like stage. The formation of bdellocysts has been reported in two strains, one of which (strain W) is the subject of a number of investigations (Burger et al., 1968; Hoeniger et al., 1972; Tudor and Conti, 1977; Tudor and Conti, 1978). Bdellocysts of strain W developing on *Rhodospirilum rubrum* mature within 4 h. The predator enlarges into a kidney-shaped cell enclosed by a structureless, amorphous outer layer. A finely particulate inner layer surrounds the more particulate plasma membrane of the predator cell. Structures resembling storage granules are present (Figure 9). Bdellocysts are more resistant than vegetative cells to dessication, high temperatures, and sonication (Tudor and Conti, 1977), and their germination is favored by L-glutamate, K^+, and NH_4^+ (Tudor and Conti, 1978).

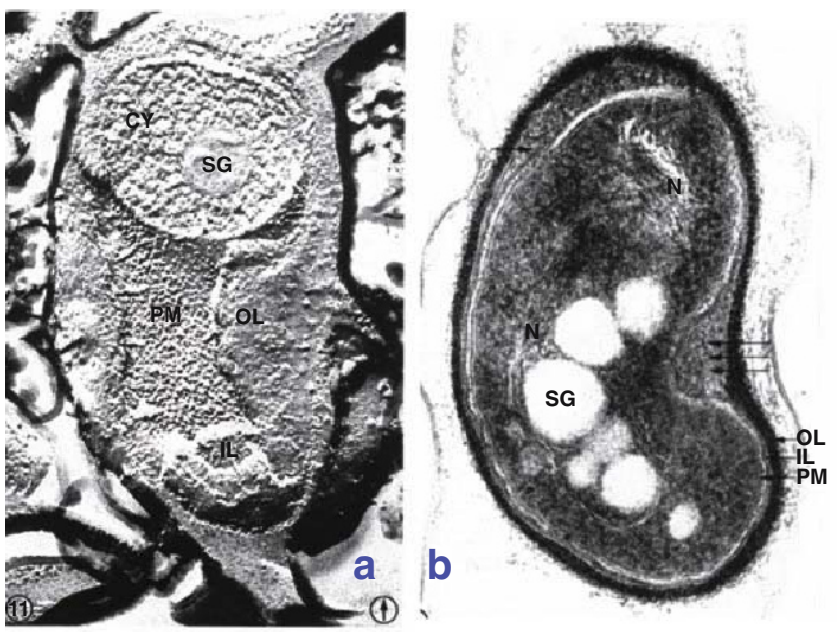

Fig. 9. Mature resting body of *Bdellovibrio* sp. strain W in *Rhodospirillum rubrum*. Panel a: Freeze-etching, × 173,000. Panel b: Negative staining, × 150,000. OL: outer layer. IL: inner layer. PM: particulate plasma membrane. CY: granular cytoplasm. SG: storage granule. Arrows: infolding of the inner layer. N: fibrillar nucleoplasm. (From Hoeniger et al., 1972.)

Cultivation

The cultivation of bdellovibrios in a diluted broth or buffer suspension of host cells routinely yields high concentrations of the predator (10^9 cells·ml^{-1}). However, these suspensions rapidly lose their viability because bdellovibrios have very high endogenous respiration rates (Hespell et al., 1973). Therefore, aerating cultures on a rotary shaker and filling flasks only to one third of their volume is strongly recommended. Viability of the predators can be augmented by adding 5 mM glutamate to the fresh lysates.

Propagation of *Bdellovibrio*

One single plaque with a small piece of its surrounding unlysed prey cell lawn is excised from a Petri dish, resuspended in 10 to 15 mL of a diluted medium, such as DN broth or YP, and shaken at 30°C for 24 to 48 h. The prey cells first multiply, creating a suspension dense enough to enable a high yield of bdellovibrios. This first lysate can then be subcultured.

Routine Culture

HM buffer or DN broth (30–40 ml) is inoculated with freshly grown, stationary phase host suspension to a final concentration of 10^8 to 10^9 cells·ml^{-1} and 100 to 200 µl of lysate. Overnight incubation on a rotary shaker usually lyses all the prey cells. The resulting bdellovibrio suspension can then be supplemented with 5 mM glutamate and stored at 4°C.

Large Scale Culture

According to Ruby (1991): In a 500-mL Erlenmeyer flask, 50 to 100 µl of a fresh *B. bacteriovorus* 109J lysate are added to 200 ml of DN broth amended with 40 ml of an *Escherichia coli* ML35 stationary phase culture, totalling 1.6×10^{11} cells. The flask is shaken overnight and total lysis is observed under a phase-contrast microscope. The culture is cooled on ice, centrifuged at 700g for 15 min, and the pellet discarded. The supernatant, containing most of the attack-phase bdellovibrios, is concentrated at 10,000g for 15 min. The pellet is resuspended in HM buffer, harvested again by centrifugation, and resuspended in HM buffer. The yield should be about 6×10^{11} cells.

Single-Cycle Growth of Synchronous Cultures

Synchronous cultures are tools essential for investigating developmentally regulated events in the cell cycle of bdellovibrios. A 2 : 1 attack-phase predator-to-prey ratio enables concomitant attack of all host cells within minutes. By separating the bdelloplasts from excess attack phase cells, a uniform synchronous single-cycle suspension is obtained. The developing intraperiplasmic bdellovibrio cells can be prematurely released from the bdelloplast for further analysis. This technique can be used to study the cell cycle of wild type cells, which are known to differ from their host-independent variants.

From Thomashow and Rittenberg (1978a) and McCann et al. (1998): *E. coli* cells are grown into stationary phase in Luria or nutrient broth, centrifuged at 5,000g for 10 min, washed once with cold HM buffer, and then resuspended in the same buffer. A fresh lysate of attack phase *B. bacteriovorus* 109J is harvested in the cold by centrifugation at 10,000g for 20 min and treated as the host suspension. Combining 10^{10} predator with 5×10^9 prey cells·ml^{-1} results in a synchronous, single-cycle culture in which host penetration occurs in less than 30 min and the cycle is complete in 3.5 h. Because the culture is very dense, proper aeration has to be ensured by vigorous shaking of the flask.

Premature Release from Bdelloplasts

From Ruby (1991): Bdelloplasts of *B. bacteriovorus* 109J can be obtained from a synchronous culture at any time in its development by cooling the culture on ice, removing the unattached, attack-phase cells by centrifugation at 1,100g for 5 min at 0°C, and resuspending the pellet by vigorous vortexing in cold HM buffer. This step is repeated twice to yield a virtually attack-phase bdellovibrio-free bdelloplast pellet as observed by phase-contrast microscopy. The pellet is warmed to room temperature, resuspended in 2 volumes of 10 mM EDTA in 120 mM Tris-hydrochloride (pH 7.6), and incubated at 30°C for 3 min to permeabilize the outer membrane. The bdelloplasts become transparent and the envelopes are lysed when 10 volumes of lytic enzyme concentrate are added and then incubated at 30°C for 15 to 20 min. The suspension is cooled to 0°C, centrifuged at 10,000g for 20 min, and resuspended in 1 ml HM buffer. The released bdellovibrios can then be purified on a Ficoll gradient in HM buffer. The band is removed from the tube and washed three times in HM buffer at 0°C (Ruby and Rittenberg, 1983). The use of a diaminopimelic acid (DAP)-deficient mutant host results in higher yields of released bdellovibrios. Culture of this mutant host in DAP-deficient medium for one doubling before harvest will weaken its envelope.

Preparation of a Lytic Enzyme Concentrate

From Ruby and Rittenberg (1983): Progeny bdellovibrios from 3 to 4 liters of a synchronous culture (300 ml in a 2-liter flask) are separated from the dithiothreitol (50 $\mu g \cdot ml^{-1}$) amended lytic solution by two successive centrifugations at 10,000g for 20 min. The supernatant is concentrated 60 times by pressure filtration using a membrane with a molecular cut-off of 30,000 daltons. The concentrate is centrifuged at 10,000g for 20 min and 0.5% polyethylene glycol is added. Aliquots are frozen in liquid nitrogen and stored at –70°C.

Preservation

Bdellovibrios can be kept as plaques on solid medium at 4°C for 1 to 2 weeks. Lysates amended with 5 mM glutamate and conserved at 4°C should be transferred every few weeks. For long-term conservation, aliquots of a fresh lysate are concentrated to half their original volume in freeze-resistant tubes and glycerol is added to a final concentration of 25%. The tubes are quickly frozen in liquid nitrogen and kept at –80°C. To revive the culture, thawed aliquots are serially diluted and plated on double agar seeded with the appropriate host. Alternatively, storage as bdelloplasts also maintains viability for long periods (Stolp, 1981): one ml of host bacteria is added to 5 ml of fresh lysate; the final concentrations of bdellovibrio and host bacteria are equal. The mixture is incubated for 30 min on a shaker to produce a high density of invaded prey cells. Glycerol is added to a final concentration of 10% and the vials are conserved in a deep freezer at –70°C.

Physiology

Upon attachment of attack phase bdellovibrios, the host cell is rapidly immobilized (Stolp and Starr, 1963). Major physiological features change quickly in the host, following an orchestrated sequence, even before the initiation of intraperiplasmic growth by the predator: the prey cell stops respiring, its peptidoglycan changes (Thomashow and Rittenberg, 1978a; 1978b; 1978d), the cell loses control over uptake, secretion, and synthesis (Varon et al., 1969; Rittenberg and Shilo, 1970), and its nucleic acids are degraded (Matin and Rittenberg, 1972; Hespell and Odelson, 1978; Hespell et al., 1976). Bdellovibrios, in contrast to viruses and most intracellular parasites, do not depend on the metabolism of their host: they normally proliferate in ultraviolet irradiated- or heat-killed prey cells (Varon et al., 1969). However, the use of prey is highly organized: degradation of the substrate cell leads to precursors that are used directly as building blocks, which drives an efficient coupling between anabolic and catabolic processes. The result is a highly efficient energy metabolism.

Lytic-Enzymatic Activities

Host morphology changes dramatically upon penetration by bdellovibrio: the host becomes a bdelloplast, which is usually round. Penetration of noncovalently bound outer-membrane components can be explained by the action of mechanical forces. However, for pore formation and passage through the peptidoglycan to occur, covalent bonds must be ruptured by enzymes (Fackrell and Robinson, 1973; Huang and Starr, 1973). The lytic activities must permit penetration on the one hand and prevent premature lysis of the host on the other. Rapid solubilization of peptidoglycan, which is the result of differentially regulated glycanase and peptidase activities, has been demonstrated during penetration, the free diaminopimelic acid (DAP) and the amino sugar being released to the extracellular medium (Thomashow and Rittenberg, 1978a). Free DAP is then rapidly incorporated into the peptidoglycan of the bdelloplast by a soluble enzyme activity only present during intraperiplasmic growth (Araki and Ruby, 1988). A lipopolysaccharidase is also active during invasion. The glycanase is inactivated rapidly by peptidoglycan deacetylation, while peptidase activity continues at a reduced pace throughout the bdelloplast stage (Thomashow and Rittenberg, 1978a; 1978c). Prevention of bdelloplast superinfection by other bdellovibrios has been attributed to deacetylation of the peptidoglycan backbone (Thomashow and Rittenberg, 1978d). Acylation of the host's peptidoglycan with long-chain fatty acids may stabilize the outer membrane of the bdelloplast, although the peptidoglycan is not essential for its osmotic stability (Thomashow and Rittenberg, 1978b; 1978c). Many hosts do not round up. Because strain W infected cells and heat-killed substrate cells, which do not round, have no detectable glycanase, Tudor et al. (1990) concluded that glycanase activity is responsible for the formation of a round bdelloplast, but deacetylation is not required for exclusion. A second burst of lytic activity takes place at the end of the intraperiplasmic growth phase, the newly synthesized enzymes degrading the remaining peptidoglycan (Thomashow and Rittenberg, 1978a; Fackrell and Robinson, 1973; Huang and Starr, 1973).

Energy Metabolism

At least some strains of bdellovibrios have a very high endogenous respiration rate, seven times the rate of *E. coli*, that increases little during the growth phase (Rittenberg and Shilo, 1970; Hespell et al., 1973).

Unlike most bacteria, free swimming and intraperiplasmically growing bdellovibrios have their endogenous respiration partially or totally shut-off by acetate and glutamate, respectively, and by mixtures of amino acids, and without increase in respiration rate (Hespell et al., 1973). This may be due to saturation of the tricarboxylic acid cycle or oxidative phosphorylation capacities (Hespell, 1976: Hespell et al., 1973). These findings and the inability of bdellovibrios to utilize (and possibly transport) sugars (Ruby, 1989) suggest substrate-level phosphorylation is not a major energy source (Rittenberg and Hespell, 1975a). Notably, bdellovibrios can use nucleoside monophosphates and ATP from the substrate cell or an exogenous source directly, and they may also use prey-derived phospholipids (Ruby and McCabe, 1986; Ruby et al., 1985; Rittenberg and Langley, 1975b). During the intraperiplasmic stage, the parasite DNases degrade the substrate cell's DNA in a timely regulated manner, providing the parasite with most of the nucleosides needed for growth (Rosson and Rittenberg, 1979; Matin and Rittenberg, 1972). The other nucleosides come from RNA breakdown and ribonucleotide and deoxyribonucleotide conversions (Rosson and Rittenberg, 1981), inasmuch as bdellovibrios seem unable to synthesize nucleotide denovo (Engelking and Seidler, 1974).

Rittenberg and Hespell (1975a) calculated that 16% of the total energy requirement for growth could be saved if the predator used intact prey fatty acids instead of denovo synthesizing fatty acids from acetate. Indeed, bdellovibrios growing intraperiplasmically are capable of totally or partially conserving substrate cell fatty acids and possibly phospholipids, thereby greatly reducing their energy need (Kuenen and Rittenberg, 1975).

Similarly, fatty acids and hexosamines from the lipopolysaccharide (LPS) of the prey's outer membrane were retrieved in large proportions from the LPS of intracellularly growing bdellovibrios (Nelson and Rittenberg, 1981a). Thin layer chromatography resolved lipid A isolated from the predator into two fractions shown to contain an unequal distribution of fatty acids originating from both substrate and bdellovibrio cells (Nelson and Rittenberg, 1981b).

Another peculiar feature of the bdellovibrio physiology is its unbalanced growth. During the growth phase, the DNA concentration increases faster than the protein concentration, the original ratio being restored by protein synthesis, which continues after DNA replication stops (Gray and Ruby, 1989). This property may permit the generation of the largest number of progeny with a minimal cell mass (Gray and Ruby, 1989).

This extraordinarily efficient metabolism, combining both scavenging and a finely regulated degradation of the substrate cell, can explain the outstanding energy efficiency of intraperiplasmically growing bdellovibrios, which were shown to achieve a YATP (biomass yield per ATP molecule expended) of 26 when compared with 10.5 for bacteria grown on rich medium (Rittenberg and Hespell, 1975a).

Transport

Outer Membrane Proteins Little is known about the transport capacities of *Bdellovibrio*, including its export pathways that involve breakdown of prey cytoplasm by predator proteases and nucleases and its import pathways that use the breakdown products and other solutes. Secretion of bdellovibrio products may involve export pathways designated as types I, II and III (Genin and Boucher, 1994; Schatz and Dobberstein, 1996) or other mechanisms. Interestingly, type III secretion pathways are found in plant and animal pathogens and are involved in the secretion of peptides directly into the host's cytoplasm (Finlay and Cossart, 1997; Baker et al., 1997).

More data are available on uptake routes. As described in energy metabolism, bdellovibrios use phosphate-ester containing molecules obtained from the prey. The molecules are transferred to the parasite, and in the case of phosphate nucleosides, transport seems to involve two different systems, one specific for the growth and the other for the free-living stage (Ruby and McCabe, 1986; Ruby et al., 1985). Inorganic phosphorus transport is low and reflects the lack of need for this element, which is obtained in organic form directly from the prey (Ruby and McCabe, 1986). Sugar transport pathways are similarly lacking (Ruby and McCabe, 1988). Mechanisms of fatty acid and lipopolysaccharide incorporation into bdellovibrio molecules are not known.

The very efficient metabolism of bdellovibrios is epitomized by the transfer of molecules that move solute: outer membrane proteins (OMPs) are routed to the outer membrane of the predator and cytoplasmic membrane of the prey (Diedrich et al., 1983; 1984; Talley et al., 1987; Tudor and Karp, 1994). The structure of the relocated proteins seems to be conserved in that

OmpF protein of *E. coli* transferred to the outer membrane of *B. bacteriovorus* 109D during intraperiplasmic growth had unaltered function in colicin A bdellovibrio-killing experiments (Diedrich et al., 1983). The process of acquiring outer membrane porin-like molecules from the substrate cell has limited adaptability. In OmpF mutants, the OmpC protein was transferred to the predator, although a clear preference for OmpF was detected when wild-type strains were the prey (Diedrich et al., 1984). However, other porin-like proteins were not found in the bdellovibrio outer membrane. Furthermore, it could be demonstrated that the protein relocalization of bdellovibrios is influenced by both the prey (smooth versus rough strains produce different results) and the history of the cultured predator (Talley et al., 1987).

The acquired proteins may play a role in the passive uptake of nutrients in the free-living phase of *Bdellovibrio* (Diedrich et al., 1983). Alternatively, proteins relocated to the host's cytoplasmic membrane may be responsible for the increased permeability of this membrane to small hydrophilic molecules and ions (Rittenberg and Shilo, 1970; Cover et al., 1984a). Thus, breakdown products from the cytoplasm might diffuse to the periplasmic space to be taken up by the predator (Tudor and Karp, 1994).

Properties of Bdelloplast and of Predator Membranes Change in the cell wall structure of the prey upon attack by *Bdellovibrio* is not limited to its peptidoglycan. The cell surface becomes more hydrophobic (Cover and Rittenberg, 1984b), maybe as a result of peptidoglycan modification with long-chain fatty acids (Thomashow and Rittenberg, 1978b) or cleavage of glucosamine residues from the substrate cell lipopolysaccharide (Thomashow and Rittenberg, 1978a). The cytoplasmic membrane of the substrate cell becomes permeable to lactose and small hydrophilic molecules (Rittenberg and Shilo, 1970; Cover et al., 1984a). However, the permeability of the outer membrane layer to small hydrophilic molecules is not altered, and most periplasmic proteins are retained (Odelson et al., 1982; Cover et al., 1984b).

Signaling The dimorphic cell cycle of bdellovibrios, which include an obligatory intracellular cell multiplication stage, is highly ordered, and physiology involved in attachment, penetration, and intraperiplasmic growth is highly regulated. The transition between the phases of the cell cycle seems to involve signals, whose function and nature are still elusive. It is obvious that during the cell cycle important changes occur in gene expression and protein synthesis. It was recently demonstrated by two-dimensional gel analysis of synchronous cultures that protein synthesis is affected by the growth stage of the cell: more than 30 polypeptides falling into nine kinetic groups were detected (McCann et al., 1998).

Wild-type bdellovibrios cultured on complex media amended with extracts obtained from prey cells have a developmental cycle similar to the one occurring intraperiplasmically (Friedberg, 1978; Horowitz et al., 1974; Reiner and Shilo, 1969; Introduction) and in host-independent (H-I) mutants. Bdellovibrios, obtained by premature release from bdelloplasts before the onset of DNA replication, differentiate into attack cells but complete their DNA synthesis round only if DNA replication has been initiated. The addition of host cell extracts enables initiation of DNA replication (Ruby and Rittenberg, 1983; Gray and Ruby, 1990). In an extensive review on the subject, Gray and Ruby (1991) proposed a two-signal model, the first triggering the differentiation of attack-phase bdellovibrios into growth-phase cells, the second initiating and sustaining subsequent rounds of DNA replication. Attempts at purifying the early and late putative signal molecules from prey cells were not conclusive, although these molecules were shown to be nondialyzable, heat stable, DNAse resistant, and possibly proteinaceous (Gray and Ruby, 1990; Friedberg, 1978; Horowitz et al., 1974; Reiner and Shilo, 1969). Interestingly, axenic growth of prey-dependent bdellovibrios in a rich medium without prey extracts can be triggered by heat shock, eliminating the need for a growth inducing signal. Heat shock may trigger changes in gene transcription (Gordon et al., 1993).

In contrast to prey-derived signals, Eksztejn and Varon (1977) detected a cell-density dependent, division-promoting activity identified as an apparent cyclic peptide produced by bdellovibrios during the middle to late growth stages.

The influence of cell density was already noted by Shilo and Bruff (1965), who reported colony growth of H-I mutants of *B. starrii* only with a high density inoculum. More recently, Cotter and Thomashow (1992a) and (1992b) reported that H-I mutants could be differentiated into two classes, defined as type I and type II: type I develop small colonies growing close one to the other, and type II exhibit large, density-independent growth. Type I mutants arise at a frequency of 10^{-6} to 10^{-7} and type II at a frequency of 10^{-8} to 10^{-9}. The latter may result from a double mutation, lending support to the two-signal hypothesis (Thomashow and Cotter, 1992). Type II mutants could be partially com-

plemented by a 1 kilobase fragment (the hit locus) containing four putative open reading frames of unknown function and not homologous to any sequence in the databases (Cotter and Thomashow, 1992b).

Cell-cell communication may therefore exist in bdellovibrios but its nature, whether peptidic like in *Myxococcus* (Dworkin, 1996), N-acyl-L-homoserine lactone based, quorum-sensing (Dunlap, 1997), or other, is unknown.

Applications

The characteristic life-style of bdellovibrios makes them attractive candidates for a number of applications concerned with reducing or modulating bacterial populations, i.e. biological control of pathogens, water purification, and biofilm control.

Surprisingly little emphasis has been put on studying the possible role of *Bdellovibrio* in agricultural applications: Bdellovibrios efficiently eradicated *Xanthomonas oryzae* from rice paddy field water and caused rapid decline in populations of *E. carotovora* sspp. *carotovora* in soil (Uematsu, 1980). *Bdellovibrio* isolates from the rhizosphere of soybean were used to control bacterial blight caused by *Pseudomonas glycinea* (Scherff, 1973). Reduction in disease severity and systemic symptoms were significant.

An attempt was made to control soft rot and black leg of potato but mixed results were obtained (Epton et al., 1989).

That bdellovibrios might be deleterious to plant growth-promoting rhizobacteria was suggested by Germida (1987), who isolated bdellovibrios parasitic to *Azospirillum brasilense* from soils and by Elsherif and Grossman (1996), who could show an increase in bdellovibrio counts from the rhizosphere of plants inoculated with a beneficial strain of *Pseudomonas fluorescens*.

A role for *Bdellovibrio* in the self-purification of natural water systems has been suggested (Daniel, 1969; Fry and Staples, 1976). Because bdellovibrios are highly sensitive to certain chemicals and metals, they can be used as indicators for those compounds in water (Varon and Shilo, 1981).

A few attempts have been made to use bdellovibrios in animal models: Nakamura (1972) effectively treated *Shigella flexneri*-induced keratoconjunctivitis in rabbit with bdellovibrio, but bdellovibrio used as predator against pathogens in the intestinal tract of rabbits was unsuccessful (Westergaard and Kramer, 1977). It has been proposed that because of its unique physiology *Bdellovibrio* may be a source of novel chemicals and biochemicals (Ruby, 1991), although the evidence is unpublished. Undeniably, this intriguing bacterial group is a great model for the study of a myriad of subjects central to biology, e.g. predator-prey interactions, host recognition, development of prokaryotes, and cell-cell signaling.

Conclusion

Although much has been done to understand the ecology and the biology of bdellovibrios, one can still ask whether bdellovibrios play a role in determining the structure of bacterial populations. How do they survive? How is their cell cycle regulated, and what special functions are needed to complete it? Those are few of the very basic questions still left unanswered.

The advent of genomics should greatly improve our understanding of bdellovibrio biology and thereby its relation with the environment. Looking at the metabolic properties of this particular microbial predator, a few comparisons with other organisms can already be drawn: transport of exogenous phosphorylated nucleosides, sometimes accompanied by a marked reduction in de novo nucleotide biosynthesis capabilities, has been shown in intracellular parasites of eucaryotic cells such as *Rickettsia*, *Mycoplasma* and, *Chlamydia* (Stephens et al., 1998; Fraser et al., 1995; Moulder, 1991). This type of adaptation points to converging phenotypic evolution between intracellular parasites, although the biochemical mechanisms widely differ. Similarly, it will be possible to assess the dynamics of genome evolution and reduction by looking for "missing" genes and for the ones pointing to the particular lifestyle of this organism when the *Bdellovibrio* genome becomes available.

CHAPTER 3.4.3

The Myxobacteria

LAWRENCE J. SHIMKETS, MARTIN DWORKIN AND HANS REICHENBACH

The myxobacteria are Gram-negative, unicellular bacteria with rod-shaped vegetative cells (Fig. 1). Because of their gliding movement, colonies develop as thin, spreading swarms, particularly on media low in organic constituents (Fig. 2). Under starvation conditions, the myxobacteria undergo an impressive process of cooperative morphogenesis: the vegetative cells aggregate into large mounds and then form a fruiting body by directed cell movement (Fig. 3). Myxobacterial fruiting bodies show various degrees of complexity. They typically measure between 50 and 500 μm and can be seen with the naked eye. Within the maturing fruiting body the vegetative cells convert into short, optically refractile myxospores (Figs. 1 and 3). The myxospores are desiccation resistant and allow the organism to survive unfavorable environmental conditions. Many features of the life cycle are richly illustrated in a series of film clips created by Hans Reichenbach and assembled by Martin Dworkin (see the online version of *The Prokaryotes*). The clips are presented with the permission of the Institut für den Wissenschaftlichen Film.

Commentary and References for Time-lapse Film.

This time lapse film is from a series of films created by Dr. Hans Reichenbach. It was assembled by Dr. Martin Dworkin and is presented with the permission of the Institut fur den Wissenschaftlichen Film, Göttingen, Germany.*

1. Movement of cells of *Archangium violaceum* on agar. Note that movement ceases while the cells are dividing. [2 frames/min. over approximately 8 hr.; Kühlwein, H. and H. Reichenbach, 1968a]

2. Movement of cells of *Myxococcus xanthus* on agar. [4 frames/min over approximately 1.5 hr.; Kühlwein, H. and H. Reichenbach, 1968b]

3. Movement of cells of *Myxococcus virescens* over agar. [8 frames/min. over approximately 1 hr.; Kühlwein, H. and H. Reichenbach, 1968c]

4. Spiral movement characteristic of masses of cells of *Chondromyces apiculatus* on an agar surface. [1 frame/min. over approximately 16 hr.; Kühlwein, H. and H. Reichenbach, 1968d]

5. Aggregation of *Chondromyces apiculatus* as a prelude to fruiting body formation. Note the streams of cells moving into the aggregation center. [1 frame/min. over approximately 13 hr.; Kühlwein, H. and H. Reichenbach, 1968e]

6–8. Side views of the development of the fruiting body of *Chondromyces apiculatus* on a cellophane membrane overlaid on agar. The aggregated spherical mass of cells excretes a slime stalk, which propels the mass of cells upward. The cells within the knob at the top of the stalk differentiate into individual sporangioles containing the myxospores. [4, 8, and 4 frames/min. over 3, 3, and 5 hr.; Kühlwein, H. and H. Reichenbach, 1968f]

9–10. Germination of sporangioles of *Chondromyces apiculatus*. The myxospores of *C. apiculatus* are contained in sporangioles arrayed around the head of the fruiting body. Prior to germination the sporangioles fall off the fruiting body. The sporangiole swells and movement of the cells within the sporangiole becomes discernable. The sporangiole lyses at one end and then at the other, whereupon the cells emerge and constitute a small swarm, leaving the empty hull behind. Note that as the swarm moves, individual cells, which can move faster than the entire swarm, never escape from the swarm. Opposing swarms move toward each other and eventually fuse. The attractive mechanism is unknown. [2 frames/min. over 23.5 hr.; Kühlwein, H. and H. Reichenbach, 1968g]

11. Germination of myxospores of *Myxococcus xanthus*. Unlike the resting cells of *Chondromyces*, which are contained in sporangioles, the myxospores of *Myxococcus* germinate as individual cells. The cells lose their optical refractility and break out of their spore coat, leaving the empty hull behind. The cells elongate, reacquire their characteristic gliding motility and move off.

* The real time of each segment can be calculated from the fact that the film was projected at a speed of 24 frames/second and that the rate at which the frames were taken will be presented for each segment.

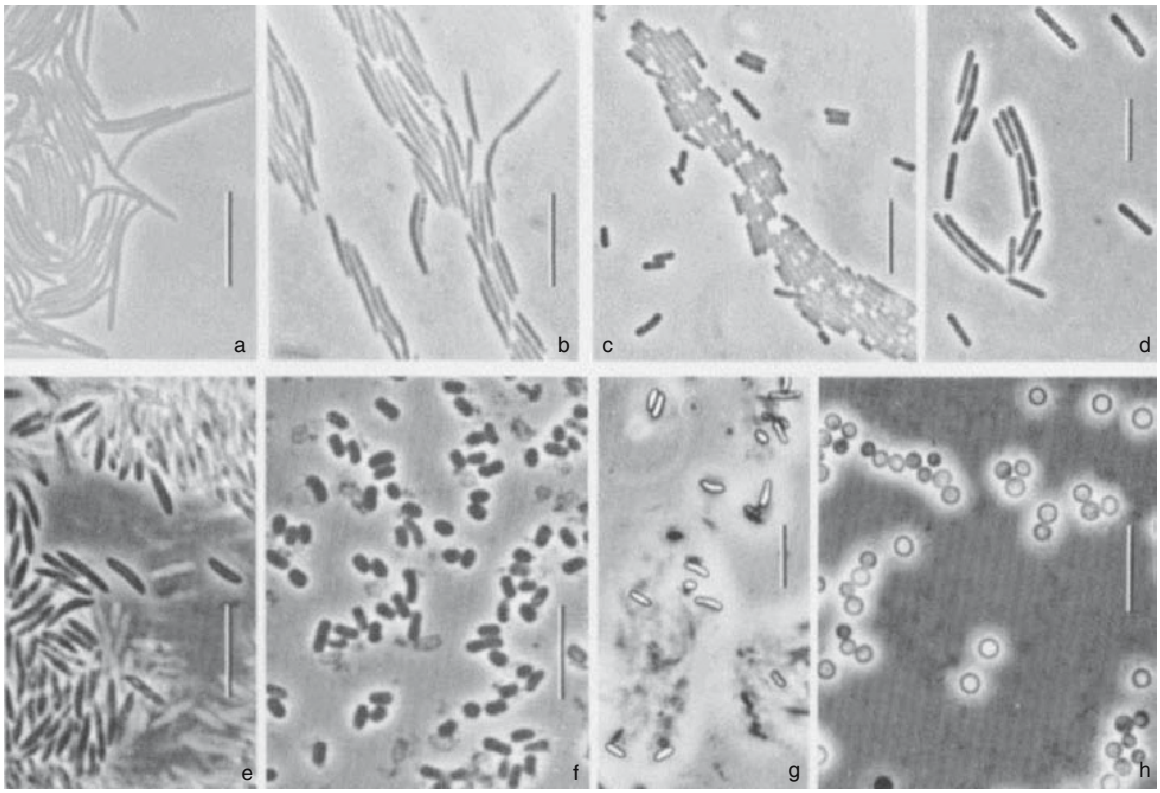

Fig. 1. Various types of myxobacterial cells. (a–d) Vegetative cells. (a and b) The Cystobacterineae type. a) *Cystobacter ferrugineus*, cells from a liquid culture. b) *Stigmatella aurantiaca*, cells in situ on agar surface in a chamber culture. (c and d) The Sorangineae type. c) *Chondromyces crocatus* in a chamber culture. d) *Sorangium compositum* in a chamber culture. Cells of the Nannocystineae resemble those of the Sorangineae. (e–h) Myxospores of members of the Cystobacterineae. e) Myxospores of *Cystobacter ferrugineus* from a crushed, degenerated, *Archangium*-like fruiting body; under oil immersion, the high optical refractility of the myxospores is not apparent. f) Myxospores of *Cystobacter velatus* from a crushed fruiting body sporangiole; oil immersion. g) Experimentally induced myxospores of *Stigmatella aurantiaca* on the agar surface in a chamber culture; under the 40X dry objective, the high optical refractility of the myxospores becomes very conspicuous. And h) myxospores from a *Myxococcus xanthus* fruiting body; the optical refractility of these spherical myxospores is so high that it is recognizable even under oil immersion. All photographs are in phase contrast. Bars = 10 μm.

Several cells can be seen dividing. [2 frames/min. over an approximately 9 hr.; Reichenbach, H. 1966]

12–13. Slime trails of *Chondromyces apiculatus*. The gliding cells leave a visible trail on the agar surface. Cells move slowly when laying the trail, but more rapidly if they move onto a previously laid trail. Cells may join on a trail and move together as a group. [5 frames/min. over a 1 and 2 hr period for *C. apiculatus*; Kühlwein, H. and H. Reichenbach, 1968h]

14–15. Rippling. Cells of the Myxococcaceae characteristically undergo what Reichenbach originally referred to as "rhythmic oscillations." Starting at the center of a swarm of *Chondrococcus coralloides* (now *Corallococcus coralloides*), rhythmically pulsating ripples travel outward. The oscillations periodically stop and start. The phenomenon is shown at a lower and higher magnification. [1 frame/min. for approximately 3 hr and, at a two-fold higher magnification, 8 frames/min. over about 0.5 hr.; Kühlwein, H. and H. Reichenbach, 1968i]

16. Edge of a swarm of *Archangium violaceum*. The cells move in a pack. If a cell occasionally moves away from the pack, it quickly returns. [8 frames/min. over 1.5 hr.; Kühlwein, H. and H. Reichenbach, 1968j]

17. Lysis of bacteria. Living cells of *Sarcina flava* are lysed by *Archangium violaceum*. Note that the cells are lysed at a distance, as evidenced by their loss of phase darkness. Note also that the cells of Archangium seem to head directly for the Sarcina, as if they can detect them at a distance. [4 frames/min. over 3.5 hr.; Reichenbach, H., 1968]

The phylogenetic position of the myxobacteria has been elucidated by a comparison of 16S rRNA (Ludwig et al., 1983; Oyaizu and Woese, 1985) and 16S rRNA gene sequences (Shimkets and Woese, 1992; Sproer et al., 1999). According

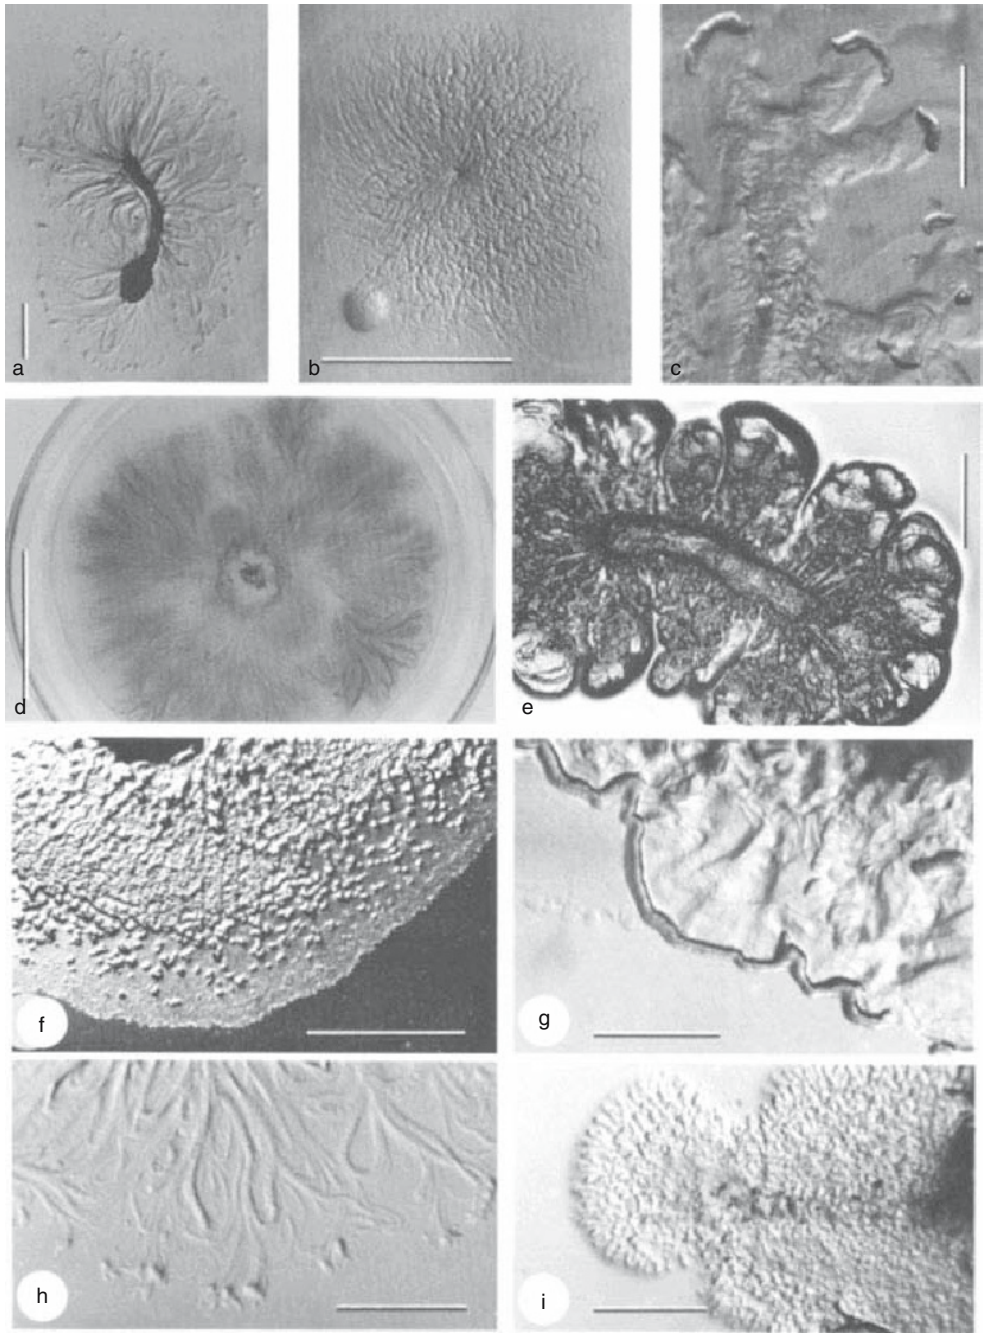

Fig. 2. Swarm colonies of various myxobacteria. (a, b, d, f and h) Swarms of members of the Cystobacterineae. (c, e and g) Swarms of members of the Sorangineae. i) Swarms of members of the Nannocystineae. a) *Stigmatella erecta* on CY agar; dissecting microscope, oblique illumination. Bar = 1 mm. b) *Myxococcus xanthus*, very young colony on Casitone agar; dissecting microscope, oblique illumination. Bar = 0.5 mm. c) *Polyangium* sp. on water agar, swarm edge; the spreading colony falls apart into cell clumps, which separate, thereby etching trenches into the agar surface; dissecting microscope, oblique illumination. Bar = 1 mm. d) *Cystobacter violaceus* (formerly *Archangium violaceum*) on VY/2 agar; from the inoculum in the center, the swarm has spread over the whole agar plate. Bar = 30 mm. e) *Nannocystis exedens* on Casitone agar; the swarm developed from the ridge in the center, and the agar plate has become deeply corroded; Leitz Aristophot. Bar = 5 mm. f) *Corallococcus coralloides* (Reichenbach, 2005) on Casitone agar; the central part of the swarm is covered with rudimentary fruiting bodies; Leitz Aristophot; Bar = 5 mm. g) *Polyangium* sp. on a streak of *Escherichia coli* (which is still recognizable at the left) on water agar; the swarm edge is a compact, ridge-shaped mass of vegetative cells, behind which the agar surface is deeply corroded; dissecting microscope, oblique illumination. Bar = 1 mm. h) *Stigmatella erecta* on Casitone agar, swarm edge with flame-like protrusions; dissecting microscope, oblique illumination. Bar = 1 mm. And i) *Nannocystis exedens* on a streak of *Micrococcus luteus* on water agar; the entire swarm has sunk into the agar, which is deeply corroded; dissecting microscope, oblique illumination. Bar = 2 μm.

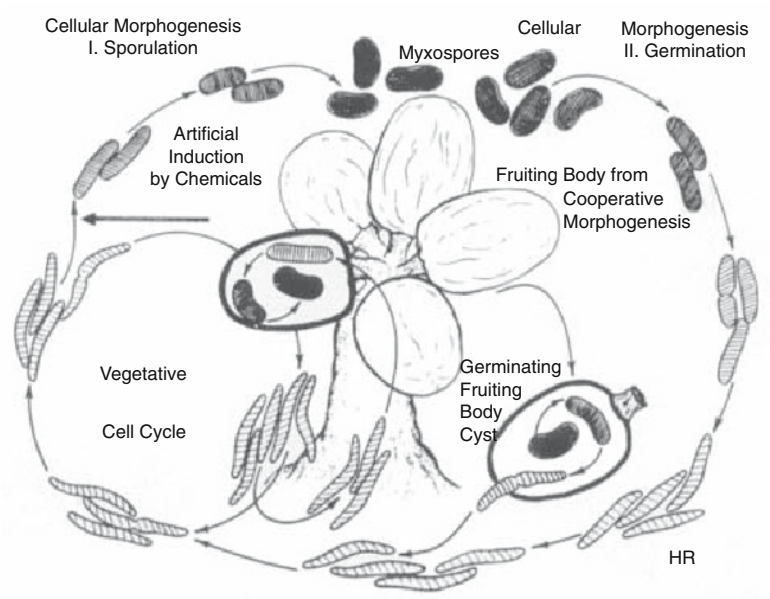

Fig. 3. Cellular morphogenesis in myxobacteria shown with *Stigmatella aurantiaca* as an example. Fruiting body and cells are not drawn to scale. From Gerth and Reichenbach (1978).

to these data, the myxobacteria belong to the Deltaproteobacteria, which also contains the genera *Bdellovibrio*, *Geobacter*, *Pelobacter* (Lonergan et al., 1996), *Anaeromyxobacter* (Sanford et al., 2002) and certain sulfate reducers such as *Desulfovibrio* and *Desulfonema* (Stackebrandt et al., 1988). About 50 species of myxobacteria have been assigned to seventeen different genera (Reichenbach, 2005; see the section Taxonomy of Myxobacteria in this Chapter).

While myxobacterial fruiting bodies had been observed by botanists early in the nineteenth century, they continued to be mistaken for fungi for almost a century. The first report in the scientific literature appears to be by Heinrich Friedrich Link (Link, 1809), who described a little "gasteromycete," *Polyangium vitellinum*, a taxon that is still valid. The description was accompanied by an exact and beautiful illustration (Link, 1809; Ditmar, 1814; see Fig. 14 below). Two more species, *Stigmatella aurantiaca* and *Chondromyces crocatus*, were defined by the British mycologist, M. J. Berkeley, who classified them as hyphomycetes (fungi imperfecti) (Berkeley, 1857). Again, both taxa are still valid. *Stigmatella aurantiaca* was described two more times as a new fungus under different names and with different systematic positions before it was finally recognized as a myxobacterium by the United States botanist Roland Thaxter (1892). Thaxter was the first to elucidate the astonishing and unexpected life cycle of the myxobacteria, which he published, together with descriptions of a substantial number of new species, in a series of brilliant articles (Thaxter, 1892; Thaxter, 1893; T. Thaxter, 1897; Thaxter, 1904). However, the reception by the scientific community was less than enthusiastic, and it took at least 20 years before Thaxter's work became widely accepted. In the first decade of the twentieth century, however, four voluminous studies on myxobacteria were published (Baur, 1905; Quehl, 1906; Vahle, 1910; Kofler, 1913) which deal with many problems that later became important topics of research. One of those four authors later became a very influential geneticist involved in breeding research (Erwin Baur). In the following decades, research was confined mainly to taxonomic, ecological and morphological questions (Jahn, 1911; Jahn, 1924; Krzemieniewska and Krzemieniewski, 1926; 1927a, 1927b; 1930). During that period, new species were discovered and the wide geographical distribution of myxobacteria was recognized. Furthermore, two large subgroups that could be distinguished by the shape of their vegetative cells were recognized (Krzemieniewska and Krzemieniewski, 1928), and some myxobacteria degrade cellulose and could be cultivated on a medium containing only cellulose and a few mineral salts (Imshenetski and Solntseva, 1936; Krzemieniewska and Krzemieniewski, 1937a, 1937b). For some time, cellulose decomposition by myxobacteria was a principal focus of interest, mainly in Russia, where it was studied in the laboratory of A. A. Imschenezki (for a review, see Imshenetski, 1959).

Footnote: In the remainder of the chapter the following abbreviations are used for genera of myxobacteria: *Ar*., *Archangium*; *Cb*., *Cystobacter*; *Cm*., *Chondromyces*; *Cl*., *Corallococcus*; *Ha*., *Haploangium*; *Ko*., *Kofleria*; *Me*., *Melittangium*; *Mx*., *Myxococcus*; *Na*., *Nannocystis*; *Pl*., *Polyangium*; *Sg*., *Stigmatella*; and *So*., *Sorangium*.

Studies utilizing pure cultures of myxobacteria did not become common practice until the middle of the twentieth century because myxobacteria were generally believed to be incapable of growth suspended in liquid media. Until then, physiological studies were tedious and only moderately conclusive, because the myxobacteria grew only as a film along the glass wall of the container and the surface of the liquid. Even under these experimental restrictions some insights were gained into the nutritional requirements of myxobacteria. Norén (1955), Loebeck and Klein (1956), and Mason and Powelson (1958) reported that at least some strains of *Myxococcus* grew well as suspension cultures. Subsequently, many more examples of myxobacteria growing in a dispersed manner have been described. Ironically, it later turned out (Dworkin, 1984) that dispersed growth of *Myxococcus* (*Mx.*) *xanthus* strains had been observed as early as 1948, but this information had never been published (Woods, 1948).

Beginning in the 1950s, the emphasis of myxobacterial research shifted to problems in developmental biology, with *Mx. xanthus* as the preferred subject. A major breakthrough was the discovery by Dworkin and Gibson (1964a) that vegetative cells of *Mx. xanthus* in suspension cultures could be induced to convert into myxospores by the addition of certain chemicals, such as 0.5 M glycerol. This was the first clearly defined experimental system for the investigation of a morphogenetic process in a myxobacterium, and it led to a long series of studies on the morphological, physiological and biochemical events that take place during induced myxospore formation.

Genetic analysis began with the development of systems for the transfer of plasmids, transposons and genes into and between strains of *Mx. xanthus*, based on the use of coliphage P1 (Kaiser and Dworkin, 1975; O'Connor and Zusman, 1983; Shimkets et al., 1983) and *Mx. xanthus* phages Mx4 and Mx8 (Campos et al., 1978; Martin et al., 1978). The availability of these genetic techniques made *Mx. xanthus* accessible as a model system for the study of morphogenetic processes and gliding motility. While these methods are not easily adaptable to other myxobacteria, a more versatile system that uses conjugation with *Escherichia coli* for the transfer of plasmids and transposons has been successfully applied to other myxobacterial genera (Breton et al., 1985). Progress in myxobacterial research has gained considerable momentum. The discovery that many myxobacterial strains produce secondary metabolites, most of which are novel compounds, has stimulated an even broader interest in myxobacterial biochemistry, physiology and taxonomy (for reviews, see Reichenbach and Höfle [1993] and Reichenbach [2001]).

Our knowledge of the myxobacteria has been summarized repeatedly in recent years. Apart from the articles mentioned above, the following reviews should be consulted for further details: 1) for books, Rosenberg (1984), Dworkin and Kaiser (1993), and Brun and Shimkets (1999); 2) for taxonomy, Reichenbach (2004); 3) for developmental biology, Shimkets (1990b), Shimkets (1992), Shimkets (1999), Zusman (1991), Kaiser (1993), Kaiser (1996), Kaiser (1998), Kaiser (1999), Kaiser (2001), Dworkin (1996), Crawford and Shimkets (1999), and Bonner and Shimkets (2001); 4) for genomics, Shimkets (1997a), Shimkets (1997b), and Ryding and Shimkets (2000); 5) for motility, Shi and Zusman (1993a), Hartzell and Youderian (1995), Youderian (1998), Ward and Zusman (1999), Kaiser (2000a), and Kearns and Shimkets (2001a). In addition, several movies are available from the Institut für den Wissenschaftlichen Film, Göttingen, Germany, that illustrate cell behavior, colony formation, and developmental processes in various species of myxobacteria (Reichenbach et al., 1965d; Reichenbach et al., 1965e; Reichenbach et al., 1965f; Reichenbach et al., 1965g; Reichenbach et al., 1980; Grimm et al., 1971; Kühlwein et al., 1971a; Kühlwein et al., 1971b).

Myxobacterial Ecology

The essential questions with regard to the ecology of any particular group of organisms are: Where are they? What is there? What do they do? How do their characteristic biochemical, physiological and developmental properties relate to their behavior in nature? With what do they interact?

Habitats

With regard to the first two questions—Where are they? and What is there?, a great deal of anecdotal and subjective information has been compiled on the habitats of the myxobacteria (e.g., Dawid, 2000; Reichenbach and Dworkin, 1992) since their recognition as bacteria by Roland Thaxter in 1892. Until recently (Dawid, 2000), however, these data have not been subjected to any sort of systematic analysis.

In addition, a number of other factors have made it difficult to draw useful quantitative descriptions. In view of the multicellular nature of the fruiting body, which may contain 10^4–10^6 resting cells, it is difficult, if not impossible, to determine the number of myxobacteria in a natural sample. Does a sample that contains one fruiting body represent 1 or 10^4–10^6 organisms?

Table 1. Convenient and preferential sources for the isolation of different myxobacteria.[a]

Substrate	Myxobacterial species typically found[b]
Soil	*Nannocystis exedens*,[5] *Sorangium cellulosum*,[4] *Archangium serpens*,[4] *Corallococcus coralloides*,[4] *Polyangium* spp.,[3] *Cystobacter* spp.,[3] *Melittangium* spp.,[3] *Myxococcus fulvus*,[2] *Mx. virescens*,[2] and *Mx. stipitatus*[2]
Dung of herbivores	*Myxococcus fulvus*,[5] *Corallococcus coralloides*,[5] *Mx. virescens*,[4] *Cystobacter fuscus*,[4] *Cb. ferrugineus*,[4] *Archangium serpens*,[4] *Nannocystis exedens*,[3] *Cb. violaceus*,[3] *Polyangium* spp.,[3] *Stigmatella erecta*,[2] *Mx. xanthus*,[2] *Melittangium* spp.,[2] and *Cb. velatus*[1]
Bark and rotting wood	*Stigmatella aurantiaca*,[4] *Chondromyces apiculatus*,[4] *Sorangium cellulosum*,[4] *Corallococcus coralloides*,[4] *Myxococcus fulvus*,[3] *Cm. pediculatus*,[2] and *Haploangium* spp.[2]

[a]The frequency of myxobacteria on a specific substrate may vary substantially in different environments. Furthermore, some species may be underestimated from a particular source because the isolation technique usually applied may not result in the isolation of a particular organism.

[b]Frequency of the encountered species: [5], ubiquitous; [4], very frequent; [3], moderately frequent; [2], relatively rare; and [1], rare.

The principal habitats of myxobacteria are soil, dung, decaying plant material, and the bark of living and dead trees. Nevertheless, myxobacteria have been isolated from marine environments as well as from a variety of climatic zones (Dawid, 2000). However, since the myxospores may tolerate considerable environmental extremes, and since most isolation techniques involve the cultivation of samples that have been extensively dried, it has not been possible to determine, in many cases, whether the myxobacteria were there adventitiously and simply survived as spores or were growing and thriving in that environment (Reichenbach, 1999). In a few cases, the isolated organisms were tested for their ability to grow under conditions similar to those in which they were isolated. Occasionally, they were able to (Dawid et al., 1988) but more often were not (Rückert, 1983). Iizuka et al. (1998) have isolated two myxobacteria from marine environments, which have been subsequently characterized and assigned to the new genus *Haliangium* (Fudou et al., 2002). The organisms were reported to require 2% NaCl for their growth. However, since this measurement was made on the basis of colony swarm expansion rather than growth per se, the claim must be viewed with caution.

A survey of common sources for different myxobacteria is given in Table 1. Most myxobacteria appear to be primarily soil organisms. However, almost all are "micropredators" (Singh, 1947) and are attracted by habitats with rich microbial communities, which they may colonize as secondary substrates. Even if certain myxobacteria can be isolated more easily from sources other than soil, their presence in the soil of the same environment can often be demonstrated. The preferred substrate of a particular species may vary under different climatic and edaphic conditions. Thus, in the central United States, *Chondromyces* species are common inhabitants of bark and rotting wood but are rare in soil (Nellis and Garner, 1964; H. Reichenbach, unpublished observations). In India, they are found regularly in soil, in the rhizosphere of plants, and on rotting wood, bark, and dung (Agnihothrudu et al., 1959; Singh and Singh, 1971). In Europe, in spite of apparently similar climatic conditions to those found in the United States, they appear to be extremely rare organisms and have been found almost exclusively on dung, rotting wood, and bark (Zukal, 1896; Quehl, 1906; Jahn, 1924; Krzemieniewska and Krzemieniewski, 1946). Dawid (1979) tested several thousand samples from the Siebengebirge, a mountain ridge near Bonn, Germany, and obtained only one isolate of *Chondromyces*, a strain of *Cm. apiculatus*, from a piece of rotting wood. Similar results have been obtained by Krzemieniewska and Krzemieniewski (1946) and by one of us (H. Reichenbach) who isolated myxobacteria over decades from all kinds of samples collected at many different sites in Europe.

Myxobacteria are very common in soils of neutral or slightly alkaline pH (Krzemieniewska and Krzemieniewski, 1927b; Norén, 1950; Norén, 1952; Sabados-Saric, 1957; Kühlwein, 1960; Brockman and Boyd, 1963; Peterson, 1965; Peterson and Norén, 1967; Michoustine, 1968; McCurdy, 1969b; Rückert, 1975b; Rückert, 1976; Rückert, 1979; Brockman, 1976; Hook, 1977; Rückert and Heym, 1977; Dawid, 1978; Dawid, 1979). They have been isolated from samples collected in tropical rain forests and in the arctic tundra, in steppes, deserts, and in bogs, at sea level as well as at high altitudes. Warm and seasonally dry areas, such as the southwestern United States, Mexico, northern India, the Mediterranean countries, and the Canary Islands, have been found to be especially rich in different myxobacteria. The same is true for areas with underground limestone in temperate climates. Still, a myxobacterial species may show an unequal distribution even within the same climatic zone. The case of *Chondromyces* has just been mentioned. Another example is *Sg. auran-*

tiaca, which is common in the middle of the North American continent (Nellis and Garner, 1964; McCurdy, 1969b; Reichenbach and Dworkin, 1969a), but very rare in Europe (Krzemieniewska and Krzemieniewski [1946] isolated myxobacteria in Europe 15 years before they found their first strain of *Sg. aurantiaca*). The decisive factor that controls the distribution may be the warm, humid American summers, which are usually in contrast to those in Europe. For unknown reasons, *Sg. aurantiaca* seems to be restricted to rotting wood and bark on both continents. Locations with acid soils and raw humus underground, such as the *Rhododendron* forests of West Virginia (H. Reichenbach, unpublished observations), can be totally devoid of myxobacteria. But under otherwise favorable conditions such as sufficiently high humidity and temperature, myxobacteria have also been isolated from soils with a bulk pH of below 5 (Rückert, 1975b; Rückert, 1979). In cool, humid environments, such as in Finland, northern Minnesota, and mountain ranges, myxobacteria may be abundant, albeit limited to a few species. Tropical rain forests are not necessarily rich in myxobacteria, perhaps owing to the nature of the underground material. Myxobacteria have also been isolated from Antarctic soil samples but at least in one case, the organisms had a temperature optimum around 30°C, which raises some doubts as to whether they were really indigenous (Rückert, 1985). In another instance, however, the isolated bacteria were true psychrophiles that developed, very slowly indeed, at temperatures between 4 and 9°C but did not grow at 18°C (Dawid et al., 1988). While the vegetative stages of the latter organisms closely resembled those of myxobacteria of the *Polyangium* and *Nannocystis* type, their identity could not be established with certainty since they did not produce fruiting bodies. No mesophilic myxobacteria were found in the Antarctic samples examined by Dawid et al. (1988).

Dung of various animals, especially of herbivores such as rabbits, hares, deer, moose, sheep and goats, is an excellent substrate for myxobacteria. Rabbit dung was the preferred source of the early myxobacteria investigators and appears to serve as natural bait. Apparently, however, myxobacteria can also pass unscathed through the digestive tract of animals (Kühlwein, 1950). Also, the observation of myxobacteria on dung pellets collected on the surface of deep snow layers suggests that, occasionally, they were deposited with the dung (Rückert, 1975b; H. Reichenbach, unpublished observations). However, the organisms primarily appear to arise in the surrounding soil after the dung has been dropped. This conclusion is based on the fact that aged dung is a better source of myxobacteria than is fresh dung, that dung collected on soil rich in myxobacteria results in a greater yield of strains than one from poor soil, and that the same species found on dung can also be found in the surrounding soil. A number of myxobacteria are regularly found on dung, such as *Mx. fulvus*, *Mx. virescens*, *Cl. coralloides*, *Cb. fuscus* or *Sg. erecta*, but no myxobacterium depends on dung-derived growth factors, as was thought for some time, and all strains isolated from dung can be cultivated on relatively simple media. Of course, occasional stimulation by substances such as vitamins found in dung extracts is conceivable.

Bark and rotting wood are good sources of certain myxobacteria. This includes the cellulose degraders of the genus *Sorangium*, but several noncellulolytic species are also regularly found in those habitats. Results vary with different species of trees: In Europe, relatively good yields have been reported with bark from living elder (*Sambus racemosa*), beech (*Fagus silvatia*), and black locust (*Robinia pseudacacia*; Dawid, 1979). In Minnesota and other locations in the United States, bark and rotting wood are reliable sources for *Stigmatella aurantiaca* and *Chondromyces apiculatus*. The latter has also been found regularly on wood samples from southeast Asia and on dry, rotten "leaves" of *Opuntia* cacti from the Canary Islands (H. Reichenbach, unpublished observations). The difference from the situation in Europe has already been pointed out. Clearly, other less obvious factors, perhaps climatic ones, also play a role in the distribution of myxobacteria. However, probably no myxobacteria have an absolute dependence on bark and wood. The cellulose degraders are also common in soil and dung, and because the other species are bacteriolytic, they often grow well on dung and in culture on media that contain peptone or protein. In fact, why in nature they grow preferentially on wood and bark is not understood. Even when they are found on dung, they may be there mainly because the dung of herbivores is always abundant in plant residues. However, *Haploangium* has only been found on bark and wood so far. It has never been cultivated, so its nutritional requirements are unknown.

Although myxobacteria have repeatedly been isolated from freshwater habitats (Geitler, 1925; Jeffers, 1964; Brauss et al., 1967; Brauss et al., 1968; Gräf, 1975; Hook, 1977; Trzilová et al., 1980; Trzilová et al., 1981), they probably are merely washed in from the soil. Myxobacteria have been used to classify rivers for the type of pollution present (Gräf, 1975; Trzilová et al., 1980; Trzilová et al., 1981). While myxobacteria appear not to be typical aquatic organisms, our experience with cultivated strains suggests that they can survive and thrive in suitable aquatic

niches. A clear indication of this is the case of a myxobacterium that parasitizes the green alga *Cladophora*, with fruiting body formation inside the emptied-out algal cells (Geitler, 1925). Another example may be the occurrence of structures resembling myxobacterial fruiting bodies on eggs of the water beetle *Dytiscus marginalis* (Jackson, 1959).

Dawid (2000) has compiled data on myxobacteria isolated from 1398 samples collected over an 18-year period from all continents. Representatives of 30 species and 11 of the 12 known genera of myxobacteria were isolated (only *Haploangium* was not). Approximately 20,000 strains representing 17 species were isolated from a limited area in Germany alone. Among the 55 nations and 9 states of the United States, myxobacteria were ubiquitous. The genera most frequently encountered were *Myxococcus*, *Corallococcus* (Reichenbach, 2005) and *Archangium*. Whether this reflects their true predominance or the bias of the isolation procedure is unclear.

Myxobacteria were found most commonly in environments with pH 6–8.

The search for new organisms able to produce novel and useful bioactive compounds has stimulated attempts to isolate bona fide marine myxobacteria. While isolation of myxobacteria from marine environments has been reported (Brockman, 1967; Rückert, 1975c; Dawid, 1979), in no case have these authors claimed that the organisms require or even can grow in the presence of the concentration of NaCl found in seawater. Several recent reports show strains with moderate halotolerance (Iizuka et al., 1998; Iizuka et al., 2003a; Iizuka et al., 2003b; Li et al., 2002).

A most unusual myxobacterium, *Anaeromyxobacter dehalogenans*, which is outside the bounds of what is usually defined as a myxobacterium, has recently been described (Sanford et al., 2002). This organism is an anaerobe that uses acetate as an electron donor and a variety of chlorinated phenols as electron acceptors. While it has not been shown to produce fruiting bodies, it is a characteristically pigmented, Gram-negative rod that moves by means of gliding motility. The result of 16S rRNA/DNA analysis places it within the Myxococcales as a separate genus. Clearly, the taxonomic and phylogenetic boundaries of the myxobacteria have not yet been reached or even defined.

Ecologically Relevant Characteristics of Myxobacteria

The features that are characteristic of the myxobacteria are gliding motility, a complex life cycle culminating in the formation of fruiting bodies and myxospores, the ability to degrade insoluble macromolecules, and the production of an extensive battery of bioactive compounds. Each of these properties plays an important role in establishing the particular ecological function of the myxobacteria.

Degradation of Insoluble Macromolecules

In the grand scheme of molecular turnover in nature, bacteria play the major role. And myxobacteria have long been known to play an important part in the degradation of such insoluble macromolecules as protein, cellulose, peptidoglycan, lipids and nucleic acids as well as intact cells, both eukaryotic and prokaryotic, and their subcellular fragments (see the section Lysis of Other Bacteria in this Chapter). They do so by excreting a powerful battery of hydrolytic enzymes. As such, however, they are at the mercy of the diluting effect of diffusion of their enzymes away from the cell and the effect of hydrolyzed products diffusing back toward the cell. Thus, the suggestion on theoretical grounds that *Mx. xanthus* when feeding on macromolecules behaves as a bacterial "wolf pack" (Dworkin, 1973a), seeking at all times to optimize its feeding by maintaining a high cell density, has been experimentally demonstrated: *Mx. xanthus* can feed on hydrolyzed protein quite efficiently at a low cell density but can only utilize the equivalent high molecular weight protein when at a high cell density (Rosenberg et al., 1977). The characteristic swarms of migrating cells accomplish this, and the fruiting body may be a mechanism for maintaining the resting myxospores at a high cell density in preparation for future germination and feeding.

The Function of Gliding Motility

Myxobacteria exist in nature on surfaces—soil particles, leaf surfaces, bark and other detritus. Thus, flagellar motility through an aqueous milieu is likely to be of little value. The ability to crawl over a surface, on the other hand, seems well suited for the myxobacterial life style. Thus, their gliding motility is consistent with their ecological niche.

Developmental Aspects of Myxobacterial Ecology

The myxobacteria, with the exception of the taxonomically problematic *Anaeromyxobacter dehalogenans*, are aerobes and are found on surfaces or close to the surface of soil. As such, they are exposed to the vicissitudes of desiccation, irradiation and temperature extremes. Myxospores

while do not possess the extraordinary resistance of endospores, but they are sufficiently resistant (Sudo and Dworkin, 1969) to withstand the kinds of extremes they are likely to encounter in normal environmental situations. The fruiting body can be assumed to maintain the resting cells packed closely enough together so that upon germination they can begin feeding at the optimally high cell density. The sporangioles, whether multiple on a stalk (as in *Stigmatella* or *Chondromyces*), or single on a stalk (as in *Haploangium* or *Melittangium*), or lying on the substrate (as in *Cystobacter*, *Polyangium*, *Sorangium* or *Nannocystis*), may be simply an optimal packaging mechanism of the resting myxospores.

Myxobacterial Bioactive Compounds

The myxobacteria produce an astounding variety of bioactive compounds (Reichenbach, 1989; Reichenbach, 1993; Reichenbach, 2001; Reichenbach and Höfle, 1998). Among over 2000 bacteriolytic strains of myxobacteria, 55% produce bioactive compounds; among over 700 cellulolytic myxobacteria, 95% produce bioactive compounds (Dawid, 2000). These include inhibitors of protein synthesis as well as compounds interfering with electron transport, nucleic acid synthesis, and actin and tubulin synthesis. Their structures include polyketides, linear and cyclic peptides and heterocyclic molecules. Clearly, when the group is fully characterized, the spectrum and number of bioactive compounds produced will rival those produced by the Actinomycetes.

The biological function of antibiotics is equivocal. While antibiotics might assist a soil organism in its struggle for nutritional "lebensraum," the matter has not been settled. How then do the myxobacteria interact with other myxobacteria and other bacteria in nature?

Lytic Activities

The ability of the myxobacteria to kill and lyse a wide variety of Gram-positive and Gram-negative bacteria, yeast, fungi, algae and protozoa was noticed early and often and came to be considered as a characteristic property of the group (see the section Lysis of Other Bacteria in this Chapter). Thus they might reasonably play some sort of role in nature, either to control other microbial populations or to clear the soil of the carcasses of other dead or dying cells. In fact, Callao et al. (1966) demonstrated that after *Mx. xanthus* and *Azotobacter* were simultaneously inoculated into soil, the number of *Azotobacter* decreased substantially.

Symbiosis

Myxobacteria have been shown to exist in a close symbiotic association with other bacteria. Early on, Pinoy (1913) demonstrated that a culture of *Cm. crocatus*, which constructs the most complex of all the myxobacterial fruiting bodies, existed in a close association with a non-myxobacterial companion. This matter was more carefully examined and defined by Jacobi et al. (1997), who showed that the growth of almost all strains of *Cm. crocatus* examined depended on a small rod-shaped bacterium tentatively identified as belonging to the genus *Sphingobacterium* present in the sporangioles of the fruiting body.

Myxobacterial Interactions and Territoriality

When observing the multicellular behavior of the myxobacteria, an obvious question is how able or inclined they are to interact with other myxobacteria. Will related species form mixed fruiting bodies? Will their migrating swarms fuse? And if not, what is the basis upon which the myxobacterial cells distinguish between self and non-self? Do the myxobacteria establish territories? These questions were examined by Smith and Dworkin, who observed the interactions between feeding and developing swarms of *Mx. xanthus* and *Mx. virescens* (Smith and Dworkin, 1994).

A common observation in natural samples of myxobacterial fruiting bodies is that the localized areas in which they occur contain only one species of fruiting body, i.e., the myxobacteria do indeed seem to establish an exclusive territory. When cultures of *Mx. xanthus* and *Mx. virescens* were mixed and placed under fruiting conditions, the cells sorted themselves out and established separate fruiting body territories. And the contents of the individual fruiting bodies were limited to a single species. Furthermore, *Mx. virescens* was able to produce an extracellular material that, when applied to *Mx. xanthus*, caused spheroplasting and loss of viability. The toxic material had no effect on other bacteria and its properties were consistent with those of bacteriocins, which have previously been described for the myxobacteria (McCurdy, 1974). Thus, the myxobacteria do establish territoriality, the cells of different species do not mix, and one mechanism of exclusion may be myxobacterial bacteriocins (Smith and Dworkin, 1994).

Isolation

Although myxobacteria are common in many types of soil (a teaspoonful of soil is usually sufficient to isolate four or five species), they are

rarely mentioned in articles on soil microbiology. The reason is that the usual dilution and plating techniques used for the isolation of soil microorganisms are unlikely to reveal the presence of myxobacteria. Owing to the slime matrix they produce, myxobacterial cells do not disperse easily when the soil sample is shaken in water, so that the organisms are highly underrepresented in number when the suspension is plated. Even when other, more suitable methods are used, the estimated numbers probably are only approximate ones; depending on the type of soil, they are in the range of 10^3 to 4.5×10^5/g and thus under favorable conditions seem to be a rather substantial component (Singh, 1947; Sabados-Saric, 1957; McCurdy, 1969b). Another problem is that on lean media the myxobacterial colonies develop as easily overlooked delicate, spreading swarms, while on rich media they remain compact and are not recognized as myxobacteria. In addition, they grow relatively slowly so they are often overgrown by other soil microorganisms, particularly fungi. The fruiting bodies, however, are conspicuous and have probably been frequently observed by soil biologists. The use of available nucleotide probes and fluorescent in situ hybridization techniques should make it possible now to arrive at a more realistic appraisal of myxobacterial numbers.

The isolation of myxobacteria can start from fruiting bodies that have developed on natural substrates or from swarms growing in agar cultures. These isolations can also be preceded by enrichment and baiting techniques. The methods have frequently been reviewed (Kühlwein and Reichenbach, 1965; McCurdy, 1969b; Peterson, 1969).

Collection and Treatment of Samples

Soil to be used for the isolation of myxobacteria should be taken from the upper few centimeters of the soil profile. Soils rich in higher organisms, and samples collected from between plant roots and near the base of stems, give the best yields. If the material cannot be processed soon after collection, it should be air-dried as quickly as possible because otherwise the sample may become moldy, creating problems later during isolation. A few cubic centimeters of soil are sufficient for most isolation techniques. In general, it is better to have several small samples from different localities than one large batch from a single spot. Dry material can be stored for long periods at room temperature. Apparently, in the natural substrate, myxobacteria are much more stable than, for example, fruiting bodies dried on filter paper. Thus, we have found essentially the same species over a 12-year period of sampling of stored soil samples, and we are regularly able to isolate myxobacteria from samples stored 10–15 years (H. Reichenbach and M. Dworkin, unpublished observations).

With dung, better results are usually obtained if the samples are neither very fresh nor very old, but are completely free of low-molecular weight components. It is very important to dry the samples if they have to be stored for more than one day, and such dry dung will yield myxobacteria even after months and years of storage. Rabbit dung to be used for baiting (see below) should be taken from wild animals; pellets from laboratory or domestic rabbits are usually unsuitable, perhaps because they become soaked with urine in the cage.

Bark and wood for the isolation of myxobacteria must be taken from tree species that are low in resins and tannin compounds, and specimens have to be quickly dried if they are not to be processed immediately. Successful isolations are often obtained with wood that has already been decomposed to a rather soft state and with bark from the base of the tree and from fallen trees.

Direct Isolation from Natural Substrates

Isolation can often be achieved directly from the natural substrate. Bark of living or dead trees, rotting wood, or dung pellets are kept in large Petri dishes lined with two to three layers of filter paper. The samples are soaked in distilled water containing cycloheximide (up to 0.08 mg/ml) for a few hours to suppress the growth of molds. The water is then decanted and appropriate amounts of water are added at intervals during cultivation. If the culture is kept too dry, it may soon be covered with molds; if the substrates are inundated, no myxobacterial fruiting bodies will develop. The air in the incubator should be kept sufficiently humid so that the crude cultures do not dry out too quickly. The initially saturated system is allowed to dry out gradually over 14–21 days; in this way it will eventually pass through the optimum for the development of myxobacterial fruiting bodies. Such crude cultures are likely to contain a variety of fungi, mites, springtails, nematodes, and other organisms that may contaminate other cultures. The danger of a contamination with mites is especially serious and can quickly spoil a culture collection. The cultures should therefore be kept in tightly closed plastic bags or, more conveniently, in a separate incubator, which should frequently be sterilized.

The cultures can be incubated at room temperature (around 20°C) or at 30°C. We have never observed unequivocal differences in the yield of myxobacteria when parallel crude cultures were kept at different temperatures, but we have found that at room temperature, the development

of myxobacteria proceeds more slowly and molds tend to spread more vigorously. Thus, we keep such cultures at 30°C (see also Krzemieniewska and Krzemieniewski, 1927b). However, samples from mountains at high altitudes or from arctic environments may contain myxobacteria that are adapted to lower temperatures (see the section Habitats in this Chapter), and even in forest soils in Central Europe, strains are occasionally found that grow reasonably well at 30°C but produce fruiting bodies only at lower temperatures.

Initially, the crude cultures should be inspected for fruiting bodies every day, beginning with the third or fourth day of incubation, because fruiting bodies often spring up and then rapidly collapse and become very inconspicuous. Also, the fruiting bodies may soon become overgrown by other organisms. Most fruiting bodies will appear during the first 10 days, either on the substrate itself or on the filter paper lining; only rarely will anything of interest develop later than 18–20 days. Sometimes, fruiting bodies appear very early on the substrate, within hours after moistening; probably, in such cases, desiccated structures have simply been rehydrated and thus have become recognizable, while the fruiting bodies that appear later are produced de novo. In the later phases of culture development, spherical or ridge-shaped masses of vegetative cells, which are usually bright yellow, orange, or red, can often be observed on the filter paper and can be used for isolation; in this way one may obtain species whose fruiting bodies are too small and inconspicuous to be recognized directly on the substrate. These organisms are almost always members of the Sorangineae, usually *Polyangium* and *Nannocystis* strains, which produce swarms with a massive ridge at the edge. Sometimes, cellulose decomposers may develop on the filter paper lining itself.

Isolation from Soil by Baiting

A baiting technique can be used to isolate myxobacteria from soil (Krzemieniewska and Krzemieniewski, 1926). A large Petri dish is filled with soil, which is moistened with distilled water up to its water-holding capacity. Autoclaved dung pellets from wild rabbits are partly buried in the soil. The culture is then incubated and examined as described above. Vegetative cells will migrate to the dung pellets, colonize them, and in time develop the characteristic fruiting bodies. Here, as with the technique described above, the discovery of the myxobacterial fruiting bodies is greatly facilitated by their tendency to appear locally in large numbers and by their brightly colored and glistening appearance. With some experience, they can be located quickly with the unaided eye, despite their relatively small size (50–500 µm). For a more careful examination of the culture, a dissecting microscope with incident illumination and a magnification between 10 and 40X is perfectly adequate (see Fig. 2).

Isolation from Swarms

The bacteriolytic properties of myxobacteria can be used for their enrichment from natural substrates, particularly from soil and plant debris. Streaks of living food organisms (e.g., *E. coli*) on water agar (WAT agar, see below), in the form of a cross-streak, three parallel streaks, or a number of circular patches, are inoculated with a small quantity (approximately the size of a lentil) of the material to be analyzed (Singh, 1947). The cross and the patches are inoculated in the center, and the parallel streaks at the ends. Care should be taken not to scatter the inoculum over the plate. To facilitate application of the sample, the soil may first be moistened with sterile water and then applied with sterile swabs.

To restrict the development of fungi, the addition of the antibiotic cycloheximide (25–100 µg/ml) to the enrichment medium has been recommended (WCX agar, see below; Brockman and Boyd, 1963). Results are indeed superior when cycloheximide is included, and the cultures can be maintained for a longer period. The antibiotic does not control the growth of amoebae, a major nuisance with this isolation technique. Also, it does not result in the selection of particular myxobacteria or in the suppression of any other gliding bacteria, such as *Cytophaga*-like bacteria, flexibacters, *Taxeobacter*, or *Herpetosiphon*, which can also be isolated with this method.

WAT Agar and WCX Agar

$CaCl_2 \cdot 2H_2O$	0.1% (w/v)
Agar	1.5% (w/v)
HEPES	20 mM

Prepare media in distilled water and adjust pH to 7.2. Autoclave the medium. Then, add 25 mg of cycloheximide per ml from a filter-sterilized stock solution, yielding WCX Agar. As the pH is very difficult to adjust in this completely unbuffered medium, addition of, e.g., 20 µM *N*-2-(hydroxy-ethyl)piperazine-*N*′-2-ethane-sulfonic acid (HEPES), is advisable.

Many bacteria and yeasts can be used as food organisms by the myxobacteria. Food organisms that are readily recognized and can be easily eliminated later are, of course, preferred. Selection for myxobacteria works better if the prey microbes used are alive rather than dead. In the first study, an *Aerobacter* strain was used as the food organism (Singh, 1947). We have found the following bacteria to be useful: 1) *Micrococcus luteus* is easy to distinguish, is nonmotile, and is relatively large, so that it is not readily spread

around; while it is not well utilized by soil amoebae, not all strains of myxobacteria, specifically *Nannocystis* strains, grow on it. 2) *Escherichia coli* is a favorable substrate for myxobacteria, including *Nannocystis*, which can be subcultured indefinitely on it; but soil amoebae also use it well, and this sometimes makes *E. coli* inconvenient. 3) Autoclaved yeast, *Saccharomyces cerevisiae*, can be cheaply prepared from commercial bakers' yeast; the pH of the suspension must be adjusted to 7.0, since the yeast cake is usually acidic; unfortunately, the autoclaved yeast is also a good substrate for many contaminants. Generally, living *E. coli* is our preferred food organism.

The cultures are incubated at 30°C and checked under a dissecting microscope for the appearance of myxobacterial swarms and fruiting bodies, at first daily, beginning on the second or third day, and later at longer intervals (Fig. 2). After about 3 weeks, no additional myxobacteria are likely to appear, and the cultures can be discarded. Most myxobacteria appear within 8–14 days. The myxobacteria grow first on the lawn of the food organism, but later often spread over the agar surface between the smears. A fast-spreading organism such as *Cystobacter* may reach the end of a streak within 1–2 days. If two streaks are made in a crossed pattern, different myxobacteria may develop on each of the four arms. Different organisms also may follow one another on the same streak. As a rule, species of the Cystobacterineae are seen first, while the Sorangineae develop later. Between two and five different myxobacteria can be expected on one plate. Three parallel plates are usually sufficient to secure most of the myxobacterial types that are readily isolated from a sample, with the exception of the cellulose degraders. Fruiting bodies are often produced within the swarms after a couple of days. Fruiting bodies may also appear on the soil crumbs or other particles of the inoculum. To detect the delicate, film-like, swarms of myxobacteria, one must use a dissecting microscope with a tilting mirror so that light can be applied at a shallow angle to the surface of the plate.

The sooner a swarm is recognized, the more easily a myxobacterium can be isolated, as at the beginning, the contaminants may still be confined to the site of the inoculum. Transfers are then made from the swarm edge, which is usually the purest part of the colony.

A disadvantage of isolating myxobacteria from the swarm stage is that most species cannot be identified by their swarm morphology. With some experience, however, at least certain genera or types can be differentiated (Fig. 2). The ubiquitous *Nannocystis*, for example, produces a network of trails outside the streak of the food organism. These trails are deeply etched into the agar and end with a small cluster of cells. On the streak, there is often a heavy, meandering ridge. *Polyangium* shows a similar pattern, but with coarser structures. Swarms with an edge that consists of a massive, often brightly colored ridge are in general typical for the suborder Sorangineae. *Cystobacter* and *Archangium* swarms are usually tough slime sheets with a pattern of delicate, but conspicuous, branched, radiating veins. The swarms of the Myxococcaceae tend to be smooth, soft-slimy sheets, often with dense fields of tiny waves or ripples. If there are radial veins, they typically are wavy and meandering. Swarms of *Mx. stipitatus* show a bright yellow fluorescence in ultraviolet (UV) light of 366-nm wavelength (Lampky and Brockman, 1977). The shape of the vegetative cells under the microscope may also provide a clue to the identification of the swarm observed.

Isolation by Direct Plating of Heated and Dried Soil on Antibiotic-containing Media

Karwowski et al. (1996) have described a method for the isolation of *Myxococcus* from soil by plating treated soil samples directly on a medium containing antibiotics.

Soil was air-dried at room temperature overnight, diluted in sterile distilled water, heated at 56°C for 10 min and then plated on CY-C10 medium. (CY-C10 medium is CY medium with 1% Casitone instead of 0.3% and with 50 μg of cycloheximide/ml.) Vancomycin, ristocetin or tiacumycin B at 10 μg/ml was also included. The combination of heat, desiccation and antibiotics killed or inhibited the growth of many non-myxobacterial cells, and the higher concentration of Casitone inhibited excessive swarming of the myxobacteria, while still allowing their colonies to be recognized. Colonies were picked and plated on media allowing fruiting body formation, and from these plates the final purification and identification were achieved. This approach was effective for isolating *Myxococcus*.

Isolation of Cellulose Decomposers

For the isolation of cellulose-degrading myxobacteria of the genus *Sorangium*, a mineral agar with cellulose as the only carbon source is used. While NH_4^+ is an excellent nitrogen source for *Sorangium*, much better results are obtained when NO_3^- is used in the isolation medium, as in ST21 agar. The cellulose is applied in the form of sterile filter paper, which is placed on top of the agar surface. Since the cultures must be incubated for a longer time before the cellulose decomposers can be recognized, inclusion of cycloheximide in the medium is essential.

ST21 Agar and ST21CX Agar

Solution A:

K_2HPO_4	0.1% (w/v)
Yeast extract (Difco)	0.002% (w/v)
Agar	1% (w/v)

Make up in about two-thirds of the water volume in distilled water.

Solution B:

KNO_3	0.1% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)
$CaCl_2 \cdot 2H_2O$	0.1% (w/v)
$FeCl_3$	0.02% (w/v)
$MnSO_4 \cdot 7H_2O$	0.01% (w/v)

Make up in the remaining water volume. Autoclave separately. Combine solutions A and B and add 1 ml of trace element solution (see below) per liter of medium. For crude and enrichment cultures, add 25 mg of cycloheximide per ml from a filter-sterilized stock solution, yielding ST21CX agar.

Trace Element Solution (10× Original Formulation; Drews, 1974)

$MnCl_2 \cdot 4H_2O$	100 mg
$CoCl_2$	20 mg
$CuSO_4$	10 mg
$Na_2MoO_4 \cdot 2H_2O$	10 mg
$ZnCl_2$	20 mg
LiCl	5 mg
$SnCl_2 \cdot 2H_2O$	5 mg
H_3BO_3	10 mg
KBr	20 mg
KI	20 mg
EDTA, Na-Fe^{+3} salt (trihydrate)	8 g

Dissolve in 1 liter of distilled water and filter sterilize. This solution is stable for months at room temperature. Use the mixture at 1 ml/liter of medium.

The filter paper is inoculated in the center with a pea-sized amount of soil or plant debris, either in one spot or in the form of a streak. The cultures are incubated at 30°C. Unequivocal cellulose decomposition cannot be expected before 8–10 days of incubation, and most *Sorangium* strains are seen only after 10–20 days. They are recognized as bright, more or less translucent patches, which are yellow, orange, brown, or even black, often several cm across, and consisting of macerated cellulose, slime, and usually masses of densely packed fruiting bodies. The latter are responsible for most of the color, but also the vegetative parts of the swarms may be tinged yellow and orange, and at the edges, dense, orange ridges often develop. Besides the sorangia, other cellulolytic bacteria may also appear. The lysed areas always contain complex mixtures of a variety of bacteria, protozoa, and nematodes. In such cultures, particularly at later stages, noncellulolytic myxobacteria can also develop that live off the cellulose degraders (Brockman and Boyd, 1963). They appear in the form of long, heavy, orange ridges, which are the edges of expanding swarms, and are usually strains of *Nannocystis*, *Polyangium* or *Chondromyces*. Often fruiting bodies are also produced, not only in the macerated areas, but also on the edges of the intact filter paper, on the inoculum, and on the agar just beyond. Of course, these latter myxobacteria, not being cellulolytic, have to be subcultured on streaks of food bacteria and not again on filter paper. As the fruiting bodies observed in the lysis zones are not necessarily those of the cellulose degraders, in case of doubt, subcultures are best started both from fruiting bodies and from the swarm edge, using both types of substrates.

Isolation from Fresh Water

Sediments and plant and animal debris collected in lakes, ponds, rivers, etc. may be processed in the same way as described above. If free-floating myxobacteria are to be isolated, between 10 and 1000 ml of water is passed through a sterile membrane filter of small pore size (0.15–0.45 µm). The filter is then placed right side up on the surface of rabbit dung agar (another lean medium, e.g., VY/2 agar with a reduced yeast content or CY agar with a lowered peptone concentration, would also do). The cultures are incubated at a suitable temperature, e.g., 34°C. After 4–5 days, myxobacterial swarms and fruiting bodies may be observed (Gräf, 1975).

Rabbit Dung Agar

Boil 20 g of dry rabbit dung (wild rabbits) in 1 liter of distilled water for 20 min. Make up the filtrate to 1 liter again, and add 1.5% agar. Adjust the pH to 7.2, and autoclave the medium.

In summary, the various direct isolation techniques all have certain limitations, and each may be more or less appropriate for the isolation of a specific organism. For the cellulose degraders there is little choice. However, with some experience, they may also occasionally be found on dung pellets. Conversely, the cellulose plates are also useful for the isolation of *Chondromyces*, *Stigmatella*, *Polyangium* and *Nannocystis*. While *Myxococcus* is most easily obtained on dung pellets; *Cb. fuscus*, *Sg. erecta*, *Archangium*, *Corallococcus*, *Chondromyces* and *Melittangium* are also often found with this technique. The most generally effective technique is the use of bacterial smears; under these conditions, myxobacteria with small and inconspicuous fruiting bodies as well as strains that do not form fruiting bodies at all under the culture conditions are reliably isolated. Bark and rotting wood incubated in a moist chamber are in some cases excellent sources for fast and reliable isolation of *Stigmatella aurantiaca* and *Chondromyces* species.

Purification Methods

In the simplest case, pure cultures of myxobacteria can be obtained in one step from fruiting bodies, which usually contain an uncontaminated population of myxospores, at least as long as they are young. By carefully transferring material from fruiting bodies to a suitable agar medium, such as CY or VY/2 agar (see below), pure swarms can be obtained. An excellent tool for such delicate work is a glass rod drawn out into a fine tip. More convenient for a swift operation is the sharp point of a disposable, 1-ml, injection syringe. Direct isolation from fruiting bodies is possible with *Myxococcus* species because they produce soft-slimy fruiting bodies, and enough myxospores to start a culture can be obtained just by touching the fruiting body at the top. The fruiting bodies of *Chondromyces* and *Stigmatella* consist of sporangioles that are borne on a relatively long stalk that lifts them above the heavily contaminated substrate surface. The sporangioles can be plucked off and used as an inoculum. With all other myxobacteria, the chance of a selective transfer from fruiting bodies is low because they are too intimately interwoven with the substrate and the slime layer of the swarm.

VY/2 Agar

Bakers' yeast (commercial yeast cake)	0.5% (w/v)
$CaCl_2 \cdot 2H_2O$	0.1% (w/v)
Cyanocobalamin	0.5 mg/µl
Agar	1.5% (w/v)

Adjust pH to 7.2. Autoclave the medium. The yeast may be stored as an autoclaved stock suspension for several weeks. To obtain a uniform suspension of the yeast cells in the agar medium, add the yeast to the molten medium.

CY Agar

Casitone (Difco)	0.3% (w/v)
Yeast extract (Difco)	0.1% (w/v)
$CaCl_2 \cdot 2H_2O$	0.1% (w/v)
Agar	1.5% (w/v)

Adjust the pH to 7.2. Autoclave the medium.

ENRICHMENT TECHNIQUES. If direct isolation is not possible, enrichment techniques must be applied. Fruiting bodies or vegetative cells are transferred to streaks of a food organism on WCX agar. Three parallel streaks can be made on one plate, and each streak can be inoculated at both ends. As the swarm is often firmly attached to the substrate or forms a very tough slime sheet, from which tiny bits cannot easily be removed, or because the myxobacteria migrate within the agar, the inoculum often with a small piece of agar must be cut out using the tools mentioned above. An inoculation loop would be much too coarse and would risk carrying over too many contaminants. The bacterial smears are best inoculated at their edge so that the developing swarm also has a chance to spread over the free agar surface, which sometimes gives a better separation from the contaminants. New transfers can be made from the purest-looking sections of the developing swarms, preferentially from the swarm edge, until swarms are obtained that seem pure enough to justify a transfer to VY/2 or CY agar. A transfer to smears of autoclaved *E. coli* on WCX agar may be necessary as an intermediary step, particularly if the myxobacterium grows only within the streaks of the living *E. coli*. Much time can be saved later if the cultures are initially transferred within short intervals (1–2 days) before the contaminants have multiplied and spread. While it is advisable to make several transfers from the crude culture—by inoculating all three streaks of the enrichment plate, if possible from different sites—to enrich for the organism and to have a choice of contaminants to deal with, transfers can also be made one at a time, so that the three streaks of a plate can be used consecutively.

Sometimes transferred fruiting bodies do not germinate. This may happen, for example, if fruiting bodies found on a dung pellet have erroneously been identified as a bacteriolytic species (which is indeed the case with almost all dung organisms) and therefore were transferred to a bacterial smear, while in reality the fruiting bodies had been produced by a cellulose degrader. The latter will readily develop if inoculated to filter paper on ST21 agar (see the section Isolation of Cellulose Decomposers in this Chapter). However, some bacteriolytic myxobacteria do not always germinate on bacterial streaks, e.g., *Cb. fuscus*. With these strains, transfer of fruiting bodies directly to VY/2 agar sometimes helps. After germination, the swarms should be inoculated as soon as possible on bacterial streaks, because many contaminants can grow vigorously on VY/2 agar. If a sufficient quantity of fruiting bodies can be obtained from the crude culture, some of them should first be heated in water (see the section Purification by Heating in this Chapter) before they are inoculated to the growth medium. Note at least one myxobacterium (*Haploangium*) will not germinate on any known medium and has not been cultivated so far.

If the myxobacteria are left growing on the streaks for a longer time, they usually will produce fruiting bodies. Fruiting bodies can be very useful as starting material for further, more sophisticated purification steps. Also, fruiting bodies are important for the identification of the isolated strains.

The main contaminants in the enrichment cultures are other bacteria. Occasionally, other gliding organisms, more often small Gram-negative rods, become trapped in the slime of the swarm and are carried around by the moving myxobac-

teria. These two types of contaminants are often difficult to eliminate. Nematodes, fungi, and especially soil amoebae may also become a serious problem.

The first step in purification is to eliminate all animals from the culture because they move very actively and thus quickly spread bacterial contaminants over the plate. The transfer of nematodes can usually be avoided if some caution is observed, because they are large enough to be easily recognized and eliminated. Occasionally, however, a culture is heavily infested with nematodes, or the worms cannot be seen because an opaque substrate is used, e.g., cellulose plates. In these cases, the plate can be frozen by simply storing it in an –80°C deep-freeze for one or two days, which seems to kill all nematodes. After thawing the plate, it is important to make a transfer to a fresh plate immediately after the surface of the plate has softened sufficiently, because the thawed agar will be very runny and soft (Reichenbach, 1983). Exposing the plate to ammonia vapors (M. Aschner, personal communication) can also kill the amoebae, which sometimes multiply extremely fast. We use a 5% ammonia solution in a Petri dish and place the culture plate upside down over the ammonia dish for 1–2 min. The plate is then left with a closed lid for another 2–5 min, and then the myxobacteria are transferred to a fresh plate because the old one is now strongly alkaline. The myxobacteria usually survive the treatment very well, even when no fruiting bodies are present. A further transfer should be made as soon as possible from the fresh culture because a few amoebae, probably encysted stages, sometimes survive. Soil amoebae do not seem to be inhibited by cycloheximide, nystatin, or freezing.

Occasionally, cycloheximide-resistant fungi are present, but dusting the inoculum with nystatin powder can almost always inhibit them. The myxobacteria grow between the nystatin particles and can then be transferred to another plate.

The remaining contaminants are bacteria. By transferring pieces from the fast-spreading swarm edge, most of the larger and less motile organisms are quickly eliminated, in particular *Bacillus* species and their spores, but the slime matrix of the swarm may still shelter many small, mainly Gram-negative bacteria. Apart from the slime, the relatively slow growth of myxobacteria compared with that of typical contaminants is a major factor that makes purification time-consuming and difficult. Usually it takes 3–6 weeks before an isolated strain is pure; only rarely can it be accomplished in 1–2 days (by direct transfer of fruiting bodies). Fortunately, those isolations that may take 1–2 years (e.g., of a cellulose degrader) are equally rare.

Often spreading growth under selective nutritional conditions is not sufficient to shake off contaminants, or the procedure becomes too time-consuming. In such cases, a number of more specific purification steps may be tried.

PURIFICATION BY PLATING. Plating of diluted cell suspensions, the technique of choice for the isolation of most soil bacteria, is only partly useful with myxobacteria. The first difficulty is that the slime makes it difficult to suspend the cells homogeneously in water. We have sometimes had success using a small (1 ml) sterilized tissue homogenizer to overcome this problem. If fruiting bodies are available, treatment with ultrasound for 1–2 min may result in a suspension of myxospores. (The use of ultrasound to kill contaminants selectively, as suggested by Sutherland [1976b], has not appeared very promising in our hands.) Cell suspensions can also be produced in a mixer with or without glass beads (McCurdy, 1963). The cell suspensions can be diluted without problems in sterile distilled water, although a special dilution medium (DM) has also been used.

Dilution Medium (DM; McCurdy, 1963)

Soluble starch	0.5% (w/v)
$MgSO_4 \cdot 7H_2O$	0.05% (w/v)
K_2HPO_4	0.025% (w/v)

The second difficulty is that quite a few myxobacteria, particularly members of the suborder Sorangineae, do not readily produce swarms from single cells. Often a long and tedious optimization and adaptation procedure is required before single-cell colonies are obtained, even from pure strains. Nevertheless, with many myxobacteria, a reasonably high proportion of the cell population will grow to form colonies, so that plating may be successful. However, in our experience, plating has a chance only if the myxobacterium is already nearly pure, which may be due to their relatively low plating efficiency and relatively slow growth rate. CY agar is often an appropriate medium for plating; sometimes the yield is improved if the peptone concentration is increased to 0.8–1.2% or if 0.5% glucose is added. ECM agar and SP agar have also been recommended. While VY/2 agar is a good growth medium, its turbidity reduces its utility and, in addition, myxospores sometimes do not germinate on this medium.

ECM Agar (McCurdy, 1963)

> Suspend washed cells of *E. coli* (100 mg of dry mass per 100 ml) in a medium containing: $MgSO_4 \cdot 7H_2O$, 0.05% (w/v); NaCl, 0.6% (w/v); and agar, 1.5% (w/v). Adjust the pH to 7.2 and autoclave the medium. On this medium, myxobacterial colonies are surrounded by lysis zones.

SP Agar (McDonald and Peterson, 1962; McCurdy, 1963)

Raffinose	0.1% (w/v)
Sucrose	0.1% (w/v)
Galactose	0.1% (w/v)
Soluble starch	0.5% (w/v)
Casitone (Difco)	0.25% (w/v)
$MgSO_4 \cdot 7H_2O$	0.05% (w/v)
K_2HPO_4	0.025% (w/v)
Agar	1.5% (w/v)
Vitamin solution	2.5 ml/liter

Vitamin Solution (McDonald and Peterson, 1962)

Thiamine	100 mg
Riboflavin	75 mg
Pyridoxine	75 mg
Ca pantothenate	200 mg
p-Aminobenzoic acid	5 mg
Nicotinamide	75 mg
Choline HCl	200 mg
Folic acid	1 mg
Inositol	1000 mg
Biotin	0.05 mg
Cyanocobalamin	0.05 mg

Dissolve these ingredients in 1 liter of 100% ethanol. Add 2.5 ml per liter of medium.

Whether the diluted cell suspensions are spread on the agar surface or included in pour plates does not seem to make much difference. In the latter case, the agar content of the medium should be reduced to about 1% and temperatures above 40°C of the molten agar should be avoided. Myxobacterial colonies may be recognized by their swarming behavior, which they also tend to show when embedded in agar. On rich media, swarming may be considerably reduced, and the colonies may become compact and look like those of ordinary bacteria. If they are dense enough, however, they may be brightly colored in shades of yellow, orange, red, or purple.

PURIFICATION BY HEATING. This procedure can be used if fruiting bodies with mature myxospores are present. The fruiting bodies are suspended in 1 ml of sterile water and incubated in a water bath. After 10, 20 and 40 min, samples are transferred to CY or VY/2 agar and carefully spread all over the plate. The useful temperature—too high for the contaminant, but still withstood by the myxobacterium—has to be found by trial and error. We usually work at 58°C, a temperature most myxospores can survive for at least 10 min. This temperature is often sufficient to kill contaminating bacteria, fungi, and amoebae. Only rarely do myxobacteria tolerate higher temperatures, and some do not withstand 58°C, in which case 56°C or less may still lead to success. However, this method should be tried in the later part of the purification process, because then the chances are higher that thermoresistant contaminants, e.g., *Bacillus* spores, will no longer be present. It may take a week or longer at 30°C before swarms can be seen on the plates, as a substantial part of the myxospore population may also have been killed. However, often swarms are visible within 1–2 days.

PURIFICATION WITH ANTIBIOTICS. This procedure may also be useful if mature myxospores are present. Fruiting bodies are suspended in 1 ml of a rich growth medium, e.g., EBS medium (see below). To this is added 0.1 ml of a concentrated mixture of potent antibiotics, and the suspension is shaken overnight at 30°C (Reichenbach, 1983). The myxospores do not germinate in the rich medium, but the contaminants will grow and be killed. If a contaminant is resistant to the inhibitors, the culture will be turbid the next morning, and the procedure must be repeated with a different mixture of antibiotics. (Occasionally the liquid becomes turbid owing to suspended dead cells. In this case, the culture fluid can be replaced by fresh medium and the culture incubated a few hours more.) We use three increasingly aggressive combinations of antibiotics, AB-1, -2, and -3 solutions (see below), which we apply consecutively when necessary. If the supernatant is still clear on the next morning, it is replaced by sterile distilled water, and the fruiting bodies are washed by shaking for an additional 4–6 h. They are then transferred to VY/2 or CY agar or to streaks of autoclaved *E. coli* on WCX agar. Usually swarms develop after 1–5 days. Sometimes an individual swarm is still contaminated, although no foreign colonies can be seen on the plate. Therefore, several swarms should always be isolated and tested separately for purity. Again, the procedure is less effective during the early stages of purification, before the majority of the contaminants have been removed. Note that the vegetative growth of myxobacteria is, in general, as sensitive to inhibition by antibiotics as is the growth of other Gram-negative bacteria. However, the metabolically quiescent myxospores within the fruiting bodies are resistant as long as their germination is prevented.

EBS Medium

Peptone from casein (Merck, Darmstadt, Germany) 0.5% (w/v)	
Proteose peptone (Difco)	0.5% (w/v)
Peptone from meat (Merck)	0.1% (w/v)
Yeast extract (Difco)	0.1% (w/v)

The peptone from casein is a tryptic digest. Adjust the pH to 7.0 and autoclave the medium.

AB-1 Solution

Chloramphenicol	20 mg
Streptomycin sulfate	30 mg
Tetracycline HCl	25 mg
Na cephalotin	20 mg

Dissolve the above ingredients in 50 ml of distilled water and filter sterilize. The solution remains stable for several weeks at 4°C.

AB-2 Solution

Chloramphenicol	20 mg
Streptomycin sulfate	30 mg
Tetracycline HCl	25 mg
Kanamycin sulfate	35 mg
Erythromycin	25 mg
Polymyxin B sulfate	20 mg

Dissolve the above in 50 ml of distilled water and filter sterilize. The solution remains stable for several weeks at 4°C. Use only as a last resort since it is often inhibitory to myxobacteria.

AB-3 Solution

Chloramphenicol	20 mg
Tetracycline HCl	30 mg
Neomycin sulfate	20 mg
Gentamycin sulfate	30 mg
Collistin methane sulfonate	30 mg

Dissove the above in 50 ml of distilled water and filter sterilize. The solution remains stable for several weeks at 4°C. This mixture is specifically designed to eliminate pseudomonads. It usually serves that purpose but is less well tolerated by the myxobacteria than is AB-1 solution.

The inclusion of inhibitors, e.g., neomycin and sulfanilamide, directly in the isolation medium has been suggested (McDonald, 1967; McCurdy, 1969b). However, while some myxobacteria can be isolated in this way, we do not recommend this approach. (Cycloheximide is of course an exception, as it does not inhibit prokaryotes.) It is remarkable how many soil bacteria can grow in the presence of high doses of powerful antibiotics, and there is always the danger of a counterselection of some myxobacteria. Addition of antibiotics to purification media is a different story, however, as some groups of myxobacteria are naturally resistant to certain potent antibiotics (see later).

PURIFICATION OF CELLULOSE DECOMPOSERS. The purification of *Sorangium* strains is especially tedious and time-consuming because the organisms only grow slowly on the selective substrate, giving the contaminants ample time to multiply. Furthermore, within the water-soaked filter pad, many contaminants spread rapidly over the whole area, complicating the problem of separating the myxobacteria from the other organisms.

The first transfer from the crude culture should be made again to filter paper on ST21CX agar (see the section Isolation of Cellulose Decomposers in this Chapter) to retain the selective conditions. For the preparation of subcultures, filter paper is cut into small rectangles, about 1.5 × 3 cm, three or four of which are placed at some distance from each other on the agar surface. The filter pads are inoculated from different parts of the original swarm. In this way, an initial reduction of the contaminants may be achieved. The next step is to remove nematodes and amoebae using the techniques recommended above. To eliminate bacterial contaminants, transfers can be made to streaks of autoclaved *E. coli* on WCX agar to which 250 mg of kanamycin sulfate has been added per liter medium (after autoclaving, from a filter-sterilized stock solution: KAN4 agar). All *Sorangium* strains tested so far are completely resistant to kanamycin as well as to neomycin and gentamycin (H. Reichenbach, unpublished observations). Most sorangia grow reasonably well on autoclaved (but not on living) *E. coli*, often forming large, delicate swarms (another advantage of this purification step). Pieces from the swarm edge that appear to be uncontaminated can be transferred to VY/2 agar. The pure strain is reinoculated to filter paper to make sure that the desired organism has been isolated. We have never observed a *Sorangium* strain that lost its ability to degrade cellulose during isolation. Addition of kanamycin initially to the crude culture would prevent the appearance of many other myxobacteria and, at the outset, select for kanamycin-resistant contaminants.

If the method just described fails, heating of the fruiting bodies or treatment with the antibiotic solution may lead to success. If the *Sorangium* isolate is already relatively pure, it may also be transferred to chitin agar (CT7 agar; see below) or to cellulose overlay agar (CEL3 agar, see below). Most but not all sorangia also decompose chitin and grow relatively quickly, producing large swarms on chitin agar with chitin as the only carbon, nitrogen, and energy source. Large swarms also arise on cellulose overlay agar, but development is delayed so that the contaminants have a better chance to predominate. On both media, the sorangia penetrate the agar, so that sometimes a pure inoculum can still be obtained from the deeper layers of the plate even though the surface is contaminated.

CEL3 Agar

Cellulose powder	0.5% (w/v)
KNO_3	0.1% (w/v)
Agar	1.0% (w/v)

Cellulose powder MN 300 from Macherey and Nagel (Düren, Germany) works well. Adjust the pH to 7.2. Autoclave the medium. Autoclave the KNO_3 separately and add when the medium has cooled. Pour as a thin layer on top of ST21 agar plates.

Another strategy often helpful in the purification of sorangia is incubation at 38°C, e.g., on KAN4 agar + autoclaved *E. coli*. Most but not all strains are able to grow at this temperature, sometimes vigorously so, while growth of the contaminants is often prevented.

TESTING FOR PURITY. The final task in pure culture isolation is to check for purity of the culture. Some swarm material may be streaked

on nutrient agar, on which myxobacteria, in contrast to most contaminants, grow only slowly or not at all. Other media useful for purity control are CY and MYX agar. Although most myxobacteria grow on those media, they are usually easily distinguished from nonmyxobacterial colonies.

MYX Agar

Glutamate Na	0.5% (w/v)
Yeast extract (Difco)	0.1% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)
Glucose	0.2% (w/v)
Agar	1.5% (w/v)

Autoclave glucose separately. Adjust the pH to 7.2. Autoclave the medium. Finally, add the autoclaved glucose to the autoclaved medium.

In addition, some material may be inoculated into a liquid medium, e.g., nutrient broth or CAS medium, and incubated with shaking for one day at 30°C. Under such conditions, myxobacteria usually grow in clumps, flakes, or as a ring around the glass wall, if at all. Dispersed growth at that stage is almost always an indication of contamination.

Myxobacteria can often be differentiated easily from other bacteria by their size, cell shape, and their inability to swim actively. Thus microscopic examination will also often quickly reveal contaminants, although this is not always reliable and requires some experience.

Counting Myxobacteria in Soil

The quantitative determination of myxobacteria in soil is not likely to give accurate results because, in the swarm and in the fruiting bodies, the cells are always linked together by slime, and in the fruiting bodies, cells are often surrounded by the tough walls of the sporangioles. Still, estimates are possible and have been obtained in the following way: Small circular smears (about 2 cm in diameter) of a food organism are placed on a water agar or a silica gel plate, and each circle is inoculated with a small quantity of soil which has been carefully homogenized and weighed (Singh, 1947). Alternatively, the weighed and homogenized soil is made into a paste with sterile water, and small drops are applied to the ends and centers of cross-streaks of a food organism on water agar or, for counting cellulose decomposers, to filter paper disks on mineral agar (Brockman, 1976). After incubation, the number of myxobacteria is calculated from the number of swarms and fields of fruiting bodies that have developed. Another approach is to add soil dilutions to antibiotic cell extract (ACE) agar (McCurdy, 1969b). This method has severe limitations because the medium allows a rapid development of contaminants, and only *Myxococcus* and *Corallococcus* cells can be counted. Nevertheless, the numbers that have been obtained are sometimes quite impressive.

ACE Agar (Antibiotic Cell Extract Agar; McCurdy, 1969b)

SP medium	
Yeast extract	0.1% (w/v)
Yeast (or *E. coli*) cells	0.5% (dry w/v)
Neomycin	10 mg/ml
Sulfanilamide	10 mg/ml
Cycloheximide	100 mg/ml

Add the remaining ingredients to the SP medium (see the section Purification by Plating in this Chapter).

The myxobacteria are detected by their swarm morphology and surrounding lysis zones.

Cultivation

Contrary to a belief that still seems widely held, myxobacteria are not particularly fastidious organisms. With the exception of *Haploangium*, all species have been cultivated, and almost all can be grown in axenic, pure culture. Of course, as with all other organisms, myxobacteria have their peculiarities, but no unusual requirements, and not even particularly complex ones, have been discovered to date. Exotic substrates such as the rabbit dung media that were so popular for a long time are not necessary. Although they were not always easy to develop, fully defined, synthetic media have been developed for some myxobacteria. In connection with possible commercial antibiotic production, quite a few myxobacteria have been cultivated in large-scale fermentors (5– 50 m^3 and greater), often on technical media, such as corn steep powder and soy meal.

Plate Cultures

Myxobacterial cultures are often incubated for extended periods (1–4 weeks) when dehydration may occur, so that plates must be poured thicker than for the usual bacterial work. Also, a high humidity in the incubator is helpful.

All myxobacteria, including the cellulose degraders, seem to grow well on yeast agar (VY/2 agar). The yeast cells are usually decomposed, but not always completely and sometimes not at all. Vitamin B_{12} is occasionally required (e.g., by many *Polyangium* strains) so cyanocobalamin is included in this standard medium. Typically, on VY/2 agar, gliding motility is considerably stimulated, and the swarm colonies tend to become very large. Fruiting bodies are often formed even after several transfers on VY/2 agar, although sooner or later most strains cease fruiting on this medium as well as on most other growth media. Cultures on VY/2 agar are usually

rather stable, and most strains need not be transferred more often than every 2–3 weeks (30°C). The reason is probably that VY/2 agar is relatively lean, nutrients are only gradually solubilized, and the pH does not change very much. The medium therefore is also well suited for stock cultures.

Another useful medium is CY agar (see the section Purification Methods in this Chapter). On this medium, growth often is more vigorous, but the swarms spread less and may become somewhat slimy and often the cells die earlier (after 1–2 weeks) because of copious ammonia production. The choice of the peptone for media of this type is critical. In general, the most suitable products appear to be pancreatic and tryptic digests of casein, e.g., Casitone (Difco), tryptone (Difco), or peptic digests (Marcor, Merck). But other peptones such as soybean peptones can also be used. Meat peptones, on the other hand, are usually not useful, perhaps because their phosphate content is too high. In any case, the suitability of a peptone for cultivation of the myxobacterial strain must first be tested. How critical the quality of the peptone can be is seen from the fact that even the specific batch of a particular peptone brand may make a difference. Thus, for example, not every batch of Difco Casitone supported successful induction of myxospore formation with *Stigmatella aurantiaca* (Gerth and Reichenbach, 1978); similar observations have also been made with glycerol induction of myxospores of *Mx. xanthus*. Replacement of peptone by a total protein hydrolysate, e.g., casamino acids (Difco), is often not possible. But casamino acids are a perfect N source for *Cystobacter* and *Sorangium* strains.

Watson and Dworkin (1968) showed that *Mx. xanthus* lacked hexokinase and was unable to take up, metabolize, or grow on sugars. This, however, cannot be generalized for the myxobacteria, despite earlier impressions that this might be the case. Many myxobacteria are known that efficiently metabolize sugars, e.g., *Stigmatella* and *Cystobacter*. In fact, it seems that only the *Myxococcus* species, *Nannocystis*, and perhaps some *Corallococcus* strains are unable to use carbohydrates. In some cases, e.g., certain *Corallococcus* strains, polysaccharides such as starch can be utilized, although no mono- and disaccharides can be used. Apparently the starch is degraded to the trisaccharide, which can be metabolized (Irschik and Reichenbach, 1985a). Thus, it may sometimes be useful to supplement a peptone medium with starch or glucose. Another beneficial effect of this may be that the pH rises more slowly, so that the culture can be maintained for a longer time. We have found the following formulations useful for plate cultivation:

CYG2 Agar

Casitone (Difco)	0.3% (w/v)
Yeast extract (Difco)	0.1% (w/v)
$CaCl_2 \cdot 2H_2O$	0.1% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)
Agar	1.5% (w/v)

Adjust the pH to 7.2. Autoclave, then add 0.3% (w/v) glucose from an autoclaved stock solution.

STK2 Agar

Base agar:

Casitone (Difco)	0.1% (w/v)
Yeast extract (Difco)	0.05% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)
Agar	1.2% (w/v)

Adjust the pH to 7.2. Autoclave the medium and pour into Petri dishes. After the agar has solidified, add the following top agar.

Top Agar

Use the same base agar ingredients, but increase the agar concentration to 1.5% (w/v), and prepare the medium in about 85% of the final total water volume. In the remaining water, dissolve (as a percentage of the total volume of the top agar) soluble starch (0.2% [w/v]; see below) and K_2HPO_4 (0.02% [w/v]). Heat the starch solution in a water bath with stirring and then autoclave to prevent clumping of the starch. Combine the two solutions (the base agar solution and the starch/K_2HPO_4 solution) after autoclaving.

In the form just described, STK2 agar can be used for checking starch degradation. If it is only to be used for cultivation, just the top agar (but with 1.2% agar) is required.

The cellulose decomposers utilize NO_3^- or NH_4^+ as the only nitrogen (N) source and can be cultivated on simple synthetic media like CK6 and CA2 agar (see below). They respond favorably to the addition of an organic N source, such as peptone (0.1–0.2%), but usually they will not grow in the absence of a suitable carbohydrate, like glucose or starch. *Sorangium* strains thus can also be grown on VY/2, CEL3, and STK2 agar, and many strains will grow as well on CT7 agar, but for the reasons just mentioned, relatively few will grow on CY agar.

CK6 Agar (Modified from Couke and Voets, 1967)

Solution A:

$MgSO_4 \cdot 7H_2O$	0.15% (w/v)
Fe^{+3} citrate	0.002% (w/v)
Agar	1.5% (w/v)

Prepare this solution in 80% of the final water volume.

Solution B:

KNO_3	0.2% (w/v)
K_2HPO_4	0.025% (w/v)

Prepare this solution in 10% of the final water volume.

Solution C:

Glucose	0.5% (w/v)
$CaCl_2 \cdot 2H_2O$	0.15% (w/v)

Prepare this solution in 10% of the final water volume. After autoclaving, combine the three solutions.

CA2 Agar (Mullings and Parish, 1984)

Base agar:
Agar 1.5% (w/v)

Stock solution A:

KNO_3 7.5 g
K_2HPO_4 7.5 g

Dissolve these ingredients to give 100 ml.

Stock solution B:

$MgSO_4 \cdot 7H_2O$ 1.5 g

Dissolve to give 100 ml.

Stock solution C:

$CaCl_2 \cdot 2H_2O$ 0.27 g
$FeCl_2$ 0.15 g

Dissolve these to give 100 ml. Autoclave. Supplement the base agar with 1% (v/v) of each of the three stock solutions, 1% (w/v) of glucose (from an autoclaved 20% stock solution) and trace elements.

Since myxobacterial swarms tend to spread quickly, cultures are more conveniently kept in Petri dishes than on agar slants in tubes. In the latter, the swarm edge soon reaches the glass surface and the cells dry out and die; also transfer of sticky, tenacious swarms is easier from plates. The plates are inoculated best at one spot at the side to give the swarm as much space as possible. In large swarms, living cells are often found only in a rather narrow band along the edge. Therefore, the inoculum should always be taken from the edge, at least as long as there are no fruiting bodies in the interior zone. Many myxobacteria of the suborder Sorangineae tend to penetrate deeply into the agar, in which case an agar strip has to be cut out and used as an inoculum.

Viable Counting

Accurate viable counts are possible only with strains that grow in a dispersed fashion in liquid media. Plating efficiency has to be tested for every strain. Given below are some media that allow plating efficiencies close to 100%: CT and CTT agar for *Mx. xanthus* FB; PT agar for *Mx. fulvus* Mx f2; and SG agar for *Sg. aurantiaca* Sg a1. CF (clone-fruiting) agar supports the formation of colonies from single cells of *Mx. xanthus*, with the subsequent production of fruiting bodies (Hagen et al., 1978). If a plating medium is not satisfactory for a specific strain, usually a modification of the peptone and ion concentrations or the addition of some yeast extract will make it suitable.

CT Agar (Dworkin, 1962)

Casitone (Difco) 2% (w/v)
$MgSO_4 \cdot 7H_2O$ 8 mM
Potassium phosphate buffer, pH 7.2 0.01 M
Agar 2% (w/v)

Autoclave $MgSO_4 \cdot 7H_2O$ separately.

A variation of the pH sometimes improves the results; a pH of 7.6 is closer to the optimum than is 7.2 (H. Reichenbach, unpublished observations).

CTT Agar (Bretscher and Kaiser, 1978)

Casitone (Difco) 1% (w/v)
$MgSO_4 \cdot 7H_2O$ 8 mM
Potassium phosphate buffer, pH 7.6 1 mM
Tris buffer, pH 7.6 10 mM
Agar 1.5% (w/v)

For semisolid media, agar is at 0.6% (w/v). Autoclave the medium.

PT Agar (for *Mx. fulvus* Mx f2)

Casitone (Difco) 0.4% (w/v)
Yeast extract (Difco) 0.4% (w/v)
$MgSO_4 \cdot 7H_2O$ 0.2% (w/v)
$CaCl_2 \cdot 2H_2O$ 0.1% (w/v)
Agar 1.5% (w/v)

Adjust the pH to 7.2. Autoclave the medium.

SG Agar (Gerth, 1975)

Casitone (Difco) 1.5% (w/v)
$MgSO_4 \cdot 7H_2O$ 0.1% (w/v)
$CaCl_2 \cdot 2H_2O$ 0.2% (w/v)
Agar 1.5% (w/v)

Adjust the pH to 7.0. Autoclave the medium.

CF Agar (Hagen et al., 1978)

Casitone (Difco) 0.015% (w/v)
Na pyruvate 0.1% (w/v)
Na citrate 0.2% (w/v)
$(NH_4)_2SO_4$ 0.02% (w/v)
$MgSO_4 \cdot 7H_2O$ 8 mM
Potassium phosphate buffer, pH 7.6 1 mM
Tris buffer, pH 7.6 10 mM
Agar 1.5% (w/v)

Autoclave the medium.

Excellent viable counts, e.g., for survival curves after treatment with mutagens, have been obtained by us with *Mx. fulvus* Mx f2 and *Sg. aurantiaca* Sg a1 by adapting a miniaturized counting technique recommended by Sharpe and Kilsby (1971). One of the plating media mentioned above is prepared with a reduced agar concentration of 0.6% (w/v). The bacteria are diluted directly in this soft agar at 40°C, and 0.1-ml drops of appropriate dilutions are put into Petri dishes, covered with a drop of sterile agar of the same composition, and incubated at 30°C. Note that vegetative cells of *Mx. xanthus*, and perhaps other myxobacteria as well, are sensitive to temperatures higher than 43°C. Microcolonies are counted under a dissecting microscope. Up

to 150 colonies per drop can easily be counted (H. Reichenbach and M. Dworkin, unpublished observations). The method has several advantages. Without difficulty, 40 drops can be placed into one Petri dish, using the bottom and the lid. Besides enormous economy in materials and incubator space, results are obtained earlier (after 3–4 days instead of 5–8 days) and with superior accuracy (more replicates, e.g., 5 instead of 3); less divergence between replicates; and a better chance to hit the optimum dilution step, because a wide interval of dilution steps can conveniently be plated. Plating efficiency can be 100%. The peripheral drops often show a reduced colony count, probably because they dry more easily. Therefore a ring of sterile agar drops should be placed around the edge of the plate.

Production of Fruiting Bodies in Culture

Usually, fruiting bodies are not produced on media that allow good growth. High nutrient concentrations seem to repress the fruiting process. As already mentioned, on VY/2 agar, fruiting bodies are often produced during several transfers, but a vegetatively propagated strain normally stops fruiting soon after isolation and often cannot be made to fruit again. The reason for this is not really understood; perhaps there is a selection for nonfruiting variants. In several cases, induction conditions for fruiting have been found for certain individual strains. Such strains reliably form fruiting bodies even after many transfers of purely vegetative growth, but other strains of the same species usually do not respond to the same conditions. With freshly isolated strains, fruiting can often be induced by transferring swarm material from a lean growth medium, like VY/2 agar, to plain water agar (WAT agar) or to sterile filter paper pads on water agar. Also, fruiting may continue for some time on streaks of living *E. coli* cells on water agar. The nutrients carried over from the growth medium and the low nutrient level provided by the lysing *E. coli* cells, respectively, allow reasonable growth for some time, leading to sufficiently high cell densities; the subsequent more-or-less abrupt depletion of nutrients then somehow triggers development. The need for a high population density for fruiting has been established for several myxobacteria, e.g., *Mx. xanthus* (Wireman and Dworkin, 1975) and *Cm. apiculatus* (H. Reichenbach, unpublished observations).

Using some simple tricks, myxobacterial strains can sometimes be maintained in the fruiting state for a long period. We were able to do so with *Sg. aurantiaca* over a period of years by storing the strain in the form of fruiting bodies on WAT agar at room temperature (20°C). After 2–3 months, when the culture began to dry out, the fruiting bodies were inoculated to VY/2 agar and incubated at 30°C. The resulting swarms were immediately reinoculated to WAT agar, incubated for a few days at 30°C, during which time the organism began to fruit again, and then stored at room temperature as before. One or two more transfers to VY/2 agar were possible, but after that the strain failed to produce fruiting bodies. This procedure of cycling the culture between rich media that support growth and lean media that induce fruiting body formation will probably work with many different myxobacteria.

With several *Chondromyces* species (*Cm. apiculatus*, *Cm. crocatus*, *Cm. pediculatus* and *Cm. lanuginosus*), we have obtained fruiting bodies when the organism was kept in a mixed culture with cellulose degrading bacteria (not myxobacteria) on filter pads placed on ST21 agar plates. The cultures are incubated in the light (on the bench top in the laboratory) at room temperature (20–24°C). Transfers are made every 3–4 weeks by inoculating macerated cellulose and *Chondromyces* fruiting bodies together onto fresh filter pads on ST21 agar. Within 4–5 days, new fruiting bodies appear. Using this procedure, several of our strains have continued to produce dense populations of fruiting bodies over a period of years (H. Reichenbach, unpublished observations). The method can also be used with pure cultures of *Chondromyces*. The swarm material is simply inoculated into a developing culture of a cellulose degrader. While *Polyangium* strains often form fruiting bodies with this procedure, myxobacteria of the suborder Cystobacterineae rarely do so. In general, a slightly reduced temperature (24–28°C) seems to favor fruiting. Also, in two cases, a requirement of light for fruiting body differentiation has been demonstrated—with *Cm. apiculatus* (Reichenbach, 1974a, b) and with *Sg. aurantiaca* (Qualls et al., 1978).

Chamber Cultures

For the study of the social behavior of myxobacteria and of morphogenetic events, chamber cultures that can be observed and followed under the microscope are extremely useful. Figure 4 illustrates one procedure for making such cultures.

Liquid Cultures

If a freshly isolated myxobacterial strain is cultured for the first time in a liquid medium in a shake flask, the bacteria almost always grow in the form of flakes and nodules and as a film along the glass wall. In static cultures, they grow as a sheet on the glass in the upper parts of the vessel

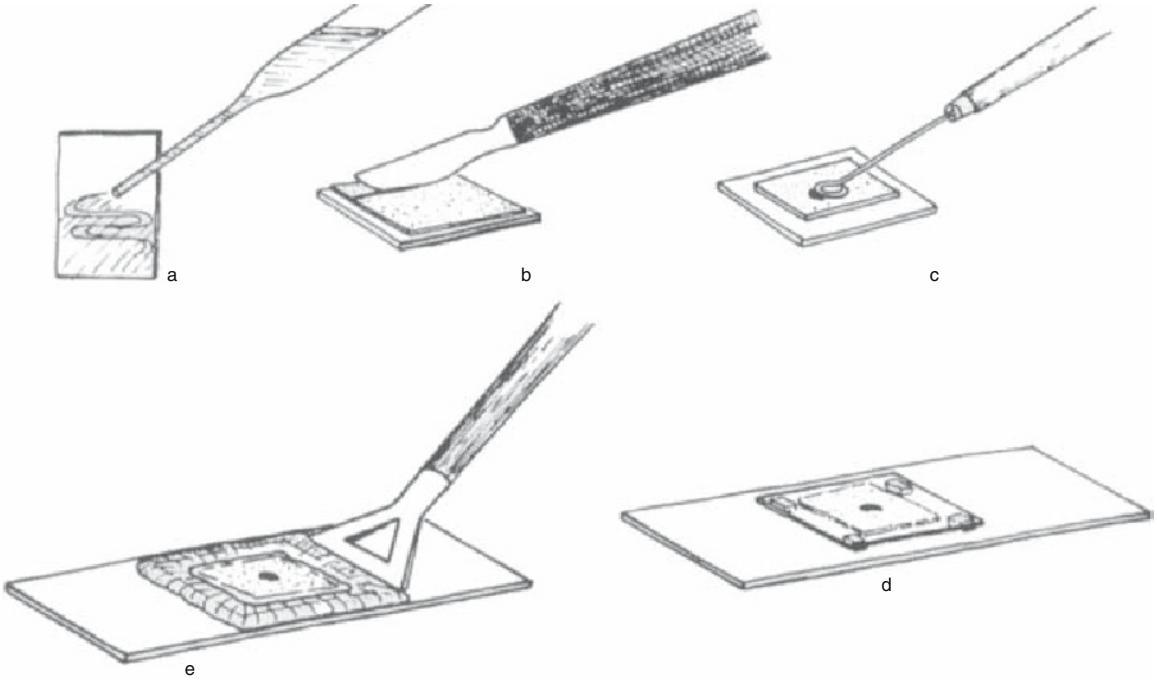

Fig. 4. Method for making a chamber culture: a) Coat a sterile cover slip (e.g., 40 × 22 mm) with a thin agar layer. The molten agar is applied with a Pasteur pipette; the hotter the agar, the thinner the resulting layer. b) Using a sterile scalpel, remove the agar layer along the edges of the cover glass. c) Inoculate the agar film. d) Mount the cover slip with the agar layer downward on a sterile slide; tiny pieces of glass from a broken microscopic slide are used as supports. e) Seal the chamber carefully with a molten mixture of paraffin and Vaseline (2 : 1) and incubate at a suitable temperature. From Heunert (1973).

and as a pellicle along the surface of the liquid. However, if repeated transfers are made from shake cultures, preferentially using the supernatant as an inoculum, strains that grow in a dispersed fashion may be obtained. While with many strains only a few such transfers are required, other strains may resist dispersed growth completely. Thus, for example, while most strains of *Myxococcus* can eventually be grown in dispersed culture, we once transferred a strain of *Mx. fulvus* for months in a variety of liquid media without ever observing the slightest inclination to dispersed growth (H. Reichenbach, unpublished observations). Cells of most members of the suborder Sorangineae show a strong tendency to stick together, and in spite of many attempts, we have never been able to get *Chondromyces*, *Polyangium* and *Nannocystis* to grow homogeneously in liquid cultures. The best that could be achieved was growth as tiny flakes with *Nannocystis* and *Polyangium*. With *Sorangium*, however, we have been able to select many completely dispersed strains. The list of myxobacteria that have been grown in a dispersed fashion is very long by now and, with the exception of the last-mentioned organisms, comprises virtually all taxa. However, even the recalcitrant species, which do not grow in a completely dispersed fashion, can at least be cultivated in suspension in liquid medium.

The main factor that determines whether *Mx. xanthus* cells will grow in clumps is the ability to produce an extracellular matrix composed of fibrils (Arnold and Shimkets, 1988a; Dworkin, 1999). Loss of type IV pili because of a *pilA* mutation, which encodes the major structural pilin subunit, also eliminates clumping (Wu et al., 1997), but this may be due to the fact that pilus mutants are often severely restricted in fibril synthesis. Fibril formation is also required for divalent cation-dependent agglutination (Shimkets, 1986), which is thought to mimic clumping in culture. The Sorangineae, which persistently fail to grow in a dispersed state, produce a slime that is chemically different from that of the Cystobacterineae (as shown by Congo red adsorption to the slime of the latter, but none to the slime of the former; McCurdy, 1969b). Thus, in the case of this group of the myxobacteria, the nature of the excreted slime may play a role in determining their mode of growth.

A homogeneously growing strain may start to clump again if growth conditions are changed, e.g., in a medium of different composition. Thus, cells of *Sg. aurantiaca* Sg a1, a strain that grows in a dispersed fashion, form tiny nodules if $CaCl_2$

is added to the medium. Freshly isolated *Cystobacter fuscus* cultures grow homogeneously when inoculated into a casamino acids medium, but produce nodules and flakes for many transfers in Casitone medium. Cells of *Sorangium cellulosum* strain So ce14 yield a homogeneous suspension when shaken overnight in Casitone medium (in which they cannot grow, however); when reinoculated into AMB growth medium, they produce nodules again. In this connection, although the myxobacteria are the classical "slime bacteria" (*myxo* is a combining form meaning "slime"), they do not produce copious amounts of slime, either on plates or in liquid media, which rarely become recognizably viscous. Only on certain agar media is a larger quantity of slime sometimes seen, e.g., with *So. cellulosum* on CA2 agar.

To facilitate the transition to dispersed growth, the addition of 0.1% agar to the liquid medium has been suggested (Schürmann, 1967). The agar forms tiny flakes that float in the liquid and are colonized by the myxobacteria. However, the selection of truly dispersed strains is not noticeably speeded up by this procedure. Sometimes replacing the usual rotary shaker with a reciprocating shaker is helpful, since the slime sheets are broken up more efficiently on the latter, and the transition to dispersed growth may be faster, although patience is still required (K. Gerth, personal communication).

Liquid media used for cultivation of myxobacteria are of the same general composition as the agar media mentioned above (see the sections Direct Isolation and Purification in this Chapter), but the nutrient requirements stand out more clearly in liquid media, and the organisms respond almost immediately to inadequacies of the medium. The prototype for the bacteriolytic myxobacteria is CT liquid medium, which was designed to provide the most rapid growth (3.5-h doubling time), maximum cell yield ($4–5 \times 10^9$ cells/ml), and uniform cell suspension of *Mx. xanthus* FB (Dworkin, 1962; the medium has the same composition as the CT agar described in the section Viable Counting, only without the agar). However, most other myxobacteria grow better when the peptone concentration is reduced, as in CAS medium and in MD1 medium (see below). The latter medium was originally developed for *Nannocystis*, but it is also often useful for *Archangium*, *Melittangium* and *Cystobacter*. Also, in many cases it is superior for starting liquid cultures with newly isolated strains.

CAS Medium

Casitone (Difco)	1% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)

Do not adjust the pH (which is 6.8) if Difco Casitone is used. Autoclave the medium.

MD1 Medium (Behrens et al., 1976)

Casitone (Difco)	0.3% (w/v)
$CaCl_2 \cdot 2H_2O$	0.07% (w/v)
$MgSO_4 \cdot 7H_2O$	0.2% (w/v)
Cyanocobalamin	0.5 mg/ml
Trace elements	(see the section Isolation of Cellulose Decomposers in this Chapter)

Do not add vitamin solution for most strains. Autoclave the medium.

What has been said about the choice of peptone in agar media holds also for liquid media. For many myxobacteria, the addition of glucose (0.2–0.5%), starch, or another useful sugar to the peptone medium may be favorable. In general, the organisms do not grow faster with the carbohydrate, but they grow for a longer time, and they reach a higher cell density; also, the rise of the pH is delayed, so that the culture becomes more stable.

As already mentioned, some myxobacteria, e.g., *Cystobacter* strains, grow well on casamino acids, e.g., in CAC medium.

CAC Medium

Casamino acids, vitamin-free (Difco)	0.2% (w/v)
Sodium glutamate	0.3% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)
Cyanocobalamin	0.5 mg/ml
Trace elements	

After autoclaving, complement the medium with 0.5% (w/v) glucose and 0.5 mM phosphate buffer (pH 6.5) from autoclaved stocks.

Stigmatella aurantiaca Sg a15 can be cultivated in the following defined medium:

STG Medium (Kunze et al., 1984)

Casamino acids, vitamin-free (Difco)	0.1% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)
$(NH_4)_2SO_4$	0.1% (w/v)
$CaCl_2 \cdot 2H_2O$	0.05% (w/v)
Phosphate buffer, pH 7.0	1 mM
Trace elements	
Vitamins (see earlier)	

Autoclave. Complement the medium with 0.5% (w/v) glucose from an autoclaved stock solution. Alternatively, fructose, maltose, starch, or dextrin 10 could also be used.

The cost of the medium is of considerable importance when large-scale culture is necessary. Many myxobacteria have been cultivated on various technical media, like corn steep powder, maize gluten, soy meal, skim milk, or yeast cells (Gerth et al., 1983; Kunze et al., 1984; Kunze et al., 1985; Kunze et al., 1987). Zein medium is an example of a production medium.

Zein Medium (Kunze et al., 1987)

Zein (maize gluten, Maizena, Hamburg, Germany)	1% (w/v)
Peptone from casein (Merck, Darmstadt, Germany)	0.1% (w/v)
$MgSO_4 \cdot 7H_2O$	0.1% (w/v)

The casein peptone is tryptic digested. Adjust the pH to 7.3. Autoclave the medium.

All myxobacteria of the bacteriolytic type rely totally, or to a large extent, on peptides and amino acids for nitrogen, carbon and energy. As a consequence, relatively large quantities of ammonia are released, which (by regulatory mechanisms and by making the medium alkaline) seriously limits growth and productivity. Thus, in cultures of *Mx. virescens* Mx v48, concentrations of 35–42 mM NH_4^+ and more were measured in the culture supernatant and were 80–140 mM within the cells (Gerth and Reichenbach, 1986). On-line extraction of ammonia from a laboratory fermentor via hydrophobic-membrane hollow fibers maintained the NH_4^+ concentration in the medium between 3 and 7.5 mM with dramatic effects: the generation time was lowered from about 4 to 2 h, the cell density increased by 233%, and the yield of the antibiotic myxovirescin rose from 8 to 115 mg/liter (K. Gerth, personal communication).

For a few strains of bacteriolytic myxobacteria, fully defined, synthetic media have been developed. Examples are given in Table 2. Gen-

Table 2. Composition of five fully defined, synthetic media for bacteriolytic myxobacteria.[a]

[b] From Dworkin (1962).

[c] From Witkin and Rosenberg (1970).

[d] Minimal medium: from Bretscher and Kaiser (1978).

[e] From Mayer (1967). The organism is now called "*Cystobacter violaceus*."

[f] Reichenbach (1984a) and H. Reichenbach (unpublished observations). Some strains also require thiamine and/or biotin when grown in this minimal medium.

eration times increase substantially in such media. Thus, with *Mx. xanthus* FB, the doubling times were 3.5 h in CT medium, 8 h in S medium, and 6.5 h in M1 medium, 6.5 h in M1 medium without lysine, 9.5 h in M1 medium without threonine, and 11.5 h in M1 medium without lysine and threonine (Filer et al., 1973).

The cellulose degraders can be cultivated on very simple media, such as CK1 or CK6 medium (see below). The addition of a small quantity of peptone, e.g., 0.05% (w/v) peptone from a tryptic digest of casein (Merck, Darmstadt, Germany), usually improves growth and keeps the cells in the dispersed state, whereas without peptone they sometimes form cell clusters or tiny clumps (Irschik et al., 1987). Media with peptone as the only N source usually also allow good growth, e.g., AMB medium.

CK1 Medium (Kleinig et al., 1971; modified from Couke and Voets, 1967)

$MgSO_4 \cdot 7H_2O$	0.3% (w/v)
$CaCl_2 \cdot 2H_2O$	0.18% (w/v)
Fe^{+3}-citrate	20 mg/liter
KNO_3	0.2% (w/v)
K_2HPO_4	0.025% (w/v)
Glucose	1% (w/v)

Autoclave nitrate and phosphate together and $CaCl_2$ and glucose together and separate from the other ingredients Then add the three solutions when cooled.

CK6 Medium (Irschik et al., 1987; modified from Couke and Voets, 1967)

$MgSO_4 \cdot 7H_2O$	0.15% (w/v)
$CaCl_2 \cdot 2H_2O$	0.15% (w/v)
$FeCl_2 \cdot 7H_2O$	8 mg/liter
KNO_3	0.2% (w/v)
K_2HPO_4	0.025% (w/v)
Glucose	0.5% (w/v)

Autoclave nitrate and phosphate together and $CaCl_2$ and glucose together and separate from the other ingredients. Then add the three solutions when cooled.

AMB Medium (Ringel et al., 1977)

Soluble starch	0.5% (w/v)
Casitone (Difco)	0.25% (w/v)
$MgSO_4 \cdot 7H_2O$	0.05% (w/v)
K_2HPO_4	0.025% (w/v)

Autoclave the medium.

MD1 medium (see above) can also be used for cellulose degraders if it is supplemented with 0.1% (w/v) glucose or soluble starch (Irschik et al., 1987). Some strains can grow in liquid media, like CB medium containing Casitone as the only C, N, and energy source (Sarao et al., 1985), but this must be exceptional because none of the many *Sorangium* strains we have tested would do so.

CB Medium (Casitone Broth; Sarao et al., 1985)

Casitone (Difco)	0.25% (w/v)
$MgSO_4 \cdot 7H_2O$	0.05% (w/v)
K_2HPO_4	0.0025% (w/v)

For liquid cultures of myxobacteria, ordinary Erlenmeyer flasks are perfectly satisfactory as culture vessels. For agitation, a rotary shaker at about 150 rpm is sufficient. As the oxygen demand of myxobacteria is rather moderate, flasks with baffles give little or no improvement in growth and actually are unfavorable with peptone-containing media because they produce too much foam. Several types of antifoam can be used with myxobacteria, but the type of antifoam acceptable in a certain situation and tolerated by a specific strain must always be tested first. We have found that with small culture volumes and limited foaming, a few drops of a 0.5% (w/v) cholesterol solution in acetone works well. In fermentors, as a rule, more efficient antifoams must be applied (Mizrahi et al., 1977; Ringel et al., 1977). We have had good results in many different myxobacterial fermentations with polyoxypropylene-based antifoams at 0.02–0.03% (w/v), for instance, of antifoam agents LB625 and M115 (both from Brenntag, Mülheim/Ruhr, Germany; Gerth et al., 1980; Irschik et al., 1983b), or with silicone antifoam agent at 0.005–0.02% (w/v; Merck, Darmstadt, Germany; these sometimes require further additions later during fermentation; Irschik et al., 1983a; Kunze et al., 1984; Kunze et al., 1985). Many, but not all, myxobacteria can be cultivated in the presence of an Amberlite adsorber resin, e.g., with 1% XAD-1180 (Röhm and Haas, Darmstadt, Germany; e.g., Gerth et al., 1983; Kunze et al., 1985). This strategy often is extremely useful for the production and recovery of secondary metabolites that are excreted by the cells.

Mass cultivation of myxobacteria in fermentors has not presented any serious problems. Mechanical stress seems not to be a limiting factor. If no continuous control and regulation of culture parameters is required, cultivation in large flasks (10–15 liters) also gives excellent results. The flasks are aerated with three air outlets of sintered glass at the ends of silicone tubing, which are lowered to close to the bottom of the vessel. The aeration produces enough turbulence in the liquid so that additional stirring is unnecessary. The appropriate temperature is achieved by placing the flask in an incubation room or by connecting a length of silicone tubing coiling within the culture broth to a thermostat with a pump. With such an inexpensive system, yields on the order of 8–12 g cells/liter (wet weight, corresponds to 2–3 g of dry weight) can be obtained.

Cultivation in commercial fermentors permits the continuous monitoring of various culture parameters and allows them to be balanced and controlled. Although the optimum conditions depend on the type of fermentor used, the strain, and the medium, some generalizations are possi-

ble: In fermentations on the scale of 50–5000 liters, typical aeration rates are between 0.01 and 0.2 liter air per liter of medium per min, which, with stirring rates between 150 and 650 rpm, result in oxygen levels between 90 and 100% saturation (Mizrahi et al., 1977; Gerth et al., 1980; Gerth et al., 1982; Gerth et al., 1983; Irschik et al., 1983b; Irschik et al., 1983a; Irschik et al., 1987; Kunze et al., 1984; Kunze et al., 1985, Kunze et al., 1987). In a special study on myxovirescin production with *Mx. virescens* Mx v48 with fed-batch fermentations in a peptone medium, a cell yield of 0.5 g (dry weight) per g oxygen consumed and of 0.31 g per g peptone was obtained (Nigam et al., 1984). The oxygen consumption was 6.25 g of O_2 per liter of culture in 55 h. Respiration quotients between 0.3 and 1.3 mol of CO_2 per mol of O_2 were calculated under different culture conditions, with values of 0.8–1.0 during logarithmic growth. The maximum dry weight yield was 3.1 g/liter. The specific growth rate, m, varied between 0.05 and 0.12/h during exponential growth, depending on the feeding rate.

Other types of special fermentations have also been performed with myxobacteria; for instance, continuous cultures of *Mx. virescens* Mx v48 have been achieved in a chemostat with on-line extraction of myxovirescin in a vortex chamber (Hecht et al., 1987), and fermentations have been established with alginate-immobilized cells (Younes et al., 1984; Younes et al., 1987; Vuillemard et al., 1988). Cells of *So. cellulosum* So ce12 immobilized in 1-mm alginate beads are extremely stable and could be maintained in fermentors under continuous exchange of the medium for up to 75 days before the cells degenerated (Becker, 1990; K. Becker, personal communication). The system allowed the production conditions for the antibiotic sorangicin to be defined more clearly, and under optimal conditions, volume/time yields are five times higher than those measured with suspended cells in batch cultures.

When fermentations are started with an inoculum of 5–10% (v/v), the results are almost always satisfactory. Sometimes the age of the inoculum is a critical factor, and beyond a certain, relatively early stage but still within the logarithmic phase, the cells will start to grow only after a long and erratic lag period or not at all. This has been observed with *Polyangium* and *Sorangium* strains (H. Reichenbach, unpublished observations).

Under optimal growth conditions the doubling times of myxobacteria are between 3.5 and 15 h, with the members of the suborder Sorangineae comprising the most slowly growing myxobacteria. Cell densities of up to 10^{10}/ml can be reached, for example, with *So. cellulosum*. Cell mass yields are in the range of 4–12 g of wet weight per liter (e.g., Irschik et al., 1983b; Irschik et al., 1983a; Irschik et al., 1985b). The dry mass is 20–25% of the wet weight.

The pH range for growth is rather narrow, approximately 6.5–8.5; in general, there is no good growth below a pH of 6.6 or above pH 8.0. While some of the cellulose decomposers will grow at a pH down to about 5.0 (Krzemieniewska and Krzemieniewski, 1937a; Couke and Voets, 1967), below pH 5.8, growth is marginal (H. Reichenbach, unpublished observations). As with other bacteria, the pH in myxobacterial cultures can be stabilized by adding a buffer. HEPES and 3-[*N*-morpholino]propanesulfonic acid (MOPS) buffers (50 mM) are well tolerated by many myxobacteria, and Tris may also be used. (Note that many of the media formulations do not contain phosphate; the low amount of phosphate contained in the peptones—in a 0.2% [w/v] solution of peptone from casein, 0.5 mM phosphate was present [Becker, 1990]—is usually sufficient to satisfy the phosphate requirement of myxobacteria.)

The temperature optimum for growth is usually between 32 and 36°C, and there is a sharp maximum around 38°C. The minimum is less clear. *Myxococcus xanthus* FB grew exponentially with a generation time of 14 h at 14°C, the lowest temperature tested (Janssen et al., 1977); the lower limit for cellulose decomposition by two *Sorangium* strains was found to be 11°C (Krzemieniewska and Krzemieniewski, 1937a). *Myxococcus fulvus* Mx f2 grows, albeit slowly, at 6°C. However, other myxobacteria obviously have a different temperature range: The psychrophilic myxobacteria from Antarctica have already been mentioned (Dawid et al., 1988), and at the other end of the scale, strains of *Archangium*, *Polyangium* and *Sorangium* that are able to grow at 40°C have been known for some time (McCurdy, 1969b). About 70% of the *Sorangium* strains grow at 40°C and about 80% at 38°C. A variety of other myxobacteria can grow at these somewhat elevated temperatures, e.g., most *Polyangium*, many *Archangium*, *Cystobacter*, *Chondromyces* and some *Mx. virescens* strains, but usually not *Mx. fulvus* and *Corallococcus*.

Most myxobacteria do not require vitamins when growing in the usual complex media, but, as already mentioned, a vitamin dependence, usually for thiamine or biotin or both, may develop when the organism is transferred to a minimal medium. *Stigmatella aurantiaca* Sg a15 needs both thiamine and B_{12} (Kunze et al., 1984); B_{12} dependence is not unusual and has also been observed with many *Polyangium* (but not with *Sorangium*), some *Nannocystis*, and one strain of *Corallococcus macrosporus*.

The mineral requirements of myxobacteria are similar to those of other bacteria. Myxobacteria seem to need relatively high Mg^{+2} concentrations (the optimum is often around 5–10 mM, equivalent to 0.075–0.15% $MgSO_4 \cdot 7H_2O$). *Sorangium* strains require Ca^{+2} as well and grow better on media with Ca^{+2} than with Mg^{+2} (McCurdy, 1969b). The addition of Co^{+2} sometimes has a stimulating effect (Ringel et al., 1977; Gerth et al., 1982). *Myxococcus xanthus* is sensitive to elevated concentrations of monovalent cations (Mason and Powelson, 1958), and the salt tolerance of myxobacteria is generally low. An exception is *Mx. virescens*, which seems to form fruiting bodies better when 0.5% (w/v) NaCl is added to the medium (Rückert, 1978). This organism can still grow on media containing 1% NaCl, although at a clearly reduced rate, and, in fact, it can be selectively isolated on streaks of *E. coli* on WCX agar at that salt concentration.

Usually, myxobacterial cultures are kept in the dark or, in an incubation room, under continuous illumination. As already mentioned, some myxobacteria produce fruiting bodies only when the cultures are illuminated. Also, a phototactic behavior has been reported for some myxobacteria (Aschner and Chorin-Kirsch, 1970). Illuminated cultures often are much more deeply colored than those grown in the dark because carotenoid synthesis is induced by light (Burchard and Dworkin, 1966b). As color is sometimes a taxonomically relevant characteristic, cultures used for taxonomic work should at least be intermittently illuminated.

Isolation of Mutants

Mutant strains of myxobacteria can be isolated without difficulty provided strains capable of dispersed growth and procedures for obtaining a high plating efficiency are available. *N*-Methyl-*N*′-nitro-*N*-nitrosoguanidine (NTG) is often (but not always) an excellent mutagen for myxobacteria. The useful concentration range is 50–150 µg NTG/ml when the cultures are treated for 1 h. Also UV irradiation has successfully been used to obtain mutants. However, in contrast to NTG, UV was ineffective in generating carotenoid mutants in *Mx. fulvus* Mx f2. Further details on the application of different mutagens and a comparison of their effects on a variety of myxobacteria can be found in the literature (e.g., Burchard and Parish, 1975; Hodgkin and Kaiser, 1977; Grimm, 1978).

In recent years, transposon insertion mutagenesis has enjoyed particular favor because of the ease in identifying the gene containing the mutation. Transposon insertions have been generated with Tn*5* (Kuner and Kaiser, 1981), Tn*5 lac* containing a *lacZ* reporter (Kroos and Kaiser, 1984), Tn*V* containing an origin of replication (Furuichi et al., 1985), and magellan-4 (Youderian et al., 2003). Transposon mutagensis typically employs a suicide vector that is introduced by specialized transduction with coliphage P1 (Shimkets et al., 1983), conjugation with RP4 (Breton et al., 1985), or electroporation (Kashefi and Hartzell, 1995).

One typically mutagenizes cells and then screens for a particular phenotype of interest. One can also take the opposite approach and eliminate specific genes whose sequences are known. Mutations can be introduced in a directed way by homologous insertion of a nonreplicating circular DNA molecule containing a small portion of a gene lacking both 5′ and 3′ coding sequences (Shimkets and Asher, 1988). Integration of a truncated gene inactivates that gene and any genes following it in the same transcriptional unit. Such systematic mutagenesis has already been applied to a large cosmid (Lancero et al., 2002). The genome sequences of *Mx. xanthus* and *So. cellulosum* are now complete. This will facilitate the directed mutagenesis approach.

Preservation Methods

Vegetative cultures of myxobacteria on agar plates kept at room temperature or at 30°C will usually remain viable for about 2–3 weeks. Storage of such cultures at 4°C leads to a rapid loss of viability.

If fruiting bodies are produced, the cultures remain viable for a much longer time. One has to be certain, however, that the fruiting bodies do indeed contain myxospores, since under some conditions the fruiting bodies are empty or contain only vegetative cells.

Storage in the Form of Desiccated Fruiting Bodies

Pieces of agar that contain fruiting bodies can be placed on sterile filter paper in an empty Petri dish, dried in an evacuated desiccator, and stored as such for years. This method is especially useful with myxobacteria such as *Nannocystis*, whose fruiting bodies are mainly located within the agar.

Alternatively, vegetative cells can be transferred from a suitable growth medium, preferably VY/2 agar, to small rectangles (about 1.5 × 3 cm) of sterile filter paper on water (WAT) agar, and the cultures are incubated at 28°C. Usually, large numbers of fruiting bodies develop within 2–3 days. These fruiting bodies are allowed to mature for about 8 days. The filter pads are then placed into suitable containers, such as screw-cap

tubes or small medicine bottles, and dried in an evacuated desiccator over silica gel for a few days. The containers are then tightly closed and stored at room temperature or at 6°C (it is not known which temperature is better). The dried fruiting bodies survive for about 5–15 years. This method has the advantage of being easy and cheap, and it conserves the ability of the strain to form fruiting bodies. It works, however, only if the strain has not been transferred too many times since its isolation. The method should therefore be applied as soon as a strain is pure and, if fruiting is a desired feature, even earlier. Sometimes myxospores are still produced on the filter although fruiting bodies are no longer formed. In that case, the filter can still be dried and a viable preparation produced. The growth medium taken from the vegetative cells must not be too rich. Thus, for example, fruiting bodies usually do not appear after transfer from CY agar. Sometimes the organism must be grown directly on the filter paper to obtain fruiting bodies. This may be done on filter pads on water agar after streaking autoclaved yeast or food bacteria onto the filter. In this way, *Chondromyces* strains are sometimes induced to fruit. The cellulose decomposers almost always produce many fruiting bodies when growing on filter paper, which has been placed on ST21 agar. As the fabric of the filter paper is destroyed during growth, the paper can no longer be removed, but the macerated mass may be transferred to a fresh filter pad, which is then treated as described above.

To start a culture from dried fruiting bodies, the filter pad is placed upside down on CY agar, VY/2 agar, or WAT agar with streaks of autoclaved *E. coli*. After 24 h, the filter strip should be shifted to another place on the plate, because reduced oxygen access may prevent germination under the wet paper. When the paper is removed, many of the soaked and softened fruiting bodies will stick to the agar surface.

Alternatively, if a sufficient quantity of fruiting bodies is obtainable, e.g., after growth on VY/2 agar, after having been transferred to water agar or, in the case of the cellulose degraders, on filter paper on ST21 agar, they may be dried in skim milk. The fruiting bodies are suspended in skim milk, and a few drops of the suspension are applied to a freeze-dried milk plug in an ampoule. The ampoules are kept at 4°C for at least 10 min, and the plug is then dried again for about 5 h (this time at room temperature) in a desiccator connected to an efficient pump. After that, the ampoules are filled with nitrogen gas and sealed. Strains thus preserved also retain their ability to form fruiting bodies and may remain viable for a longer time than on filter paper. While drying in skim milk also works well with myxospores, including those that were experimentally induced (Dworkin and Gibson, 1964a), results with vegetative cells are highly erratic. Vegetative cells invariably die during drying, and only those cultures that contain myxospores survive. Experiments with true lyophilization and with protective substances other than skim milk did not give better results.

An excellent and convenient method for the preservation of myxobacteria is freezing at –80°C. Samples of 1 ml are transferred from exponentially growing liquid cultures to screw-cap tubes and placed directly into the deep freeze. Alternatively, the bacteria may be scraped from the surface of a young agar culture, transferred to 1 ml of CAS medium, and frozen. All of the myxobacteria that we have tested so far (26 species) have survived in the deep freeze for 8–10 years, the longest period over which data have been collected. Storage at ultra-low temperature is the best way to preserve strains growing in the dispersed state, nonfruiting, nonspore-forming strains, and mutants. It is also a fast and reliable method for the storage of all kinds of strains of a culture collection. However, if the temperature rises above –30 to –25°C, the cells will die unless they are transferred to a growth medium within 5–10 h.

For safe long-term storage, freezing in liquid nitrogen is the method of choice. We use the same cell suspension as described above, but add 5% dimethyl sulfoxide (DMSO) to the suspension medium, which is usually CAS medium. We fill 0.5-ml amounts of the suspension into glass ampoules, seal them, and immerse them in liquid nitrogen without further precautions. The DMSO may not be required since all strains stored without DMSO have survived thus far for 2 years.

Storage of frozen cell suspensions at –25°C is not recommended because most myxobacteria will die within several days or, at the most, a few weeks.

To reactivate frozen cultures, the tubes or ampoules are immersed in cold water to speed up thawing. The cells must be transferred to fresh medium immediately after they have thawed because if the cells remain in the original medium after thawing, they will lyse within 15–30 min. We generally use VY/2 agar for the reactivation of the culture, usually with good results, but CY agar, CAS medium, and MD1 medium can also be used. If experience is lacking with a certain strain, the thawed suspension should always be inoculated into several different media, including a liquid medium. Sometimes, albeit rarely, recovery will occur only on a specific medium, although the other media normally support growth. For example, we have observed that some strains can be reactivated only in a liquid medium or only on agar plates. If a liquid

medium is used, care should be taken not to dilute the organisms too much, e.g., by inoculating a few drops into 100 ml. In some cases, for example with particularly fragile mutants, reactivating the cells by embedding them in a growth medium containing 0.6% (w/v) agar is useful. The soft agar appears to provide a matrix that protects cells that have been slightly damaged by freezing and thawing (D. Zusman, personal communication).

At least some myxobacteria can be stored in a 1% (w/v) NaCl solution at room temperature. The cell suspension must not be too dense: the liquid should be just visibly turbid; otherwise the cells will lyse overnight. For one strain of *Mx. xanthus*, a suspension of vegetative cells has been kept alive for 5 months in this way. In another case, we suspended vegetative cells and glycerol-induced myxospores of *Mx. xanthus* FB in 1% (w/v) NaCl solution and kept the suspensions in sealed ampoules for 7 years at room temperature. After that time, a culture could be started from the myxospores, but not from the vegetative cells. While the original strain was very sensitive to NaCl, the revived strain grew on CY agar with 1% (w/v) NaCl. This clearly indicates that in such cases the bacteria are not completely dormant and that a selection for certain characteristics may have taken place.

Characterization

Nutrition and Energy Metabolism

All myxobacteria decompose macromolecules, but there are two sharply separated metabolic groups. Group 1 myxobacteria decompose cellulose and are classified in two genera, *Sorangium* and *Byssophaga*. The few strains that have been studied in detail are all able to grow on inorganic nitrogen (NH_4^+ or NO_3^-) as the only nitrogen source, although their growth is stimulated if a small quantity (0.05–0.1% [w/v]) of peptone is added. They also grow on organic nitrogen compounds as the only nitrogen source, provided a carbohydrate is also present. A few strains appear even to grow on peptone alone (Sarao et al., 1985). These organisms utilize cellulose and sugars such as glucose equally well, but cellulase production is repressed in the presence of sugar (Krzemieniewska and Krzemieniewski, 1937a; Krzemieniewska and Krzemieniewski, 1937b; Pronina, 1962; Couke and Voets, 1967).

Group 2 myxobacteria, by far the majority of species, depend on an amino acid-containing medium such as peptone for growth. They obtain oligopeptides by hydrolyzing proteins. Their dependence on peptides may be such that developing defined amino acid media for them is difficult or impossible. In other cases, the organisms grow on remarkably simple media with glucose, glutamate, and two essential amino acids (see the section Cultivation in this Chapter). In nature, these organisms seem to subsist mainly on other organisms, which they degrade by means of a variety of hydrolytic exoenzymes. Proteases, nucleases, lipases, glycanases, and cell wall lytic enzymes have been demonstrated. These myxobacteria are particularly efficient in the destruction of other bacteria and of yeast cells and therefore have been called "micropredators" (Singh, 1947). However, they do not depend on living organisms and could as well be regarded as scavengers. Their association with animal dung is probably due to its rich mixture of many types of living and dead cells and to its content of organic matter at every level of decomposition.

Almost all known myxobacteria (with the possible exception of *Anaeromyxobacter dehalogenans*) are strictly aerobic organotrophs. As a prerequisite for aerobic energy generation, *Myxococcus* possesses *a*-, *b*-, and *c*-type cytochromes as well as reduced β-nicotinamide adenine dinucleotide (NADH)-oxidase (Dworkin and Niederpruem, 1964b; Kleinig, 1972) and a complete tricarboxylic acid cycle (Watson and Dworkin, 1968; McCurdy and Khouw, 1969c; Sarao et al., 1985). The genus *Myxococcus* cannot utilize mono- and disaccharides (Watson and Dworkin, 1968) and depends on amino acids (or pyruvate) as a carbon and energy source (Bretscher and Kaiser, 1978). Recently it was discovered that methyl oleate dramatically increases the growth yield of *Mx. xanthus*, suggesting the presence of a fatty acid β oxidation pathway (Lau et al., 2002). Some myxobacteria can take up and metabolize oligosaccharides, which they produce from polysaccharides such as starch through the action of special hydrolytic enzymes (Irschik and Reichenbach, 1985a). This ability may be more common than presently believed, for virtually all *Myxococcus* and *Corallococcus* strains are able to degrade one or more polysaccharides, e.g., yeast cell wall β-glucan, xylan, and starch.

An overview of the metabolism of myxobacteria has been given by Shimkets (1984). Apparently, myxobacterial metabolism is similar to that of other bacteria, and unique biochemical pathways have not been discovered. Of course, myxobacterial metabolism has often been studied mainly in relation to biochemical reorganization during morphogenesis, and many enzymes have been described that are turned on or off at certain stages of development. These data will be found among the reviews cited earlier.

The glycolytic pathway seems to play a major role in the glucose metabolism of *So. cellulosum* (Sarao et al., 1985; D. Hofmann, personal com-

munication). In *Mx. xanthus*, glucose is not metabolized, presumably because hexokinase (ATP-dependent) and pyruvate kinase are absent (Watson and Dworkin, 1968). Nevertheless, an intact phosphofructokinase and a fructose-1,6-diphosphatase are present (Watson and Dworkin, 1968), implying that glycolysis and gluconeogenesis are both possible. The explanation for this apparent contradiction is not obvious. In *Cl. coralloides* strain Cc c127, fructose-1,6-diphosphate aldolase activity is very weak, and intracellular hexose seems to be metabolized via the pentose phosphate pathway (Irschik and Reichenbach, 1985a). The latter pathway is present in other myxobacteria, e.g., *So. cellulosum* (D. Hofmann, unpublished observations). In fact, this pathway must be present in all myxobacteria because all are able to synthesize the pentose required in anabolic reactions. In *Mx. xanthus*, the initial enzyme, phosphoenolpyruvate carboxylase, has been shown to be present (Watson and Dworkin, 1968). The conversion of fructose-6-phosphate into cell wall precursors has also been demonstrated (Filer et al., 1977). In *So. cellulosum*, gluconeogenesis appears to be blocked, which may explain the dependence of this organism on external carbohydrates (D. Hofmann, unpublished observations).

Morphology and Fine Structure

The vegetative cells of the myxobacteria are rod-shaped, typically 3–6 μm long and 0.7–1.0 μm wide. They are found in two morphological types: 1) slender, flexible rods with more-or-less tapering ends and 2) cylindrical, somewhat rigid rods with bluntly rounded ends (Krzemieniewska and Krzemieniewski, 1928; Fig. 1a–d). These different cell types correlate with a number of other basic characteristics and represent suborders of the Myxobacterales, the Cystobacterineae and the Sorangineae/Nannocystineae. The cell shape makes it possible to assign a strain at once to one of the two groups.

Most electron microscopic studies on myxobacteria are rather old now, and a thorough reinvestigation would be desirable. In addition to *Mx. xanthus*, several other myxobacteria have been studied, including *Mx. fulvus*, *Mx. virescens*, *Cystobacter*, *Stigmatella*, *Sorangium* and *Chondromyces* species (Voelz and Dworkin, 1962; Voelz, 1965; Voelz, 1966a; Voelz, 1966b; Voelz, 1967; Abadie, 1967; Abadie, 1968; Abadie, 1971a; Abadie, 1971b; Schmidt-Lorenz and Kühlwein, 1968; McCurdy, 1969a; Reichenbach et al., 1969b; MacRae and McCurdy, 1975; Lampky, 1976; Galván et al., 1986). The myxobacteria are typical Gram-negative bacteria. Both the tapered and the cylindrical cell types appear to be identical in fine structure, with ultrathin sections revealing a typical triple-layered outer membrane and a thin peptidoglycan sheet. The cells divide by septum formation (Abadie, 1971b; MacRae and McCurdy, 1975). Within the cells, mesosomes and mesosome-like membrane bodies are often seen (Voelz, 1965; Abadie, 1967; Abadie, 1968; Abadie, 1971b; MacRae and McCurdy, 1975; Lampky, 1976; Galván et al., 1986). The visualization of ribosomes was initially a problem, because they were difficult to fix properly (Voelz, 1967), but it later turned out that they are of the usual type. At low phosphate levels, the formation of polysomes seems to be induced in *Mx. xanthus* (Voelz, 1966a). Polysomes were also observed in cells of *Cm. crocatus*, and they were often attached to the cytoplasmic membrane and arranged in a helical fashion (Abadie, 1971b). Unusual disk-shaped, membrane-associated structures have been described from *Cm. crocatus* (MacRae and McCurdy, 1975). In cross sections they appear as two double tracks, each 7.5–11 nm wide and between 55 and 130 nm long, connected to the interior of the cytoplasmic membrane by 11- to 15-nm-long, fibrillar extensions. Several classes of intracellular granules, or inclusion bodies, have been found. Black granules, apparently produced by all myxobacteria, have been identified as polyphosphate (Voelz et al., 1966c). Electron-transparent granules are of at least two types: 1) granules that are pale gray, containing material that does not contrast well; these have been suggested to be polysaccharide (Reichenbach et al., 1969b), "slime vacuoles" (Schmidt-Lorenz and Kühlwein, 1969; Abadie, 1971b), or glycogen (Voelz et al., 1966c). This has been corroborated by light microscopy after performing the periodic-acid Schiff reaction (Schmidt-Lorenz and Kühlwein, 1969). 2) Completely empty, large, circular areas, which are sudanophilic under the light microscope, have been seen in the cells of *So. cellulosum* (Lampky, 1976) and may be lipid material. Also, poly-β-hydroxybutyric acid has been demonstrated chemically in *So. cellulosum* (H. Jansen, personal communication). In cells of *Mx. xanthus* grown under suboptimal conditions, large parts of the cytoplasm sometimes appear to have a crystalloid pattern (Voelz, 1966a; Voelz, 1967; Voelz, 1968).

In many myxobacteria, intracellular microtubules and fibrils may be seen (Schmidt-Lorenz and Kühlwein, 1968; Abadie, 1971b; MacRae and McCurdy, 1975; A. C. Burchard et al., 1977). The diameter of the microtubules is 10–16 nm (with *Cm. crocatus* 15–19 nm), and that of the fibrils is 4–5 nm (with *Cm. crocatus* 7.5–10 nm). Once it was thought that microtubules and fibrils were just two different aspects of the same structure depending on the plane of sectioning (Schmidt-Lorenz and Kühlwein, 1968), but this is not the

case. The fibrils are usually arranged in bundles that may be 40 nm wide and 3.5 μm long. The bundles usually lie close to the cytoplasmic membrane and often follow the long axis of the cell, sometimes to the cell poles, but they also may cross the cell from one side to the other. A herringbone-like periodicity with a 12-nm spacing has occasionally been seen (A. C. Burchard et al., 1977). Also, transverse bands with a very regular, crystal-like pattern may occur (A. C. Burchard et al., 1977). Originally, fibrils were found only in cells from swarming agar cultures (Schmidt-Lorenz and Kühlwein, 1968), but they were subsequently found in cells from liquid cultures as well (A. C. Burchard et al., 1977; H. Reichenbach, unpublished observations). These systems of fibrils and microtubules have been interpreted as contractile elements responsible for gliding motility by producing contraction waves (Schmidt-Lorenz and Kühlwein, 1968; A. C. Burchard et al., 1977), but there is no evidence that those structures can really contract, and they could have some other function or even be artifacts. In *Cm. crocatus*, those structures were assumed to be composed of ribosomes (paracrystalline system; Abadie, 1971b).

An extremely complex structure has been discovered in the surface layers of *Mx. fulvus*, just below the outer membrane (Lünsdorf and Reichenbach, 1989). One or several helical belts appear to be wrapped around the periphery of the cell, beginning close to the cell pole. From isolated material, it was deduced that the unit element consists of a long series of tiny rings at a regular, periodic distance, connected to each other by two longitudinal structures, perhaps two fibrils. Several of these unit elements, or strands, form a ribbon, and it could be shown that the rings in those ribbons can change their conformation, thereby producing a reduction of the transverse dimension of the ribbon by 40%. The belt is composed of about seven ribbons, and conceivably a coordination of the conformational changes occurring in the ribbons could produce a traveling wave in the belt and concomitantly in the cell surface, which would propel the cell. Nothing is known yet about the biochemistry of the system, and not even the structural details are fully understood. However, the components of the apparatus have been seen also in other myxobacteria, including *Mx. xanthus*.

Chemical Composition

While much has been learned about the chemical composition of the myxobacterial cell, the precise nature of the extracellular polysaccharides remains undetermined, as it is usually accompanied by a variety of other large and small excreted molecules (Sudo and Dworkin, 1972; Hanson and Dworkin, 1974). The excreted slime appears usually to be a heteropolysaccharide containing, among others, *N*-acetyl aminosugars (Sutherland and Thomson, 1975; Sutherland, 1979). Slime from fruiting bodies resembles in its overall composition that produced in vegetative cultures. A large extracellular protein-polysaccharide-lipid complex with proteolytic activity has been isolated from culture supernatants of *Mx. virescens* (Gnosspelius, 1978b). A glycopeptide with a heat-stable blood anticoagulant activity, named "myxaline," has been obtained from the culture broth of *Mx. xanthus* (El Akoum et al., 1987; Masson and Guespin-Michel, 1988). The glycan part contains *N*-acetyl aminosugars, and the peptide is rich in glutamic acid and serine. The excreted slime must be chemically different in the suborders of myxobacteria, since Congo red (0.01% [w/v] aqueous solution) stains the slime of the Cystobacterineae but not that of the Sorangineae/Nannocystineae (McCurdy, 1969b).

LIPOPOLYSACHARIDES AND CELL WALLS. There are several studies on the chemistry of the lipopolysaccharides (LPS) of various myxobacteria (Weckesser et al., 1971; Rosenfelder et al., 1974; Sutherland and Thomson, 1975; Sutherland, 1979). Contrary to the statement of Ruiz et al. (1987), myxobacterial LPS, including lipid A, can be readily and completely extracted from the cells by the usual phenol procedure (e.g., Sutherland and Smith, 1973; Rosenfelder et al., 1974; Sutherland and Thomson, 1975; Panasenko, 1985). Typical LPS yields are 0.5–1.0% (up to 1.9%) of the cell dry weight. Chemically, the LPS of the myxobacteria resembles that of the enterobacteria. The LPS of *Mx. fulvus* contains mannose, galactose, glucose, rhamnose, arabinose, glucosamine, and 3-*O*-methyl-D-xylose, a sugar only very rarely seen in bacterial LPS (Weckesser et al., 1971; Rosenfelder et al., 1974). The LPS of other myxobacteria may differ somewhat in sugar composition, but 2-keto-3-deoxyoctonic acid is always present, and heptose is never present. The 3-*O*-methyl-D-xylose may or may not be found, and in some cases, similar nonpolar but thus far unidentified sugars have been observed (Sutherland and Smith, 1973; Sutherland and Thomson, 1975; Sutherland, 1979). While the scant data do not really allow generalizations, a complete lack of rhamnose seems to be characteristic for *Sorangium* and may be another distinguishing characteristic of that suborder. The lipid A moiety contains glucosamine and the usual 3-hydroxy fatty acids, mostly *iso*-3-OH-C15 and *iso*-3-OH-C17 (Rosenfelder et al., 1974).

Man (1998) has carefully analyzed the LPS of *Mx. xanthus* and has found that the O-antigen portion consists of a small, repeating disaccha-

ride comprising → 4) -α -D-Gal*N*Ac*p* - (1 → 6)-α -D-Glcp - (1 →, where about 40% of the Gal*N*Ac*p* residues are methylated at their 6-positions. The "*p*" denotes pyranoside. The core LPS was found to consist of glucose, mannose, 2-acetamido-2-deoxy-galactose, and 2-acetamido-2-deoxy-6-*O*-methyl-galactose, in relative molar ratios of 1.00 : 0.41 : 0.40 : 0.32, respectively. Also present in the core LPS were small amounts of rhamnose, arabinose, xylose, galactose, and 2-acetamido-2-deoxyglucose.

Several mutations have been described that eliminate LPS O-antigen biosynthesis in *Mx. xanthus*. Fink et al. discovered that mutants resistant to phage Mx8 lack O-antigen and fail to react with monoclonal antibodies specific to O-antigen (Fink et al., 1989c). The genes containing these mutations have not been identified. The *wzm* and *wzt* gene products are predicted to encode an ATP-binding cassette (ABC) transporter involved in export of the O-antigen to the periplasm (Bowden and Kaplan, 1998). The *wbgA* and *wbgB* genes share similarity with bacterial glycosyltransferases and are suggested to be required for O-antigen synthesis (Bowden and Kaplan, 1998; Yang et al., 2000a). In all of these reports the authors noted deficiencies in motility, but there is some discrepancy as to whether the deficiencies are in A motility, S motility, or both. The consensus appears to be that both A and S motility are greatly reduced (Yang et al., 2000a). Man (1998) examined the LPS of two O-antigen mutants of *Mx. xanthus* (Fink and Zissler, 1989b) and found that both lacked the O-antigen repeating polysaccharide present in the wild-type parental strain. Man speculated that the corresponding reduction in cell surface hydrophilicity may be responsible for the motility defect.

During sporulation of *Mx. xanthus*, the LPS, or at least its polysaccharide part, is completely lost (Sutherland, 1976a), and a capsule composed of an α-1,3-glucan is produced (Sutherland and Mackenzie, 1977). That capsule is ruptured and discarded during germination rather than enzymatically solubilized (Voelz, 1966b). Monoclonal antibodies have also been obtained against O-antigens and against a core antigen of *Mx. xanthus* LPS (Gill and Dworkin, 1988; Fink and Zissler, 1989a). Several O-antigen mutants were defective in the A system but not in the S system of gliding. They were still able to form normal fruiting bodies (Fink and Zissler, 1989b). Endotoxin-like effects (anticomplement test and Shwartzman skin reaction) could be produced with whole cells and myxospores of *Mx. xanthus* (Ruiz et al., 1987).

Myxococcus xanthus, the only myxobacterium for which the organization of the cell wall has been investigated, has a thin peptidoglycan layer that seems to be organized in patches rather than in a homogeneous sacculus (White et al., 1968). The composition of the peptidoglycan resembles that of *E. coli*, with diaminopimelic acid at the cross-links. Apparently during sporulation, the degree of cross-linking increases. At the same time, galactosamine and glycine accumulate in the wall layer. The peptidoglycan content of vegetative cells and myxospores is, however, the same (0.6% of the dry weight).

LIPIDS. The fatty acid composition of the myxobacteria has not been thoroughly examined. However the data that are available suggest characteristic differences among the suborders (Fautz et al., 1981). While all myxobacteria contain substantial quantities of iso-branched fatty acids, mainly saturated C15:0 and C17:0, the fatty acid composition is dominated by them only in the suborder Cystobacterineae (usually between 50 and 70% total fatty acid; Schröder and Reichenbach, 1970; Ware and Dworkin, 1973; Fautz et al., 1979; Fautz et al., 1981; Yamanaka et al., 1988). *Nannocystis exedens* (suborder Nannocystineae) is the only myxobacterium so far in which larger amounts (about 30%) of *iso*-C15:1 and *iso*-C17:1 are found (Fautz et al., 1981). *Sorangium cellulosum*, suborder Sorangineae, has an intermediate phenotype with a more balanced representation of the saturated and unsaturated members of the iso odd family (Fautz et al., 1981).

The distribution of 2-hydroxy(OH) fatty acids also follows a trend, being high in the Cystobacterineae and virtually absent in the Nannocystineae and Sorangineae (Fautz et al., 1981). *Iso*-2-OH C17:0 was first seen as a contaminant from phospholipid in LPS preparations of *Mx. fulvus* and *Cb. ferrugineus* (Rosenfelder et al., 1974). Later, proof was presented for the chemical structure of the 2- and 3-OH fatty acids of *Mx. fulvus* and *C. ferrugineus*. In total cell hydrolysates, 2-OH fatty acids, mainly *iso*-2-OH C17:0, constitute 10–12% of the total fatty acids, while 3-OH fatty acids only play a minor role (2.5– 4.5%; Fautz et al., 1979). In members of the Cystobacterineae, two types of phosphatidylethanolamine have been demonstrated, one of which contains exclusively nonhydroxy fatty acids and the other 50–70% 2-OH fatty acids (Yamanaka et al., 1988).

Another major component of the fatty acid pattern of the Cystobacterineae is C16:1 (15–39%), which is greatly reduced in the Nannocystineae and Sorangineae. This fatty acid was later identified as 16:1 ω5c (which is extremely rare in nature; Kearns et al., 2001b). Anteiso fatty acids have also been reported in *Mx. xanthus* (Ruiz et al., 1985; Toal et al., 1995; Kearns et al., 2001b). In another study, a clear difference was seen between the fatty acid patterns of *Cor-*

allococcus and those of *Myxococcus* species (Monteoliva-Sanchez et al., 1987): branched and unbranched C17:0 fatty acids were present in large quantities in the latter (27–38%) but completely absent in the former. While such a clear difference would be useful for taxonomic reasons, it is not supported by other investigations (Yamanaka et al., 1988).

Myxococcus fulvus Mx f2 contains phosphatidylethanolamine as the main component (72%), with phosphatidylglycerol (9%), phosphatidylinositol (7%), and an unknown, ninhydrin-positive phospholipid (8%) as minor components (Kleinig, 1972). A small proportion of the phospholipids were alk-I-enyl-acyl (1–15%) and alkyl-acyl compounds; however, they comprised 22% of the phosphatidylinositol compounds. The phospholipid content of the isolated membranes was 25% (dry weight). The occurrence of two species of phosphatidylethanolamine in myxobacteria has already been mentioned (Yamanaka et al., 1988). The outer membrane of *Mx.* xanthus MD-2, an S motility mutant, showed an unusually low buoyant density (1.221 g/ml) which was probably due to an exceptionally high phospholipid content (Orndorff and Dworkin, 1980). The low buoyant density of the outer membrane was recently confirmed in the fully motile derivative DK1622 (Simunovic et al., 2003). The main phospholipid in both membranes was phosphatidylethanolamine (60–70% of total phospholipid). The other major phospholipids were phosphatidylglycerol and two unknown phospholipids. Phosphatidylserine and cardiolipin were found only in the cytoplasmic membrane. Substantial amounts of lysophospholipids were found in both membranes, although somewhat more in the outer membrane. They obviously indicate lipase activities, which seem not to be restricted to the outer membrane.

In *Sg. aurantiaca* the main phospholipid was phosphatidylethanolamine (50%), followed by phosphatidylinositol (20%) and phosphatidylglycerol (12%; Caillon et al., 1983). Very high amounts of lysophosphatidylethanolamine were also found. Each phospholipid had a different fatty acid composition. Alkyl ether linkages were common; phosphatidylinositol occurred only as the dialkyl compound. The structural details of an alk-I-enyl-acyl-phosphatidylethanolamine, i.e., a plasmalogen, from *Mx. stipitatus* have been elucidated (Stein and Budzikiewicz, 1987).

From the amount of phosphorus in the lipid fraction of *Sg. aurantiaca*, it has been estimated that only about 40% of the fatty acids are present in phospholipids (Schröder and Reichenbach, 1970). Ceramides and cerebrosides have been isolated from *Cystobacter fuscus* and chemically characterized (Eckau et al., 1984; Dill et al., 1985). Ceramides are long-chain, 1,3-dihydroxy-2-amino bases (sphinganine) with an amide-bound fatty acid. Cerebrosides are sphingolipids consisting of a ceramide with a C-1-sugar. The myxobacterial ceramides all contain 2-hydroxy fatty acids. A novel, long-chain base, 17-methylsphinga-4E,8E-dienine, was found in two of them. The cerebrosides are all galactosides. Cerebrosides are common in eukaryotes, where they play a role in cell-cell recognition and cell adhesion. They have also have been found to be fruiting-body inducers in basidiomycetes.

The capnoids, discovered as a characteristic constituent of the lipids of another group of gliding bacteria, the *Cytophaga*/*Flavobacterium* group, have not been found in myxobacteria (Godchaux and Leadbetter, 1983). The capnoids are C-1 sulfonic acids of sphinganine bases and their ceramides.

With one exception, *Methylococcus capsulatus* (Bird et al., 1971), myxobacteria are the only prokaryotes that are known to synthesize true steroids. *Nannocystis* strains produce cholestenols (Kohl et al., 1983; Zeggel, 1993); *Polyangium* (but not *Sorangium*) and *Cb. minus* produce lanosterol; and *Cb. violaceus*, *Sg. erecta* and *Sg. aurantiaca* contain cycloartenol (Bode et al., 2003). Squalene has been found in many myxobacteria. The cholestenol and squalene content of *Na. exedens* may be up to 0.4% of the dry weight. In contrast to most secondary metabolites, steroids are found in all strains of a species. Recently the key enzyme 2,3(S)-oxidosqualene oxidase has been demonstrated in *Sg. aurantiaca* (Bode et al., 2003).

PIGMENTS AND RESPIRATORY COMPOUNDS. Carotenoids are the main pigments of most myxobacteria. They have been extensively characterized by Kleinig et al. (1970) and especially in *Mx. fulvus* by Reichenbach and Kleinig (1971), who reported the presence of 50–60 different carotenoids and were able to identify 24 of these. Among the Cystobacterineae, the main compounds are always monocyclic carotenoid glycosides containing glucose with a fatty acid attached to the sugar via an ester bond (Kleinig et al., 1970; Kleinig et al., 1971; Reichenbach and Kleinig, 1971). While the Cystobacterineae have glycosides with keto but not with hydroxyl groups, members of the suborder Sorangineae produce glycosides with hydroxyl but not keto functions on the chromophore. *Sorangium* has also been shown to produce a nonesterified carotenoid rhamnoside (Kleinig et al., 1971). Four new carotenoids were recently identified in *Polyangium fumosum* (Jansen et al., 1995). *Nannocystis* contains mainly aromatic carotenoids and no glycosides. Thus apparently certain pigment types are characteristic for taxonomic subgroups (for a review, see Reichenbach and Kleinig, 1984b).

Carotenoid pigments forming esterified glycosides are rather unusual. The main pigment of many myxobacteria, including *Mx. xanthus*, is the deep-red myxobacton, which comprises 70% (by weight) of the total carotenoids of *Mx. fulvus*; it consists of 1′,2′-dihydro-1′-hydroxy-4-keto-torulene glucoside, esterified via glucose to a variety of unbranched, straight-chain fatty acids. This structure has been reinvestigated and corroborated (Eckau et al., 1984). An additional 10% of the total carotenoids consists of myxobacton esters, which contain 3,4-dehydro torulene rather than 4-keto torulene. In *Myxococcus*, complex mixtures of carotenoids are found, but only monocyclic and acyclic compounds occur. The carotenoid content of late log-phase cultures of *Mx. fulvus* Mx f2 has been determined. Acetone extracted carotenoids of such cells typically represent 0.003% of the dry weight of dark-grown cells and 0.03–0.06% of light-grown cells (Reichenbach and Kleinig, 1971). This difference between light- and dark-grown cells increases to 20-fold as the cells enter stationary phase. The carotenoids are exclusively located in the cytoplasmic membrane fraction, where they constitute up to 0.14% of the dry weight (Kleinig, 1972).

The effect of various inhibitors of the cyclization reaction of carotenoid synthesis has also been studied (Reichenbach and Kleinig, 1971; Kleinig, 1974a; Kleinig, 1975). In laboratory cultures, there is virtually no turnover or degradation of carotenoids. A system for the in vitro synthesis of C15 to C60 polyprenols from isopentenylpyrophosphate with a crude enzyme preparation from *Mx. fulvus* has been developed (Beyer and Kleinig, 1985).

The only demonstrated role of carotenoids in myxobacteria is to provide protection against photooxidation (Burchard and Dworkin, 1966b). Dark-grown cultures, which produce only small amounts of carotenoid, lyse quickly if illuminated upon entry to stationary phase of growth. If, however, the cells are exposed to light during exponential growth, carotenogenesis is photoinduced and the cells become resistant to photokilling. In *Mx. xanthus*, protoporphyrin IX was shown to be the photosensitizing pigment (Burchard and Dworkin, 1966b). Photokilling has also been demonstrated with carotenoid-free mutants of *Mx. fulvus* Mx f2. The killing effect is seen only if the mutants are illuminated with daylight intensities (about 40,000 lux; H. Reichenbach, unpublished observations). However, whether all myxobacteria accumulate protoporphyrin IX as a photosensitizer is unclear; protoporphyrin IX could not be detected, for example, in *Mx. fulvus* (H. Reichenbach, unpublished).

The carotenoid synthesis of myxobacteria is induced by light (Burchard and Dworkin, 1966b; Burchard and Hendricks, 1969; Reichenbach and Kleinig, 1971), and its control in *Mx. xanthus* involves a complex regulatory circuit (for reviews, see Hodgson and Murillo [1993] and Hodgson and Berry [1998]). Many carotenoid biosynthetic genes (*crt* genes) are clustered in the *crtEBDC* and *carB* operons, which are repressed in the dark by CarA. In outline, the reception of a blue light signal by CarF results eventually in the inactivation CarA. The light receptor, CarF, is remarkably similar to Kua, a family of proteins of unknown function that is widely distributed among eukaryotes (Fontes et al., 2003). But little is known about its interaction with protoporphyrin IX. Central to this response is the activation of the light-inducible promoter, *PcarQRS*, and the transcription of three downstream genes, *carQ*, *carR* and *carS* (Gorham, et al., 1996). CarQ is a member of the ECF (extracytoplasmic function) subfamily of RNA polymerase σ factors that is responsible for initiation at *PcarQRS*. CarR is an anti-σ factor that sequesters CarQ in a transcriptionally inactive complex. CarR was found to be unstable in illuminated stationary phase cells, providing a possible mechanism by which the CarR-CarQ complex is disrupted (Browning et al., 2003). In the light, CarS is synthesized and activates the *crtEBDC* operon by preventing CarA from binding to its operator (Whitworth and Hodgson, 2001). CarS is therefore an antirepressor. CarA is a novel protein consisting of a DNA-binding domain of the MerR family of transcriptional regulators, directly joined to a cobalamin-binding domain. The presence of vitamin B_{12} or some other cobalamin derivatives is absolutely required for activation of the *carB* promoter by light (Cervantes and Murillo, 2002).

Pigments other than carotenoids are also produced by myxobacteria. A pale-yellow pigment is found in *Mx. xanthus* (Gerth et al., 1983). On certain media, the colonies of *Cb. violaceus* (= *Ar. violaceum*) develop a deep purple-violet color, probably due to melanoid pigments (Kuhlwein and Gallwitz, 1958; Reichenbach, 1965c). A red pigment of *Cb. violaceus* is probably a dopachrome (Mayer, 1967). Melanoid pigments are also relatively often seen with individual strains of many other species, especially on peptone-containing media, e.g., with *Cystobacter*, *Archangium*, *Corallococcus* and *Stigmatella*. Liquid cultures of *Sg. aurantiaca* in peptone medium turn a deep black color within 1–2 h after reaching the stationary phase (Reichenbach and Dworkin, 1969a). The slimy swarms of some strains of *So. cellulosum* on CA2 agar become deep violet to black after 2–4 weeks. *Myxococcus virescens* and *Kofleria flava* are bright greenish-yellow, especially on protein-containing media. Several myxococci, especially

Mx. virescens, excrete a greenish-yellow diffusing pigment that appears to be myxochromid (Trowitzsch-Kienast et al., 1993). Plate cultures of *Mx. stipitatus* show under the UV lamp at 366 nm a bright yellow fluorescence (Lampky and Brockman, 1977) that is caused by phenylamides, or stipiamides (Kim et al., 1991; Trowitzsch-Kienast et al., 1992). Often the various shades observed with different strains and species are only due to differences in the quantitative proportions of the same pigments. Fruiting bodies, and especially the walls of the sporangioles, are often very intensely colored, but the chemical nature of these pigments is not known.

The respiratory quinones of the myxobacteria are exclusively menaquinones (Kleinig, 1972; Kleinig et al., 1974b). A survey of 11 genera and 20 species of both suborders showed that the menaquinone pattern of the myxobacteria is completely uniform and comprises virtually only MK-8 (Yamanaka et al., 1987; M.D. Collins, personal communication). Dworkin and Niederpruem (1964b) have characterized the terminal respiratory pigments of *Mx. xanthus* and have shown them to include cytochromes *a*, *b* and *c* in addition to presenting tentative evidence for the presence of flavin-linked enzymes.

MEMBRANES AND MEMBRANE PROTEINS. The membranes of *Mx. fulvus* consist of about 64% protein and 29% lipid, the latter comprising mainly (25%) phospholipid (Kleinig, 1972). The inner and outer membranes of *Mx. xanthus* strain DK1622 were fractionated (Simunovic et al., 2003). Membranes were enriched from spheroplasts of vegetative cells and then separated into three peaks on a three-step sucrose gradient. The high density fraction corresponded to inner membrane (IM), the medium density fraction corresponded to hybrid membrane (HM), and the low density fraction corresponded to outer membrane (OM). Each fraction was subjected to further separation on discontinuous sucrose gradients, resulting in the emergence of discrete protein peaks within each major fraction. The purity and origin of each peak were assessed using succinate dehydrogenase (SDH) activity as the IM marker and reactivity to lipopolysaccharide core and O-antigen monoclonal antibodies as the OM markers. As previously reported (Orndorff and Dworkin, 1980), the OM markers localized to the low density membrane fractions, while SDH localized to high density fractions (Simunovic et al., 2003). Immunoblotting was used to localize important motility and signaling proteins within the protein peaks. CsgA (the developmental C-signal producing protein) and FibA (a fibril-associated zinc metalloprotease) were localized in the IM. The motility lipoproteins Tgl and Cgl were localized in the OM. FrzCD (a methyl-accepting chemotaxis protein) was predominantly located in the IM, although lesser amounts were found in the OM. PilA (the major subunit of type IV pili) was distributed in all the fractions. Two-dimensional polyacrylamide gel electrophoresis illustrated the presence of proteins that were unique to the inner and outer membranes. Characterization of proteins within an unusually low density (ρ = 1.072–1.094 $g \cdot cm^{-3}$) membrane peak showed the presence of Ta-1 polyketide synthetase, which synthesizes the antibiotic myxovirescin (Simunovic et al., 2003).

Six of the membrane polypeptides changed substantially during aggregation (Orndorff and Dworkin, 1982): during the early stages of fruiting, protein T disappeared from the soluble fraction of *Mx. xanthus*, when proteins S and U first appeared, and then increased dramatically. Protein S (Inouye et al., 1979b) has been particularly well studied. In vegetative cells it amounts to less than 1% of the soluble protein, but during fruiting body formation, its rate of synthesis rises to 15% of total protein synthesis. In the presence of Ca^{+2}, protein S assembles on the surface of the maturing myxospores (Inouye et al., 1979a). Certain domains in the amino acid sequence of protein S show homologies to the Ca^{+2}-binding sites of calmodulin. The functional correspondence of those areas was demonstrated by site-specific mutations, which eliminated the Ca-binding property of protein S together with its ability to accumulate on the myxospores. Protein S also has some homology with the bovine-lens protein, α-crystallin (Inouye et al., 1983a; Teintze et al., 1988; Wistow, 1990).

Another development-specific protein is a myxobacterial hemagglutinin (MbhA), a lectin that is induced during the developmental aggregation of *Mx. xanthus* (Cumsky and Zusman, 1981). It appears to be localized in the periplasmic space or loosely bound to the cell surface and to recognize a galactose-containing, complex receptor. Its distribution over the cell surface is uneven, as it is found in patches mainly at the cell poles (Nelson et al., 1981). The 28-kDa protein contains four highly conserved domains of 67 amino acids each, which are reflected in four strong internal homologies in its gene (Romeo et al., 1986). MbhA is produced primarily by the peripheral rods, which never enter fruiting bodies or sporulate (O'Connor and Zusman, 1991a; O'Connor and Zusman, 1991b; O'Connor and Zusman, 1991c).

Using an iodination technique, substantial changes in the pattern of accessible surface proteins of *Mx. xanthus* were shown to take place during development (Maeba, 1983). A glycoprotein, probably a peripheral membrane protein that is present only in vegetative cells, was further characterized (Maeba, 1986). The 74-kDa

protein contained about 15% carbohydrate, mainly neutral sugars, but also some hexosamines and uronic acids. It made up 1% of the total cell protein and might play a role in cell-cell interactions.

A different approach to the study of the dynamics of the cell surface during development has been the use of monoclonal antibodies against cell-surface antigens (CSAs) of vegetative and developing cells (Gill et al., 1985). In this way, many different CSAs of *Mx. xanthus* have been identified (e.g., Gill and Dworkin, 1986; Gill and Dworkin, 1988). While most of the antibodies are directed against cell-surface proteins, some are directed against LPS or, in the case of CSA 1604, against a large, 150-kDa complex consisting of at least two protein subunits and LPS (Jarvis and Dworkin, 1989a; Jarvis and Dworkin, 1989b). Other monoclonal antibodies are directed against cell-surface proteins that appear uniquely during development (Gill and Dworkin, 1986).

Transfer and expression of myxobacterial genes in *E. coli* have identified some proteins. An 18.7-kDa basic protein coded by the *vegA* gene of *Mx. xanthus* turned out to have amino acid homologies with certain histones and may function as a DNA-binding protein. It is essential for vegetative growth (Komano et al., 1987). Also, the *Mx. xanthus* gene *fprA* was shown to code for a protein that binds flavin mononucleotide. Overexpression of the gene in *E. coli* leads to a spectacular increase in flavin biosynthesis, but the FprA protein seems to be an enzyme not in the flavin biosynthetic pathway (Shimkets, 1990b) but rather in vitamin B_6 biosynthesis (Lam and Winkler, 1992).

NUCLEIC ACIDS. The G+C content of myxobacterial DNA is between 67 and 72 mol% (as measured by buoyant density, thermal melting, and high pressure liquid chromatography [HPLC]; Mandel and Leadbetter, 1965; McCurdy and Wolf, 1967; Behrens et al., 1976; Mesbah et al., 1989).

As a group, the myxobacteria have among the largest bacterial genomes. The genome size of *Mx. xanthus* FB is 9450 kilobase pairs (kbp; Chen et al., 1990), double that of *E. coli* (4700 kbp). The genome size of *So. cellulosum* So ce56 is about 12.2 Mb (Pradella et al., 2002). Genome sequencing of these two species is in progress. The genome size of *Sg. aurantiaca* DW 4/3.1 is 9350 kbp (Neumann et al., 1992). Genome sizes of a variety of *Sg. aurantiaca* and *Sg. erecta* isolates were examined and ranged from 9.2 to 10.01 Mb. Thus the genome size of this group appears to be uniformly large. In the two species that have been examined, the genome is arranged in a single circular chromosome (Chen et al., 1990; Chen et al., 1991; Neumann et al., 1993).

The DNA of *Mx. xanthus* strain FB is methylated at cytosine sites (Yee and Inouye, 1982). In rapidly growing cells, the DNA is undermethylated, and the degree of methylation increases when growth slows. *Myxococcus xanthus* RNA polymerase shows the usual subunit composition, but two slightly different σ factors have been obtained from vegetative cells (Rudd and Zusman, 1982).

A most unusual kind of nucleic acid, msDNA, which was first discovered in *Mx. xanthus*, has raised many intriguing questions (Yee et al., 1984). Found in nearly all myxobacteria (Dhundale et al., 1985), msDNA is a single-stranded DNA and 500–700 copies of it are present per genome. The DNA is 162 bases long, and its 5′-end is linked via a 5′ to 2′-phosphodiester bond with a guanidine residue in an RNA (msdRNA), which is 77 bases long. The RNA has an extremely stable stem-and-loop structure. The coding regions for msDNA and msdRNA are found side by side at one specific site in the *Myxococcus* genome, but they are oriented in opposite directions and overlap with 8 bases at their 3′-ends (Dhundale et al., 1987). A very similar msDNA (81% sequence homology) with a corresponding genome structure has been found in *Sg. aurantiaca* (Furuichi et al., 1987a; Furuichi et al., 1987b). A second species of such DNA (mrDNA) was later discovered in *Mx. xanthus* (Dhundale et al., 1988b). However, mrDNA is much shorter, and it has a completely different DNA and RNA base sequence, but the RNA still has a similar secondary structure to that of msRNA. Also, there seem to be only 100 copies of mrDNA per genome.

The msDNA is synthesized by a reverse transcriptase with an associated ribonuclease H activity. The enzyme uses a folded RNA precursor as a primer and a template (Lampson et al., 1989). The gene of the reverse transcriptase has been found immediately downstream from the msdRNA region and codes for 485 amino acids, which show sequence homology with retroviral reverse transcriptases (Inouye et al., 1989). In fact, *Mx. xanthus* actually contains two reverse transcriptases (Inouye et al., 1990b). The wide distribution of msDNA in myxobacteria, as well as a comparison of codon usage in the reverse transcriptase gene and in other *Myxococcus* genes, suggests that the system is very old and was not acquired recently (in contrast to a similar system in certain *E. coli* strains). By deletion mutation, msDNA synthesis could be eliminated, but this had no significant effects on growth, motility and morphogenesis compared to the wild-type strain (Dhundale et al., 1988a).

No evidence has been found for the presence of a poly(dT-dG) · poly(dC-dA) (TG) element in *Mx. xanthus* (Morris et al., 1986).

While the half-life of mRNA is about 3.5 min in vegetative cells of *Mx. xanthus*, 5–10 species of mRNA with a much longer half-life (13–30 min) could be demonstrated during fruiting body formation (Smith and Dworkin, 1981; Nelson and Zusman, 1983). One of the long-lived mRNAs is for protein S. The stable mRNA can amount up to 30–40% of the total mRNA.

Although no clear evidence has been presented for free, self-replicating plasmids in myxobacteria, several early reports suggest that extrachromosomal DNA may be present. Thus, after chloramphenicol resistance was induced in *Mx. xanthus* RB, a burst of synthesis of circular, covalently linked, extrachromosomal DNA was observed (Brown and Parish, 1976a). The resistance was due to chloramphenicol acetylation (Burchard and Parish, 1975). Also, it was possible to transfer resistance to several different antibiotics from R factor-containing strains of *E. coli* to several *Myxococcus* species by conjugation (Parish, 1975). In some cases, extrachromosomal DNA could be demonstrated in the resistant *Myxococcus* strains, and the resistance could be transferred to other *Myxococcus* strains by conjugation.

PHAGES AND BACTERIOCINS. All myxophages that have been found thus far contain double-stranded DNA of around 50 kbp. The first myxophage to be isolated was *Mx. xanthus* phage MX-1. It came from a sample of cow dung and is a virulent phage resembling coli phage T2 with an icosahedral head and a contractile tail sheath. It has a latent period of 2–2.5 h (30°C), a 2-h rise, and a burst size of about 100 (Burchard and Dworkin, 1966a). MX-1 attacks *Mx. xanthus* as well as the related species *Mx. virescens* and *Mx. fulvus* (Tsopanakis and Parish, 1976). It has a genome size of 130–150 $\times$ 10^6 Da and a G+C content of 56 mol% (using buoyant density; a reinvestigation with a chemical method gave 50–52 mol%; Brown et al., 1976c).

MX-1 shows the classical pattern of infection and propagation known for *E. coli* phages (Voelz and Burchard, 1971). However, if cells are infected with MX-1 during glycerol induction of myxospores (see the section Functions of Myxospores and Fruiting Bodies in this Chapter), there is a brief period during which the phage may be taken up without interfering with myxospore induction. The phage is trapped in the myxospore and is released upon germination (Burchard and Dworkin, 1966a).

Defective phage particles, originally described as rhapidosomes (Reichenbach, 1965a), have been seen in several myxobacteria (Reichenbach, 1967; McCurdy and McRae, 1974; Brown et al., 1976b). When the ultracentrifugal pellets of culture supernatants of six strains of *Mx. xanthus*, *Mx. virescens* and *Mx. fulvus* were examined under the electron microscope, all six strains produced small quantities of phage particles (Brown et al., 1976b). An endogenous bacteriophage was detected in a derivative of *Mx. xanthus* FB through the use of transposon tagging (Starich et al., 1985). Transposon mutagenesis with Tn*5* revealed a class of bacterial mutants that transduced the transposon through the culture supernatant. Virus-like particles, 30–35 nm in diameter, co-purified with the transducing activity. A physical map of this region of the genome comprised multiple units of about 80 kbp each (Starich and Zissler, 1989). All but one of these has been deleted in *Mx. xanthus* DK1622, which was subjected to UV irradiation, resulting in a genome that is 220 kbp smaller than that of FB (Chen et al., 1990).

Restriction of phage MX-1 has been shown directly with a strain of *Mx. virescens* (Morris and Parish, 1976). The strain became fully sensitive after curing by UV irradiation. Also, two restriction endonucleases have been demonstrated in the restrictive strain. Such enzymes have been found in many different myxobacteria (Mayer and Reichenbach, 1978). Mx8 expresses a nonessential DNA methylase, Mox, which modifies adenine residues in *Xho*I and *Pst*I recognition sites, CTCGAG and CTGCAG, respectively, on both phage DNA and the host chromosome (Magrini et al., 1997). Mox may protect Mx8 phage DNA against restriction upon infection of some *Mx. xanthus* hosts.

A strategy was applied to isolate transducing phages from a collection of *Mx. xanthus* strains using certain sensitive strains as indicators, such as strain FB. Several *Mx. xanthus* phages have been isolated (Brown et al., 1976b; Campos et al., 1978; Geisselsoder et al., 1978; Martin et al., 1978), including morphological types either with very short tails, e.g., MX-4, or with long tails, e.g., MX-8 and MX-9. Also isolated have been λ-like myxophages (Rodriguez et al., 1980). MX-8, which has been particularly well characterized (e.g., Orndorff et al., 1983; Stellwag et al., 1985), is a generalized transducing phage with a linear, double-stranded DNA (56 kbp). The genome has a terminal redundancy of 8% and is circularly permuted over at least 40% of its length. The MX-8 prophage is integrated into the bacterial genome by a site-specific recombination between the *attB* and *attP* sites that has been extensively examined (Tojo et al., 1996; Salmi et al., 1998; Magrini et al., 1999a; Magrini et al., 1999b; Tojo and Komano, 2003). Another well-studied transducing phage is MX-4 (Campos et al., 1978; Geisselsoder et al., 1978).

Myxobacteria have been shown to produce bacteriocins, termed "myxocins." The first, xanthacin, was discovered in *Mx. xanthus* (McCurdy and McRae, 1974). This myxocin is produced

after mitomycin C induction, is active exclusively on a few myxobacteria, and consists of spherical bodies of somewhat variable size. It resembles membrane vesicles and may in fact have been a defective phage. Fulvocin C, one of three substances with bacteriocin activity from *Mx. fulvus* Mx f16 (Hirsch, 1977), turned out to be a protein consisting of 45 amino acid residues (molecular weight 4672 Da) with no lipid or carbohydrate attached. Disulfide bridges (probably four) make it a very compact molecule (Tsai and Hirsch, 1981). It was the first bacteriocin for which a complete structure could be presented. Fulvocin C, at a minimal inhibitory concentration of 0.1–0.25 μM, killed 16 out of 17 tested *Mx. fulvus* strains, the exception being the producer, and appeared to exert its effect on the cell membranes (Hirsch et al., 1978).

Gliding Motility

Gliding is the translocation of cells on surfaces without the use of flagella (McBride, 2001). The speed of gliding cells varies, depending on the substrate and the temperature; typically it is between 3 and 13 μm/min (*Mx. virescens*, 32°C, on peptone agar, measured in movie frames; Reichenbach, 1966). Gliding cells always deposit slime trails (Fig. 5). *Myxococcus xanthus* cells glide on solid surfaces in the direction of the long cell axis at rates of 1–2 μm/min (Kaiser and Crosby, 1983) and reverse their direction of movement every 6.8 min on average (Blackhart and Zusman, 1985).

Genetic analysis of *Mx. xanthus* motility has revealed the presence of two nearly separate motility systems enabling cell translocation over solid surfaces (Hodgkin and Kaiser [1979a] and Hodgkin and Kaiser [1979b]; for reviews, see Shimkets [1990b], Shi and Zusman [1993a], Hartzell and Youderian [1995], Youderian [1998], Ward and Zusman [1999], Kaiser [2000a], and Kearns and Shimkets [2001a]). The "A" system (for adventurous) enables cells to move as individuals without direct contact with other cells. In nature this system may allow cell dispersal for foraging. The A system also contributes to the movement of cells within groups. Thus far, 33 genes known to be essential for A motility have been identified and sequenced. From the frequency of mutagenesis and the target sizes of the genes it has been estimated that about half of the A motility genes have been discovered (Youderian et al., 2003). Six of these genes encode different homologues of the TolR, TolB and TolQ transport proteins, suggesting that A motility is dependent on biopolymer transport (Youderian et al., 2003).

The mechanism of A motility is unknown. One hypothesis is that A motility may involve extrusion of a propellant that swells as it hydrates, pushing the cell forward (Wolgemuth et al., 2002). Another hypothesis is suggested by the presence of a complex cell surface apparatus, revealed by electron microscopy in *Mx. xanthus*, *Mx. fulvus* and implied in *Sg. aurantiaca*. It has been suggested that the apparatus produces traveling waves along the surface of the cell which in turn may propel the cell (Freese et al., 1997; Lünsdorf and Reichenbach, 1989; Lünsdorf and Schairer, 2001). To this point, the A motility mutants have not been studied carefully enough to provide support for any particular model.

The "S" system (for social) enables cell movement only if cells are within one cell length of one another (Kaiser and Crosby, 1983). In nature this system plays an important role in multicellular behaviors like fruiting body formation. S motility is genetically and functionally similar to twitching motility of many Gram-negative bacteria including *Pseudomonas* and *Neisseria* (Kaiser, 2000a). Twitching and S motile cells

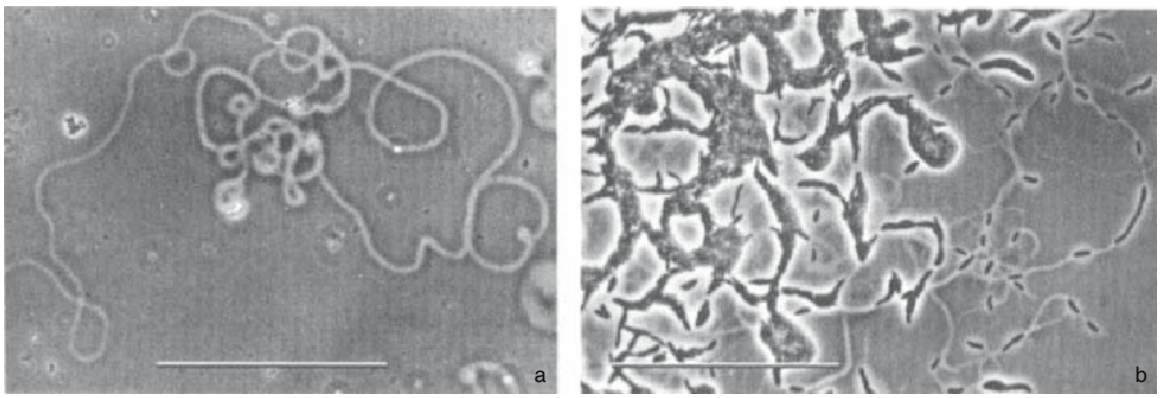

Fig. 5. Slime tracks as seen on thin agar layers in chamber cultures. a) *Nannocystis exedens*. b) *Myxococcus fulvus*; the spots on the left are cell clusters, not single cells. Bar = 100 μm. Phase contrast.

display tufts of type IV pili (also called "fimbriae") on the leading cell pole (Kaiser, 1979a; Henrichsen, 1983). Pili are 5–8 nm wide and may exceed the length of a cell (MacRae and McCurdy, 1975; MacRae and McCurdy, 1976; MacRae et al., 1977; Dobson and McCurdy, 1979; Arnold and Shimkets, 1988a). Fimbriae have been observed with many different species of both suborders; the only negative result was with *Nannocystis*, but this may have been due to technical problems. The fimbriae may be restricted to one of the two cell poles, and up to six have been seen per cell (Kaiser, 1979a). Tiny holes in the outer membrane, 6.5–8.5 nm wide and surrounded by a collar of 2.6 nm, which sometimes shows a ring of 12 spikes, have been proposed to be the insertion sites of the fimbriae (MacRae et al., 1977). Movement appears to result from pilus extension, pilus attachment, and pilus retraction to pull the cell forward like a grappling hook (Merz et al., 2000; Sun et al., 2000; Skerker and Berg, 2001). The pilus retraction motor, PilT, is the most powerful molecular motor yet examined. The force exerted by a single retracting *Neisseria* pilus was estimated to exceed 100 pN (pico Newtons; Maier et al., 2002). When a cell reverses direction, the pili on one cell pole are replaced by pili on the opposite cell pole (Sun et al., 2000). It has been suggested that the pili from one cell attach to cell surface appendages known as fibrils from another cell to mediate group movement (Li et al., 2003). There is an excellent correspondence between genetics and physiology with regard to S motility. The majority of the known S motility genes are involved in the production of type IV pili or the pilus receptor on the cell surface (Wu and Kaiser, 1995; Wu et al., 1997; Wu et al., 1998; Lancero et al., 2002; Li et al., 2003).

A mutant becomes nonmotile if it is A^-S^-, which normally requires two mutations. A single mutation in one gene, *mglA*, has the same effect, suggesting that it is shared between the two systems. The *mglA* gene encodes a 22-kDa GTPase that is thought to act as a switch between the two motility systems (Hartzell and Kaiser, 1991). MglA interacts with MasK, a protein of the STY kinase family (Thomasson et al., 2002). MasK, expressed in *E. coli*, was shown to phosphorylate tyrosine residue(s). The gain-of-function *masK815* mutant is restored in S motility and displayed increased production of cell surface fibrils. Attempts to eliminate the *masK* gene have been unsuccessful, suggesting that it is essential for growth. The A motility system also utilizes a tyrosine kinase, AgmO, although the role of this protein has not yet been determined (Youderian et al., 2003).

Myxococcus xanthus cells show directed movements towards glass and latex beads and clumps of prey bacteria (Dworkin, 1983a). The mechanism(s) of such long range directed movement remain a mystery. Elasticotaxis, a phenomenon first described by Roger Stanier, results from delicate structural disturbances in the substrate surface, such as are produced in agar plates by mechanical stress. Cells orient their movement perpendicular to stress forces within the agar (Stanier, 1942a). Elasticotaxis is mediated by the A motility system (Fontes and Kaiser, 1999). Cells also direct their movement to certain chemicals. Chemotaxis has been observed to complex chemical mixtures (Shi et al., 1993b) and to certain isomers of the major membrane lipid phosphatidylethanolamine (PE; Kearns and Shimkets, 1998).

Myxococcus xanthus exhibits the hallmarks of chemotactic behavior, excitation and adaptation in response to PE. Certain molecular PE species increase the reversal period as much as sixfold (excitation; Kearns and Shimkets, 1998). Cells return to the pre-stimulus reversal frequency in about an hour (adaptation; Kearns and Shimkets, 1998). Dilauroyl PE (PE-12:0/12:0), dioleoyl PE (PE-18:1ω9c/18:1ω9c), and PE with 16:1ω5c at both the *sn*-1 and *sn*-2 positions (PE-16:1ω5c/16:1ω5c) cause excitation, whereas many other species do not (Kearns and Shimkets, 1998). These results begin to bring into focus properties of the as yet unknown PE binding protein that serves as the receptor (hereafter called "PE receptor"). A major unresolved point is whether the PE receptor recognizes the *sn*-1 fatty acid, the *sn*-2 fatty acid, or both.

Chemosensory systems analogous to those found in the enteric bacteria appear to play roles in the response to PE. Excitation to PE appears to be mediated by the Dif signal transduction pathway. The *difA* gene encodes a methyl-accepting chemotaxis protein (MCP), *difC* encodes a CheW homolog, *difD* encodes a CheY homolog, and *difE* encodes a CheA homolog. Excitation to both PE-12:0/12:0 and PE-16:1ω5c/16:1ω5c requires DifA (Kearns et al., 2000). The DifA ligand is unknown, but binding of PE to DifA directly is unlikely. The periplasmic face of DifA is approximately 15 amino acids, much smaller than that of Tar (Kearns and Shimkets, 2001a). Thus understanding the nature of the stimulus for DifA is important.

Another set of chemosensory genes, the "*frizzy*" (*frz*) genes, also regulates the frequency with which the cells change the direction of their movement (Blackhart and Zusman, 1985) and the response to PE (Kearns and Shimkets, 1998). While wild type cells reverse their direction of movement every 6–7 min, some Frz mutants do so every 2 h or every 2 min. The genes and their gene products have been analyzed in considerable detail (for review, see Ward and Zusman,

1997). The FrzCD protein encodes the MCP (McBride et al., 1989b) and the FrzE protein is a fused CheA-CheY homolog (McCleary and Zusman, 1990a; McCleary and Zusman, 1990b). The *frzCD* and *frzE* mutants exhibit excitation to PE but had aberrant adaptation (Kearns and Shimkets, 1998). As in the enteric bacteria, the direction of *Mx. xanthus* movement is controlled by methylation and demethylation reactions in the Frz system (McCleary et al., 1990c).

Extracellular Matrix

An extracellular matrix composed of polysaccharide and protein connects bacteria living in biofilms. The extracellular matrix of *Mx. xanthus* appears to be extruded as long thin fibrils, about 30 nm in diameter, that emanate from many points on the cell surface. Fibrils have been visualized using a wide variety of fixation techniques and microscopy methods (Arnold and Shimkets, 1988b; Behmlander and Dworkin, 1991; Behmlander and Dworkin, 1994; Merroun et al., 2003), most notably transmission electron microscopy of freeze-substituted cell thin sections (Kim et al., 1999), which is the most advanced approach for examining surface layers (Beveridge, 1999). Fibril synthesis is induced by starvation (Arnold and Shimkets, 1988b), stimulated by cell contact (Behmlander and Dworkin, 1991) and Ca^{+2} (Kim et al., 1999), and repressed by the *stk* locus (Dana and Shimkets, 1993).

The extracellular matrix is composed of a polysaccharide core with noncovalently associated protein (Behmlander and Dworkin, 1994). Mutants lacking the ability to secrete the extracellular matrix polysaccharide fail to bind Congo red or calcofluor white (Arnold and Shimkets, 1988a; Arnold and Shimkets, 1988b; Dana and Shimkets, 1993; Ramaswamy et al., 1997; Kim et al., 1999). The most carefully studied of these mutants has been isolated twice; the first was based on loss of S motility, where it was called *dsp* (Shimkets, 1986), and the second based on loss of development, where it was called *dif* (Yang et al., 1998). Now clearly these two sets of mutants are defective in the same genes (Lancero et al., 2002). The phenotype of the *dsp*/*dif* mutants provides one level of insight into the many functions of the extracellular matrix. These mutants are defective in adhesion to surfaces, cohesion to other *Mx. xanthus* cells, S motility (also known as twitching in other Gram-negative bacteria), fruiting body morphogenesis, sporulation, developmental gene expression, and chemotaxis to phosphatidylethanolamine (PE). The *dsp*/*dif* mutants are blocked about 8 h into the developmental program and fail to express roughly one-third of the developmentally regulated genes (Li and Shimkets, 1993). The *dsp*/*dif* locus encodes components of a chemotaxis pathway with homology to the Che proteins of enteric bacteria (Yang et al., 1998).

Fibrils are extracted from cells with 0.5% sodium dodecylsulfate (SDS) and sedimented by low speed centrifugation (Behmlander and Dworkin, 1991). Fibrils can restore cohesion, chemotaxis, and fruiting body development to mutants that cannot produce fibrils by simply adding them back to cells (Chang and Dworkin, 1994; Yang et al., 2000b; Kearns et al., 2002). The functions of the many proteins in the matrix are as yet unknown. One fibril protein, a zinc metalloproteinase known as FibA, is essential for PE chemotaxis to dilauroyl PE and PE-16:1ω5c/16:1ω5c but not dioleoyl PE (Kearns et al., 2002).

The excreted polysaccharide appears to contain amino sugars, among others (Sutherland and Thomson, 1975; Sutherland, 1979). Slime from fruiting bodies resembles in its overall composition that produced in vegetative cultures. In *Mx. xanthus*, fibril polysaccharide is composed of galactose, glucosamine, glucose, rhamnose and xylose (Behmlander and Dworkin, 1994). A large extracellular protein-polysaccharide-lipid complex with proteolytic activity has been isolated from culture supernatants of *Mx. virescens* (Gnosspelius, 1978b). A glycopeptide with a heat-stable blood anticoagulant activity, named "myxaline," has been obtained from the culture broth of *Mx. xanthus* (El Akoum et al., 1987; Masson and Guespin-Michel, 1988). The glycan part contains *N*-acetyl amino sugars, and the peptide is rich in glutamic acid and serine. The excreted slime must be chemically different in the three suborders of myxobacteria, since Congo red (0.01% [w/v] aqueous solution) stains the slime of the Cystobacterineae but not that of the Sorangineae (McCurdy, 1969b) or the Nannocystineae.

Myxobacterial Colonies

On media with a relatively low nutrient content (like VY/2 and CY agar), colonies of myxobacteria spread over the agar surface. Such colonies are called "swarms." With a few exceptions the colony does not move as a whole but simply increases in diameter because of gliding motility and cell division.

The appearance of a swarm depends on the species and the medium. On rich media, such as those with a high peptone content (around 1%), myxobacterial colonies may remain small and more or less compact; sometimes they are even circular, convex, and with an entire edge like ordinary bacterial colonies. The typical myxobacterial colony is, however, a swarm sheet consisting of cells and excreted slime; much of the latter

is probably composed of interwoven slime trails. The swarms often contain conspicuous veins, rings, and ridges or even depressions in the agar surface. Such patterns can be characteristic for specific taxonomic groups (see below). The swarm sheet can sometimes be loosened from the agar surface with water (e.g., with *Cystobacter* and *Stigmatella*); sometimes, however, it sticks tenaciously to the agar surface, occasionally to such an extent that the agar is torn into pieces when the aging swarm sheet contracts (especially with *Sorangium*). In some cases, the swarm sheet becomes so tough that it is very difficult to cut with the inoculating loop (with *Archangium*, *Cystobacter* and *Melittangium*); in other cases, it is soft and slimy and can easily be scraped off the plate (with *Myxococcus*). Often the myxobacteria penetrate the agar (even 1.5% agar), and the swarm spreads below the agar surface, sometimes penetrating to the very bottom of the dish (often with *Polyangium*). In such cases, the swarm may completely disappear below the surface, and its former position can be recognized only by a shallow depression. All members of the Sorangineae and Nannocystineae tend to grow within the agar. However, some members of the Cystobacterineae also do so, although here it is often a consequence of swarm degeneration. Some myxobacteria corrode the agar surface to the extent that they produce long tunnels or large, cavern-like holes in the plate. This is typical of *Polyangium* and especially of *Nannocystis*.

The swarm edge usually shows characteristic flame-like protrusions, or flares. Sometimes wide, tongue-like depressions are produced (by *Chondromyces* and other members of the Sorangineae), or isolated narrow trenches radiate from the swarm center far into the surrounding agar surface (*Polyangium* and *Nannocystis*). Occasionally, massive ridges are also seen at the swarm edge (*Chondromyces*, *Polyangium* and *Nannocystis*). At the swarm edge, the swarm may consist of only one cell layer, but as a rule the swarm sheet is composed of many layers that quickly pile up behind the margin. When growing on very lean media, most of the swarm may be only one cell thick, although even then the bacteria tend to concentrate themselves in certain areas, such as along radial tracks. In large swarms, most of the cell population may be found in the outer regions, and if no fruiting bodies or myxospores have been produced, the interior may be completely deserted. The speed of the advancing edge is in the range of 1 mm in 9 h (*Cb. violaceus* at 22°C; Reichenbach, 1965b) to about 1 mm in 1.6 h (*Cystobacter* and *Stigmatella* strains at 30°C).

Various taxa may be recognized by their swarm morphology. When plate cultures are flooded with an aqueous 0.01% (w/v) Congo red solution for 5–10 min, the swarm sheets of the Cystobacterineae stain a deep violet-red, while those of the Sorangineae and Nannocystineae remain unstained (McCurdy, 1969b). The swarms of *Myxococcus* and *Corallococcus* typically develop meandering radial veins, which may be particularly conspicuous on CY agar; the swarm sheet usually remains soft and slimy. In contrast, long, more or less straight, branching veins are seen in the swarms of *Cystobacter*, *Archangium*, *Melittangium* and *Stigmatella*. On VY/2 agar, the swarms of most Sorangineae are sunk into the agar and appear as wide shallow depressions at the surface. *Chondromyces* and *Sorangium* often develop long, cable-like veins on the surface that sometimes curl into a ring at one end. Also, isolated rings are often seen in those swarms. With *Chondromyces* swarms, the swarm edge typically consists of a series of tongue- and shell-like shallow depressions. *Polyangium* swarms on VY/2 agar often penetrate the agar to the bottom and characteristically are surrounded by a more or less perpendicular, curtain-like zone composed of tiny, well-separated cell clumps. *Polyangium* and *Nannocystis* growing on streaks of autoclaved *E. coli* often produce long, radiating, narrow trenches in the agar surface, with small cell clusters (and, later on, fruiting bodies) at the end. The two can often be distinguished because the tracks and cell clumps of *Nannocystis* are more delicate. On mineral salts-glucose media, like CA2 and CK6 agar, *Sorangium* often produces swarms with a beautiful, dense network of branching cable-like veins.

Note that the swarm structures described above are usually only seen with strains that have recently been isolated. The swarms of strains that have been transferred many times, or that have been adapted to growth in liquid media, are often very different. Such swarms may be soft and slimy, lacking all morphological differentiation, and, in the case of the Cystobacterineae, sometimes no longer grow on the surface but are sunk into the agar.

A colony dimorphism has been described for *Cb. violaceus* and *Mx. xanthus* and is probably quite common among myxobacteria (Reichenbach, 1965c; Grimm and Kühlwein, 1973a; Grimm and Kühlwein, 1973b; Grimm and Kühlwein, 1973c; A. C. Burchard et al., 1977). This dimorphism may regulate cell motility and consequently the spreading behavior of the colonies. The dimorphism in *Cb. violaceus* affects the slime, the capacity to fruit, and the ability to grow as a homogeneous cell suspension. Also, pigmentation can be affected (deep and pale violet in *Cb. violaceus*, tan or yellow in *Mx. xanthus*). Usually one colony type is more stable, but segregation in both directions is possible, sug-

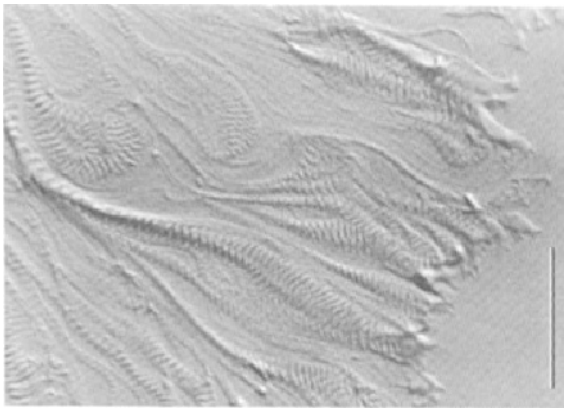

Fig. 6. Oscillating ridges or ripples. *Stigmatella erecta* on Casitone agar; dissecting microscope, oblique illumination. Bar = 200 μm.

gesting a phase variation. Both cell types may serve essential functions in nature. In *Mx. xanthus*, the tan cells preferentially make spores in spite of the fact that tan locked mutants are incapable of completing sporulation unless yellow cells are provided (Laue and Gill, 1995). The results suggest that the yellow cells provide a factor enabling spore maturation.

A striking feature of myxobacterial swarms is the ability of the cells to organize their movement in waves that have been referred to as "ripples," "oscillatory waves," or "traveling waves." Dense fields of regularly arranged ridges are found in long, parallel rays. They are positioned parallel to one another and perpendicular to the direction of the ray. The distance between the ridges is uniform and is approximately equal to the width of the ridges (Fig. 6). In *Mx. xanthus*, a distance of 45 μm from crest to crest has been measured (Shimkets and Kaiser, 1982). The phenomenon was discovered when movies of developing *Corallococcus* and *Myxococcus* swarms were first made. They showed that the ridges actually move, so that the whole field appears to oscillate; hence, the ridges were called "oscillating waves" (Reichenbach, 1965a; Reichenbach et al., 1965f; Reichenbach et al., 1965g). In fact, the movements of the ridges may even speed up and slow down, or pulsate, over a period of several hours. The movement of the ridges is fast enough to be recognized under the dissecting microscope; a speed of about 2 μm/min has been measured in *Mx. xanthus* (Shimkets and Kaiser, 1982). Traveling waves were later found in many other myxobacteria. They appear to occur with all Cystobacterineae and occasionally are also observed with members of the Sorangineae, e.g., *Chondromyces*. With *Sg. aurantiaca*, even waves travelling in opposite directions along the same path have been seen (Reichenbach et al., 1980).

The mechanism of cell movement in the traveling waves has been examined extensively in *Mx. xanthus* (Shimkets and Kaiser, 1982; Sager and Kaiser, 1994; Sager, 1996; Igoshin et al., 2001; Welch and Kaiser, 2001; Borner et al., 2002). Rippling can be induced by purified peptidoglycan and peptidoglycan components, such as *N*-acetyl-glucosamine, *N*-acetylmuramic acid, diaminopimelic acid, and D-alanine (Shimkets and Kaiser, 1982). The CsgA cell signaling protein is essential (Shimkets and Kaiser, 1982). Cell movement occurs along the same axis as the rippling movement and is periodic (Sager and Kaiser, 1994; Sager, 1996; Welch and Kaiser, 2001). The periodicity of individual cells matches the period of macroscopic rippling. When two cells moving in opposite directions meet end to end, they reverse their gliding direction. This periodicity is thought to be linked to the C signal, a cell contact-mediated signaling molecule. Mathematical models quantitatively reproduce the experimental observations and illustrate how intracellular dynamics, contact-mediated intercellular communication, and cell motility can coordinate to produce this behavior (Igoshin et al., 2001; Borner et al., 2002). These models of traveling waves illustrate how cell-contact interactions rather than reaction diffusion can regulate biological pattern formation.

Finally, the shape of myxobacterial swarms may become distorted by stress lines in the agar plate produced, for example, by mechanical pressure and stretching, a phenomenon known as "elasticotaxis" (Stanier, 1942). Elasticotaxis is due to A motility (Fontes and Kaiser, 1999).

Fruiting Bodies

The outstanding trait of the myxobacteria is their ability to form multicellular fruiting bodies (Figs. 7–10), which serve as the housing for the resistant resting cells, the myxospores. The processes that lead to their formation make the myxobacteria the object of considerable interest as model systems for the study of development. There are some excellent reviews focusing on different aspects of fruiting body and myxospore development: Kaiser (1989), Dworkin (1991), Dworkin (1996), White (1993), Shimkets and Dworkin (1997c), Shimkets (1999), and Ward and Zusman (2000).

DESCRIPTION OF FRUITING BODIES. The terminology used to describe the structural components of myxobacterial fruiting bodies is illustrated in Fig. 13. Although complete consistency with usage of terms in other biological systems is not possible, terms that have already acquired a well-defined meaning in other systems should be avoided if they are inappropriate. The term "fruiting body" has a long tradition of

use and may be acceptable in connection with myxobacteria, although in biology, fruiting usually implies sexual processes, and no such events seem to be involved in the case of the myxobacteria. The term "sporangium" has also been applied to these structures, but this term is even more suggestive of sexuality and is best avoided. Most types of fruiting bodies are composed of myxospores, and the walled portions containing these myxospores are in fact communal cysts; they have traditionally been referred to as "cysts." However, since the term "cyst" in microbiology is applied to quite a different structure (i.e., dormant, encapsulated single cells), we propose to use the term "sporangiole" instead and to accept its obvious shortcomings. The advantage of the term sporangiole over "sporangium" is that it is a relatively unusual term and has been used only in connection with a restricted group of fungi (Mucorales), where it is not even used with a consistent meaning. Its use here is thus less likely to cause confusion. Incidentally, the term sporangiole was applied to these myxobacterial structures by Link (1809) in the very first description of a myxobacterium, *Pl. vitellinum* (Fig. 14). The simplest myxobacterial fruiting bodies are mounds of either soft or hardened slime, in the latter case often having bizarre shapes (*Corallococcus* and *Archangium*) or in the former typically having a knob or head with a constriction or a stalk at the base (*Myxococcus*).

The size of myxobacterial fruiting bodies varies between 10 and 1000 µm or greater depending on the species. Many can be seen with the naked eye, especially as they are normally produced in large numbers and often are brightly colored in hues of yellow, orange, red, brown or black. The distribution of fruiting bodies over the swarm usually is random, but sometimes fruiting bodies arise in concentric rings or along radial veins or in various patterns controlled by elasticotaxis (Stanier, 1942a). Fruiting proceeds in the swarm from the center to the periphery. The shape, structure and color of fruiting bodies is species specific—in fact myxobacterial species are mainly defined by their fruiting bodies—but similar shapes were developed by completely unrelated species, e.g., *Stigmatella* and *Chondromyces*, or *Cystobacter*, *Polyangium*, *Byssophagia*, *Jahnia* and *Sorangium*. Also, the shape and color of fruiting bodies may vary substantially within the species.

Most myxobacteria enclose their myxospores in sporangioles, i.e., containers with well-defined walls; the interior of the sporangioles is always hard and tough. The sporangioles may occur singly or in groups; they may rest either directly on or in the substratum or on simple or branched slime stalks.

The following key gives a survey of the different fruiting body types and their relation to the various myxobacterial taxa. Photographs of fruiting bodies of most species are provided for reference (Figs. 7–10). Keep in mind, however, that fruiting body structure and morphology often degenerate quickly after a few transfers upon isolation. Also, strains may be isolated that produce degenerate fruiting bodies from the very beginning. In such cases, only completely atypical knobs and ridges of slime and myxospores are formed. In addition, the fruiting bodies of several myxobacteria have also been studied with the scanning electron microscope, and some very impressive pictures have been obtained (e.g., Brockman and Todd, 1974; Stephens and White, 1980b; Galván et al., 1981; Stephens et al., 1982).

Key to the Fruiting Body Types of Myxobacteria

1. Naked masses of slime and myxospores 2
1′. Myxospores encased in sporangioles 3
2. Fruiting body soft-slimy . . . . . *Myxococcus* (*Kofleria*)
2′. Fruiting body hard, cartilaginous. . . . . *Corallococcus*, *Archangium*
3. Sporangioles single 4
3′. Sporangioles in groups 5
4. Single sporangiole located on or in the substrate . . . . . *Nannocystis*, *Haploangium*
4′. Single sporangiole on top of a stalk . . . . . *Melittangium*, *Stigmatella erecta*
5. Group of sporangioles on or in the substrate . . . . . *Cystobacter*, *Pyxicoccus*, *Polyangium*, *Sorangium*, *Nannocystis*, *Haliangium*, *Byssophaga*
5′. Group of small spherical sporangioles that are often empty and then look glassy transparent, arranged in extended, dense sheets, or often in chains. . . . . *Hyalangium*
5″. Coils of sporangioles sitting on a slime cushion or soft slime stalk . . . . . *Jahnia*
5‴. Cluster of sporangioles on top of an unbranched stalk . . . . . *Stigmatella aurantiaca*, most *Chondromyces* species
5⁗. Clusters of sporangioles on a branched stalk . . . . . *Chondromyces crocatus*

More or less the same morphological types of fruiting bodies are found in the suborders Cystobacterineae and Sorangineae (with the qualification that the Sorangineae produce only fruiting bodies with sporangioles). Still, the course of morphological differentiation may be different

l

with seemingly identical fruiting body types. Thus, *Chondromyces* and *Sg. aurantiaca* both form little treelets, but the stalks and sporangioles are produced in a different way in the two cases. While *Chondromyces* excretes a slime stalk that lifts the undifferentiated cell mass upward, and differentiation of the sporangioles occurs as the last step, *Sg. aurantiaca* piles up a mass of cells with approximately the shape and size of the final fruiting body, then the cells either withdraw from the stalk area or degenerate and lyse in that part, and the sporangioles mature (Fig. 11).

As has already been mentioned, stalks, sporangiole walls, and pigments are produced during fruiting but nothing is known about the chemical composition of these structures and substances. Under the electron microscope, the stalk of *Cm. crocatus* is seen to consist of numerous parallel tubes, which are approximately the diameter of a cell and run in the direction of the long axis of the stalk (McCurdy, 1969a; Abadie, 1971b). The stalk of *Sg. aurantiaca* was found to be composed of tubules wedged against each other and containing cell debris but only rarely a cell or myxospore; the stalk was surrounded by a thin, dense surface layer resembling the wall that surrounds the sporangioles (Voelz and Reichenbach, 1969). The stalk of *Sg. erecta* also was found to be cell free and to consist of slime, although in this case tubules could not be distinguished (Galván et al., 1987). In contrast, scanning electron micrographs suggested that the stalk of *Sg. aurantiaca* is cellular (Stephens and White, 1980b). The contradiction is not yet resolved; perhaps the fruiting bodies examined with the scanning electron microscope had not yet fully matured. In any case, under the light microscope the stalk of *Sg. aurantiaca* looks translucent, unpigmented, and white and thus completely different from the opaque, dark brown sporangioles.

The base of fruiting body stalks is often clearly disk-shaped. The disks apparently arise early during fruiting body development when the aggregated cells move on a circular path at the site of fruiting.

Little is known about the arrangement of the cells within the developing fruiting body, but it appears that this arrangement, and perhaps rearrangements by migrations of certain cell populations, may play a major role during fruiting body morphogenesis (O'Connor and Zusman, 1989; Sager and Kaiser, 1993). Many species surround the cell mass with a tough wall, often after a subdivision of the original mass into portions of approximately equal size, thus creating sporangioles, either single or in clusters. In *Me. boletus*, a very regular pattern of three or more layers of strictly parallel cells has been observed (Jahn, 1924). The cells are perpendicularly arranged on the outer surface of the fruiting body, and it has been suggested that they are responsible for the secretion of the sporangiole wall. In developing *Cb. fuscus* sporangioles, the cells in the outer layers lie parallel to the surface.

The wall of the sporangioles is very thin, about 30 nm in *Cm. crocatus* (Abadie, 1971b) and 200–300 nm in *Cystobacter* (Vahle, 1910; Jahn, 1924). It dissolves in potassium hypochlorite solution (Vahle, 1910) and is intensely colored by pigments that are not identical with those of the cells and cannot be extracted by any of the normal solvents (Vahle, 1910). The chemical composition and the origin of the wall are not known. It has been suggested that cells lying at the surface excrete the wall (Jahn, 1924). Or perhaps it is formed by fusion of the cells forming the top layer. In *Me. boletus*, the cells in the developing sporangiole are arranged in a regular pattern in rows of parallel rods standing perpendicular to the surface. Thus, in this case it seems that the wall is excreted from one cell pole only (Jahn, 1924). How the size of the sporangiole is determined within the undifferentiated cell mass is one of the many unsolved questions in myxobacterial morphogenesis. During germination the sporangiole wall is ruptured mechanically, and an empty husk remains after the cells leave.

Fruiting Body Morphogenesis

The fruiting bodies are produced by the coordinated movement of 10^5 to 10^7 swarm cells that

Fig. 7. Myxobacterial fruiting bodies. a) *Cystobacter ferrugineus* on VY/2-agar; culture is 4 weeks old; the organism has spread all over the plate and produced numerous dark brown fruiting bodies; the diameter of the plate is 9 cm. (b–d) *Corallococcus coralloides*: b) swarm on VY/2 agar, with numerous fruiting bodies; the delicate swarm edge and the clear lysis zone in the yeast agar are well recognizable; c) field of fruiting bodies at higher magnification; d) a single fruiting body, in situ on the agar surface. e) *Myxococcus stipitatus*, fruiting body at the edge of a piece of filter paper, in situ. f) *Myxococcus fulvus*, fruiting bodies on a soil crumb, in situ. (g–j) *Archangium*-like fruiting bodies: g) *Archangium gephyra*, large fruiting body in situ on agar surface; h) *Cystobacter ferrugineus*, fruiting body with only rudimentary differentiation into sporangioles, in situ on agar surface; i) *Cystobacter*, probably *Cb. ferrugineus*, with totally degenerated fruiting bodies, in situ on agar surface; j) *Cystobacter* strain with typical "*Archangium*" fruiting bodies, in situ on agar surface; k) *Cystobacter velatus*, fruiting bodies in situ on agar surface, covered with a delicately plicated slime sheet; and l) the same organism at lower magnification; one can see some of the enormous number of fruiting bodies that may be produced under suitable conditions. Bar = 5 mm in b), 500 µm in c), 200 µm in l), and 100 µm in the remaining micrographs.

(a–c) *Stigmatella aurantiaca*: a) fruiting body in situ on an agar surface; b) fruiting body with its sporangioles on exceptionally long peduncles, in situ; c) early developmental stage of a fruiting body, mounted in "Miracle Mount" (Cunningham, 1972) to make it transparent; the stalk still consists mainly of cells that later migrate into developing sporangioles or degenerate; the young sporangiole in the upper left corner shows the developing sporangiole wall that ends in a collar at the base of the sporangiole; phase contrast. d) Although this fruiting body strikingly resembles those of certain *Polyangium* (see h) or *Sorangium* species (see g), it still is that of a *Cystobacter*, *Cb. minus*, as is clearly shown by the shape of the vegetative cells; interference contrast. e) *Stigmatella erecta*, fruiting bodies in situ on agar surface. f) *Melittangium lichenicola*, fruiting bodies in situ on a piece of wood. g) *Sorangium cellulosum* on filter paper, cautiously squeezed slide mount; the shape of the fruiting bodies is often controlled by the orientation of the remnants of the wood fibers and tracheids, along and within which they develop; phase contrast. h) *Polyangium* sp., fruiting body in crude culture in situ on agar surface; note the deep path that has been etched into the agar surface by the migrating bacterial mass (compare with Fig. 2c) before it encased itself in sporangioles; the tiny dots all over the agar surface are encysted amoebae. i) *Jahnia thaxteri*, fruiting bodies on filter paper, in situ. (j–m) *Chondromyces apiculatus*: j) cluster of fruiting bodies on surface of filter paper, in situ; dissecting microscope; k) early (club) stage of sporangiole differentiation; dissecting microscope; l) mature fruiting body; m) small, mature, fruiting body in "Miracle Mount" (Cunningham, 1972) to make it transparent; the myxospores within the turnip-shaped sporangioles can just be recognized; the slime stalk, in contrast, is cell free; phase contrast. And n) *Nannocystis exedens*; the fruiting bodies are single sporangioles of very variable size and are embedded in the agar substrate; slide mount, phase contrast. Bar = 50 μm in (c), 200 μm in (i), 400 μm in (j), and 100 μm in the remaining pictures.

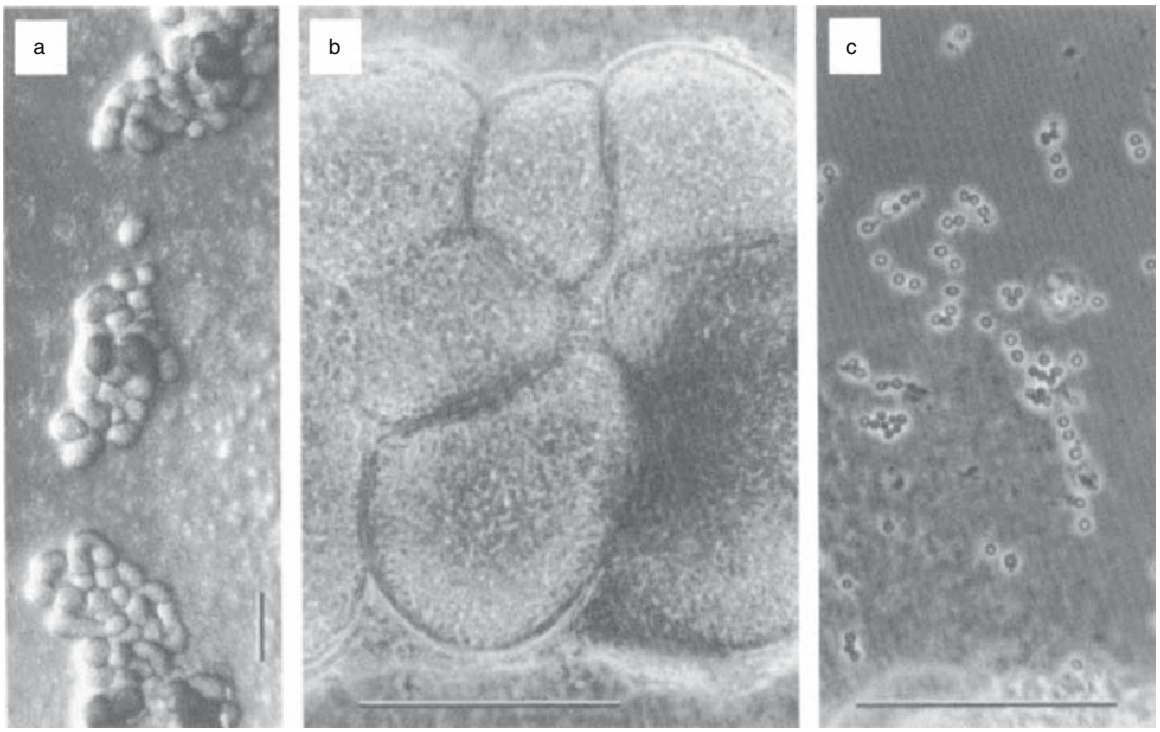

Fig. 9. Myxobacterial fruiting bodies: *Pyxicoccus fallax*. a) In crude cultures and on natural substrates the sporangioles tend to be disk-shaped and loosely stacked but, as shown here, in pure culture, they are more or less spherical and tightly attached to each other. b) At high magnification, the walls of the sporangioles, although only about 1 mm thick, become clearly recognizable. c) When the sporangioles are crushed, they release optically refractile, spherical myxospores, shown here at the same magnification as the sporangioles in (b), which look exactly like *Myxococcus* myxospores. (b) and (c) are in phase contrast. Bar = 100 μm in (a), 50 μm in (b) and (c).

retain their physical individuality throughout this process of cooperative morphogenesis (Fig. 12). Formation of fruiting bodies can schematically be divided into a number of developmental stages: 1) environmental signal(s) to direct the vegetatively growing cells to a developmental path (Kaiser, 2000b); 2) cell aggregation or accumulation; 3) emergence of molecules on the cell surface that mediate cell adherence; 4) rearrangement or clustering of the cells within the original undifferentiated mass; 5) creation of the specific shape of the fruiting body, perhaps the most fascinating event in the whole sequence; 6) production of special structural

Fig. 10. Myxobacterial fruiting bodies. a) *Sorangium cellulosum*, on VY/2 agar in situ (compare with Fig. 9). (b and c) *Jahnia thaxteri*; b) on agar surface in situ; a mass of tightly packed sporangioles is situated on a stalk-like cushion of slime: the whole fruiting body looks like a false morel; c) when mounted in "Miracle Mount" (Cunningham, 1972), the individual sporangioles can easily be distinguished. d) *Chondromyces pediculatus*, fruiting body on a soil crumb, embedded in Miracle Mount. (e and f) *Chondromyces crocatus*, both in Miracle Mount: e) a young, not yet fully differentiated stage; in dark field illumination, the translucent, cell-free stalk and the densely packed cell masses on its top are clearly distinguished; f) mature fruiting body; at the base of the stalk some encysted soil amoebae are seen. (g and h) *Chondromyces lanuginosus*, both in Miracle Mount: g) survey of the whole fruiting body; and h) view from above showing the end face of the sporangioles covered with little tails. (f to h) in phase contrast. All bars = 100 mm.

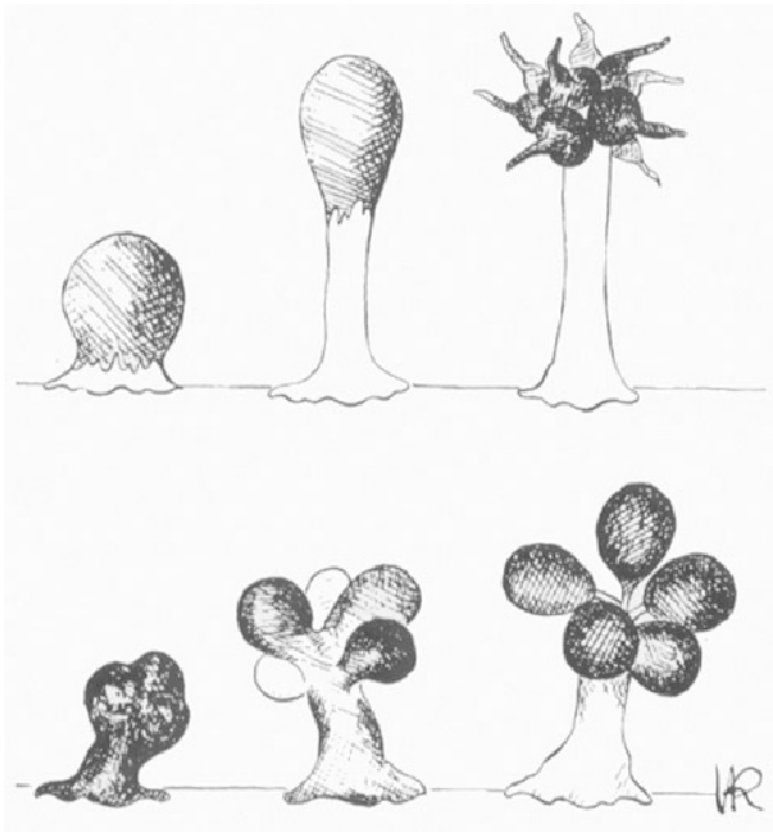

Fig. 11. Similar fruiting body shapes may be reached in different ways, as shown here for *Chondromyces apiculatus* (above) and *Stigmatella aurantiaca* (below), two organisms formerly thought to be closely related. The hatched areas indicate where the cells are located at the various stages.

elements (stalks and sporangiole walls; sporangial walls are produced only after the shape of the fruiting body has been obtained); and finally, 7) during the maturation phase, conversion of the vegetative cells into myxospores (White, 1993). In addition, cell-cell signals are exchanged throughout the entire process.

Under optimal conditions, the bacteria may go through the whole developmental cycle within 12–24 h. Fruiting body induction as well as the individual steps of differentiation are subject to control by environmental factors such as nutrients, pH, divalent cations, and temperature. In at least two cases (*Cm. apiculatus* and *Sg. aurantiaca*), normal development takes place only in illuminated cultures (Reichenbach, 1974a; Reichenbach, 1974b; Qualls et al., 1978; Stephens and White, 1980a). The course of fruiting body formation has been documented for different genera and species in several scientific films (Reichenbach et al., 1965d; Reichenbach et al., 1965e; Reichenbach et al., 1965f; Reichenbach et al., 1965g), which show the sequence of events during fruiting.

Fruiting body formation by *Mx. xanthus* has been the subject of the most intense scrutiny, and a great deal is known about the various signals that are exchanged during conversion of the vegetative cells to the simple *Myxococcus* fruiting body (Fig. 8). Five such signals, A through E, have been identified and are described in detail in Shimkets (1999). On the other hand, the signal(s) that directs movement of the vegetative cells into the aggregation center has remained mysterious. While it is intuitively plausible that the process is driven by chemotaxis, and indeed,

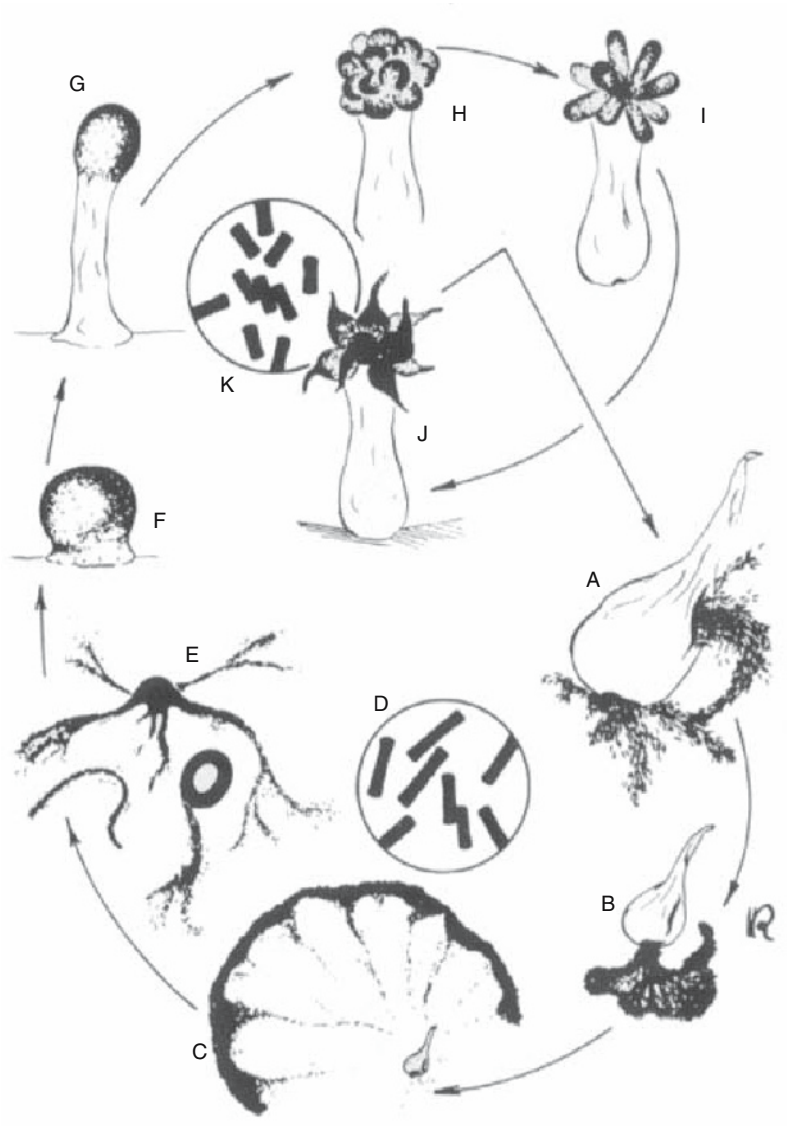

Fig. 12. Cooperative morphogenesis in myxobacteria. The organism shown in the diagram is *Chondromyces apiculatus*. Symbols: A, germinating sporangiole; B, C, development of a swarm colony; D, vegetative cells; E, aggregation of vegetative cells at various places within the swarm. F to J, fruiting body development; F, knob stage; G, excretion of the slime stalk, cells all concentrated in the terminal knob; H, the terminal mass begins to differentiate, forming wart-like protrusions which later elongate into (I) club-like structures and finally mature into (J) turnip-shaped sporangioles; K, myxospores.

chemotactic behavior has been demonstrated (see the section Gliding Motility in this Chapter), whether chemotaxis per se directs the cells into the centers has not been demonstrated.

Myxospores

Within the maturing fruiting body, a cellular morphogenesis takes place, i.e., the production of myxospores. In the suborder Cystobacterineae, this always means a rather dramatic shortening and fattening of the vegetative rods into spheres or at least into short, fat rods. The myxospores surround themselves with a capsule that may, however, be rather thin and recognizable only under the electron microscope. Also, they become optically refractile. In the suborders Sorangineae and Nannocystineae, the shape change is much less extensive. The vegetative cells may become somewhat shorter and slightly constricted in the middle. Often they also become optically refractile and may (e.g., in *Cm. crocatus*; Abadie, 1971b) or may not develop a thin capsule. The fine structure of myxospores, formerly also called "microcysts," has been studied with six organisms: *Mx. xanthus* (Voelz and Dworkin, 1962; Voelz, 1966a; Bacon and Eiserling, 1968; Kottel et al., 1975), *Sg. aurantiaca* (Reichenbach et al., 1969b; Voelz and Reichenbach, 1969), *Sg. erecta* (Galván et al., 1987), *Archangium gephyra* (Galván et al., 1992), *So. cellulosum* (Lampky, 1976), and *Cm. crocatus* (McCurdy, 1969a; Abadie, 1971b). *Myxococcus xanthus* has a very thick, layered capsule, which can be seen under the light microscope, especially after staining with India ink. The capsule appears to be reduced in thickness during germination and is left back by the emerging vegeta-

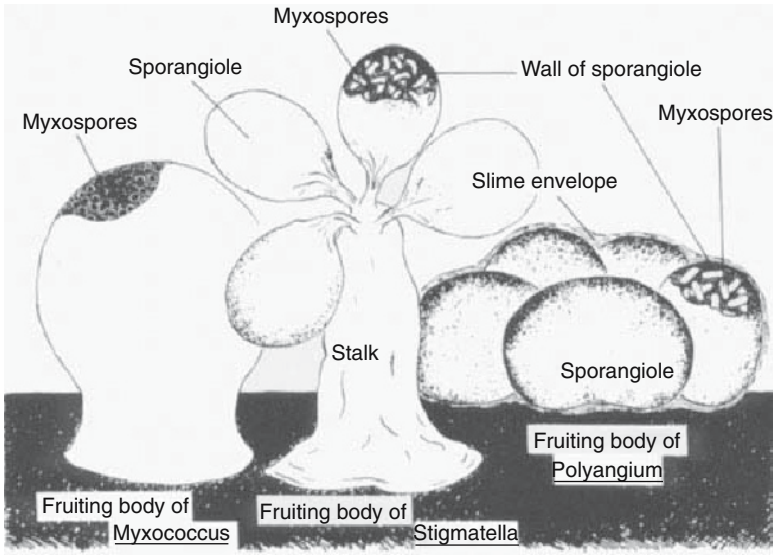

Fig. 13. The terminology for myxobacterial fruiting bodies and their structural components.

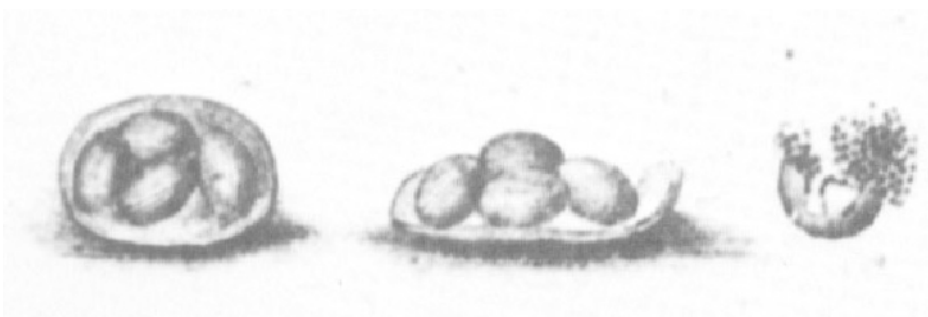

Fig. 14. *Polyangium vitellinum*, probably the first drawing of a myxobacterium to be published (Link, 1809). The original description of this still-valid genus and species reads as follows: "Among the Gasteromycetes in front of *Endogene* is to be inserted: *Polyangium*. Sporangium spherical or distortedly ovoid. Sporangioles very large in relation to the sporangium, ovoid, crammed full with a granular material. The sporangium consists of a thin, translucent, gelatinous, vesicular membrane enclosing four to six ovoid sporangioles which are filled with a colored granular mass. Sporidia could not be distinguished. *P. vitellinum*, with small yolk-colored spots, is to be counted among the smallest (species) of the order. It is found on old tree trunks, either singly or in groups of two or three, and can be recognized by its intense yolk color. Discovered by my friend Ditmar. Is to be inserted among the Gasteromycetes after *Tremella*." (Translated from the Latin.)

tive cell as an empty shell. The cell wall is retained intact during sporulation. In the cytoplasm, polyphosphate and polysaccharide granules can be seen. In glycerol-induced spores (see below), about 75% of the capsule is a polysaccharide consisting entirely of galactosamine and glucose (Kottel et al., 1975). Artificially induced myxospores fold their outer membrane into vesicular and tubular structures. An interesting open question is what happens with the gliding apparatus during shape change.

With S*g. aurantiaca* fruiting body myxospores, the outer membrane also becomes ruffled or folded; in artificially induced myxospores, these folds form densely packed membrane bodies between the cytoplasmic membrane and the capsule. Presumably, the outer membrane cannot be melted in during cell conversion and therefore is conserved in this way. As artificially induced cells change their shape much faster than cells in developing fruiting bodies, the phenomenon is more pronounced in the former. In both types of myxospores, polyphosphate and polysaccharide granules can be seen; the surface of the latter is densely covered by small, dark, ribosome-like particles. Essentially the same type of myxospores is found in fruiting bodies of *Sg. erecta* and *Ar. gephyra*; the latter may contain large, fusiform bodies with a crystalline internal structure, probably protein crystals. Fruiting body

myxospores of *So. cellulosum* seem to be devoid of a capsule. They are full of large, electron translucent granules, probably polysaccharide, which is also found near the poles of vegetative cells. In fact, phase (bright–pole) regions are observed under the phase contrast microscope in older vegetative cells. Mesosome-like membrane stacks are seen deep in the interior of the myxospores. Fruiting body myxospores of *Cm. crocatus* were found with and without a capsule. Also in this case mesosomes were present. Further, polysaccharide granules, slime vesicles, a ruffled outer membrane, and areas of vesicular or tubular outer membrane structures do occur. The arrangement of myxospores within the sporangioles is normally at random, but for *Me. boletus* an orientation strictly perpendicular to the outer wall has been described (Jahn, 1924). In *Cystobacter fuscus* sporangioles, a pattern of surface-parallel myxospores can be seen impressed on the inner face of the wall (Jahn, 1924). In cultures, myxospores are often produced free, outside of fruiting bodies.

With the discovery that the addition of glycerol to suspension cultures of *Mx. xanthus* induces the vegetative cells to convert synchronously within 90 min into myxospores (Dworkin and Gibson, 1964a), a well-defined experimental system for the study of morphogenesis in myxobacteria became available. This led to a host of studies on the events during induction and conversion. Nevertheless, as yet, there are no compelling insights into the mechanism of glycerol induction or sequence of the events leading to the formation of the myxospore. Details can be found in the reviews mentioned in the beginning of this section. Many other myxobacteria can also be induced to sporulate by adding chemicals to suspension cultures. *Stigmatella aurantiaca* can be induced by 40 different chemicals acting on at least three different receptors, as is suggested by reciprocal induction-resistant mutants (Gerth et al., 1993; Gerth and Reichenbach, 1994). Induction in *Sg. aurantiaca* is also possible by high temperatures just below the temperature maximum, and inductions by heat and by chemicals complement each other. This could mean that stress receptors and heat shock proteins play a role in myxospore induction, possibly within fruiting bodies, too (Heidelbach et al., 1993).

Myxospores are clearly designed for survival under unfavorable environmental conditions. Myxospores of *Mx. xanthus* are much more resistant to elevated temperatures (60°C), ultraviolet light, and sonic vibration than vegetative cells are (Sudo and Dworkin, 1969). In contrast to vegetative cells, myxospores are completely desiccation resistant and can be lyophilized. Dried myxospores may survive for at least 20 years at room temperature. In the dried state, temperature resistance of myxospores becomes especially impressive. Strains of *Myxococcus*, *Corallococcus*, *Archangium*, *Cystobacter*, *Polyangium* and *Sorangium* survived for 30 min at 140°C; *Corallococcus*, *Archangium*, *Polyangium* and *Sorangium* survived for 45 min; and *Archangium* and *Polyangium* even survived for 60 min. But 140°C for 240 min or 145°C for a short time killed all myxobacteria (H. Reichenbach, unpublished results).

Heat resistance of myxospores is often useful for the isolation of pure strains. To eliminate contaminants, fruiting body suspensions can be heated at 58°C for 15 or 40 min with good success. In *Mx. xanthus*, myxospore resistance to heat and desiccation appears to be accompanied by the accumulation of trehalose up to 1.1 μg/mg protein (McBride and Zusman, 1989a). To discuss here other details of the numerous studies on morphogenesis in myxobacteria is impractical; they will be found in several of the reviews mentioned at the beginning of this section (however, see also Sudo and Dworkin [1973], Shimkets [1987], Shimkets [2000], Ward and Zusman [2000], and White and Schairer [2000]).

Functions of Myxospores and Fruiting Bodies

The function of the myxospore is intuitively obvious. The metabolic quiescence of myxospores of *Mx. xanthus* (Dworkin and Niederpruem, 1964b) and their resistance to desiccation, temperature extremes, and UV light (Sudo and Dworkin, 1969) allow the organism to withstand environmental extremes and to persist for long periods during conditions that may not be optimal for growth. However, the function of the fruiting body is more subtle; "The most important question involving life history strategies is Why does one have fruiting bodies at all . . . ?" (Bonner, 1982).

While Bonner's question pertained to *Dictyostelium discoideum*, it is equally applicable to the myxobacteria. The function of the fruiting body, whether structurally simple as in *Myxococcus* or complex as in *Chondromyces*, relates ultimately to the "wolf pack" mode of feeding that is characteristic of all myxobacteria (Dworkin, 1973a). All the myxobacteria that have been so examined feed by means of excreting a battery of hydrolytic enzymes that enable them to degrade macromolecular debris or to lyse and feed on other cells (see the section Lysis of Other Bacteria in this Chapter). As a result, they are at the mercy of diffusion—of their enzymes away from the cell and of solublized nutrients toward the cell. Thus, feeding at a high cell density and thereby concentrating the hydrolytic enzymes and the resultant products is an advantage.

Rosenberg et al. (1977) has experimentally verified this hypothesis in *Mx. xanthus*. One may therefore view the fruiting body as a device for concentrating the cells, prior to their entrance into the resting state, so that upon germination they may immediately be present at a sufficiently high cell density to generate a swarm and thus to feed efficiently. The particular organization of the sporangioles that is characteristic for each species may simply reflect the optimal packaging of the myxospores, so that upon germination, multiple emerging swarms are poised to begin feeding at their optimal cell densities.

Lysis of Other Bacteria

The ability of the myxobacteria to lyse and feed on other cells and to hydrolyze a variety of insoluble macromolecules is well documented (Rosenberg and Varon, 1984), is characteristic of the myxobacteria, and accounts for the life style and multicellular proclivity of this group. This ability was observed early in the history of the myxobacteria, and the literature is full of such reports (e.g., Beebe, 1941; Singh, 1947; Nolte, 1957; Margalith, 1962; Bender, 1963; Raverdy, 1973). For this activity, a battery of cell-wall lytic enzymes, lipases, nucleases, polysaccharidases and nucleases as well as antibiotics and bacteriocins are produced (Rosenberg and Varon, 1984).

Studies on bacteriolytic activities led to the first studies on myxobacterial exoenzymes (e.g., Norén, 1960a; Bender, 1962; Hart and Zahler, 1966, Haskå, 1969; Hüttermann, 1969; Sudo and Dworkin, 1972). Some of the responsible enzymes have since been purified to varying degrees and have been biochemically characterized. While a complete bacteriolysis obviously requires many different enzymes, all of the studies on bacteriolytic enzymes of myxobacteria have concentrated on peptidoglycan-degrading enzymes. A glucosaminidase, an amidase, and an endopeptidase cleaving D-Ala/diaminopimelic acid and D-Ala/Lys bonds and proteases have been obtained from culture supernatants of *Mx. xanthus* (Sudo and Dworkin, 1972). Three bacteriolytic enzymes have been isolated and highly purified from *Mx. virescens* (Haskå, 1972a; Haskå, 1972b; Haskå, 1974); two of them proved to be endo-β-*N*-acetylglucosaminidases and the third an endopeptidase which could be purified by adsorption to montmorillonite followed by selective desorption (Haskå, 1974; Haskå, 1975). The fact that the bacteriolytic enzymes retain some of their activity when they are adsorbed to clay minerals may be of ecological relevance (Haskå, 1981). The addition of C11 through C15 fatty acids (about 2 mM) to suspensions of the target bacteria increased the efficiency of the bacteriolytic enzymes substantially (Haskå et al., 1972c). In contrast to the two myxococci, *Cc. coralloides* excreted an enzyme with a muramidase (i.e., lysozyme) activity (Harcke et al., 1972). (Additionally, the "*Sorangium*" isolate whose enzymes are often discussed in this connection was in reality a species of *Lysobacter*.)

Little is known about the enzymes with which microorganisms other than bacteria are attacked. Living cells of four yeast species could not be degraded by *Mx. xanthus* enzymes, but they were digested after a prior treatment with cysteine or organic solvents or after heating; in contrast, living cells of the yeast-like fungus *Pullularia* (*Dematium*) *pullulans* were partially decomposed (Bender, 1963). Isolated cell walls of *Saccharomyces cerevisiae* also could not be degraded by enzymes from *Mx. fulvus* Mx strain f80 without a brief heat treatment (Borchers, 1982). Apparently, the mannoprotein layer on the outside of the yeast cell wall protects the susceptible material. Two inducible enzymes have been demonstrated in the culture supernatant of *Mx. fulvus* Mx f80: 1) a laminarinase with a high specificity for β-1,3-glucosidic bonds cleaving laminaran endolytically with laminaritriose as the main product; and 2) a β-1,3-glucanase that can remove a high-molecular-weight polysaccharide other than β-1,3-glucan from the cell wall. The yeast cell wall is not completely broken down by *Mx. fulvus* Mx f80: The inner, fibrillar, glucan layer and the bud scars remain undigested, as can be seen under the electron microscope.

Several *Mx. xanthus* and *Mx. fulvus* strains were shown to control populations of the cyanobacterium, "*Phormidium luridum*," with predator-prey cycles of 9 days under experimental conditions. As few as 50 *Myxococcus* cells per 100 ml containing 10^7 cells of the prey were sufficient to start a lytic cycle (Burnham et al., 1984). The myxobacteria produced a lysozyme type enzyme (Daft et al., 1985). However, evidently because of insufficient supply of inorganic nutrients, myxobacteria cannot control natural blooms of cyanobacteria (Fraleigh and Burnham, 1988). In two cases myxobacteria have been observed to eat holes into the cell wall of the fungi *Cochleobolus* and *Rhizoctonia* (Homma, 1984) and of the green alga *Cladophora* (Geitler, 1924), respectively. The myxobacteria enter the cells and produce fruiting bodies inside.

Most myxobacteria excrete strong, diffusible proteases, as can be readily seen through the clearing action that occurs around colonies growing on skim milk agar. A few of these enzymes have been further characterized: From the culture supernatant of *Mx. virescens*, at least three proteases have been obtained (Gnosspelius,

1978b). One of them has been purified and was found to be an alkaline serine protease (26 kDa) that preferentially cleaved peptide bonds between hydrophobic amino acids. Three different proteases have also been demonstrated in the culture supernatant of *Mx. xanthus* FB (Coletta and Miller, 1986). They have tentatively been classified as alkaline serine proteases. There were qualitative differences among the proteases of different *Mx. xanthus* strains. A coagulase, myxocoagulase (57 kDa), has been isolated from the culture broth of *Mx. fulvus* strain NK35 (Bojary and Dhala, 1989). The enzyme was clearly different from *Staphylococcus* coagulase; it did not contain sugar and was active only on rabbit plasma.

While myxobacteria can hydrolyze many other macromolecules by means of diffusible exoenzymes, those enzymes have not been characterized so far. Thus, many myxobacteria decompose starch; quite a few are potent chitin degraders, e.g., all strains of *Cb. fuscus*, *Cb. ferrugineus*, *Sg. aurantiaca* and *Sg. erecta* and many strains of *Me. lichenicola* and *So. cellulosum*. Also, many myxobacteria appear to attack xylan. Two enzyme activities could be demonstrated in the culture supernatant of the cellulose degrader *So. compositum*, growing in a liquid medium with suspended cellulose powder. The enzymes produced only glucose and cellobiose from cellulose. One was a cellobiase and was destroyed by heating at 55°C for 10 min. After that, an enzyme releasing cellobiose from cellulose was still intact (Couke and Voets, 1968). These two enzymes probably did not constitute the entire cellulase complex of the organism; rather another endocellulolytic enzyme may exist that was not released from the cells. In fact, in plate cultures of *So. cellulosum* on filter paper or on cellulose powder agar, the lysis zone always exactly coincides with the size of the swarm colony. Thus, there seems to be no diffusible cellulase efficient enough to break down the crystalline cellulose completely.

During fruiting body formation of *Mx. xanthus* autolysis of a major part of the cell population takes place before sporulation begins. Approximately 85% of the vegetative cells in the population undergo lysis, the surviving cells completing myxospore formation and formation of the fruiting bodies (Wireman and Dworkin, 1977). Varon et al. (1986) have characterized the activities necessary for this developmental autolysis and have isolated five different autocides. Among these, AM I is a mixture of fatty acids and AM V is a phosphoethanolamine with unsaturated fatty acids (Gelvan et al., 1987). In the latter case, the cells release the fatty acids apparently through the action of a phospholipase; also in AM I, unsaturated fatty acids are the most efficient autocides. While AM I and AM V act specifically on *Myxococcus* species, the other autocides have wider specificity, acting on a variety of myxobacteria. Mutants that are resistant to autocides are no longer able to produce fruiting bodies.

Taxonomy and Identification

(Note: Much of the material in this section is taken verbatim from the recent revision of the taxonomy of the myxobacteria by Hans Reichenbach in the second edition of *Bergey's Manual of Systematic Bacteriology* [Reichenbach, 2005]).

All known myxobacteria are united in the single order Myxococcales. The name was changed from Myxobacterales (McCurdy, 1989) in accordance with Rule 9 of the International Code of Nomenclature of Bacteria (which requires that the name of an order be derived from the name of the type genus).

The phylogenetic position of the myxobacteria has been put on a solid base by 16S rRNA/DNA studies (Ludwig et al., 1983; Shimkets and Woese, 1992; Sproer et al., 1999). These studies have shown that the myxobacteria are a phylogenetically coherent group within the Deltaproteobacteria (Stackebrandt et al., 1988). Also apparent is that the order Myxococcales is divided into three suborders: a major division that separates the suborders Cystobacterineae and Sorangineae (Reichenbach, 1974b) and a second one separating the Nannocystineae (Reichenbach, 2005).

As discussed earlier in this chapter, the members of the suborders differ in cell shape, myxospore development, colony structure, fatty acid and carotenoid pattern, and the chemical composition of their slime (Congo red reaction). The suborders are divided into families based on the organization of the fruiting bodies and the shape of the myxospores. The definition of genera and species is based on the same characteristics and on a few complementary physiological facts. There are different possibilities for splitting and rearrangement, and in the absence of more compelling arguments, personal preference must still determine which route to follow. All in all, we can distinguish three suborders, five families, 17 genera and about 50 different species of myxobacteria, a number that while far from complete, is not likely to increase dramatically in the future. Note, however, that myxobacterial taxonomy cannot yet be regarded as settled and we are still confronted with major problems in distinguishing species, e.g., in the genera *Corallococcus*, *Archangium*, *Cystobacter*, *Nannocystis*, *Sorangium* and *Polyangium*.

Table 3. Taxonomic survey of the myxobacteria.[a]

Order: Myxococcales
Suborder: Cystobacterineae
Families and genera:
Myxococcaceae
Myxococcus
Corallococcus (formerly *Chondrococcus*)[2]
Pyxicoccus nov. gen.[b]
Cystobacteraceae
Archangium
Cystobacter
Melittangium
Stigmatella
Hyalangium nov. gen.[b]
Suborder: Sorangineae
Families and genera:
Polyangiaceae
Sorangium
Polyangium
Haploangium
Chondromyces
Byssophaga nov. gen.[b]
Jahnia nov. gen.[b]
Suborder: Nannocystineae
Families and genera:
Nannocystaceae
Nannocystis
Kofleriaceae
Kofleria nov. gen.[b]
Haliangium nov. gen.[b]

[a]Three recently described and unusual genera, *Anaeromyxobacter* (Sanford et al., 2002), *Enhygromyxa* (Iizuka et al., 2003b), and *Plestiocystis* (Iizuka et al., 2003a), are missing from Table 3 and the illustrated key (Fig. 15) because they have not yet been characterized thoroughly enough to accurately place them in this taxonomic scheme.

[b]These novel genera are validly described in Reichenbach (2004).

A survey of the taxonomy of myxobacteria derived from the taxonomy presented in *Bergey's Manual* (Reichenbach, 2005) is presented in Table 3. An annotated and illustrated key to the genera follows in Fig. 15. Note that three recently described genera, *Anaeromyxobacter* (Sanford et al., 2002), *Enhygromyxa* (Iizuka et al., 2003b) and *Plesiocystis* (Iizuka et al., 2003a), do not appear because they have not been characterized thoroughly enough for accurate placement.

Illustrated Key to the Genera of Myxobacteria

1. Vegetative cells are slender rods with more or less tapering ends, cigar- , boat- or needle-shaped, about 3.5–12 μm long and 0.6–0.8 μm wide. Swarms (e.g., on VY/2 agar) tend to remain thin, film-like, and often show a striking surface structure in form of radial veins and fields of tiny ridges or waves. Swarm edge usually has delicate fringes and flame-like protrusions. Myxospores arise through a striking cellular morphogenesis: the vegetative cells always shorten and fatten substantially. Myxospores always seem to have a capsule, which, however, is often seen only under the electron microscope. Slime and swarm sheets are stained with Congo red. The fatty acid pattern is dominated by branched-chain fatty acids; 2- and 3-hydroxy fatty acids are present in substantial amounts. All species are of the bacteriolytic type.

Suborder: Cystobacterineae 2

1′. Vegetative cells are stout, cylindrical rods, sometimes almost cube-shaped, with broadly rounded ends, about 2.5–8 μm long and 0.6–1.0 μm wide. Swarms (e.g., on VY/2 agar) tend to sink into and to penetrate the agar, sometimes to the bottom of the plate; they usually form shallow pits and bowl-like depressions; their surface structure is often less pronounced, although radial veins, ring-shaped ridges, and fanlike structures may be produced. The agar surface in the swarm area may be more or less corroded. Often, the cells concentrate at the swarm edge as a band or a massive ridge, or they form spherical or kidney-shaped clusters that migrate away from the center and leave deeply etched paths in the agar surface. Myxospores differ only slightly from vegetative cells in shape and seem to possess no capsule or, at the most, a very thin one; they are, however, optically refractile. Slime and colonies do not stain with Congo red. Branched-chain fatty acids are reduced in the fatty acid pattern, and hydroxy fatty acids are completely absent. Several species are cellulose decomposers.

Suborder: Sorangineae 5

1″. There are two types corresponding to two families. A. Swarm colonies without a slime sheet, on certain media tend to corrode the agar plate very deeply, transforming it into a spongy mass. Vegetative cells, short rods. Fruiting bodies tiny to moderately sized sporangioles, solitary or aggregated. Or, B. Vegetative cells are slender rods with rounded ends, like those of the Sorangineae but more delicate, 4–6 μm long and 0.6–0.7 μm wide. Swarm colonies with a well-developed slime sheet and massive, branching veins, resembling the colonies of the genus *Cystobacter*. Fruiting bodies not known.

Suborder Nannocystineae 10

2. Myxospores are regular spheres or ovoids with a smooth surface and a heavy capsule, diameter 1.2–2.5 μm. Vegetative cells are 3–6 μm long, boat- or cigar-shaped. Swarms often consist of a relatively soft slime sheet, although occasionally tough and tenacious sheets are also produced.

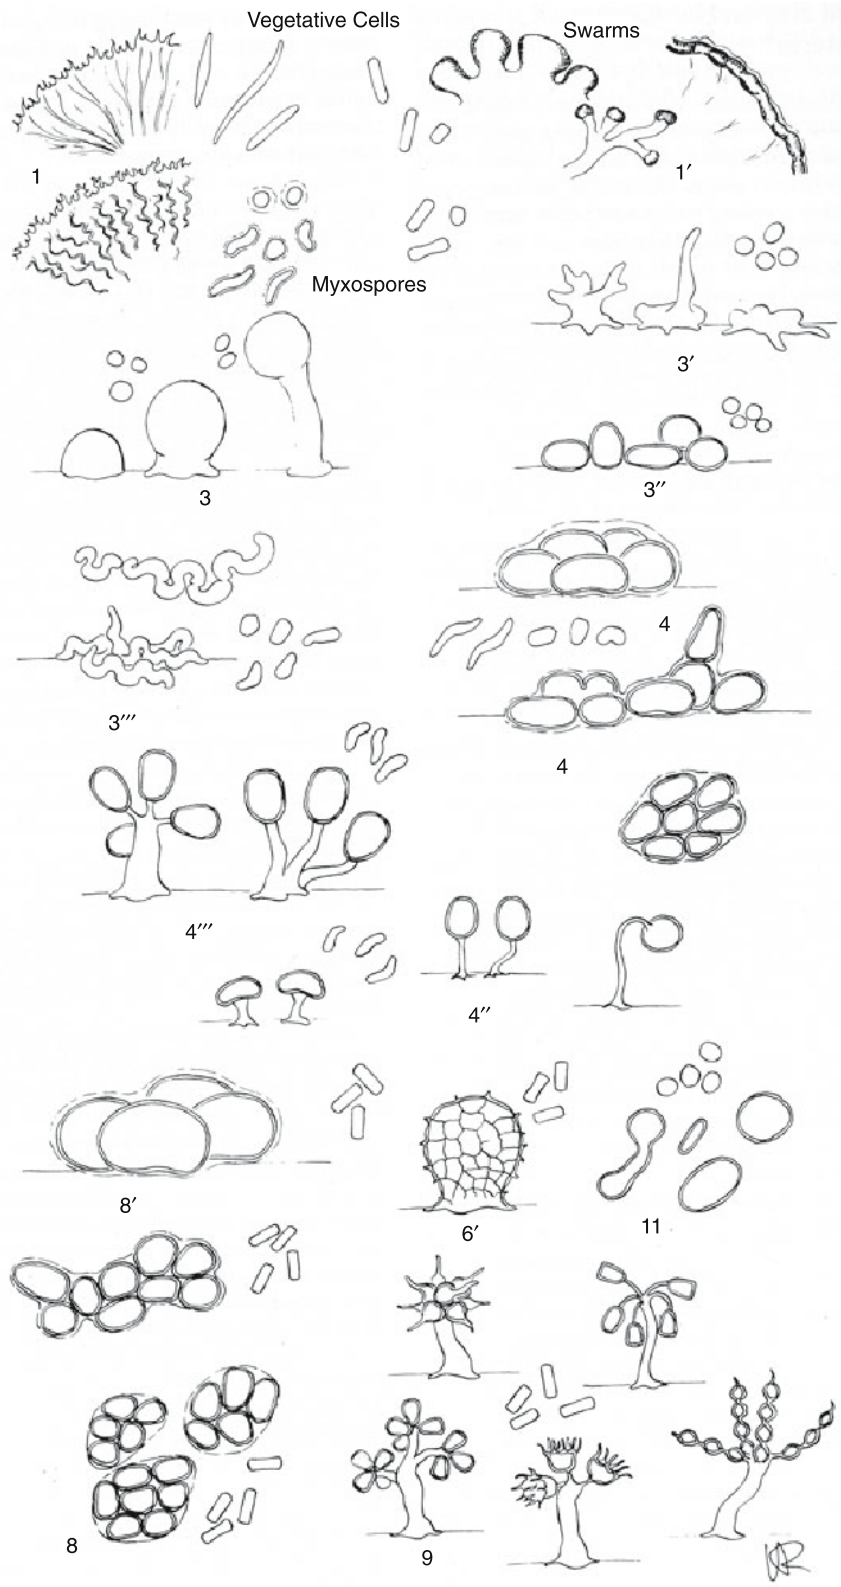

Fig. 15. A diagrammatic illustration of the key to the myxobacterial genera. The numbers in the figure refer to those in the key. The cells shown next to the fruiting bodies are myxospores.

The surface structure of the swarm is often rudimentary, but characteristic meandering radial veins may develop. Fruiting bodies are simple, spherical, soft-slimy mounds and heads or are cartilaginous columns and ridges that are sometimes branched, both without a distinct outer wall, or are sporangioles with a tough wall.

Family: Myxococcaceae 3

Comments: The differentiating characteristic of the family is the smooth, spherical myxospore. Myxospores that are nearly spherical are found with three other myxobacteria (*Archangium*, *Cystobacter* and *Nannocystis*), which can, however, easily be distinguished by the characters mentioned below.

3. Fruiting bodies are soft-slimy spherical heads or drops, often constricted at the base, in one species with a long slime stalk . . . . . *Myxococcus*

Comments: In agar cultures the shape of the fruiting body often deviates from the type, and only flat, cushion-like mounds or ridges are produced. There are four species: *Mx. fulvus* has white, pink, brick red, or even violet fruiting bodies with small myxospores (1.2–1.8 μm). *Mx. xanthus* and *Mx. virescens* produce orange and greenish yellow fruiting bodies, respectively, and have large myxospores (1.8–2.5 μm); they may be only one species, although, apparently, typical *Mx. virescens* strains produce very large myxospores and often gray, fruiting bodies on VY/2 agar. *Myxococcus stipitatus* has white-to-brownish fruiting bodies with a long slime stalk; these bodies are often found in groups on a common cushion-like base. Fruiting-body myxospores are small and they are often, but not always, clearly oval in shape. The swarms show a strong yellow fluorescence with UV light illumination at 366 nm; however, whether this quality is exclusive for the species is not yet established.

3′. Fruiting bodies are tough cartilaginous columns or ridges, sometimes staghorn- or coral-like, branched, very variable in shape, often more or less deeply rooted within the agar . . . . . *Corallococcus*

Comments: This genus has formerly been called *Chondrococcus*. The name is improper because it has been previously used for an alga. In *Bergey's Manual* (McCurdy, 1989), the genus is united with *Myxococcus*, but we prefer to retain it and suggest a new generic name. Because of its enormous variability, many species have been described in this genus, only two or three of which may be realistic. But a final decision will require more information. *Cc. coralloides* has small myxospores (1.2–1.8 μm) and produces relatively large pink or red fruiting bodies that are often branched or bear finger- or horn-like projections. Strains that also have small myxospores and produce large numbers of tiny, brownish fruiting bodies in dense fields have been described as *Cc. exiguus*. They represent either a species of their own or a variety of the former. *Chondrococcus macrosporus* has large myxospores (1.8–2.4 μm) and sturdy, yellow fruiting bodies. In contrast to the other two species, it is relatively rare.

3″. Fruiting bodies consist of sporangioles with a wall. Sporangioles are spherical, arranged in packages and sheets . . . . . *Pyxicoccus*

Comments: The third genus of the family, which is now called "*Pyxicoccus*," is somewhat confusing. The origin of the genus was a bacterium described by Thaxter (1904) as *Myxococcus disciformis*. As the spherical myxospores of the species are enclosed in sporangioles with a wall, Jahn (1924) created a new genus, *Angiococcus*, for it, apparently without ever having seen the organism. In spite of the fact that the same organism had been reported again from Poland (Krzemieniewska and Krzemieniewski, 1926), it was later concluded that *Angiococcus* does not exist (Peterson, 1966). But then the bacterium was rediscovered in the fossa of an alkaline bog (Hook et al., 1980). So the old species and genus names were reanimated, and a neotype strain of *Angiococcus disciformis* was deposited (ATCC 33172). The morphology of the organism suggests that it is really Thaxter's organism. But it does not belong to the Myxococcaceae. In the last edition of *Bergey's Manual* it was consequently classified as "*Cystobacter disciformis*." It has vegetative cells and a swarm morphology as is found in that genus. Its present classification is supported by 16S rRNA/DNA sequence data, which place the neotype strain close to *Cystobacter minus* (Sproer et al., 1999). There are, however, also organisms with spherical myxospores, a swarm morphology (as is characteristic for the Myxococcaceae), and a 16S rRNA/DNA sequence that position them close to *Myxococcus* (Sproer et al., 1999). For organisms of this type, exemplified by strain An d1, a new genus name, *Pyxicoccus*, will be used here. This avoids confusion, especially as it is not yet established whether the species *disciformis* really belongs to the genus *Cystobacter*. If not, the genus name *Angiococcus* may have to be used for it again. Note that *Pyxicoccus* fruiting bodies often degenerate into *Corallococcus*-like structures. The 16S rRNA/DNA study also proved that *Pyxicoccus* may easily be confused with other myxobacteria, as two of the three strains

tentatively identified as *Angiococcus disciformis* clustered in the Archangium group (Sproer et al., 1999).

3‴. Fruiting bodies consist of irregular masses of hardened slime (in which the myxospores are embedded) and lack an outer wall. They are either cushions with a bulging, brain-like surface or ridges that consist of meandering rolls often with rising, fingerlike projection . . . . . *Archangium*

Comments: The variability of *Archangium* fruiting bodies, and the degeneration of the fruiting bodies of other myxobacteria to *Archangium*-like structures, makes it impossible at the moment to distinguish different species. In fact, it is not even possible to recognize *Archangium* reliably, and it would be more honest to name such strains "*Archangium*-like myxobacteria." *Chondromyces serpens* is the first species for which *Archangium*-type fruiting bodies have been described, but because there are doubts about its identity, the later name, *Ar. gephyra* Jahn 1924, is used for relevant strains. This genus was formerly classified in a genus of its own, Archangiaeceae, but is now attached to the Cystobacteraceae. *Archangium violaceum* must be regarded as a degenerated *Cystobacter*, *Cb. violaceus*, under which name the organism was originally described.

2′. Fruiting bodies consist of sporangioles with a distinct outer wall, often with stalks. Myxospores are short, fat rods. Vegetative cells are slender rods with tapering ends, either boat- or needle-shaped.
Family: Cystobacteraceae 4

Comments: Aberrant fruiting bodies are common in cultures.

4. Fruiting bodies are clusters of sporangioles that sit directly on the substrate, often embedded in a clearly recognizable, common, transparent slime envelope or covered by a slime sheet . . . . . *Cystobacter*

Comments: There are myxobacteria with very similar fruiting bodies in the suborder Sorangineae, and some of these were originally united with the present *Cystobacter* species in a common genus, *Polyangium*, which, incidentally, is the oldest generic name in myxobacterial taxonomy (Link, 1809). The original family name was Polyangiaceae. Subsequently, it was realized that the genus *Polyangium* was heterogeneous. The genus was therefore split, and the Sorangineae-type species were united with species of the genus *Sorangium*. For reasons of priority, the name of the newly defined genus was *Polyangium*, and for the remaining species, the old generic name *Cystobacter* Schroeter 1886 was reactivated. The genus *Sorangium* disappeared completely, and as a consequence the family name Sorangiaceae was also eliminated and replaced by Polyangiaceae, which now, of course, had a completely different meaning than before. Here we redefine the genus *Sorangium* and replace it in the Polyangiaceae.

The species of the genus *Cystobacter* are not well studied, and it is not clear at the moment how many there are. The type species, *Cb. fuscus*, is readily recognizable from its large, glistening, chestnut brown sporangioles. *Cystobacter ferrugineus* has large, elongated, dull, dark brown sporangioles; they are often arranged in chains that tend to curve upwards in a fingerlike fashion. Both species have relatively long and slender, often slightly curved myxospores and are strongly chitinolytic. There are strains that produce light to reddish brown and often kidney-shaped sporangioles covered by a thin, translucent, and delicately plicated slime sheet; the myxospores are short, fat rods; these strains clearly represent a separate species, *Cb. velatus*. Other strains form somewhat smaller but still large, dull, dark brown, spherical sporangioles that contain myxospores in the shape of short, fat rods; they often produce a deep violet pigment and appear to constitute the species *Cb. violaceus*. Still other strains form tiny, light to golden brown, spherical sporangioles that are tightly packed together in small clusters and are often embedded in the agar substrate, resembling *Sorangium* or *Polyangium* fruiting bodies in all these respects; but the vegetative cells are long, slender needles, the myxospores are short, fat rods, and the swarms are of the *Cystobacter* type. These organisms belong to *Cb. minus*. The problem of *An. disciformis* has already been discussed.

4′. Vegetative cells are delicate, slender rods with tapering ends. Fruiting bodies consist of small spherical sporangioles that are often empty and then look glassy transparent, arranged in extended, dense sheets, or often, in chains. Myxospores are short rods to irregularly spherical, optically refractile. Swarm colonies have a thin but tough slime sheet with fine veins and adsorb Congo red, producing a purple red color. They are of the proteolytic–bacteriolytic nutritional type . . . . . *Hyalangium*

Comments: This organism differs substantially from the *Cystobacter* species discussed above and is therefore classified in a different, new genus. The distinguishing characteristics are as follows. The vegetative cells are shorter and more delicate than those of the *Cystobacter* spe-

cies. The sporangioles are small and often empty and glassy. They are arranged in monolayer sheets or in short chains and do not pile up or do so only slightly. The swarm colonies have a delicate slime sheet with very fine veins. The only species known so far resembles somewhat "*Cystobacter disciformis*," which, however, has much different fruiting bodies. Also, some traits are like those of *Polyangium minus* in the original description of Krzemieniewska and Krzemieniewski (1926). The identity with that organism cannot be ruled out with certainty, but even if the two organisms should be the same, a reclassification would be required.

4″. Fruiting body consists of a tiny sporangiole sitting on a delicate, white stalk . . . . . *Melittangium*

Comments: Most species were formerly attached to the genus *Podangium*. The type species of *Podangium*, *Pd. erectum*, has since been transferred to *Stigmatella*; the remaining species have been united in the genus *Melittangium*, so that the genus *Podangium* is now dissolved. There are at least three *Melittangium* species: *Me. boletus* has sporangioles that resemble mushroom caps and are located on very short stalks. *Mellitangium lichenicola* forms spherical, light brown sporangioles on short and relatively sturdy stalks. *Mellitangium alboraceum* is described as having a spherical sporangiole on a long and bent stalk. There are also strains that produce very tiny and delicate fruiting bodies; they may represent still another species, *Me. gracilipes*. The myxospores are always short, fat rods, and the vegetative cells are long, slender needles.

4‴. Fruiting bodies consist of dull, orange-brown to dark brown, ovoid sporangioles, which are arranged as either several on a common stalk or each on a stalk of its own . . . . . *Stigmatella*

Comments: *Stigmatella* is easily distinguished from *Melittangium*: its fruiting bodies are much coarser, and the vegetative cells are boat-shaped and of moderate length. The myxospores are short, fat rods and often S- or C-shaped. There are two species: *Sg. aurantiaca* with several sporangioles attached to a common stalk, often via tiny peduncles, and *Sg. erecta* with one sporangiole on each stalk. Clear as this may appear, the two species still are sometimes difficult to differentiate, because *Sg. erecta* often produces several fruiting bodies side by side on a common base and sometimes with partially fused stalks, so that the resulting structure may be confused with a *Sg. aurantiaca* fruiting body. These two species occupy different ecological niches: While *Sg. aurantiaca* almost always appears on rotting wood, *Sg. erecta* is found preferentially on dung and sometimes in soil. *Stigmatella erecta* was formerly classified as *Podangium erectum* (see "Comments" on *Melittangium*), *Sg. aurantiaca* as *Chondromyces aurantiacus*.

5. The suborder Sorangineae contains only one family. Vegetative cells are slender, cylindrical rods with blunt, rounded ends. Often containing optically bright granules of reserve material. The fruiting bodies always consist of sporangioles, that may be single or, more often, clustered in sedentary sori or borne on a slime stalk. In cultures, strains often refuse to produce fruiting bodies, yet degenerate fruiting bodies, as are so typical for the Cystobacteraceae, are only rarely formed. The myxospores in the fruiting bodies are morphologically not very different from vegetative cells, perhaps somewhat shorter and slightly constricted around the middle. But they are true, optically refractile resting cells, which are as desiccation and heat resistant as the myxospores of the two previous families. The swarm colonies tend to etch the agar, producing radial tracks, holes, and pits in the surface of the plate, and often penetrate the substrate deeply. In the genera *Polyangium* and *Byssophaga*, discontinuous swarm colonies with scattered cell clusters do also occur besides the more typical, coherent swarms with slime sheets and veins. Congo red is not adsorbed to the slime of the swarms. Most species are of the proteolytic–bacteriolytic nutritional type, but some are cellulose degraders and, in contrast to all other myxobacteria, may be cultivated on very simple media with an inorganic nitrogen source and a sugar as the only carbon source.

Family Polyangiaceae 6

6. Fruiting bodies consisting of several sporangioles clustered together 7

6′. Fruiting bodies consisting of large, solitary sporangioles, golden yellow, with a wrinkled or netlike surface structure when mature, found on bark and decaying wood . . . . . *Haploangium*

Comments: This genus is easily recognized by its peculiar fruiting bodies that so far have only been encountered on the bark of living or dead trees in North America and in Europe. It also has a special position in that these are the only myxobacteria that have resisted all efforts to cultivate them. (The "*Haploangium*" species, described and cultivated by Singh and Singh, 1971, were obviously misnamed because their vegetative cells were long, slender rods with tapering ends.) There may be two species that differ in size: *Ha. rugiseptum* with large sporangioles and *Ha. minus* with small ones.

7. Sporangioles located directly on or within the substrate 8

7′. Sporangioles borne on long, white stalks. 9

7″. Sporangioles orange to red brown, in convoluted, brain-like chains, often on a prominent slime cushion . . . . . *Jahnia*

8. Grows in the form of independently migrating cell companies, or pseudoplasmodia, that finally contract into intensely cinnabar- to carmine-red knob-like masses, resembling *Myxococcus* fruiting bodies. Fruiting bodies are clusters of large, red sporangioles, but are only exceptionally produced. Cellulose is decomposed . . . . . *Byssophaga*

8′. Fruiting bodies consist of tiny sporangioles that are tightly packed together and consequently are often polyhedral rather than spherical. A large number of the small parcels thus formed may lie together in more or less densely packed masses, but also the parcels themselves may become rather large. The fruiting bodies are often produced in enormous quantities, especially on digested filter paper, so that they determine the color of the swarm: bright yellow, orange, all shades of brown, and even pitch black. The vegetative swarm is usually more or less bright orange. Decomposes crystalline cellulose (filter paper) . . . . . *Sorangium*

Comments: We propose to restrict this genus to the cellulose decomposers. Cellulose degradation is such an unusual and stable character and in addition parallels a series of other morphological, physiological and biochemical characteristics in the respective strains that a separation of these cellulolytic species seems justified. The organisms have not been sufficiently studied to allow satisfactory classification of species. In addition, the original descriptions do not always indicate whether an organism was a cellulose decomposer, because not all strains have been cultivated. Also, the organisms are very variable. There appear to be at least three species: *Sorangium compositum* produces yellow-orange fruiting bodies, *So. cellulosum* brown or gray ones, and *So. nigrum* black ones, but this characteristic appears insufficient to differentiate the species reliably. There are many other morphological, chemosystematic, and physiological differences among strains, but the taxonomic relevance of these observations is presently still under study.

8″. Fruiting bodies consist of more or less spherical sporangioles that may be yellow, orange, brown or gray. Several of them may be embedded in a common, translucent slime envelope . . . . . *Polyangium*

Comments: For some time, this genus also contained the species of *Cystobacter* (see there for further comments). *Polyangium vitellinum* produces large, golden yellow sporangioles in groups of 1–20 in a common envelope. Apparently, in culture the color often changes to greenish yellow. *Polyangium luteum* has smaller, golden yellow sporangioles embedded in a yellow slime envelope. *Polyangium aureum* may be another species of this group of polyangia with orange sporangioles. There are further strains with small sporangioles that are densely clustered together in the same way as with certain *Cystobacter* and *Sorangium* strains. The fruiting bodies are light brown or gray in color and usually are embedded in the agar substrate. Probably, all strains of this type can be classified as *Pl. fumosum* and *Pl. spumosum. Polyangium parasiticum* seems to parasitize fresh-water algae; it produces red-brown sporangioles within the emptied alga cells. This species has not been reported since its first description in 1925, and its parasitic growth and even its appearance in freshwater may have been an exceptional situation. The polyangia are somewhat difficult to handle and are not well-studied organisms. There are some doubts whether the present genus is really homogeneous.

9. Fruiting bodies consist of a conspicuous, unbranched or branched white slime stalk, bearing a cluster of bright orange sporangioles. . . . . *Chondromyces*

Comments: The myxobacteria with the most beautiful and complex fruiting bodies are found in this genus. There are six species. One species, *Cm. aurantiacus*, had to be transferred to the genus *Stigmatella. Chondromyces crocatus* has a branched stalk with clusters of small, ovoid sporangioles at the ends of the branches. All other species have unbranched stalks. *Chondromyces apiculatus* produces conspicuous, turnip-shaped sporangioles, and *Cm. pediculatus* produces bell-shaped sporangioles, often drooping on long, delicate peduncles; both species are relatively common, the former especially on rotting wood, the latter often in soil and decaying plant material. *Chondromyces catenulatus* produces chains of sporangioles, and several chains originate from one stalk. *Chondromyces lanuginosus* (formerly *Synangium*) has a cluster of a few large sporangioles, each of which ends in a ring of long tips; the sporangiole thus resembles the young fruit of a hazelnut. *Chondromyces robustus* has large, fat, more or less spherical sporangioles with one to three tips.

10. Vegetative cells are short, stout, cylindrical to somewhat bulging rods with rounded to squarish ends. Fruiting bodies consist of spherical to ellipsoidal, sometimes irregular sporangioles. Most of the sporangioles are solitary, scattered on top and within the agar plate; many strains also produce dense clusters, sheets, and packets of sporangioles. The size of the sporangioles usually varies very widely. Myxospores are very short rods, ellipsoidal or spherical. Swarm colonies etch and corrode the agar more or less, depending on the medium, from shallow depressions and pits (on yeast agar) to deep holes and channels, often transforming the agar plate into a spongy mass down to the bottom of the dish.
Family Nannocystaceae 11

Comments: This family belongs to the third suborder of the Myxococcales, the Nannocystineae, together with the family Kofleriaceae. The suborder can presently be defined only by 16S rRNA/DNA sequence data, which clearly show a separate position of the organisms classified here (Sproer et al., 1999). The family, however, with only one genus, *Nannocystis*, is clearly defined by its phenotypic characteristics. Some of the more unusual myxobacteria appear to belong to this taxonomic group, in particular psychrophilic myxobacteria (Dawid et al., 1988).

10′. Vegetative cells are delicate, slender cylindrical rods with rounded ends. Swarm colonies consist of a slime sheet with more or less prominent radial veins, do not etch the agar, resemble the swarms of the Cystobacteraceae but do not adsorb Congo red. Produce usually many small to large globular knobs all over the swarm surface and dense, spherical cell aggregates within the agar resembling sporangioles, but without a wall, and sporangioles and myxospores have yet to be found. Besides terrestrial organisms also some marine, halophilic myxobacteria appear to belong to this group.
Family Kofleriaceae 12

11. Fruiting bodies are tiny, ovoid or spherical, solitary sporangioles that are produced in large numbers and are mostly embedded in the substrate. Myxospores are spherical or ovoid. Vegetative cells are often very short, stout, almost cube-shaped. Swarm is etched more or less deeply into the agar. The agar plate may become completely corroded . . . . . *Nannocystis*

Comments: Presently only two species, *Na. exedens* and *Na. pusilla*, are known, but probably other species do exist. *Nannocystis exedens* is easily recognized by its typical swarm pattern, which is especially conspicuous on water agar with streaks of living or autoclaved *E. coli*, and by its unique fruiting bodies. The latter may become considerably larger and very irregular in shape when they are produced on the agar surface. Some strains produce composite fruiting bodies that consist of clusters of small sporangioles that are more or less tightly squeezed together. Such strains may represent a different species ("*Na. aggregans*"). *Nannocystis* is perhaps the most common myxobacterium, although it is often overlooked; it is present in virtually every soil sample that contains any myxobacteria. While *Nannocystis* fits, in general, rather well with the other members of the order Myxococcales, it shows certain peculiarities that clearly set it apart, such as the nature of its carotenoid pigments and its synthesis of cholestenols.

12. Vegetative cells are long, slender, cylindrical rods with rounded ends. Swarm colonies have radial veins in a tough slime sheet, and there are numerous small to very large globular masses, or knobs, all over the swarm. Congo red is not adsorbed, and the agar is not etched. Mature fruiting bodies have not been observed but may consist of sporangioles. Cells within the knobs are long, cylindrical rods, optically refractile. They are of the proteolytic-bacteriolytic nutritional type, chitin degraders, and found in soil and similar substrates. Only one species, *Ko. flava*, is described. . . . . *Kofleria*

12′. Marine myxobacterium. Vegetative cells have rounded, blunt ends. Yellow colonies are spread and usually slightly sunk into the agar surface. Fruiting bodies are yellow to brown and consist of one or more sessile sporangioles in dense packs. They are moderately halophilic, requiring 1–3% NaCl for optimal growth (Fudou et al., 2002) . . . . . *Haliangium*

Applications

The most promising opportunity for biotechnological applications with myxobacteria is in the production of secondary metabolites that inhibit the growth of other organisms. The ability of the myxobacteria to produce antibiotics has been known for some time (Oxford, 1947; Norén, 1953; Kato, 1955; Norén and Raper, 1962). Apart from trivial fatty acids that inhibit the germination of fungal spores (Norén and Odham, 1973), until relatively recently, no chemical structure was proposed for any of these inhibitors. The first myxobacterial antibiotic for which the chemical structure has been elucidated was ambruticin, a potent antifungal compound from *So. cellulosum* (Ringel et al., 1977). In the past two decades, about 100 basic structures and 600 structural

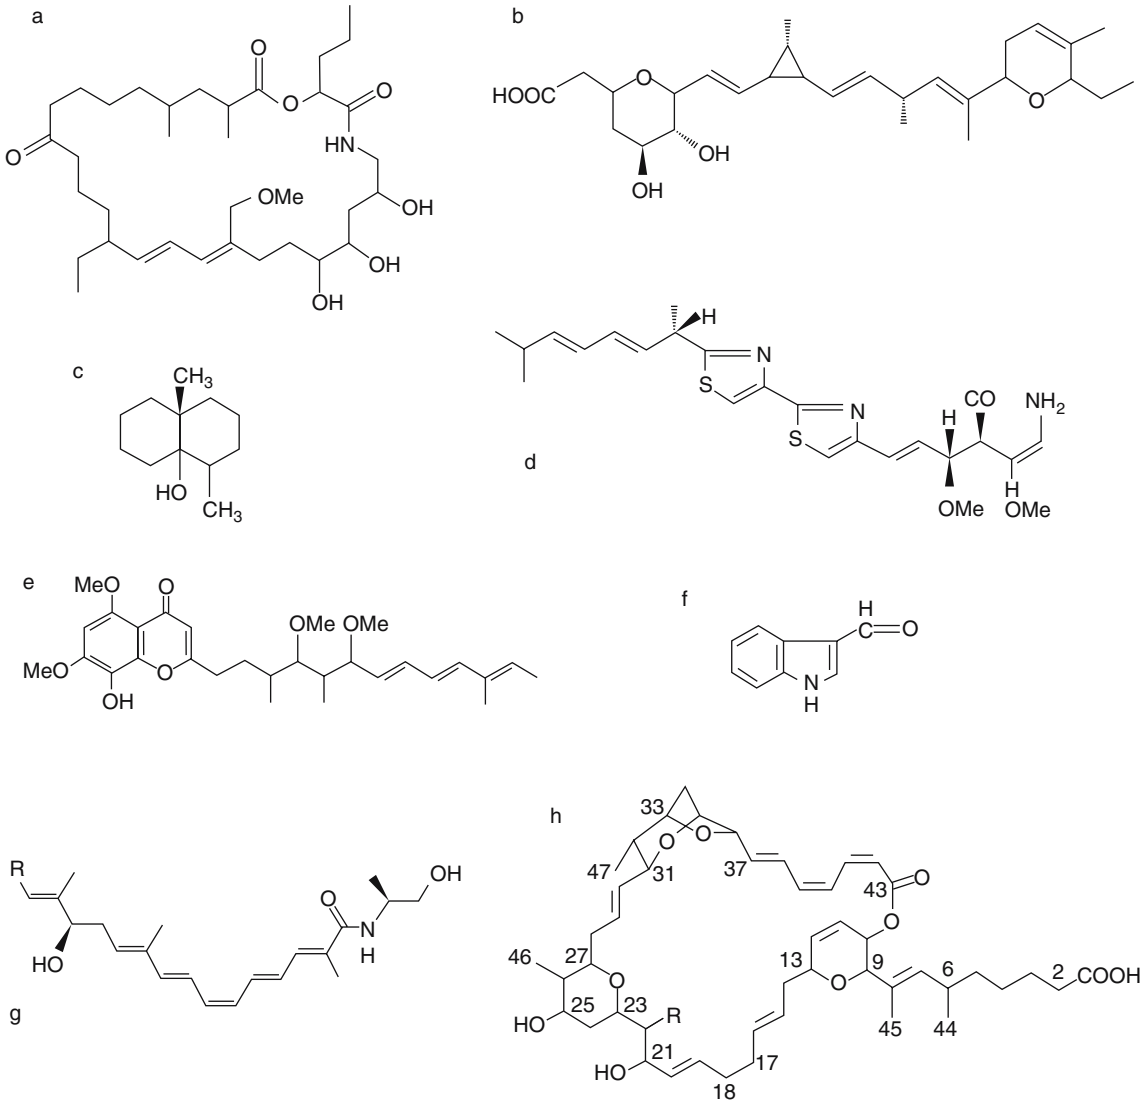

Fig. 16. A few examples of secondary metabolites produced by myxobacteria. a) Myxovirescin A; the compound, or variants of it, has been described as antibiotic TA and as megovalicins; b) ambruticin; c) geosmin; d) myxothiazol; e) stigmatellin; f) 3-formylindole; g) myxalamid; R is 2-butyl, 2-propyl, ethyl, and methyl for myxalamids A, B, C, and D, respectively; and h) sorangicin; R is OH and H for sorangicin A and B, respectively.

variants have been discovered in myxobacteria and have been fully characterized chemically (Reichenbach and Höfle, 1999; Reichenbach, 2001). The more significant insights can be summarized as follows: 1) A high proportion of myxobacterial strains (about 50% of the Cystobacterineae and almost 100% of the *Sorangium* strains) produce some kind of compound with biological activity. 2) The substances produced are chemically very different, including aromatic, heterocyclic, and polyenic compounds, alkaloids, macrocycles, polyethers, and peptides. A few examples are shown in Fig. 16. 3) Most of these compounds have not been isolated from other organisms and thus appear to be unique to the myxobacteria. The only exceptions are pyrrolnitrin and althiomycin; saframycin has been found with a new variant. 4) The ability to produce a specific compound is typical for particular but not all strains of that species. In fact, different strains of the same species may produce totally different antibiotics, but the same antibiotic may also be found in different species and even genera and families. Interestingly, the border between the suborders is also a division line for secondary metabolism, and so far only a few compounds have been found that are produced by representatives of the different suborders (e.g., pyrrolnitrin). 5) A strain may produce, at the same time, two or more compounds that are

totally different chemically. 6) Often a family of chemical variants of the same basic structure is synthesized by a strain; up to 40 different variants have been isolated from one single strain. 7) The initial yields are usually low (0.5–20 mg/liter), but with conventional methods, yield increases to more than 1 g/liter have already been achieved. 8) Interesting mechanisms of action have been discovered; compounds have been discovered that are specific inhibitors of eubacterial RNA and protein synthesis or are extremely efficient inhibitors of electron transport in respiration and photosynthesis. Two of the latter are used as specific biochemical probes and are commercially available (myxothiazol and stigmatellin). Among the compounds discovered also are iron transport metabolites of the myxobacteria (myxochelin and nannochelin). 9) An astonishing number of myxobacterial compounds interfere with the eukaryotic cytoskeleton, either actin (rhizopodin and chondramide) or tubulin (disorazol and epothilone).

At the moment, several of the myxobacterial inhibitors are being studied for potential application and large-scale production. The most promising of these is epothilone, which is currently being evaluated in phase three human clinical trials as an antitumor drug by three different pharmaceutical companies (Gerth et al., 1996). Epothilone isomers stabilize polymerized microtubules, leading to mitotic arrest at the G_2-M transition and cytotoxicity in proliferating cells (Bollag et al., 1995).

Antibiotic TA was discovered in *Mx. xanthus* strain TA (Rosenberg et al., 1973). Published chemical data, specifically NMR data (Rosenberg et al., 1982), suggest that the compound may be identical to one of the 20 variants of myxovirescin (Gerth et al., 1982; Trowitzsch et al., 1982; Trowitzsch-Kienast et al., 1989). This identification is further supported by the observation that myxovirescins are produced by many *Mx. xanthus* and *Mx. virescens* strains (H. Reichenbach, unpublished observations). In fact, the same antibiotic has been described a third time from another *Mx. xanthus* strain (Onishi et al., 1984). Furthermore, the megovalicins (Miyashiro et al., 1988; Takayama et al., 1988) are identical with previously published variants of myxovirescin; a new species, *Mx. flavescens*, has been created to describe the producing organism (Yamanaka et al., 1987), which cannot, however, be distinguished from existing species.

Another good opportunity for application may lie in the field of myxobacterial proteins and enzymes, a potential that has not yet been thoroughly investigated. Thus, restriction endonucleases (Morris and Parish, 1976; Mayer and Reichenbach, 1978) and special proteases could be of interest in the future. A lectin is produced by *Mx. xanthus* during development (Cumsky and Zusman, 1981; Nelson et al., 1981). *Myxococcus xanthus* also secretes a blood anticoagulant, myxaline, which is a heat-stable glycopeptide (El Akoum et al., 1987; Masson and Guespin-Michel, 1988). The same or a similar compound is also produced by other myxobacteria.

The efficient secretion of proteins observed with myxobacteria is unusual for Gram-negative bacteria and points to another conceivable application, as expression hosts for foreign proteins (Breton et al., 1984b; Breton et al., 1986; Nicaud et al., 1984). *Myxococcus xanthus* has been shown to secrete more than 50 different proteins into the medium, amounting to about 4% of the intracellular protein. This is impressive even if the actual number may be somewhat lower because some of the bands may have been due to proteolytic activity (Nicaud et al., 1984). Apparently, the outer membrane of the myxobacterial cell is less of a barrier than in most other cells, perhaps due to its more dynamic behavior. Two *E. coli* periplasmic enzymes, acid phosphatase and TEM2 β-lactamase, have been shown to leave the periplasm quickly when they are expressed in *Mx. xanthus* and appear in the extracellular medium (Breton and Guespin-Michel, 1987). The extracellular pectate lyases of *Erwinia* are also expressed in *Mx. xanthus* and secreted into the medium, although in this case the myxobacterial proteases inactivate the lyase (Breton et al., 1986).

There are no known myxobacterial pathogens for humans, animals or plants. The fish pathogen *Chondrococcus columnaris* is a *Cytophaga*-like bacterium and has been wrongly classified as a myxobacterium. Because of their many aggressive enzymes, myxobacteria may occasionally contribute to the deterioration of materials such as rawhide or cellulose fabrics (e.g., Heyn, 1957), but their importance in that respect is doubtful. However, although not yet demonstrated experimentally, myxobacteria reasonably play a substantial role in solubilizing large macromolecules, cell carcasses, and other biological detritus. As myxobacteria may reach rather high population densities in soil, it has been argued that they could become antagonistic to useful soil organisms like *Azotobacter* (Callao et al., 1966). However, although a suppression of *Azotobacter* by *Mx. xanthus* can indeed be demonstrated in the laboratory, whether this occurs in nature is an open question. Myxobacteria are obviously able to destroy cyanobacteria in mixed cultures in aqueous environments, and their possible use to control cyanobacterial water blooms has been suggested (Burnham et al., 1981; Burnham et al., 1984; Daft et al., 1985). But that potential has not yet been demonstrated under practical condi-

tions. Still another application of myxobacteria in environmental problems may be their use as pollution indicators (Gräf, 1975; Trzilová et al., 1980; Trzilová et al., 1981). This scheme is presently being perfected and may eventually become a useful addition to conventional biological water analysis.

Certain chemical compounds produced by myxobacteria may occasionally become troublesome. Many myxobacteria produce a strong earthy smell, which, in the case of *Na. exedens*, has been demonstrated to be due to geosmin (Trowitzsch et al., 1981). While that smell may be pleasant in connection with soil, it is disagreeable in drinking water, from which it has to be removed.

In conclusion, the economic potential of the myxobacteria is only beginning to be exploited and many potential products have yet to be adequately assessed.

Color Plates

1. *Pyxicoccus fallax* nov.gen., nov.spec., strain Ang D2, fruiting bodies on agar surface consisting of numerous small sporangioles.

2. *Pyxicoccus fallax* nov.gen., nov.spec., fruiting body in slede mount at high magnification showing sporangioles with clear walls.

3. *Cystobacter fuscus*, mature fruiting body on agar surface, sporangioles with typically shining surface.

4. *Cystobacter fuscus*, developing fruiting bodies on agar surface.

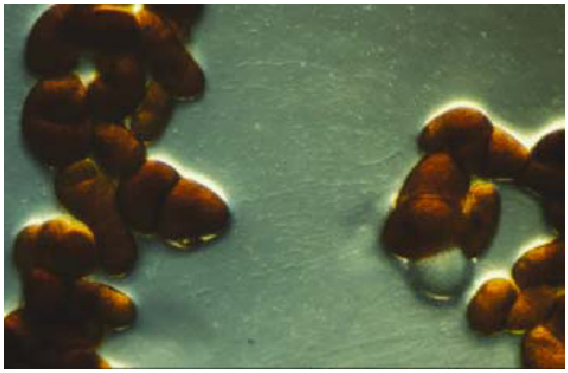
5. *Cystobacter ferrugineus* strain Cb2056, fruiting body on agar surface with dull sporangioles.

8. *Cystobacter velatus* strain Cb v37, fruiting bodies on agar surface with upward looping chains of sporangioles.

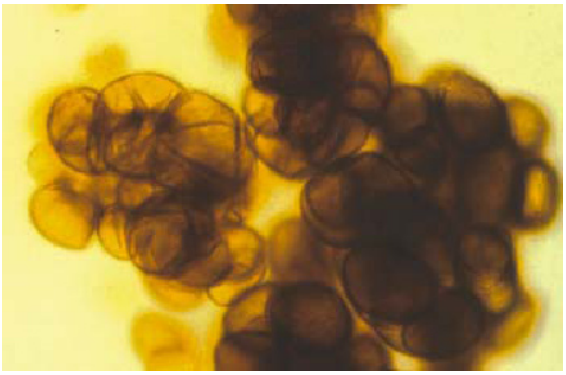
6. *Cystobacter ferrugineus* strain Cb2056, fruiting body in slide mount, several sporangioles show the elongated shape typical for that species.

7. *Cystobacter velatus*, fruiting bodies on agar surface, spoangioles covered with a delicate, plicated slime sheet.

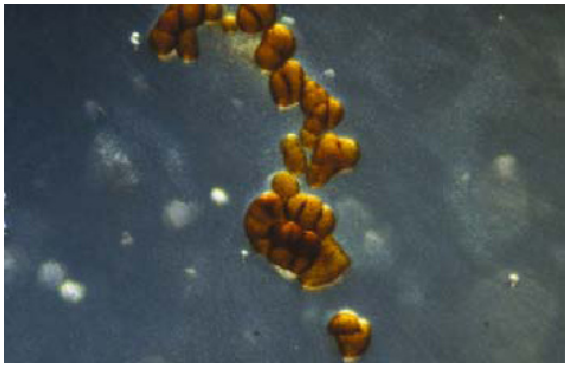
9. *Cystobacter violaceus*, original (now lost) type strain, violet swarm colonies on agar plate.



10. *Cystobacter violaceus* strain Cb vi67, fruiting body on agar surface.



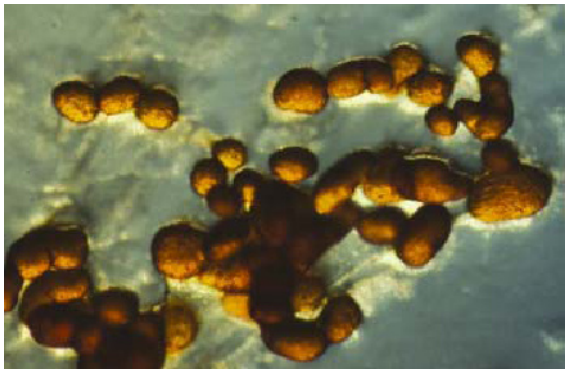
13. *Cystobacter gracilis* nov.spec., strain Cb g53, fruiting body on agar surface under cover glass.



11. *Cystobacter* minor strain Cb m29, fruiting body on agar surface.

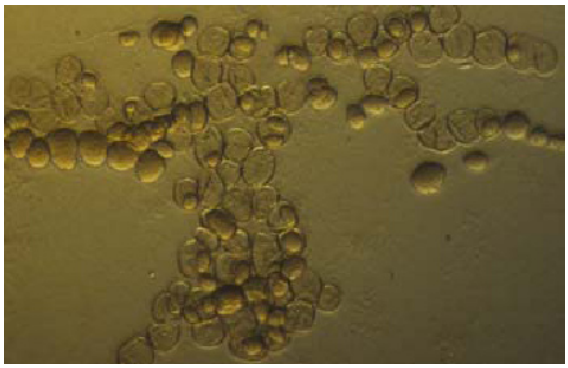
12. *Cystobacter* minor strain Cb m29, fruiting body on agar surface.

14. *Cystobacter miniatus* no.spec., strain Cb mi1, fruiting body consisting of densely packed sporangioles in a column-like, erect mass typical for that species.



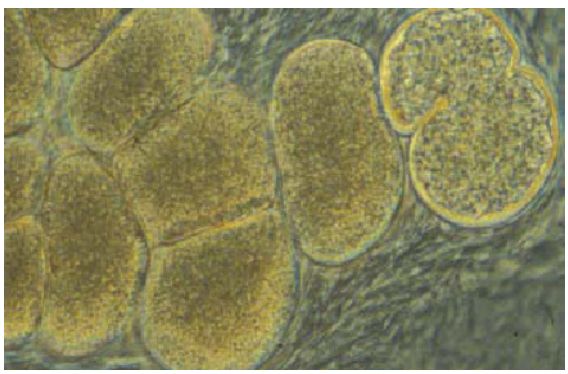
15. *Cystobacter badius* nov.spec., fruiting bodies on agar surface; besides chains of sporangioles, there also are found individual sporangioles, often on a short pedicel.

18. *Jahnia thaxteri* nov.gen., nov.spec., strain Pl t3, fruiting body on agar surface under cover glass; a wound chain of large sporangioles is sitting on a more or less obvious slime cushion.



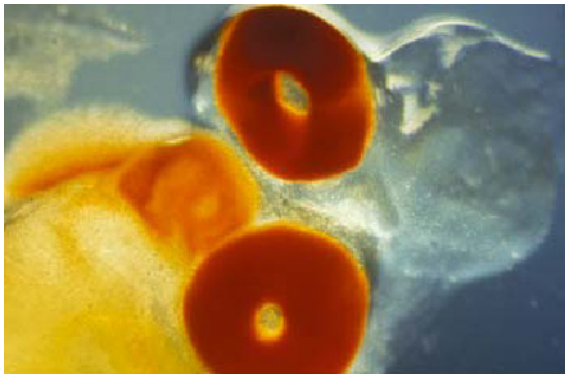
16. *Hyalangium minutum* nov.gen., nov.spec., strain Hy m3, fruiting bodies on agar surface under cover glass, with tiny sporangioles in a dense, mostly monolayer sheet; many sporangioles are empty looking, as if made of glass, as is typical for this organism.

19. *Byssophaga cruenta* nov.gen., nov.spec., strain By c1, swarm pseudoplasmodia on agar surface.

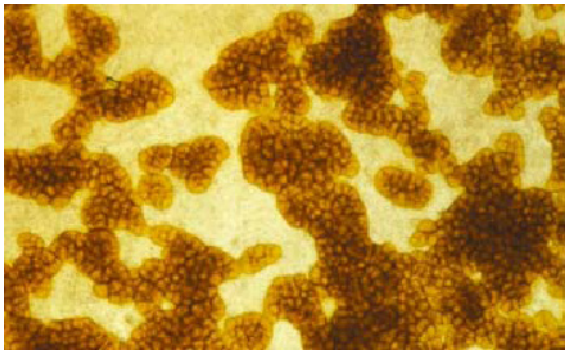


17. *Hyalangium minutum* nov.gen., nov.spec., strain NOCB-2, sporangioles in slide mount at high magnification, some of them showing invaginations of the sporangiole wall.

20. *Byssophaga cruenta* nov.gen., nov.spec., strain By c2, type strain), piled up cell mass on agar surface resembling a Myxococcus fruiting body.

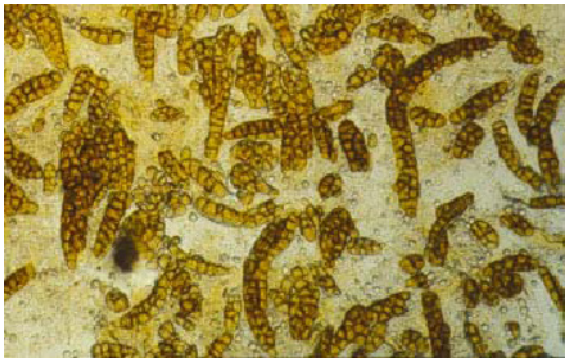


21. *Byssophaga cruenta* nov.gen., nov.spec., strain By c2 (type strain), cells assembled in massive rings on the agar surface.



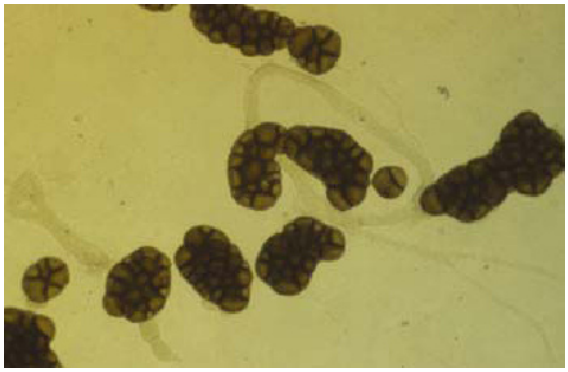
24. *Sorangium cellulosum* strain So ce1569, fruiting bodies on agar surface under cover glass.

22. *Byssophaga cruents* nov.gen., nov.spec., strain By c1, fruiting body on agar surface under cover glass consisting of large, densely packed sporangioles.



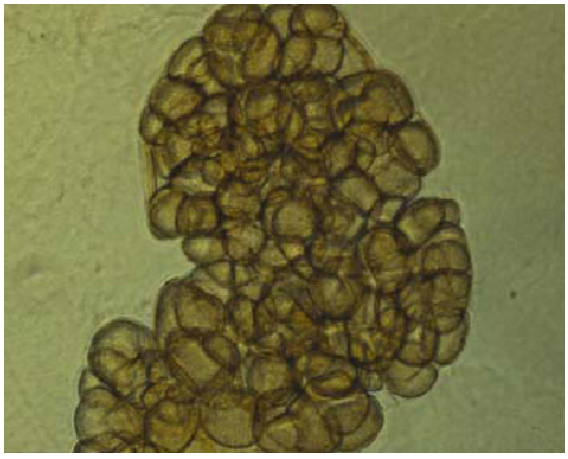
25. *Sorangium nigrum* nov.spec., strain So ce1600, fruiting bodies from macerated filter paper in slide mount.

23. *Sorangium cellulosum* strain So ce1569, fruiting bodies from macerated filter paper in slide mount; the tiny sporangioles are often arranged in chains because they were produced along cellulose fibers.

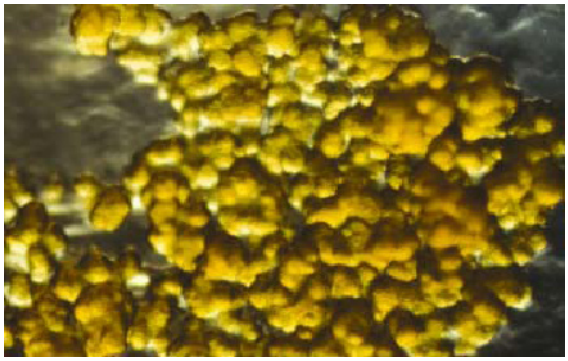


26. *Sorangium nigrum* nov.spec., strain So ce 1602, fruiting bodies on agar surface under cover glass.

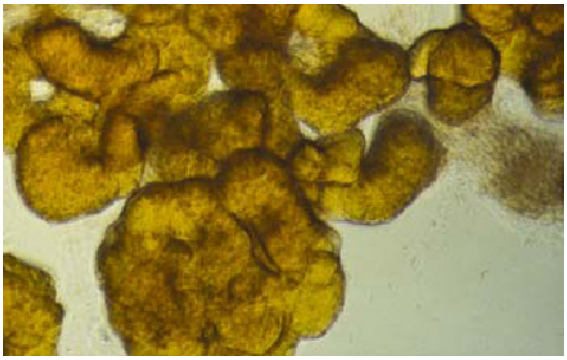
27. *Polyangium fumosum* strain Pl fu12, fruiting body on agar surface under cover glass.



28. *Polyangium spumosum* strain Pl sm4, fruiting body in slide mount.



29. *Kofleria flava* nov.gen., nov.spec., strain Pl vt10, growth on agar surface with numerous spherical knobs which are, however, not fruiting bodies.



30. *Kofleria flava* nov.gen., nov.spec., strain Pl vt10, nodules in slide mount.

CHAPTER 3.5.1

The Genus *Campylobacter*

TRUDY M. WASSENAAR AND DIANE G. NEWELL

Introduction

The genus *Campylobacter* comprises a diverse group of Gram-negative bacteria, which colonize the mucosal surfaces of the intestinal tracts, oral cavities, or urogenital tracts of a wide range of bird and animal hosts. Both commensals and pathogens are represented within this group of organisms.

Phylogeny

The genus *Campylobacter* is placed in the Epsilonproteobacteria (Trust et al., 1994) and now classified in the bacterial family Campylobacteraceae (Vandamme and De Ley, 1991a), which includes the genera *Campylobacter*, *Arcobacter* and *Sulfurospirillum* (formally known as free-living campylobacters) and certain misclassified *Bacteroides* species. The closest genetically related genera are *Helicobacter* and *Wolinella*, which together form the family, Helicobacteraceae (Vandamme, 2000).

Currently, the genus *Campylobacter* comprises 15 species (one of which is still disputed) and 6 subspecies: *Campylobacter coli*, *C. concisus*, *C. curvus*, *C. fetus* subsp. *fetus*, *C. fetus* subsp. *venerealis*, *C. gracilis*, *C. helveticus*, *C. hyoilei* (controversial), *C. hyointestinalis* subsp. *hyointestinalis*, *C. hyointestinalis* subsp. *lawsonii*, *C. jejuni* subsp. *jejuni*, *C. jejuni* subsp. *doylei*, *C. lari*, *C. mucosalis*, *C. rectus*, *C. showae*, *C. sputorum* and *C. upsaliensis* (Fig. 1). Recently a new species was described as *Campylobacter lanienae* sp. nov. The type strain for the genus is *Campylobacter fetus* subsp. *fetus*. The most commonly isolated pathogenic species are (in order of frequency) *C. jejuni*, *C. coli* and *C. fetus*.

Taxonomy

Historical Overview

Originally, campylobacters were described as members of the genus *Vibrio*. The first citation in the literature (McFadyean and Stockman, 1913) described the isolation of "*Vibrio fetus*" from an aborted lamb. This organism became *C. fetus* subsp. *fetus*, which is the type species for the genus. Later other veterinary pathogens were isolated. The first campylobacter, then called *Vibrio jejuni*, was isolated by Jones and Little (1931) from the jejunum of calves with enteritis, followed by *V. coli* isolated from pigs by Doyle (1944). The first report of an isolate from human gastrointestinal disease was by Levy (1946). However, one can argue that Escherich, in 1889, was the first to describe small vibrios in the large intestinal mucus of infants who had died of "cholera infantum," presumably caused by *C. jejuni* or *C. coli*. Important bacteriological progress was made by King (1957), who cultured microaerophilic vibrios at 42°C. She correctly hypothesized that the organism was involved in diarrheal illness (King, 1962). The genus *Campylobacter* was introduced in 1963 (Sebald and Veron, 1963) to differentiate, from the traditional members of the genus *Vibrio*, those organisms with a low G+C DNA content, a strict microaerophilic nature, and a nonsaccharolytic biochemistry. In 1973, Veron and Chatelain (1973) published the first accepted taxonomy of the genus *Campylobacter*.

The human gastric pathogen *Campylobacter pyloridis* (later corrected to *C. pylori*) was added to the genus (Marshall et al., 1984) in 1984. Five years later, this organism and related organisms were relocated into the new genus *Helicobacter* on the basis of 5S and 16S RNA sequence data and DNA-DNA hybridization experiments (Goodwin et al., 1989).

Campylobacter hyointestinalis was added to the genus in 1983 (Gebhart et al., 1983). Subsequently this species was divided into *C. hyointestinalis* subsp. *hyointestinalis* and *C. hyointestinalis* subsp. *lawsonii* (On et al., 1995). *Campylobacter upsaliensis* was included in the genus in 1991 (Vandamme et al., 1991b).

Ribosomal sequence data resulted in a recent reclassification of certain *Wolinella* and *Bacteroides* species as part of the genus *Campylobacter*. *Wolinella curva* was described in 1984 and added

to the genus *Campylobacter* as *C. curvus* (also referred to as *C. curva*) and *Wollinella rectus* was added to the genus as *C. rectus* (also *C. recta*) in 1991 (Vandamme et al., 1991b). *Bacterioides gracilis* was included in the genus as *C. gracilis* in 1995 (Vandamme et al., 1995).

In 1985, *C. sputorum* subsp. *mucosalis* was renamed *C. mucosalis* (Roop et al., 1985a). The other subspecies of *C. sputorum* (*C. sputorum* subsp. *sputorum* and *C. sputorum* subsp. *bubulus*) and "*C. fecalis*" are classified as biovars of *C. sputorum* (Roop et al., 1985b).

Campylobacter helveticus sp. nov. was described in 1992 (Stanley et al., 1992). *Campylobacter showae* was described in 1993 (Etoh et al., 1993). In 2000, a new species was isolated from the feces of healthy abattoir workers. The proposed name for this species is "*Campylobacter lanienae* sp. nov." (Logan et al., 2000).

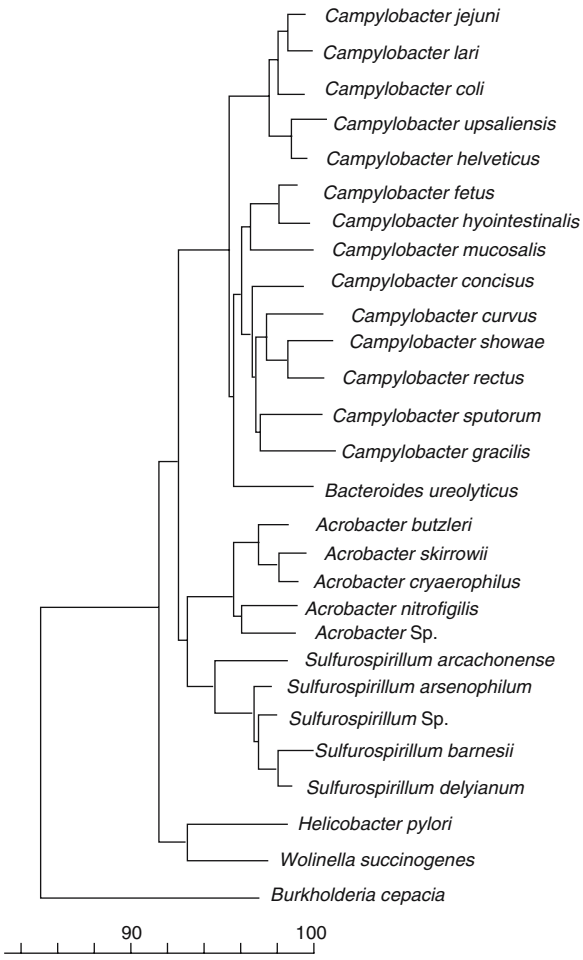

Fig. 1. Phylogenetic tree of the family Campylobacteraceae and its closest neighbors, based on the percent 16S rRNA gene sequence similarity. *Burkholderia cepacia* was used as an outgroup organism. From Vandamme (2000), with permission.

In 1991, a number of putative campylobacters were moved to the new genus *Arcobacter* or *Helicobacter* on the basis of ribosomal sequence analysis (Vandamme et al., 1991a; Vandamme and DeLey, 1991b). *Campylobacter cryaerophila* was added to the genus *Campylobacter* in 1985 and subsequently became *Arcobacter cryaerophilus*. *Campylobacter nitrofigilis* was added in 1983 and became *Arcobacter nitrofigilis*. *Campylobacter fennelliae* was added in 1988 and became *Helicobacter fennelliae*. In addition, *Campylobacter cinaedi* was reassigned as *Helicobacter cinaedi*.

The relatedness of the 15 species and 6 subspecies within the genus *Campylobacter* is shown (Fig. 1). In 1994, minimal standards were proposed for describing new species of the family Campylobacteraceae (Ursing et al., 1994). Despite these recommendations, some debate remains over the designation of *C. hyoilei* (Alderton et al., 1995), the characteristics of which may be identical to those of *C. coli* (Vandamme et al., 1997). The position of *Bacteroides ureolyticus*, formerly known as "*C. ureolyticus*" (or urease-positive thermophilic campylobacter), is also debatable (Vandamme et al., 1995).

Physiology

Table 1 summarizes the biochemical characteristics of the various Campylobacter species. All members of the genus have a low G+C content (29–47 mol%) and an optimal growth temperature (30–42°C). All the species are nonspore-forming, are sensitive to 3% or more NaCl, reduce fumarate to succinate, are oxidase-positive (except for *C. gracilis*), are indole-negative and reduce nitrate (except *C. jejuni* subsp. *doylei*).

All campylobacters are microaerophiles (optimal concentrations of O_2 [5–10%] and CO_2 [3–5%]). Some species (*C. gracilis*, *C. hyointestinalis*, *C. showae* and *C. sputorum* bv. *fecalis*) can grow under anaerobic conditions. *Campylobacter concisus*, *C. mucosalis*, *C. rectus*, *C. curvus*, *C. showae* and *C. gracilis* also require H_2 and/or formate or fumarate for growth. Energy metabolism occurs by respiration, not by fermentation or oxidation of carbohydrates.

The bacterial cells are slender, helical or curved rods (0.2–0.8 μm × 0.5–5.0 μm; Fig. 2). Certain species have cells that are straighter rods (i.e., *C. showae*), and in *C. jejuni* strains, cells are occasionally straight rods. Helical or curved rods can be observed in short or longer chains that can be V-, S-, or comma-shaped. In old cultures or cultures exposed to environmental stresses such as atmospheric oxygen, the cells can change to spherical or coccal forms.

Table 1. Biochemical differentiation of species within the Campylobacteraceae.

Characteristics[a]	*C. jejuni jejuni*	*C. jejuni doylei*	*C. coli*	*C. lari*	*C. upsaliensis*	*C. concisis*	*C. fetus*[b]	*C. hyointestinalis*[c]	*C. rectus*	*C. curvus*	*C. mucosalis*	*C. gracilis*	*C. helveticus*	*C. sputorum*[d]	*C. showas*

Abbreviations: H_2S on TSI, hydrogen sulfide production on triple sugar iron medium.

[a]The data represent a consensus from various tables published in the last 10 years, with significant divergence from the consensus (more than once reported) indicated in parentheses. (*Bergey's Manual*, 1994; Cowan and Steel, 1993; On, 1996; Tenover and Fenell, 1992; Skirrow, 1990; Topley, 2000; Nachamkin, 1995; Vandamme, 2000).

[b]*Campylobacter fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis* are identical in most tests but for growth on glycine, which is negative for *C. venerealis*. Although this test is regarded as discriminative, the outcome can be unreliable since glycine-tolerant *C. venerealis* does occur. Growth at 42°C is negative for *C. venerealis*.

[c]*Campylobacter hyointestinalis* subsp. *hyointestinalis* and *C. hyointestinalis* subsp. *lawsonii* are identical in most tests but for growth in 1% glycine, which is variable for *C. lawsonii*.

[d]All three biovars of *C. sputorum* are identical in most tests except catalase, which is positive for subsp. *fecalis*; nitrite reduction, which is sometimes reported variable for subsp. *sputorum* and *bubulus*; and growth in 3.5% NaCl, which is negative for subsp. *sputorum* and sometimes reported as negative for subsp. *fecalis*.

[f]In some publications this test is performed according to Roop et al., 1984, and in those cases, *C. jejuni* subsp. *jejuni*, *coli*, and *lari* are reported positive.

[g]Hippurate-negative *C. jejuni* subsp. *jujuni* has been reported (Totten et al., 1987).

[h]Only reported once, so that this entry may be erroneous.

[i]*Campylobacter hyoilei* is reported nitrite-reduction positive but is regarded as a *C. coli* strain on the basis of overall characteristics.

[j]*Campylobacter fetus* subsp. *fetus*.

[k]*Campylobacter fetus* subsp. *venerealis*.

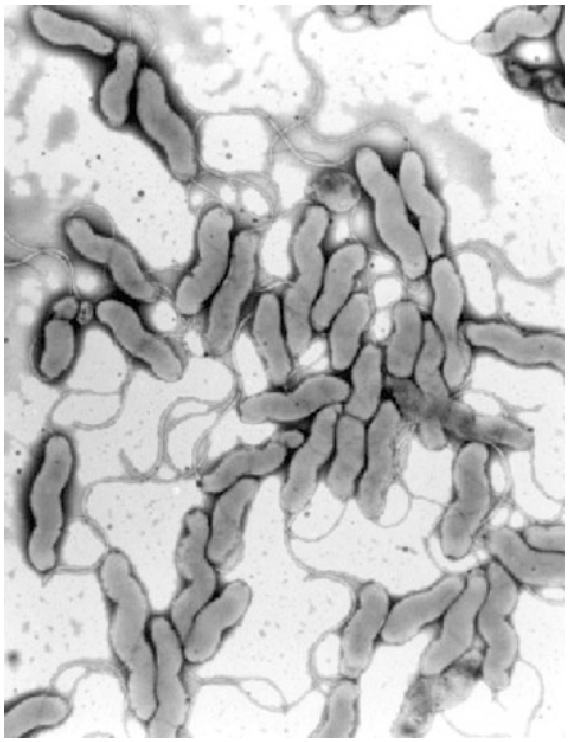

Fig. 2. Electronmicrograph of *Campylobacter jejuni*.

In general, campylobacters have a characteristic darting, corkscrew-like motility conferred by a single, polar non-sheathed flagellum. However, *C. showae* has a unipolar bundle of flagella, and *C. gracilis* is nonmotile and lacks flagella (Vandamme and De Ley, 1991a; Vandamme, 2000). Both *C. jejuni* and *C. coli* can produce nonmotile variants, especially on frequent subculture.

Habitat

Campylobacter species colonize the mucous overlying the mucosal surfaces of mammals and birds. Their darting motility enables them to maintain station in the mucous flow.

The thermophilic organism *C. jejuni* subsp. *jejuni* appears to have evolved to optimally colonize the intestinal mucosa, especially the cecum, of birds (body temperature 42°C). In this habitat, the organism appears to act as a commensal. It is most frequently isolated from broiler chickens. However, *C. jejuni* also colonizes the intestinal mucosa of mammals with lower body temperatures, where it acts as a pathogen. In some humans, particularly those who are immunocompromised, survival and growth at extraintestinal sites can also occur. The microaerophilic nature and temperature dependence of these organisms preclude growth outside their intestinal niches. Nevertheless, these species can be isolated from fecally contaminated environmental sources, such as surface water and animal products, including meat and milk.

The intestinal mucosa is also the usual habitat of most other *Campylobacter* species. Some species are frequently, but not exclusively, host-associated. *Campylobacter coli*, *C. mucosalis* and *C. hyointestinalis* are most frequently isolated from the intestinal contents of pigs. *Campylobacter lari* is usually isolated from wild birds, although it has also been isolated from shellfish, presumably from the filtration of water fecally contaminated by sea gulls. *Campylobacter upsaliensis* and *C. helveticus* are found in the intestines of cats and dogs.

Campylobacter fetus subsp. *fetus* also colonizes the intestinal tract, usually of cattle and sheep and sometimes of humans, but can translocate from the gut to cause systemic infection. In particular this organism appears to have a tropism for the urogenital tract, where it can colonize the uterine mucosa and fetal tissues. In contrast, *C. fetus* subsp. *venerealis* has bovine host specificity and has only rarely been recovered from the intestine. This organism specifically colonizes the prepuce of bulls and the vagina and fetal tissues of venereally infected cows. *Campylobacter sputorum* bv. *bubulus* is also found primarily in these bovine urogenital sites, whereas *C. sputorum* bv. *fecalis* colonizes bovine genitalia and the intestines of various host species.

Several *Campylobacter* species specifically colonize the oral cavity. *Campylobacter sputorum* subsp. *sputorum*, *C. concisus*, *C. rectus*, *C. curvus* and *C. showae* are recoverable from human oral flora. *Campylobacter gracilis* has been isolated from gingival crevices. Some of these bacteria are also recoverable from feces, though whether this reflects intestinal tract colonization or transient passage is debatable.

Isolation

Isolation methods for *Campylobacter* spp. have improved considerably over the last few decades. Isolation of clinically relevant thermophilic campylobacters from stool samples is generally based on selective antibiotics and growth at 42°C to inhibit contaminating flora. The isolation of bacteria from food and environmental samples, or any sample with low numbers of stressed bacteria potentially present, usually involves pre-enrichment procedures followed by culture on selective media. One drawback of this is the possible overgrowth and inhibition by competing bacteria during the pre-enrichment period. A further problem is that different culture tech-

niques recover different species and strains. Available isolation procedures and media have recently been reviewed (Corry et al., 1995). The most recent strategies for isolation from food and water are reviewed elsewhere (Hunt and Abeyta, 1995; International Organization for Standardization, 1995; Jacobs-Reitsma, 2000).

Most enrichment media for *Campylobacter* are based on selective antimicrobials (especially cefoperazone, cycloheximide, trimethoprim and vancomycin), which are sometimes added with delay to allow resuscitation of damaged organisms. Campylobacters, especially stressed organisms, are very sensitive to peroxides despite their possession of superoxide dismutase and catalase. Such organisms benefit from media with radical scavengers (e.g. charcoal or sheep or horse blood) and from improved atmospheric conditions (H_2 in combination with formate). The use of selective antibiotics and a high incubation temperature may prevent isolation of certain sensitive, less-common *Campylobacter* species, e.g., *C. hyointestinalis*, *C. upsaliensis*, *C. mucosalis* or *C. jejuni* subsp. *doylei*. Many of these species are slower growing and incubation periods should be extended for their isolation.

A nonselective protocol for the isolation and identification of campylobacters and related organisms from stools and blood, primarily of human origin, is described below (see the section Identification in Stools and Blood Samples: The Cape Town Protocol in this Chapter).

Genetic Detection

The polymerase chain reaction (PCR) has recently been applied to the detection of campylobacters. Such genetic detection techniques can be very sensitive; however, depending on the type of sample, they generate a number of problems. In samples with low bacterial numbers (i.e., foods), pre-enrichment is required. This greatly reduces the benefit of PCR as a fast one-step method. The presence of potential PCR inhibitors ensures the need for robust PCR protocols (Thunberg et al., 2000). Purification procedures to remove PCR inhibitors are effective but add extra work (Wang et al., 1999). In feces, numbers of campylobacters may vary and the presence of significant numbers of other microorganisms demands a high specificity. The desirability of detecting viable but not culturable forms in the environment is questionable. At the moment, the tendency is to ignore such damaged organisms because they are insignificant in terms of infectivity (Fearnley et al., 1996). However, the debate is not yet closed (Cappelier et al., 1999). Some PCR detection methods developed for *Campylobacter* spp. detect directly at the species level; others do not differentiate a number of species. (See the section Genetic Identification: Methods for Speciation in this Chapter.)

Identification

Biochemical Identification

A comparison of the recent literature regarding the systematic bacteriology of campylobacters (Skirrow, 1990; Tenover and Fenell, 1992; Cowan and Steel, 1993; *Bergey's Manual*, 1994; Nachamkin, 1995; On, 1996; Topley, 2000; Vandamme, 2000) reveals many inconsistencies in their biochemical properties. This variation, largely a consequence of experimental variation and the subjective nature of such tests, highlights the need for standardization. A consensus of biochemical and growth properties of all *Campylobacter* species is given in Table 1. Such tables should be treated circumspectly as rigid adherence to these properties may result in mistyping. Some strains have anomalous properties, e.g., hippurate-negative *C. jejuni* has been reported (Totten et al., 1987). Some tests give inconsistent results, i.e., H_2S production on triple sugar iron (TSI) medium is extremely inconsistent for *C. jejuni*, *C. coli*, *C. lari*, *C. concisus*, *C. hyointestinalis* and *C. sputorum*. Some properties are dependent on the age of the culture and the test conditions applied.

For the speciation of clinically relevant isolates, distinguishing campylobacters from other organisms with similar morphology and ecology (especially certain helicobacters and arcobacters) is important. Because *C. jejuni/coli* and *C. fetus* are thought to be the most relevant pathogens, identification of campylobacters, other than these three, is not always carried out. Indeed in most studies *C. jejuni* and *C. coli* are by far the most commonly isolated pathogens. However this may, in part, reflect the use of selective antibiotics, which does not allow growth of most other campylobacters. When a filter technique is used, without antimicrobial selection, significantly higher numbers of other campylobacters are detected.

Identification in Stools and Blood Samples: The Cape Town Protocol

One of the best protocols to isolate every possible member of the genus is the Cape Town protocol (developed at the Red Cross Children's Hospital in Cape Town, South Africa; Le Roux and Lastovica, 1998). In this laboratory, most *Campylobacter* species (with the notable exception of *C. sputorum* subsp. *sputorum*) have been isolated from blood of patients with bacteremia. One therefore may speculate that, under certain

conditions, every *Campylobacter* species may be pathogenic. However, these findings may be a consequence of the socio-economic, hygienic and nutritional status of the patients. A brief version of the protocol is included here with the permission of Dr. Albert Lastovica.

For stool samples, a watery emulsion of fecal material in saline should be applied, without pressure, to 0.6-µm pore filters placed directly on agar plates containing 10% horse blood. The filter is flooded three times with emulsified specimen. Blood samples are applied directly to the plate without filtration. Primary culture plates should be incubated in an H_2-containing atmosphere for 6 days, checking for growth every 2 days. Plates should not be checked within the first 24 h to prevent lethal damage to fastidious organisms. An H_2-containing atmosphere can be generated by anaerobic Gas Pack without using a catalyst, alternatively by the application of a gas mixture of 15% CO_2 and 85% H_2. *Campylobacter* colonies are mostly buff colored or dirty yellow. *Campylobacter helveticus*, *Helicobacter fennelliae*, *H. cinaedi* and *H. rappini* spread, forming thin, flat films, which often become visible after 6 days. *Arcobacter* colonies are whiter. A Gram stain should confirm the cell morphology. The cells of *H. fennelliae* and *H. cinaedi* are thin, long spirals; those of *C. mucosalis* are short and stubby. *Campylobacter hyointestinalis* and *Arcobacter* are big and slightly curved bacteria, whereas *C. concisus*, *C. rectus*, *C. curvus* and *C. ureolyticus* are straight or hardly curved.

Putative campylobacters are subcultured on two tryptose blood agar plates (TBA containing 10% horse blood). One plate is incubated in the H_2-containing atmosphere, the other in 13% CO_2 in air. All subsequent tests are performed using a 48-h old culture from the culture grown in the H_2-containing atmosphere, with the exceptions of the lead acetate (PbAc) and TSI tests, which could give false-positive results under such culture conditions. The CO_2 culture is used for these tests. Growth in the plate incubated in a CO_2-containing-atmosphere is checked for up to 4 days. Table 2 lists the organisms expected to grow in the CO_2-containing atmosphere.

The tests performed for species identification are listed in Table 2. Inconsistencies appear between Tables 1 and 2; the former is a compilation of available determination tables from the literature; however, the test results of Table 2 were obtained from one laboratory.

Identification in Veterinary Venereal Specimens

Campylobacter fetus infection in bovines is a challenging diagnostic problem. *Campylobacter fetus* subsp. *venerealis* can be venereally transmitted from bulls to cause infertility and abortion in susceptible cows. This infection is of statutory significance for import-export regulations in many countries. This is of major importance in the international trade of bovine semen and embryos. The major diagnostic problem, however, occurs because other *Campylobacter* species and *C. fetus* subspecies may also be present in bovine genital tract and fetal samples. One simple method of differentiation of *C. fetus* from the commensal, *C. sputorum*, is the rapid H_2S test and growth in bile esculin (Table 1). Some regulations call for freedom from all *C. fetus* and others for freedom from *C. fetus* subsp. *venerealis* only. Thus, differentiation between subspecies may be crucial. Currently subspeciation is based on growth tolerance to 1% glycine (Table 1). However, tolerant variants of *C. fetus* subsp. *venerealis* occur. There is little serotypic diversity within the species: *C. fetus* subsp. *fetus* comprises two serotypes (A and B), whereas *C. fetus* subsp. *venerealis* is always of serotype A (Marsh and Firehammer, 1953). Complementary genotypic methods have now been developed for the subspeciation of *C. fetus*.

Genetic Identification: Methods for Speciation

Tests have now been described to identify *Campylobacter* species by means of genetic methods. Most of these tests are based on PCR and some commercial PCR tests are now available. Potentially PCR should be easier to perform and more reliable than biochemical tests, but PCR identification for campylobacters has not been accepted for routine use. Available genetic identification methods have been reviewed recently (On, 1996).

Some PCR detection methods developed for *Campylobacter* spp. detect the thermophilic campylobacters directly at the species level with variable levels of discrimination (Table 3). Most of these methods are based on amplification of (fragments of) flagellin genes or ribosomal genes. In some of the methods, the target gene for species-specific amplification has been selected by hybridization experiments and has not been further characterized (Korolik et al., 1995). Species-specific hybridization of PCR products obtained with degenerate primers is also used (Al Rashid et al., 2000). The methods described vary in complexity from a single PCR directly from the sample to pre-enrichment and/or filtering, amplification, and gel electrophoresis followed by Southern blotting (or spot blots) and hybridization. The relative efficacy of these methods has yet to be determined. In one comparative study, speciation by PCR was at least as

Table 2. The Cape Town protocol for the differentiation of clinically relevant campylobacters and related organisms.

Lysed cells from enriched carcass washes	*C. jejuni*	U	NA	Filtration, culturing required	Winters, 1995
DNA from pure cultures	*C. jejuni*	U	1 CFU	Hybridization required	Stonnet, 1993
DNA from pure cultures	*C. jejuni*, *coli*, *lari*	U	NA	RAPD PCR followed by hybridization	Giesendorf, 1993
PCR independent methods:					
Pure cultures	*C. jejuni* + *coli* + *lari* or *jejuni*, *coli*, *lari*	16S rRNA	6 CFU in presence of 4×10^6 CFU Gram-negative bacteria	NASBA followed by hybridization, speciation is dependent on probe	Uyttendaele et al., 1994
Pure cultures	*C. jejuni* + *coli* + *lari*	NS	NAp	One-step DNA hybridization	Tenover et al., 1990
DNA from pure cultures	*C. jejuni*, *coli*	NAp	NAp	Slot blot hybridization to speciate atypical Campylobacters	Ng et al., 1987
DNA from pure cultures	*C. jejuni*, *coli*	U	NAp	Southern blot hybridization	Korolik et al., 1995

Abbreviations: PCR, polymerase chain reaction; CFU, colony-forming units; NA, not available; RAPD PCR, randomly amplified polymorphic DNA-PCR; NASBA, nucleic acid sequence-based amplification; NS, not specified; NAp, not applicable.

[a]When multiple species are detected that cannot be differentiated this is indicated by "+." When a single species is given the method is specific for that species. When the method allows differentiation between species, these are separated by ","

sensitive as classical biochemical techniques (Steinbrückner et al., 1999).

Genetic identification methods (independent of PCR) have also been described, for instance, hybridization of Southern blots with species-specific probes derived from the rRNA genes (Tenover et al., 1990). The technique known as "NASBA" ("nucleic acid sequence-based amplification") is based on Taq-independent, room temperature amplification, and this can be used for speciation when it is followed by hybridization (Uyttendaele et al., 1994). Atypical thermophilic campylobacters can be identified as *C. jejuni* or *C. coli* (or neither of these) by slot-blot hybridization (Ng et al., 1987). Positive identification of *Campylobacter* species should be confirmed, ideally, by DNA-DNA hybridization with the type-strain. DNA hybridization has revealed the existence of hippurate-negative *C. jejuni* isolates (Totten et al., 1987). Such techniques are generally considered too complex to be applied on a routine basis.

Isolates specified by classical biochemical identification are sometimes found more likely to be members of different species based on their genotype (Duim et al., 2001; Waino et al., 2003). Such observations indicate that biochemical identification is often unreliable when not backed up with DNA-DNA hybridization or other genetic methods. On the other hand, some genetic tests do not have a sufficient level of discrimination to be used for species identification. An example of the latter is the flagellin gene restriction fragment length polymorphism (RFLP), in which *C. coli* cannot be distinguished from *C. jejuni* because both species can share identical flagellin genotypes.

The subspeciation of *C. fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis* has been addressed by genotyping techniques. Pulsed field gel electrophoresis (PFGE) of chromosomal DNA enables differentiation of the two subspecies, both on the basis of restriction enzyme banding patterns (Fujita et al., 1995a) and on their difference in genome size (*C. fetus* subsp. fetus has 1.1 Mb and *C. fetus* subsp. *venerealis* 1.3 Mb; Salama et al., 1992). In addition, a PCR test has been described that apparently can discriminate between *C. fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis* (Hum et al., 1997). Finally, amplified fragment length polymorphism (AFLP) is also proving an extremely useful discriminatory method for these subspecies (Wagenaar et al., 2000).

Phenotypic Methods for Subtyping

Subtyping is a routine tool for epidemiological investigation, particularly tracing food-borne bacteria, such as *C. jejuni*/*coli*, through the food chain. Serotyping has been the most commonly used method of phenotyping. Early studies demonstrated considerable serologic variation in both the heat-stable (Penner and Hennessy, 1980) and heat-labile antigens (Lior et al., 1982) of *C. jejuni*/*coli* strains. The lipopolysaccharide (LPS) is considered the heat-stable antigenic component (Moran and Penner, 1999), but recent studies suggest that a surface polysaccharide may also be involved (Karlyshev et al., 2000). Similarly the heat-labile antigen may be a mixture of flagellin polypeptides modified by strain-specific posttranslational glycosylation (Doig et al., 1996a). Recently a further serotyping scheme has been developed for routine use in the United Kingdom (Frost et al., 1998). Although serotyping has been a useful tool, the poor availability and expense of production and quality control of antisera have generally precluded the extensive use of this method. In addition, a considerable proportion (up to 40%) of isolates are not typeable by this method.

Phage typing has also been developed (Grajewski et al., 1985; Salama et al., 1990; Khakhria and Lior, 1992). Recently a layered strategy combining serotyping and phage typing (Frost et al., 1999) has been applied to the typing of human campylobacter strains in the United Kingdom (Newell et al., 2000).

Other phenotyping techniques applied to campylobacters have included fatty acid profiling and sodium dodecyl sulfate polyacrylamide gel electrophoresis protein profiling, but such techniques rarely have the discriminatory power required for epidemiological purposes.

Genetic Methods for Subtyping

Many genetic methods have been described for the subtyping of Campylobacter strains, and these were recently reviewed (Wassenaar and Newell, 2000). Genetic subtyping studies have revealed an enormous genetic diversity within the species *C. jejuni* and *C. coli* and to a lesser extent within *C. lari*, *C. consisus* and *C. upsaliensis*. Genetic typing methods (such as PFGE [of digested chromosomal DNA], ribotyping, and AFLP) have been found satisfactory for epidemiological investigations and have given insight into the population structure of *C. jejuni* and *C. coli*. The findings suggest a complex, weakly clonal population which has been confirmed by multilocus enzyme electrophoresis studies (Meinersmann et al., 2002) and multilocus sequence typing (MLST; Dingle et al., 2002; Manning et al., 2003). Genetic characterization of isolates is potentially hampered by frequent exchange of DNA between strains (as suggested by MLST), possibly by the property of natural competence to take up and incorporate chromosomal DNA (Wang and Taylor, 1990). The fre-

quent exchange of (parts of) genes or loci may preclude recognition of particular pathotypes (Meinersmann et al., 2002). In addition to exchange of alleles, *Campylobacter* genomes may undergo inversions and translocations, rendering their genotypes unstable. This has been observed by changes in PFGE genotypes and seems to be strain-dependent rather than a general characteristic (Wassenaar et al., 1998). Finally, experimental mixed infections in animals have resulted in the selection of novel genotypes (Boer et al., 2002). These observations suggest that genotypic identification of isolates requires careful interpretation.

Preservation

Campylobacter cultures age quickly and rapidly, become coccoidal in form, and lose viability. Short-term storage (up to 7 days) of plate cultures is possible at 4°C under microaerobic conditions. Long-term storage should be of actively growing cultures. Campylobacters can be freeze-dried but specialist skills and equipment are required, and recovery is sometimes poor. In most routine laboratories, campylobacters are frozen in media containing a cryopreservative, such as 10% glycerol, and stored in –70° to –80°C freezers or in liquid nitrogen. Strains stored in this way have remained viable for over 20 years. Recovery from frozen stocks may require pre-enrichment for recovery of damaged cells.

Epidemiology

Epidemiology of *C. jejuni* and *C. coli*

Campylobacter jejuni and the closely related organism *C. coli* are the most common cause (worldwide) of acute bacterial enteritis (Tauxe, 1992). The clinical outcome of infection varies throughout the world. In industrialized countries, such as the United States and United Kingdom, infection results in acute watery or bloody diarrhea. The required infectious dose for disease, as determined by volunteer studies, was large (10^4 colony forming units; Black et al., 1992) but asymptomatic infection occurs at lower doses, and the outcome of disease is dependent on the immune status of the host. In nonindustrialized countries, diarrhea associated with infection is usually apparent only in children under the age of 2 years. Thereafter, infection appears to be asymptomatic. The reason for this difference is not clear but may reflect differences in the immune status of individuals in the non-industrialized world.

Surveillance of infection has been in place in England and Wales since the early 1980s. The data demonstrate a clearly increasing trend in reported cases. Initially this trend may have reflected improved diagnosis. The cause of the more recent increases is, as yet, unknown. In 1998, 58,000 cases were reported. Community-based studies (Tompkins et al., 1999) suggest that over 8 times as many cases are unreported. This indicates that in this geographical region there are half a million cases per annum. The World Health Organization (WHO) estimates approximately 1% of the population is infected each year. The social and economic cost of this disease is considerable.

The sources and routes of human infection are still debatable. Human-to-human spread rarely occurs. The organisms are ubiquitous in the environment and can be recovered from most food-producing and domestic animals and birds, as well as from surface waters, soil, etc. The vast majority of infections are sporadic. Outbreaks are occasionally detected. In large outbreaks, contaminated water and milk appear to be major vehicles. For sporadic cases, the vehicles are very difficult to detect. However, some case control studies indicate that the consumption or handling of raw or undercooked poultry meat is a major risk factor. Other recognized risk factors include young domestic pets (kittens or puppies with diarrhea), unpasteurized milk, swimming in surface waters, and barbecues.

The epidemiology of these organisms in mammalian species other than humans is unknown. Most young mammals become colonized early, presumably with organisms transmitted by occasional excretion from dams. These infections are rarely symptomatic.

Many poultry flocks are colonized asymptomatically with *C. jejuni* or *C. coli*. This infection is usually only detectable when the birds are 2–3 weeks of age. Once detected, 100% of chickens become infected within 72 h. The sources of infection for these birds are unknown, and although organisms can be recovered from the oviducts, vertical transmission is not considered a major source. Most likely birds are infected from organisms around the external environment of the poultry house.

Epidemiology of *C. fetus*

Campylobacter fetus subsp. *venerealis* is venereally transmitted and is a frequent infectious cause of bovine infertility in those countries where natural mating, rather than artificial insemination (AI), is standard agricultural practice (Garcia et al., 1983). For the purposes of AI, bulls standing at AI centers are screened for infection and semen is antibiotic treated. This has

significantly reduced the risk of transmission of bovine *C. fetus* subsp. *venerealis* infection. The statutory testing of bulls, semen and embryos for import and export is in place in most countries to protect cattle herds.

Campylobacters, mostly *C. fetus*, can cause fetopathology, leading to fetal death, in both cattle and sheep. In the United Kingdom Campylobacter infections in cattle represent a significant proportion (7%) of diagnosed infectious causes of bovine fetopathy and infertility (VIDA, 1996) and constitute the third most common cause of all ovine abortions (10%) diagnosed at veterinary investigation centers (VIDA, 1996). Serious economic loss results from abortion, which can affect up to 70% of a flock. Ovine *C. fetus* abortion is reported throughout the world and is of particular importance in Middle Eastern countries such as Jordan (Aldomy, 1992). In New Zealand, where it is the most common cause of ovine abortion, *C. fetus* subsp. *fetus* is responsible for 60–70% of cases (Skirrow, 1994). *Campylobacter fetus* abortion may be underdiagnosed in the United States (Hansen et al., 1990). This organism is not venereally transmitted but readily colonizes the intestinal tract. Infection appears to be transmitted via contact with active fecal shedders. Non-ovine reservoirs of infection may exist in some wildlife, including birds.

Especially in immunocompromised individuals, *C. fetus* subsp. *fetus* can cause severe human infection, which is thought to occur by the ingestion of fecally contaminated food, for example beef or lamb. The incidence of human disease is unknown.

Pathogenicity

Disease Caused by *C. jejuni* and *C. coli*

Human infection with *C. jejuni* or *C. coli* usually presents with fever followed by diarrhea. Intestinal illness may be accompanied by bacteremia and systemic infection, especially in persons at the extremes of age or who are immunocompromised. However, in most cases, infection is confined to the intestine. Colonic biopsies demonstrate an acute inflammatory response with infiltration of the epithelium and lamina propria by neutrophils and mononuclear cells. The diarrheic stools of affected individuals from industrialized countries usually contain leukocytes and erythrocytes, even when the stools are watery and not grossly bloody. Thus, *Campylobacter* colitis and enteritis should be considered an inflammatory illness. The disease is generally self-limiting and antibiotic treatment is not normally required. The duration of diarrhea is usually less than one week; however, excretion of the organism may continue for several weeks. In up to 20% of cases, a relapse, usually mild, may occur within a few days of spontaneous remission. Such cases may indicate an incomplete immune response. Immunocompromised hosts, including patients infected with human immunodeficiency virus, often have severe, extraintestinal, prolonged and relapsing illnesses, sometimes with a permanent inability to clear the organism (Melamed et al., 1983; Perlman et al., 1988).

An important sequelum of *C. jejuni* infections is the development of the Guillain-Barré Syndrome (GBS), an acute neurological disease marked by ascending paralysis resulting from demyelination of peripheral nerves (for a recent review, see Nachamkin et al. [1998]). In the United States, an estimated 0.05% of *C. jejuni* infections induce GBS (Nachamkin et al., 1998). The symptoms are evident about 7–21 days following onset of infection. This timing suggests that the host immune response to C. jejuni, rather than the acute toxicity of the infection, is responsible for the disease. Certain heat-stable serotypes, especially O:19 (in the United States and in Japan; Kuroki et al., 1993) and O:41 (in South Africa; Lastovica et al., 1997) are predominantly linked to the onset of GBS. However, in European countries the correlation with certain serotypes is less clear (Endtz et al., 2000). Autoimmune responses, as a consequence of mimicry of host neurological tissue antigens by bacterial antigenic components (especially LPS) of these serotypes, are considered to be the trigger for GBS.

Pathogenicity of *C. jejuni/coli*

The pathogenic mechanism(s) by which *C. jejuni* and *C. coli* cause diarrheal disease remains surprisingly obscure. Although a number of virulence factors have been implicated, a satisfying explanation for this most common outcome of infection cannot be given. The main reason for this is the absence of suitable laboratory animal models of disease (Newell, 2001).

The complete genome sequence of strain *C. jejuni* 11168 confirmed the absence of an identifiable virulence-associated pathogenicity island; however, this strain may not be representative of the species. Furthermore, virulence factors (enterotoxin, shiga-toxin, or hemolysin genes, and invasion loci) recognized as key in other enteropathogens were all absent (Parkhill et al., 2000). As recognized by genotypic analysis, *C. jejuni/coli* are diverse species (see the section Genetic Methods for Subtyping in this Chapter). This diversity is apparently reflected in pathogenic phenotype: many different toxins have been described (for a review, see Wassenaar

[1998]); fimbriae and other adhesion structures can be present under specific growth conditions (Doig et al., 1996b), and invasion properties and mechanisms vary or may be absent (Lindblom et al., 1990; Wassenaar and Blaser, 1999). This resembles the situation with *Escherichia coli* and *Salmonella enterica*, where many different pathotypes exist. However, in *C. jejuni/coli*, different pathotypes have not yet been sufficiently characterized; tissue tropism or host-specificity of strains within these bacterial species seems to be absent, and the genetic basis for the observed phenotypic variation is largely unknown.

All strains of *C. jejuni* and *C. coli* can produce flagella, and motility has long been recognized as a virulence property. Inactivation of the structural genes for flagellin results in loss or attenuation of colonization potential (Nachamkin et al., 1993; Wassenaar et al., 1993). Phase variation results in colonies of nonmotile cells and is regulated at the level of transcription of flagellin (Nuijten et al., 1989). The two tandem flagellin genes, present in a single locus, have different roles, with the first gene being predominantly expressed (Wassenaar et al., 1994). Flagellin protein is immunodominant during infection and can elicit a protective immune response for homologous but not heterologous strains (Pavlovskis et al., 1991).

The role of adhesive structures, like fimbriae, is unclear. Fimbrial-like protrusions (Doig et al., 1996a) are now considered an artifact of exposure to bile salts (Gaynor et al., 2001). No structural genes for fimbrial proteins have been identified. Both LPS and flagella have been shown to have adhesive properties. Proteinaceous adhesins have also been identified (reviewed in Konkel et al. [2000]). Adhesion may not be required for colonization because motility enables the bacteria to overcome peristaltic flow. However, invasion depends on prior adhesion to the mucosal cells. Different invasion mechanisms have been described that may depend on actin polymerization (reviewed in Konkel et al. [2000]). Either microfilament-dependent pseudopods are formed, or the microfilaments do not reorganize; instead, microtubules are involved in the uptake mechanism (Oelschlaeger et al., 1993). Both clathrin-coated pits (Oelschlaeger et al., 1993) and clathrin-independent caveolae (Wooldridge et al., 1996) have been implicated in endocytosis. These different findings may reflect strain and pathotype differences.

Cell damage, as a result of bacterial invasion, is probably one of the major factors resulting in diarrhea. This damage, combined with invasion into deeper tissue, would account for the inflammatory response. The bacteria may enter the bloodstream where they are quickly cleared by complement activation. Some *C. jejuni* strains that are highly resistant to serum have been detected, although the mechanisms for this resistance have not been clarified (Blaser et al., 1986). Most circulating bacteria eventually will be phagocytosed by leukocytes or macrophages of the reticuloendothelial system. Recent studies on the behavior of *C. jejuni* after phagocytosis in vitro using monocytes stimulated with cytokines showed that macrophages are able to kill all tested strains with high efficiency (Wassenaar et al., 1997). These findings are in agreement with the self-limiting nature of most *C. jejuni* infections.

One of the mechanisms for virulence proposed in the early days of *Campylobacter* research was the production of toxins. Research concentrated on exotoxins (as opposed to the toxic effects of LPS), which were called either "enterotoxins" or "cytotoxins." Cytotoxic activity with similarity (both in mode of action and immunological crossreaction) to that observed with the enterotoxins of *Vibrio cholera* and *E. coli* was detected. Nevertheless, enterotoxin genes are absent in *C. jejuni* (Perez-Perez et al., 1992). The cytotoxic activity is most likely the result of one or several cytotoxins. In a recent review (Wassenaar, 1997), at least six different toxins, or classes of toxins, were recognized. Of these, the cytolethal distending toxin (Cdt) is the first toxin for which the genetic locus has been cloned and its sequence analyzed (Pickett et al., 1996). This toxin blocks HeLa (a line derived from human adenocarcinoma) cell division in the G_2/M phase, ultimately leading to cell death (Whitehouse et al., 1998). The direct role of Cdt in disease remains to be demonstrated. All *C. jejuni* isolates studied to date possess the *cdt* gene; however, differences in expression of Cdt have been demonstrated (Johnson and Lior, 1988; Pickett et al., 1996). The genetic basis for this variation in levels of expression is not yet known; however, Cdt negative strains naturally occur as a result of deletions or point mutations (AbuOun et al., 2004). The strong conservation of the *cdt* locus in Cdt-negative strains suggests that toxicity is not the sole function of this locus.

As with other Gram-negative bacteria, the lipid A component of *C. jejuni* lipopolysaccharide (LPS) has endotoxic activity (Moran, 1996). Systemic infection can lead to sepsis and shock, presumably as a result of LPS release. The role of LPS in the development of GBS is discussed in "Disease Caused by *C. jejuni* and *C. coli*."

Since *C. jejuni* and *C. coli* are frequently associated with inflammatory diarrhea, a role for the immune system of the host can not be excluded. A number of cytokines are activated in host cells in the presence of campylobacter antigens

(Mellitis et al., 2002; Jones et al., 2003). That asymptomatic colonization of chickens, which occurs together with induced apoptosis of lymphocytes, further suggests a role of active lymphocytes in symptomatic human colonization (Zhu et al., 1999).

Human Disease Caused by *C. fetus*

Campylobacter fetus subsp. *fetus* infections in man have been well documented (Blaser, 1998). Infection is usually associated with systemic disease and is often reported in immunocompromised individuals. Clinical presentations include diarrhea, bacteremia, endocarditis, meningitis, arthritis, peritonitis, cellulitis, prosthetic infections, and even abortion (Blaser, 1998). The pathology of abortion resembles that previously observed in sheep (Simor et al., 1986). The recent development of a model of ovine abortion has enabled some understanding of the pathogenic mechanisms involved in systemic infections (Grogono-Thomas et al., 2000). Oral ingestion probably results in colonization of the intestinal tract, and if the organisms invade, portal bacteremia may result. In normal hosts, phagocytosis of the bacteria by the reticuloendothelial system in the liver may result in transient bacteremia. Immunocompromised individuals may be unable to prevent systemic bacteremia, which may lead to sepsis or the seeding of distant foci to produce at a secondary site disease that is often associated with a high mortality rate (Skirrow, 1990). Some have speculated that an ageing population combined with a global Acquired Immune Deficiency Syndrome epidemic could precipitate an increased incidence of *C. fetus* subsp. *fetus* infections (Blaser, 1998).

Bovine Infertility and Abortion

Campylobacter fetus subsp. *venerealis* is the causal agent of bovine venereal campylobacteriosis. The organism asymptomatically colonizes the epithelial crypts of the penis and prepuce of bulls. Infection is transferred to cows at coitus, where the primary sites of infection are the uterine glands. Mild endometritis results in infertility. Abortion can occur and usually happens in the fifth or sixth month of gestation. Infection is usually cleared from the uterine tubes and uterus presumably by the host immune response, but the organism can persist in the vagina for several years, during which time a new bull could be infected (Osburn and Hoskins, 1970; Corbeil et al., 1981). Unlike *C. fetus* subsp. *venerealis*, *C. fetus* subsp. *fetus* is commonly isolated from the bovine gut (Atabay and Corry, 1998). If bacteremia follows ingestion of *C. fetus* subsp *fetus* during the last three months of pregnancy, then abortion may follow; however, the organism is not venereally transmitted.

Ovine Abortion

Ovine abortion is a consequence of bacteremia following ingestion of material contaminated with *C. fetus* subsp. *fetus* during the last three months of pregnancy. Pathologic changes are limited to the uterus and its contents. The placenta is not retained, which is in contrast to cattle. Many of the pathological changes associated with *C. fetus* infection are not distinctive. However, the presence of pale necrotic foci in the enlarged and hemorrhagic livers of aborted fetuses is indicative (Gilmour, 1991; Grogono-Thomas et al., 2000). Extensive edema is often seen in the uterus, placentomes and chorion.

Pathogenicity of *C. fetus*

Myers et al. (1970) described the only well-defined virulence factor of *C. fetus* as a "rather loosely attached capsular envelope protein." This material has been characterized as a microcapsular protein existing in a complex with LPS (Pei et al., 1988). Recently this microcapsule has been shown to be a paracrystalline S-layer. The S-layer proteins confer serum-resistance by inhibiting binding of complement (C3b) to the cell surface, preventing the formation of the terminal C5–C9 membrane attack complex, and opsonization via the C3b cellular receptors (Blaser et al., 1988). Moreover, the S-layer covers the underlying immunogenic LPS layer (Fogg et al., 1990), rendering it inaccessible or undetectable by the host. These proteins are essential for the induction of ovine abortion (Grogono-Thomas et al., 2000).

The S-layer proteins are products of surface array protein (*sap*) genes. The *sap* locus apparently contains eight homologues (*sapA*, *A1–A7*) in type A strains and a parallel family in type B strains (Tummuru and Blaser, 1992; Fujita et al., 1995b). A single promotor that is invertible between flanking *sap* genes regulates *sap* gene expression (Tummuru and Blaser, 1992). The *sap* gene cassettes rearrange around this promotor by RecA-dependent reciprocal recombination, resulting in alternate expression (Dworkin and Blaser, 1996; Dworkin and Blaser, 1997a, 1997b). However, RecA-independent recombination can also occur (Ray et al., 2000).

The eight homologues of the *sap* gene appear to encode proteins of three different apparent molecular masses (97, 127 and 149 kDa) but with different antigenicities (Dubreuil et al., 1990; Wang et al., 1993). Experimental infections in sheep indicate that this variation occurs in vivo with time (Grogono-Thomas et al., 2000) and delays the onset of host immune response. Such

antigenic variation may provide a bacterial mechanism for survival in an immunologically hostile host environment and enable chronic infection.

Genetics

The complete genome of strain *C. jejuni* subsp. *jejuni* 11168 has been sequenced (Parkhill et al., 2000). Within the genome 1654 open reading frames (ORFs), 3 rRNA loci and 54 tRNA's were identified. Two regions with relatively low G+C content encoded genes for lipo-oligosaccharide (LOS) and extracellular polysaccharide (EP) biosynthesis clusters, respectively. A surprising finding was the presence of 23 polymorphic homonucleotide repeats (mainly G or C tracts) that varied in length within a locus. These interrupted ORFs in 14 cases and fused (or separated) 2 ORFs in 6 cases. Many of these hypervariable sites cluster in regions containing genes responsible for LOS biosynthesis, EP biosynthesis, and flagellar modification (Parkhill et al., 2000). Such hypervariable regions have since been detected experimentally in other strains of *C. jejuni* (Wassenaar et al., 2002).

The elucidation of the genome sequence has allowed the construction of *C. jejuni*-specific microarrays, printed either with complete ORFs (produced by gene-specific PCR; Pearson et al., 2003; Stinzi, 2003) or with the shot-gun clones used for the sequence analysis (Dorrell et al., 2001).

Unfortunately, the strain (NCTC11168) used for the genome sequence has an unusual phenotype in that it is nonmotile, has a straight and not a curved bacterial morphology, is poorly invasive, and has a low colonization capacity in chickens. Meanwhile, variants of this strain have been characterized that have a more typical phenotype (Carrillo et al., 2004; Gaynor et al., 2004). Transcriptome comparison of the original isolate and the genome sequence variant (Gaynor et al., 2004) has shown that metabolic adaptation to increased oxygen tension contributes to the changed phenotype, including differences in colonization potential, possibly in combination with mutations in sigma factors. Similar studies using two other variants indicate that the flagellar regulatory system of the sequenced variant of 11168 may be impaired (Carrillo et al., 2004).

The genome sequence indicated a relatively low number of operons in which flanking genes are involved in similar processes. Compared to other microbial genomes, that of *C. jejuni* seems more scrambled, although operons are not completely absent. The presence of only three sigma factors and few regulatory proteins makes coordinate gene expression a subject of interest. Gene expression during the transition of growth from 37°C to 42°C was investigated by microarray analysis (Stinzi, 2003). A transient global change in expression was detected for 20% of the genes. Although either temperature is permissive, a temporary down regulation of ribosomal genes, and an upregulation of chaperonins, suggests a temporary halt in growth. Interestingly, expression of genes involved in membrane structure displayed temperature-specific activity (Stinzi, 2003).

Previous laboratory observations that few *Campylobacter* genes are expressed well in *E. coli* and vice versa can be explained by the finding of an atypical -35 promoter region in front of *C. jejuni* genes (Peterson et al., 2003). The absence of this *C. jejuni*-specific promoter sequence in front of many genes with an intergenic upstream region <100 bp suggests that operon transcription may not be uncommon. However, such co-expressed genes may not have putative roles in common biochemical pathways as in *E. coli*.

With the first genome sequence available, the search has begun to identify the gene set characteristic of all isolates within the species *C. jejuni* (core gene complement) rather than genes that are more or less strain-specific. DNA micro arrays are now being extensively used to compare the genetic content of many strains (Dorrell et al., 2001; Pearson et al., 2003). These investigations suggest that at least 15% of the gene content can vary between strains, notably genes encoding surface structures. However, genes not present on the arrays, which still largely comprise the gene complement of strain 11168, cannot be detected. In contrast, the technique of subtractive hybridization can be used for strain comparison (Ahmed et al., 2002) and has been successfully used to identify novel genes in *C. jejuni*. The genome of *C. jejuni* RM1221, a strain with a more typical phenotype, is currently being annotated and will become available in future.

CHAPTER 3.5.2

The Genus *Helicobacter*

JAY V. SOLNICK, JANI L. O'ROURKE, PETER VANDAMME AND ADRIAN LEE

Historical Background

Spiral-shaped bacteria were first seen in human gastric mucosa early in the twentieth century (Krienitz, 1906) and were subsequently described by several investigators (reviewed in Marshall, 1989). Similar organisms were also seen in the gastric mucosa of dogs, cats and a variety of other animals (Rappin, 1881; Bizzozero, 1892; Salomon, 1896; Lim, 1920; Doenges, 1939). The significance of these organisms was alternately debated and forgotten until Marshall and Warren isolated a Gram-negative, microaerophilic bacterium from human gastric biopsies and proposed that the organism may be the cause of chronic gastritis and peptic ulcer disease (Marshall and Warren, 1984a). The bacterium was thought originally to be a member of the genus *Campylobacter* and named "*Campylobacter pyloridis*," later corrected to "*Campylobacter pylori*." Subsequent 16S rRNA sequence analysis showed that the distance between the true campylobacters and *C. pylori* was sufficient to exclude it from the *Campylobacter* genus (Romaniuk et al., 1987), and it was renamed "*Helicobacter pylori*" (Goodwin et al., 1989a), the first member of the new genus *Helicobacter*.

Description of the *Helicobacter* Genus

The *Helicobacter* genus consists of a group of organisms that colonize the mucus layer covering the epithelial surface of the gastrointestinal tract of humans and a variety of animal species. There are currently 6 validated *Helicobacter* species isolated from gastric tissue (Tables 1 and 3) and 16 validated enterohepatic species (Tables 2 and 3). Some *Helicobacter* species may be commonly (*Helicobacter aurati*) or occasionally (*Helicobacter bilis* and *Helicobacter muridarum*) isolated from both gastric and enterohepatic sites. There is, in addition, a growing list of candidate and unvalidated species (Tables 4 and 5).

Cellular Morphology and Ultrastructure

In general, *Helicobacter* spp. are spiral/helical-shaped, although variant forms include short or tapered rods, and they are motile by means of flagella (Fig. 1). These characteristics are thought to be advantageous for survival in their niche of gastrointestinal mucus. Ultrastructural studies reveal bacteria with a typical Gram-negative cell wall structure, i.e., outer and inner membranes separated by a 30-nm periplasmic space and a dense cytoplasm containing nucleoid material and ribosomes (Fig. 2). Electron-lucent areas and a "polar membrane," an additional electron-dense band 6–8 nm thick located 20 nm below the plasma membrane, are often seen at the terminal region of organisms (Lee and O'Rourke, 1993a; Figs. 2A, C–E). A similar membrane has been seen in other spiral-shaped bacteria, where it has been found to be an assembly of ATPase molecules and, as such, has been implicated in energy production for motility or cell wall synthesis (Murray and Birch-Andersen, 1963; Ferris et al., 1984; Brock and Murray, 1988). Such a membrane was not seen in *H. mustela*; instead, O'Rourke et al. identified a large electron dense area, 80 × 100 nm, adjacent to or below the flagella insertion point, and proposed this may perform a similar function to the polar membrane seen in the other helicobacters (O'Rourke et al., 1992; Fig. 2B). Another feature associated with energy supply for these organisms is intracellular granules, which in several instances have been identified as polyphosphate (Bode et al., 1993; Fig. 2F).

A number of cell surface structures have been identified on *H. pylori*, including urease (Bode et al., 1989; Hawtin et al., 1990), a GroEL homolog (Hp60K; Austin et al., 1992), and outer membrane proteins, including lipopolysaccharide, porins and proteins of unknown function (Doig and Trust, 1994). Electron microscopic studies have also revealed that the structure of the vacuolating cytotoxin (VacA) of *H. pylori* resembles that of the A–B toxins seen in a number of other bacteria (Lupetti et al., 1996; Cover et al., 1997).

Table 1. Gastric *Helicobacter* taxa.

Taxon	Natural host	Strain/clone	GenBank 16S rRNA accession no.	References

Abbreviations: Please refer to footnote in Table 1.

All helicobacters possess flagella, which in most cases are sheathed, with configurations ranging from single polar flagella to bipolar tufts of up to 20 flagella. The flagella of *H. pylori* are 30 nm in diameter with an internal filament (~12 nm in diameter) surrounded by a sheath whose outer membrane is continuous with the outer membrane of the cell (Goodwin et al., 1985; Jones et al., 1985). Periplasmic fibers, located just below the outer membrane in the periplasmic space, have been reported in a number of *Helicobacter* species (On et al., 2002). They are distinct from the flagella and have a striated appearance due to electron dense banding. It has been suggested they are contractile proteins involved in motility (Lee and O'Rourke, 1993a).

Methods for Distinguishing *Helicobacter* Species

Classical Phenotypic Characteristics

General biochemical reactivity, morphology and growth characteristics are listed in Tables 3 and 5. The basic biochemical tests used for the identification and differentiation of all *Campylobacter*-like organisms are generally used to identify *Helicobacter* strains. The lack of application of highly standardized procedures and the well-known biochemical inertness of *Campylobacter*-like organisms render biochemical identification of all of these bacteria very difficult. There are no biochemical characteristics to separate members of the genus *Helicobacter*

Table 3. Characteristics of cultivated and validated *Helicobacter* species.

Taxon	Catalase production	Nitrate reduction	Alkaline phosphatase hydrolysis	Urease	Indoxyl acetate hydrolysis	γ-Glutamyl transferase	Growth at 42°C	Growth with 1% glycine	Susceptibility to: Nalidixic acid (30-µg disc)	Susceptibility to: Cephalothin (30-µg disc)	Periplasmic fibers	No. of flagella	Distribution of flagella	G+C content (mol%)

[a]"*H. heilmannii*" 1 and *Candidatus* H. suis are probably identical. Bacteria with the 16S rRNA sequence present in "*H. heilmannii*" 1 have to date been identified in humans, pigs, and nonhuman primates (O'Rourke et al., 2001a).

from the genus *Campylobacter*. (*Arcobacter* strains can be differentiated from campylobacters and helicobacters by their ability to grow in air and at low temperatures.) Therefore, genus level identification is only achieved through the identification of strains at the species level. As a consequence, one has to differentiate over 35 validly named species and subspecies and various unnamed taxa. It should be mentioned that minimal standards for the description of new *Helicobacter* species have been described (Dewhirst et al., 2000b). These minimal standards outline tests (biochemical tests and others) and test procedures that are recommended for the description and hence differentiation of helicobacters.

One of the remarkable features of helicobacters is the extensive variability in cellular morphology (see above). It should be emphasized that although morphology may be helpful to guide the identification process, many species are morphologically indistinguishable. In this context it is worth mentioning two morphologically defined *Helicobacter* taxa: "*Flexispira rappini*" and "*Gastrospirillum*." The former is a provisional name given to Gram-negative, microaerobic, motile, spindle-shaped bacteria with spiral periplasmic fibers and bipolar tufts of sheathed flagella (see below). Strains with this distinctive morphology have been isolated from various sources and belong to the genus *Helicobacter* by phylogenetic analysis. They share their unusual morphological features with several named *Helicobacter* species, including *H. bilis*, *H. trogontum* and *H. aurati*. Extensive polymorphism in 16S rRNA gene sequences of "*Flexispira rappini*" strains and substantial taxonomic diversity among strains with this distinctive morphotype have been described (Dewhirst et al., 2000a). A recent analysis has shown that "*F. rappini*" phylotypes 1, 4 and 5 represent the same species, for which the name "*Helicobacter rappini*" has been proposed (Hänninen et al., 2001).

Similar nomenclatural and taxonomic problems exist for the group of gastric bacteria known as "gastrospirilla" or "*H. heilmannii*." These organisms too are primarily characterized by their cell morphology (large, tightly coiled rods without periplasmic fibers) and such cells have been observed in gastric biopsies of many hosts including humans, cats, dogs, pigs, monkeys, rats, and various captive exotic carnivores. Gastrospirilla are also characterized by their extremely fastidious growth requirements. The uncertainty concerning their taxonomic status is a result of the inability of investigators to culture the strains in vitro. The taxonomy of these gastrospirilla is discussed in detail below.

Table 5. Characteristics of cultivated but unvalidated *Helicobacter* taxa.

Taxon	Catalase production	Nitrate reduction	Alkaline phosphatase hydrolysis	Urease	Indoxyl acetate hydrolysis	γ-Glutamyl transferase	Growth at 42°C	Growth with 1% glycine	Susceptibility to: Nalidixic acid (30-μg disc)	Susceptibility to: Cephalothin (30-μg disc)	Periplasmic fibers	No. of flagella	Distribution of flagella	G+C content (mol%)
Gastric:														
"*H. suncus*"	+	+	+	+	–	–	ND	ND	R	R	–	2	Bipolar	ND

A) *H. pylori*: S-shaped with 2–3 turns, B) *H. mustelae*: straight or curved rods with lateral and polar flagella, C) *H. felis*: tight helical shape with 5–7 turns and periplasmic fibers entwining the cell singularly or in pairs (arrow), D) *H. muridarum*: S-shaped with 2–3 turns and periplasmic fibers entwining the whole cell (arrow), and E) "*H. heilmannii*": tight helical shape with 5–7 turns. Bars = 0.5 μm. (Reproduced with permission from Lee and O'Rourke, 1993a.)

DNA-DNA Hybridization

Whole-genomic DNA-DNA hybridization is the major cornerstone of bacterial species determination in current taxonomic practice (Wayne et al., 1987). However, the method is not widely used because it is not easily implemented. The fastidious growth characteristics of many *Helicobacter* species are a serious hindrance for the isolation of sufficient quantities of highly purified high-molecular-weight DNA required for these hybridization experiments. Therefore, relatively few DNA-DNA hybridization studies have been performed among *Helicobacter* species. Significant levels of DNA-DNA hybridization have been reported between 1) *H. pylori* and *H. mustelae* (Fox et al., 1989); 2) *H. cinaedi*, *H. fennelliae* and *H. canis* (Stanley et al., 1993); and 3) *H. felis*, *H. bizzozeronii* and *H. salomonis* (Jalava et al., 1997). Most other species have not been included in quantitative DNA-DNA hybridization studies.

Chemotaxonomic Methods

It is obviously not practical to implement DNA-DNA hybridization in a routine laboratory or to use it for routine identification in a reference laboratory. The need for an alternative but equivalent method for species delineation prompted researchers in the 1980s and 1990s to evaluate the discriminatory power of chemotaxonomic methods, including whole-cell protein and fatty acid analyses.

The comparison of whole-cell protein profiles obtained by highly standardized sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) has proven to be extremely reliable to screen and identify large numbers of strains. Numerous studies revealed a correlation between high similarity in whole-cell protein content and level of DNA-DNA hybridization (Vandamme et al., 1996). PAGE of whole-cell proteins has been a most successful method for the differentiation of helicobacters (Vandamme et al., 1990; Vandamme et al., 1991b; Vandamme et al., 2000; Costas et al., 1993; van der Ven et al., 1996; Jalava et al., 1998; Sorlin et al., 1999), and strains of all *Helicobacter* species are readily distinguished by means of simple numerical analysis. However, this method is not appropriate for routine identification studies because it is laborious, time-consuming and technically demanding to run the patterns in a sufficiently standardized way.

The total cellular fatty acid methyl ester (FAME) composition is a stable parameter, provided cells are grown in highly standardized conditions. The methylated fatty acids are typically separated by gas-liquid chromatography, and both the occurrence and the relative amounts characterize the fatty acid profiles. The procedure is cheap, rapid, and has reached a high degree of automatization as developed by Microbial Identification Systems (MIS, Newark, Delaware, United States). Isolates can be identified by using libraries supplied by the manufacturer. Only a few of the presently known *Helicobacter* species have been included in published FAME studies, but the results are very promising (Lambert et al., 1987; Goodwin et al., 1989b). *Helicobacter cinaedi*, *H. fennelliae*, *H. pylori*, *H. mustelae* and *H. nemestrinae* were readily distinguished (Lambert et al., 1987; Goodwin et al., 1989b).

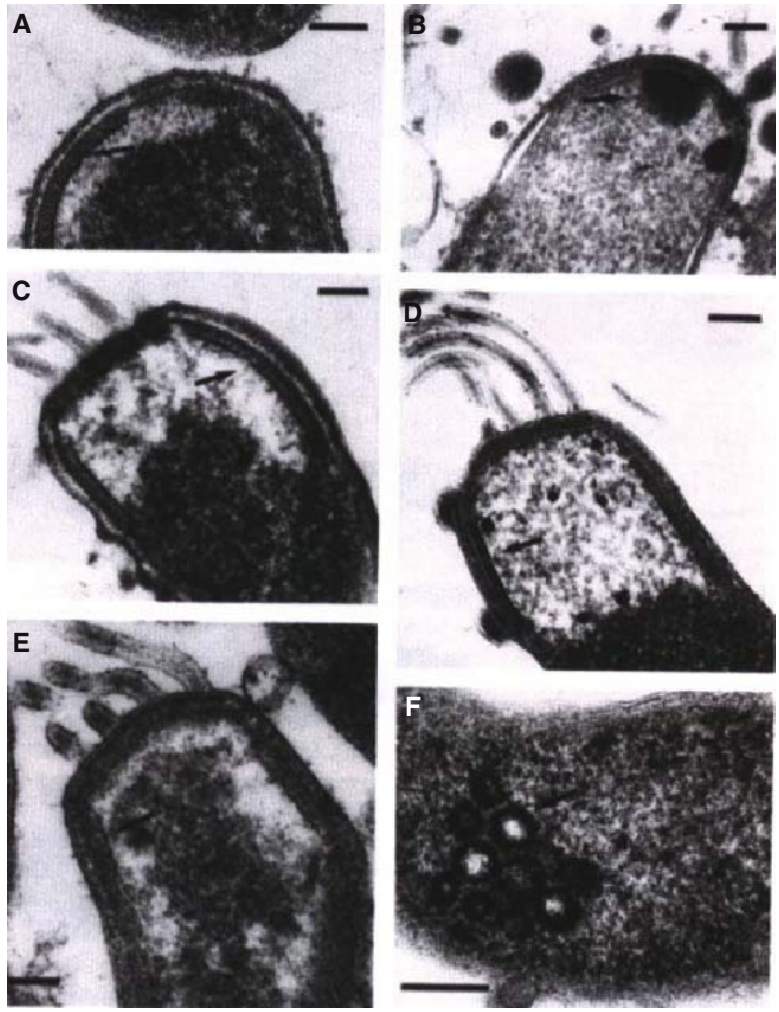

Fig. 2. Transmission electron micrographs of thin sections of *Helicobacter* species showing their cell wall and internal appearance. A) *H. pylori*, B) *H. mustelae*, C) *H. muridarum*, D) and F) *H. felis* and E) "*H. heilmanni*." All organisms exhibit the typical cell wall structure of Gram-negative bacteria with a "polar membrane" visible (arrow) on those organisms with polar flagella only (A, C, D and E). Large electron-dense bodies are noted beneath the periplasmic membrane, near flagella insertion points in *H. mustelae* (B, arrow). An example of intracellular granules occasionally noted in some preparations is shown in F. Bars = 0.1 µm. (Reproduced with permission from Lee and O'Rourke [1993a] and Fox et al. [1986].)

Sequence Analysis of the Small Subunit rDNA

Comparison of (near) entire 16S rDNA sequences is one of the most powerful procedures to establish the phylogenetic neighborhood of an unknown organism. Commercial identification services based on sequence analysis of ribosomal RNA genes have become readily available. With organisms that are otherwise difficult to identify, such as helicobacters, it has become common practice to determine the 16S rDNA sequence (or a fragment of it) of isolates that are of special interest and to compare this sequence with sequences available in public databases. Many taxonomic studies have revealed that this approach is often not sensitive enough to identify strains to the species level. The reported intraspecies diversity in 16S rDNA sequences of *Campylobacter hyointestinalis* and *H. cinaedi* was up to 4.5% of the total 16S rDNA sequence, which is exceptionally high (Harrington and On, 1999; Vandamme et al., 2000). Similar diversity was seen among phylotypes 1, 4 and 5 strains of "*F. rappini*," which were shown to represent a single species (Hänninen et al., 2001). In phylogenetic trees, strains of such species may cluster far apart and erroneously suggest that they represent different species.

On the other hand, 16S rDNA sequences may be too conserved to reveal diversity among species. This has been documented in many groups of bacteria. In *Helicobacter*, this is illustrated by comparison of 16S rDNA gene sequences of multiple *H. felis*, *H. bizzozeronii* and *H. salomonis* strains (Jalava et al., 1997). Although DNA-DNA hybridization studies demonstrated unambiguously that these three taxa represent three distinct species, 16S rDNA sequence analysis showed that all three species have virtually identical 16S rDNA genes. An example of a phylogenetic tree derived from the 16S rDNA sequences of a number of the *Helicobacter* species is shown in Fig. 3.

It should be clear that identification strategies by means of whole-cell protein or fatty acid analysis, extended biochemical testing, or restriction

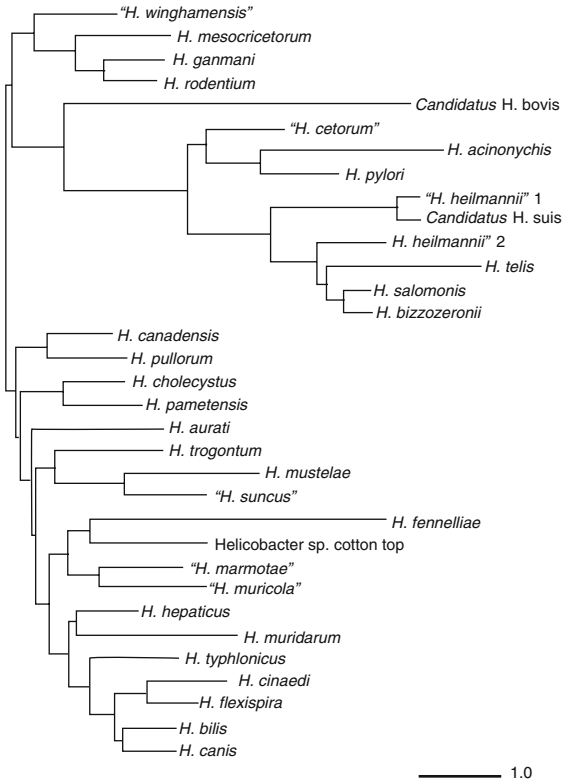

Fig. 3. Phylogenetic tree for 22 validated *Helicobacter* species and for provisional species selected on the basis of 16S rRNA sequences. Sequences from strains shown in Tables 1 and 2, and selected sequences from Table 4, were aligned with PILEUP and compared with DISTANCES (Wisconsin Sequence Analysis Package; Genetics Computer Group). Only sequence positions for which data were available for at least 90% of strains were included in the analysis (*E. coli* positions 28 to 1473). Intervening sequences were removed from *H. bilis*, *H. typhlonicus*, and *Helicobacter* sp. Cotton top. Percentages of difference were corrected for multiple base changes by the method of Jukes and Cantor. The tree was constructed from the distances matrix using TREEVIEW (Page, 1996). The scale bar represents a 1% difference in nucleotide sequence as determined by measuring the lengths of horizontal lines connecting any two species.

profile analysis of polymerase chain reaction (PCR) amplicons derived from conserved genes (see below) should be considered to endorse tentative identification results obtained by comparison of complete 16S rDNA genes. As useful as the 16S rDNA sequence analysis method is, present data clearly indicate that it cannot be regarded as the "gold standard" for species-level identification of helicobacters and other epsilon Proteobacteria.

Molecular Diagnostics

The information content of the rRNA cistrons and other genomic information has been used in several alternative ways for the identification of bacteria by the development of a range of DNA or RNA probes and amplification assays. Although the overall rDNA sequence similarity may be very high, the presence of variable regions in 16S or 23S RNA genes can provide the basis for specific and sensitive targets for identification procedures.

A range of specific oligonucleotide probes and PCR assays have been described for *H. pylori* (On, 1996) and several other *Helicobacter* species including *H. pametensis*, the *Helicobacter* Bird-B and Bird-C groups, *H. felis*, *H. hepaticus*, *H. pullorum*, *H. bilis*, *H. trogontum*, *H. canis*, "*Candidatus H. suis*" and "*Candidatus* H. bovis" (Stanley et al., 1993; Stanley et al., 1994; Dewhirst et al., 1994; Battles et al., 1995; Fox et al., 1995; Fox et al., 1998b; Mendes et al., 1996a; Germani et al., 1997; De Groote et al., 1999a; De Groote et al., 2000; Roosendaal et al., 2000; Shen et al., 2000; Choi et al., 2001; Ge et al., 2001). It should be stressed that because of the constant developments in the taxonomy of *Helicobacter*, the specificity and sensitivity of these probes and PCR assays have not been fully evaluated against all species described to date. Alternatively, polymorphisms can also be revealed by restriction profile analysis of PCR amplicons derived from conserved genes such as 16S and 23S rRNA genes. Restriction fragment length polymorphism (RFLP) analysis of 23S rRNA genes (Hurtado and Owen, 1997) was shown to differentiate 13 *Helicobacter* species (including "*F. rappini*") but not *H. felis*, *H. bizzozeronii* and *H. salomonis* (Jalava et al., 1999b). RFLP analysis of 16S rRNA genes was successfully used by Shen et al. (Shen et al., 2000; Shen et al., 2001) to differentiate strains from 10 enterohepatic species. ("*Flexispira rappini*" strains could not be differentiated from *H. bilis* strains.) The same workers reported on preliminary results of gastric species, indicating that the same approach was useful for the discrimination of some gastric species as well. Riley et al. (1996) used a similar approach, but amplified a rather small (374 bp) portion of the 16S rDNA to examine rodent isolates of *H. hepaticus*, *H. bilis* and *H. muridarum.* Several other studies have focused on rDNA-RFLP analysis of clinical isolates, but did not include balanced sets of reference strains of established *Helicobacter* species. Recently, O'Rourke et al. (2001a) have highlighted the possibility of differentiating between closely related species on the basis of analysis of a protein-encoding gene. Sequence analysis of a section of the urease gene complex enabled these workers to differentiate between the closely related gastric species *H. felis*, *H. bizzozeronii*, *H. salomonis* and "*H. heilmannii*."

Isolation, Culture and Preservation

Specimens

Gastric *Helicobacter* species are most commonly isolated by culture of endoscopic biopsies from the antral portion of gastric mucosa. For human patients, recent administration of antibiotics, including bismuth compounds, will decrease the yield of culture. Under conditions of acid suppression, such as in persons treated with proton pump inhibitors or H2 antagonists, *H. pylori* culture may also be less sensitive, and the bacteria may be found in larger numbers in the gastric corpus. Infection is usually spotty, so several biopsies must be obtained for optimal results. Cultivation of gastric juice by aspiration or through use of the string test (Torres et al., 2001) may yield positive results, but usually with lower sensitivity. *Helicobacter pylori* may also be cultivated from other sites within the gastrointestinal tract, such as areas of gastric metaplasia in the duodenum and occasionally from other sites of ectopic gastric mucosa. Recent evidence suggests that *H. pylori* may be found in large numbers in vomitus from infected persons, which may serve as a route for transmission (Parsonnet et al., 1999). Although gastric *Helicobacter* species have typically not been cultivated from feces, relative achlorhydria (Fox et al., 1992) and rapid transit times may favor positive fecal cultures (Parsonnet et al., 1999). *Helicobacter pylori* has occasionally been identified from human liver tissue by PCR, with one recent report of a positive culture (Nilsson et al., 2000; Queiroz and Santos, 2001).

The lower bowel is the natural reservoir of enterohepatic *Helicobacter* species, which are most commonly cultivated from feces or mucosal biopsies from the colon or cecum; however, isolation from liver and gallbladder is also common. Occasionally enterohepatic *Helicobacter* species may migrate to the stomach (Lee et al., 1993b) or cause bacteremia, particularly in persons infected with the human immunodeficiency virus or other immunocompromised hosts (Mammen et al., 1995; Weir et al., 1999; Cuccherini et al., 2000).

Transport and Sample Preparation

Gastric biopsies may be transported immediately to the laboratory with or without media such as Stuarts transport medium or brucella broth. Phosphate buffered saline is less desirable as a transport medium, especially if a delay from biopsy to cultivation is expected. Excellent recovery of *H. pylori* can also be obtained from gastric biopsies stored without transport medium for days to weeks at –20°C or preferably –80°C. Biopsies may be plated by direct inoculation onto agar plates followed by spreading in the conventional manner or by first grinding the tissue and then plating. Quantitative culture results (colony forming units [CFU]/g tissue) can be obtained by placing biopsies in preweighed vials that contain media, homogenizing the tissue, and plating serial dilutions. This method is effective for some species such as *H. pylori*, but not for others such as *H. felis* and many enterohepatic species that typically do not form colonies. Optimum cultivation of the other gastric helicobacters is achieved by placing fresh gastric specimens onto moist agar plates as soon as possible. Enterohepatic helicobacters are typically isolated directly from intestinal mucus or homogenates, fresh fecal slurries, or freshly homogenized liver tissue.

Selective and Nonselective Media

Primary isolation of gastric *Helicobacter* species is generally performed with solid media supplemented with 5–10% horse or sheep blood or with bovine calf serum. Brucella or Columbia agar is commonly used as the agar base, although brain heart infusion (BHI), trypticase soy agar and others are also adequate. If blood-free culture media are required, agar may be supplemented with cyclodextran (Olivieri et al., 1993) or egg yolk emulsion (Westblom et al., 1991). Defined media have also been developed for cultivation of *H. pylori* (Reynolds and Penn, 1994; Albertson et al., 1998), including Hams F-12 nutrient mixture supplemented with cholesterol or cyclodextran (Testerman et al., 2001). Most *Helicobacter* species grow poorly or not at all in liquid media, although *H. pylori* and some others can often be adapted to grow in liquid culture.

The yield from culture of gastric tissue may be improved if both selective and nonselective agar are used. Commonly used antibiotic supplements are those of Skirrow (1977) and Dent (Dent and McNulty, 1988):

Skirrows Supplement

Vancomycin	10 mg/liter
Trimethoprim	5 mg/liter
Polymyxin B	2,500 IU/liter

Dents Supplement

Vancomycin	10 mg/liter
Trimethoprim	5 mg/liter
Cefsulodin	5 mg/liter
Amphotericin B	5 mg/liter

Commercially prepared agar plates are also available (BBL, Cockeysville, MD) that contain 10% defibrinated whole sheep blood with an antibiotic supplement described by Blaser (Blaser et al., 1979) for isolation of *Campylobacter jejuni*.

Blasers Supplement

Cephalothin	15 mg/liter
Polymyxin B	2,500 IU/liter
Trimethoprim	5 mg/liter
Vancomycin	10 mg/liter
Amphotericin B	2 mg/liter

Enterohepatic *Helicobacter* species are typically isolated using media and antibiotic supplements similar to those used for isolation of gastric helicobacters. When enterohepatic helicobacters are isolated from feces or cecal contents, a slurry is usually inoculated onto a 0.45- or 0.65-μm filter that is placed directly onto either selective or nonselective agar. The plates are incubated for approximately two hours in a CO_2 incubator, if possible. The filter is then removed and the plates are incubated under the appropriate conditions. This same technique is also useful for the cultivation of possible novel species obtained from either gastric or intestinal mucus samples. Preliminary studies suggest that the combination of the filtration method with nonselective media and high hydrogen concentration may improve the recovery of fastidious helicobacters from stool (Lastovica and le Roux, 2000a; Lastovica and Skirrow, 2000b).

Growth Conditions

Nearly all *Helicobacter* species are microaerobic, exhibiting growth in 3–7% O_2. No growth is observed under aerobic conditions, although occasional species will grow in anaerobic as well as microaerobic conditions (Fox et al., 1994; Shen et al., 1997; Robertson et al., 2001). Hydrogen is required for some enterohepatic species and may promote growth of others, sometimes in a strain-dependent fashion. For example, isolates originally described as "*Helicobacter westmeadii*" were subsequently identified as hydrogen-requiring *Helicobacter cinaedi* (Vandamme et al., 2000). Many laboratories routinely use anaerobic jars with commercial gas generating envelopes (CampyPak Plus, Becton Dickinson, Cockeysville, MD; Campylobacter Gas Generating Kits, Oxoid, Basingstoke, United Kingdom) for culture of helicobacters. After primary isolation, some helicobacters can be adapted to grow in 5–10% CO_2, although this is not usually reliable for primary culture and is not effective for all species.

The majority of the *Helicobacter* species are fastidious with respect to isolation and cultivation and require freshly poured plates incubated with lids uppermost to maintain a moist environment. *Helicobacter pylori* is less demanding in this regard than many of the other species. A high degree of humidity during incubation, obtained by placing wet paper towel in anaerobe jars or by setting CO_2 incubators to run at 95% humidity, is often essential for culture of many different species. Culture is routinely performed at 37°C.

Identification

Helicobacter species grow as small (0.5–2 mm) translucent colonies or as a thin watery film, which typically appear after 3–7 or occasionally up to 10 days of incubation. Organisms are Gram-negative and often pleomorphic. After prolonged incubation, most helicobacters assume a coccoid morphology, the significance of which remains controversial (Cellini et al., 1994; Eaton et al., 1995; Kusters et al., 1997; Nilsson et al., 2002). Routine identification of many *Helicobacter* species relies on their positive tests for urease, catalase, and oxidase, although many enterohepatic species are urease negative. As discussed above, definitive identification requires a polyphasic approach to taxonomy, but there is an obvious role for molecular diagnostic tests provided their specificity and sensitivity have been evaluated using balanced and well-chosen sets of reference strains. 16S rRNA sequence analysis may be insufficiently sensitive to distinguish different species, while in other cases it may exaggerate differences that are not confirmed by other methods.

Preservation

Helicobacter species can be preserved in brucella broth with 20% (vol/vol) glycerol at –80°C.

Gastric *Helicobacter* Species

Validated gastric *Helicobacter* taxa are listed in Table 2, along with the type strain and GenBank 16S rRNA accession number. Characteristics of cultivated and validated gastric *Helicobacter* species are shown in Table 3.

Helicobacter pylori

Helicobacter pylori was initially isolated from the gastric mucosa of humans presenting with dyspepsia (Marshall et al., 1984b; Goodwin et al., 1989a). *Helicbacter pylori* has also been detected in certain primate species, particularly rhesus monkeys (Dubois et al., 1994; Solnick et al., 1996), in sheep (Dore et al., 2001) and in a closed colony of barrier-maintained cats (Handt et al., 1994). Morphologically the bacterial cells are curved to S-shaped rods, 0.5 μm × 2.5–5 μm (Fig. 4). They are motile by means of 4–8 unipolar or bipolar, sheathed flagella. The bacteria grow as small, translucent colonies (1–2 mm) or a spreading film with increased periods of incubation.

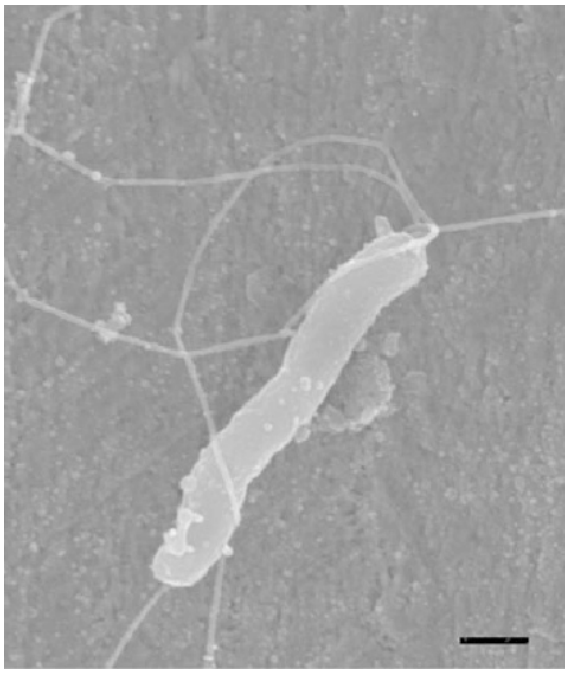

Fig. 4. Field emission scanning electron micrograph of a critical point dried preparation of *Helicobacter pylori* showing its S-shaped morphology and bipolar, sheathed flagella. Bar = 0.5 μm. (Micrograph courtesy of L.Thompson, University of New South Wales, Sydney, Australia).

Optimum growth is obtained under microaerobic conditions at 37°C with no growth obtained at 42°C or under anaerobic conditions. For primary isolation, 4–5 days of incubation are required, which can be reduced to 2 days for subsequent subculture.

All strains have been reported to be urease, catalase and oxidase positive. They do not reduce nitrate and do not hydrolyze indoxyl acetate or hippurate. Activities for γ-glutamyl transpeptidase, leucine arylamidase, and alkaline phosphatase are present. *Helicobacter pylori* is sensitive to 1% glycine, 1.5% NaCl, and cephalothin. It is resistant to nalidixic acid, with variable resistance to metronidazole. The G+C content is 39 mol%. The major fatty acid of *H. pylori* is $C_{14:0}$ with smaller amounts of $C_{18:0}$, $C_{18:1}$ and $C_{19:0}$ cyclic, and the major isoprenoid is MK-6 (Goodwin et al., 1989b; Moss et al., 1990). *Helicobacter pylori* was originally thought to be asaccharolytic, on the basis of data obtained using standard methods to detect carbohydrate metabolism; however, recently it has been shown to utilize glucose via the pentose phosphate and Entner-Doudoroff pathways. Glycolysis is also utilized with fermentation of glucose, possibly leading to the production of mixed acid products or the provision of metabolites for the Krebs cycle (Mendz et al., 1993; Mendz et al., 1994; Chalk et al., 1994). *Helicobacter pylori* also has a requirement for amino acids whose deamination could lead to the production of nitrogen, carbon and energy for the cell (Nedenskov, 1994; Reynolds and Penn, 1994). Features of both aerobic and anaerobic respiration have been reported (Hazell and Mendz, 1997).

The complete DNA sequences of two *H. pylori* strains have been published (Tomb et al., 1997; Alm et al., 1999). *Helicobacter pylori* 26695 has a single, circular chromosome of 1,667,867 bp with 1,590 predicted coding regions, of which 1,091 match known database entries (Tomb et al., 1997). Comparison of the two sequenced genomes revealed that the overall genomic organization and predicted proteins were quite similar, although a group of genes (about 7%) in one hypervariable region was unique to each strain (Alm et al., 1999). This relative similarity between these two sequenced strains was in contrast to previous studies employing pulse field gel electrophoresis (PFEG; Taylor et al., 1992), random amplified polymorphic DNA (RAPD) PCR (Akopyanz et al., 1992a), restriction fragment length polymorphism (RFLP; Akopyanz et al., 1992b), and multilocus electrophoresis (Go et al., 1996), all of which showed a high degree of genomic variability among strains. Recently, a whole-genome microarray analysis showed that 22% of the genes present in *H. pylori* 26695 and J99 were absent in one or more of 15 clinical isolates (Salama et al., 2000). This is consistent with marked genetic heterogeneity among *H. pylori* isolates and suggests a panmictic population structure (Suerbaum et al., 1998). Approximately 50% of *H. pylori* strains harbor cryptic plasmids that range in size from 3.5–>148 kb (Tjia et al., 1987; Graham et al., 1988; Penfold et al., 1988).

Helicobacter mustelae

Helicobacter mustelae was isolated from the gastric mucosa of ferrets (Fox et al., 1986; Goodwin et al., 1989a). Morphologically the bacterial cells are small rods, 0.5–1 μm × 2–5 μm (Fig. 5). They are motile by means of bipolar and lateral sheathed flagella. The bacteria grow as small (1–2 mm), translucent colonies or as a spreading film under microaerobic conditions at 37°C. Growth also occurs at 42°C and under anaerobic conditions. For primary isolation, 3–5 days of incubation are required, which can be reduced to 2 days for subsequent subculture.

All strains have been reported to be urease, catalase and oxidase positive. They are able to reduce nitrate, hydrolyze indoxyl acetate, but not hippurate, and have no activity for leucine arylamidase. *Helicobacter mustelae* is sensitive to 1.5% NaCl, metronidazole, and nalidixic acid

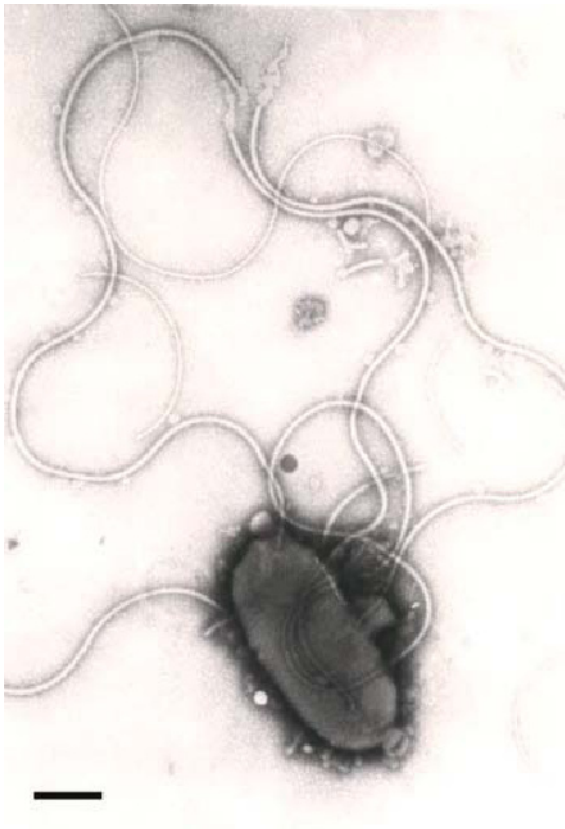

Fig. 5. Transmission electron micrograph of a negatively stained preparation of *Helicobacter mustelae* showing its short rod shape with lateral and polar flagella. Bar = 0.4 μm.

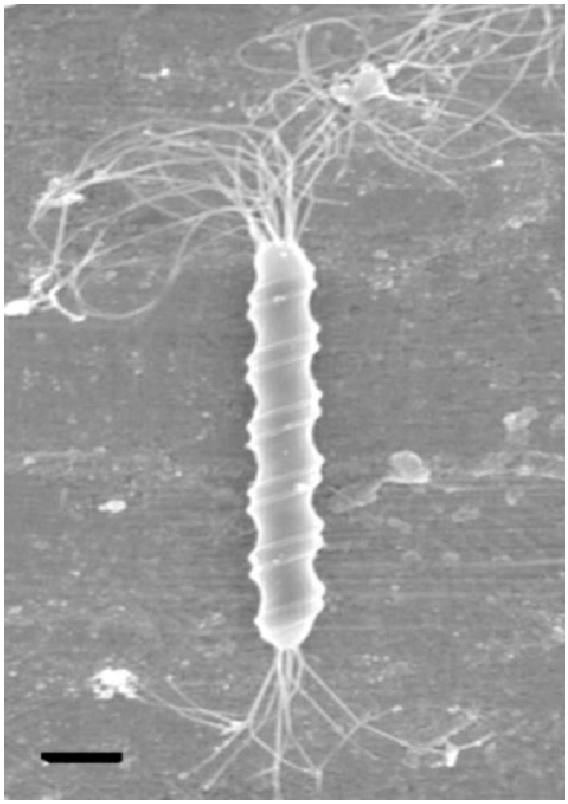

Fig. 6. Field emission scanning electron micrograph of a critical point dried preparation of *Helicobacter felis* showing its tight helical morphology with bipolar tufts of flagella and periplasmic fibers entwining the cell in pairs. Bar = 0.7 μm. (Micrograph courtesy of L. Thompson, University of New South Wales, Sydney, Australia).

and resistant to cephalothin and 5-fluorouracil. There is variable growth on media containing 1% glycine. *Helicobacter mustelae* has a G+C content of 36 mol%. The major fatty acid of *H. mustelae* is $C_{16:0}$ with small amounts of $C_{14:0}$, $C_{18:1}$ and $C_{19:0}$ cyclic.

The genome size of *H. mustelae* is approximately 1.7 Mb (Taylor et al., 1994), which is very similar to that of *H. pylori*. In contrast to the marked heterogeneity among *H. pylori* strains, there is significant genomic conservation among isolates of *H. mustelae* (Morgan and Owen, 1990; Taylor et al., 1994).

Helicobacter felis

Helicobacter felis was isolated from the gastric mucosa of cats and dogs (Lee et al., 1988; Paster et al., 1991). Morphologically the bacterial cells are tightly coiled helical rods (0.4 μm × 5–7.5 μm; Fig. 6). Most strains are surrounded by periplasmic fibers, in pairs, triplets or singly. They have a rapid corkscrew-like motility by means of bipolar tuffs of sheathed flagella. The bacteria grow as a thin, spreading nonhemolytic film, occasionally with pinpoint colonies. Optimum growth is obtained under microaerobic conditions at 37°C, with growth also possible at 42°C and under anaerobic conditions. For primary isolation, 3–5 days of incubation are required, which can be reduced to 2 days for subsequent subculture.

All strains have been reported to be urease, catalase and oxidase positive. They are able to reduce nitrate but not TTC (2,3,5-triphenyltetrazolium chloride), do not hydrolyze indoxyl acetate or hippurate, and exhibit activities for γ-glutamyl transpeptidase, alkaline phosphatase, arginine aminopeptidase, leucine aminopeptidase and histidine aminopeptidase. *Helicobacter felis* is sensitive to 1% bile, 1% glycine, 1.5% NaCl, metronidazole, cephalothin, erythromycin and ampicillin and is resistant to nalidixic acid and 5-fluorouracil.

Genetically, *H. felis* forms a very tight cluster with *H. bizzozeronii*, *H. salomonis*, "*Candidatus* Helicobacter suis" and "*H. heilmannii*." These organisms show greater than 97% sequence similarity in their 16S rRNA genes, although further discrimination is hampered by the inability to culture "*H. heilmannii*" and "*Candidatus* Helico-

bacter suis" in vitro. *Helicobacter felis*, *H. bizzozeronii* and *H. salomonis* can be differentiated by morphology, protein profiling, and DNA-DNA hybridization assay (Jalava et al., 1998) but not by biochemical testing or 23S rRNA RFLP analysis (Jalava et al., 1999b). Strains of *H. felis* have been shown by various techniques (pulsed field gel electrophoresis [PFGE], plasmid profiling and ribotyping) to be heterogeneous with no association to host species or country of origin (Jalava et al., 1999a). *Helicobacter felis* has a genome size of 1.6 Mb and G+C content of 42.5 mol%. Most strains have multiple plasmids, ranging from 2 kb to more than 16 kb.

Helicobacter acinonychis

Helicobacter acinonychis (formerly *H. acinonyx*) was isolated from the gastric mucosa of cheetahs (*Acinonyx jubilatus*) and tigers (Eaton et al., 1993a; Schroder et al., 1998). Morphologically it is a small spiral rod (0.3 μm × 1.5–2 μm; Fig. 7). The bacteria are motile and possess 2–5 unipolar, sheathed flagella. Primary culture was performed by blind subculture for 3 days after an initial 4–5 days of incubation (Eaton et al., 1993a). *Helicobacter acinonychis* will not grow under anaerobic conditions or at 25 or 42°C.

All strains have been reported to be urease, catalase and oxidase positive. They exhibit activities for γ-glutamyl transpeptidase and alkaline phosphatase but do not reduce nitrate or hydrolyze indoxyl acetate or hippurate. *Helicobacter acinonychis* is sensitive to 1% glycine, 1.5% NaCl, metronidazole and cephalothin but is resistant to nalidixic acid. *Helicobacter acinonychis* appears to be most closely related to *H. pylori* by analysis of protein profiles and sequencing of 16S rRNA genes; however, *H. acinonychis* has a lower G+C content (30 mol%) than that of *H. pylori* (39 mol%).

Helicobacter bizzozeronii

Helicobacter bizzozeronii was isolated from the gastric mucosa of dogs (Hänninen et al., 1996) and named in honor of Guilio Bizzozero, who provided one of the first descriptions of spiral bacteria in the gastric environment (Bizzozero, 1892). Recently a similar bacterium cultivated from a human patient has been identified as *H. bizzozeronii* (Jalava et al., 2001). Morphologically the bacterial cells are tight helical rods (0.3 μm × 5–10 μm), and they exhibit a rapid corkscrew-like motility by means of bipolar tuffs of sheathed flagella (Fig. 8). The bacteria grow as a thin, spreading nonhemolytic film and do not readily form discrete colonies. Optimum growth is obtained on fresh, moist brain heart infusion (BHI) blood agar under microaerobic conditions

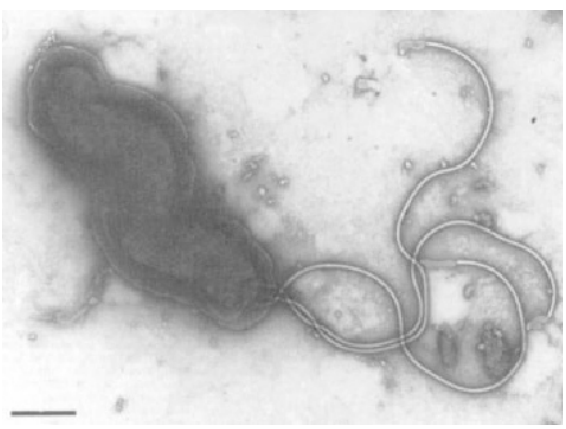

Fig. 7. Transmission electron micrograph of a negatively stained preparation of *Helicobacter acinonychis* showing its S-shaped morphology with a tuft of polar, sheathed flagella. Bar = 0.5 μm. (Reproduced with permission from Eaton et al., 1993a.)

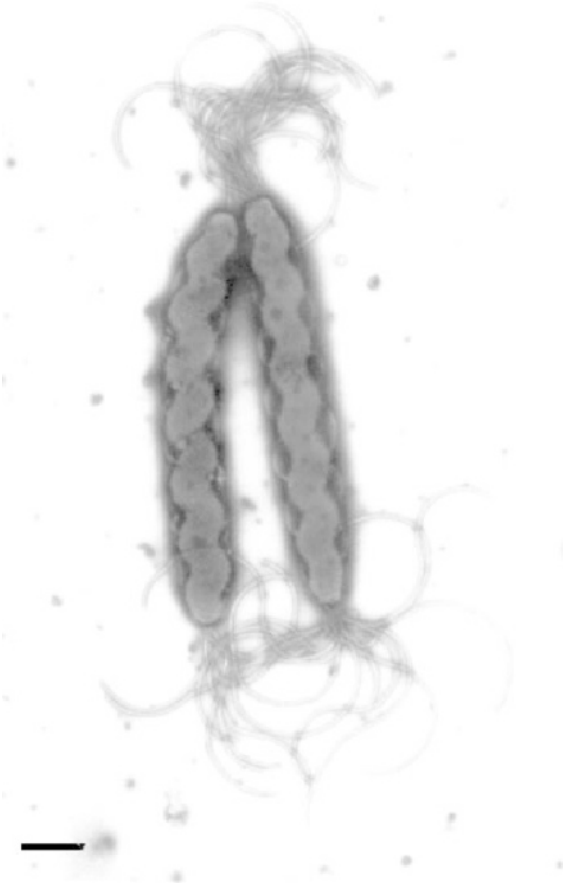

Fig. 8. Transmission electron micrograph of a negatively stained preparation of *Helicobacter bizzozeronii* showing its tight helical morphology with bipolar tufts of flagella. Bar = 0.45 μm. (Micrograph courtesy of K. Jalava, University of Finland, Helsinki.)

at 37°C, with growth also possible at 42°C. For primary isolation, 5–10 days of incubation are required, which can be reduced to 3–5 days on subsequent subculture.

All strains have been reported to be urease, catalase and oxidase positive. They are able to reduce nitrate and TTC, can hydrolyze indoxyl acetate but not hippurate, and exhibit activities for γ-glutamyl transpeptidase and alkaline phosphatase. *Helicobacter bizzozeronii* is sensitive to 1% bile, 1% glycine, 1.5% NaCl, metronidazole, cephalothin and cefoperazone and is resistant to nalidixic acid and 5-fluorouracil.

Helicobacter bizzozeronii shares detectable DNA-DNA hybridization levels with *H. felis* (2–30%) and *H. salomonis* (11–34%) but not with *H. pylori* or *H. mustelae*. It appears to be heterogenetic in nature, with different PFGE patterns obtained from 15 strains using 5 different enzymes (Hänninen and Hirvi, 1999). The genome size is 1.6–1.9 Mb.

Helicobacter salomonis

Helicobacter salomonis was isolated from the gastric mucosa of dogs (Jalava et al., 1997) and named in honor of Hugo Salomon, who initially described different morphological types of gastric bacteria in a variety of animal species (Salomon, 1896). The bacterial cells are loosely helical or wavy rods (0.8–1.2 μm × 5–7 μm), and they exhibit a slow wave-like motility by means of bipolar tuffs of sheathed flagella (Fig. 9). The bacteria grow as a thin, spreading nonhemolytic film and do not readily form discrete colonies.

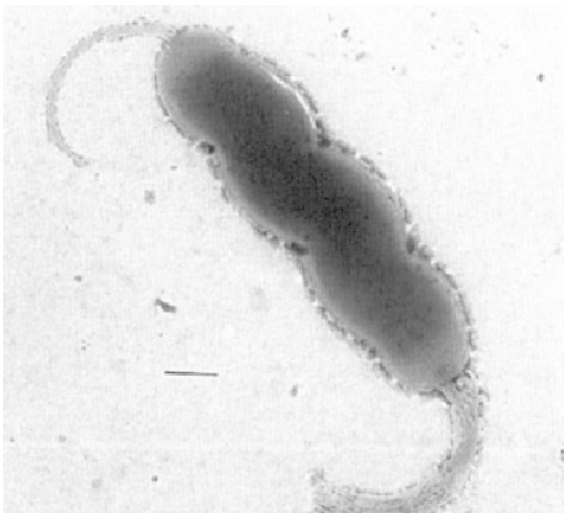

Fig. 9. Transmission electron micrograph of a negatively stained preparation of *Helicobacter salomonis* showing its undulating S-shaped morphology with bipolar tufts of flagella. Bar = 1 μm. (Reproduced with permission from Jalava et al., 1997.)

Optimum growth is obtained on fresh, moist BHI blood agar under microaerobic conditions at 37°C (no strains were able to grow at temperatures >40°C) after 3–6 days for primary isolation and 2 days for subsequent subculture.

All strains have been reported to be urease, catalase and oxidase positive. They are able to reduce nitrate and TTC, can hydrolyze indoxyl acetate but not hippurate, and exhibit activities for γ-glutamyl transpeptidase and alkaline phosphatase. *Helicobacter salomonis* is sensitive to 1% bile, 1% glycine, 1.5% NaCl, metronidazole (one strain resistant), cephalothin and cefoperazone. *Helicobacter salomonis* is resistant to nalidixic acid.

Helicobacter salomonis shares detectable DNA-DNA hybridization levels with *H. felis* (26–39%) and *H. bizzozeronii* (11–34%). In contrast to *H. felis* and *H. bizzozeronii*, *H. salomonis* appears to be relatively homogenetic. Testing of five strains by PFGE showed diversity in their patterns, although common fragments were noted with some enzymes (Hänninen and Hirvi, 1999). The genome size of *H. salomonis* is 1.7–1.8 Mb.

Helicobacter nemestrinae

An organism isolated from pig-tailed macaques (*Macaca nemestrina*) reportedly differed from *H. pylori* by virtue of growth at 42°C and its cellular fatty acid profile (Bronsdon et al., 1991). DNA-DNA hybridization and 16S rRNA studies also suggested that this was a novel species, which was designated "*H. nemestrinae*." The G+C content was reportedly only 24 mol%, markedly lower than that of all other known *Helicobacter* species, which prompted a reappraisal. Sequence analysis of seven housekeeping genes and two flagellin genes from the single strain of *H. nemestrinae* (ATCC 49396^T) showed that all sequences clustered together with those from multiple isolates of *H. pylori* (Suerbaum et al., 2002). Furthermore, repeat sequence analysis of the 16S rRNA gene from *H. nemestrinae* showed that it differed by 38 bp from that previously reported and was less than 1% different from multiple *H. pylori* strains. In addition, repeat analyses of the G+C content of *H. nemestrinae* type strain yielded a reproducible value of 39 mol% (P. Vandamme, unpublished observations). These results show that the single strain previously classified as *H. nemestrinae* is a junior heterotypic synonym for *H. pylori*.

Enterohepatic *Helicobacter* Species

Validated enterohepatic *Helicobacter* taxa are listed in Table 2, along with the type strain and GenBank 16S rRNA accession number. Charac-

teristics of cultivated and validated enterohepatic *Helicobacter* species are shown in Table 3. *Helicobacter aurati*, which has been isolated from both gastric and intestinal sites, has been included in Tables 2 and 3.

Helicobacter cinaedi

Helicobacter cinaedi has been isolated from rectal swabs and blood of homosexual men, blood, cerebrospinal fluid and feces of adults and children with and without risk factors for human immunodeficiency virus (HIV) infection, and the intestinal tract of hamsters, cats, dogs and foxes (Totten et al., 1985; Vandamme et al., 1991a; Vandamme et al., 2000; Kiehlbauch et al., 1995). Asymptomatic captive rhesus monkeys (*Macaca mulatta*) are also commonly infected (Fernandez et al., 2002), although sometimes infection may be associated with colitis (Fox et al., 2001a). The name is derived from the Latin word for "homosexuals." Recent polyphasic taxonomic studies show that "*Helicobacter westmeadii*" and *Helicobacter* sp. strain Mainz are correctly identified as *H. cinaedi*, rather than novel species as originally proposed (Vandamme et al., 2000).

Helicobacter cinaedi is an S-shaped rod (0.3–0.5 μm × 1.5–5 μm), with rapid motility by means of a single sheathed bipolar flagellum. *Helicobacter cinaedi* may form pinpoint colonies but more typically forms a translucent spreading film on moist blood agar. All strains are able to grow at 37°C under microaerobic but not aerobic or anaerobic conditions. Growth at 42°C is variable.

Strains are oxidase and catalase positive, urease negative, and reduce nitrate. They do not hydrolyze indoxyl acetate or hippurate, and there is little or no alkaline phosphatase activity. *Helicobacter cinaedi* is sensitive to 2% NaCl and is variably resistant to nalidixic acid and cephalothin. It is resistant to 1% glycine, 0.04% TTC, and trimethoprim. The G+C content is 37–38 mol%.

Helicobacter cinaedi is most closely related to *H. canis* (52% DNA:DNA hybridization; Stanley et al., 1993) and *H. fennelliae* (3–10% DNA homology; Totten et al., 1985). Ribotyping discriminates distinct patterns depending upon the host source (Kiehlbauch et al., 1995); however, high levels of similarity by phenotypic and protein-electrophoretypic traits between human and dogs strains have been reported (Vandamme et al., 2000).

A recent report indicates that the type strain of *H. cinaedi* held by the American Type Culture Collection (ATCC 35683) is mislabeled, since the 16S rRNA and *rpoB* sequences from this strain are identical to that reported for *H. fennelliae* (Kuhnert and Burnens, 2001; On and Vandamme, 2001). Until this is clarified, *H. cinaedi* should be ordered from the Culture Collection of the University of Göteborg, Dept. of Clinical Bacteriology, Göteborg, Sweden (CCUG18818^T) rather than the ATCC.

Helicobacter fennelliae

Helicobacter fennelliae was isolated from rectal swabs and blood of homosexual men, blood and feces of children with diarrhea, and the intestinal tract of hamsters and dogs. The organism was named after the technologist who first isolated it, C.L. Fennell (Totten et al., 1985; Vandamme et al., 1991a; Kiehlbauch et al., 1995). *Helicobacter fennelliae* is an S-shaped rod (0.3–0.5 μm × 1.5–5 μm), with rapid motility by means of single, sheathed bipolar flagella. Colonies are pinpoint, are translucent, may spread on moist blood agar, and have a distinctive hypochlorite odor. All strains are able to grow at 37°C under microaerobic but not aerobic or anaerobic conditions. Growth at 42°C is variable. Hydrogen is required for growth.

Strains are oxidase and catalase positive, urease negative and do not reduce nitrate. They hydrolyze indoxyl acetate but not hippurate, and there is little or no alkaline phosphatase activity. *Helicobacter fennelliae* is sensitive to 2% NaCl, metronidazole, cephalothin and nalidixic acid and is resistant to 1% glycine, 0.04% TTC, 5-fluorouracil, trimethoprim and streptomycin. The G+C content is 37–38 mol%.

Helicobacter fennelliae is most closely related to *H. canis* (30% DNA homology; Stanley et al., 1993), *H. cinaedi* (10–30% DNA homology; Totten et al., 1985), and *H. pullorum* (95.9% sequence similarity of 16S rRNA gene; Shen et al., 1997).

Helicobacter muridarum

Helicobacter muridarum was isolated from the intestinal mucosa of rats and mice (Phillips and Lee, 1983; Lee et al., 1992). It is a helical rod (0.5–0.6 μm × 3.5–5 μm), with 2–3 spirals, exhibiting a rapid, darting motility due to bipolar tufts of 10–14 sheathed flagella (Fig. 10). Ultrastructurally the cells are characterized by the presence of 9–11 periplasmic fibers coiled around the protoplasmic cylinder. Bacteria grow as a fine spreading translucent film on moist blood agar plates after 2–3 days incubation at 37°C under microaerobic conditions. There is no growth at 25 or 42°C or under aerobic or anaerobic conditions.

All strains are urease, catalase and oxidase positive. They do not reduce nitrate or hydrolyze hippurate and do exhibit activities for γ-glutamyl transpeptidase, alkaline phosphatase, arginine

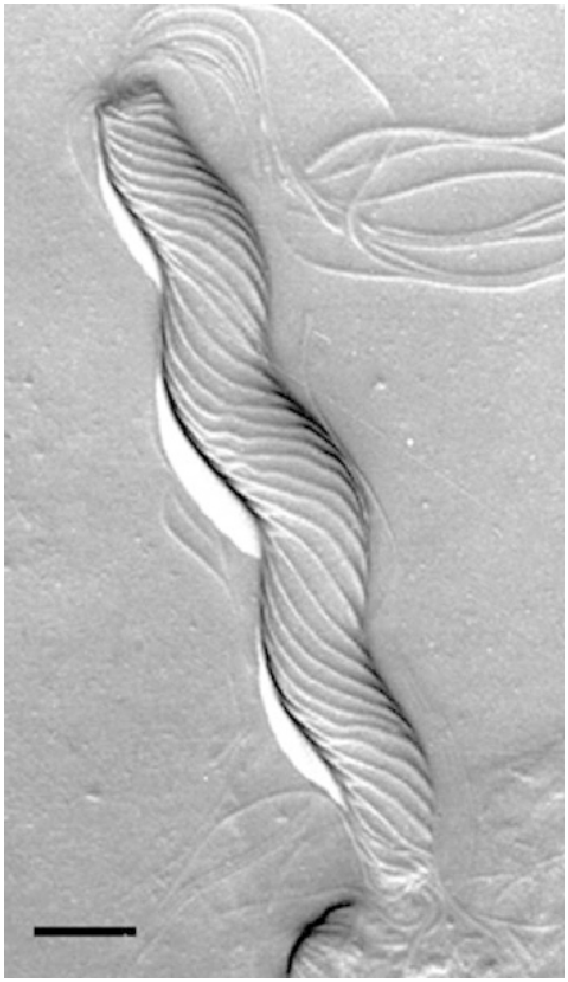

Fig. 10. Transmission electron micrograph of a freeze-dried preparation of *Helicobacter muridarum* showing its S-shaped morphology with bipolar tufts of flagella and periplasmic fibers entwining the cell. Bar = 0.5 μm. (Micrograph courtesy of M. Phillips, University of New South Wales, Sydney, Australia.)

aminopeptidase, and leucine aminopeptidase, but not histidine aminopeptidase. *Helicobacter muridarum* is sensitive to 2% bile, 1% glycine, 1.5% NaCl and is resistant to nalidixic acid and cephalothin. The G+C content is 34%. *Helicobacter muridarum* is most closely related to *H. hepaticus* (96.6% sequence similarity of 16S rRNA gene).

Helicobacter canis

Helicobacter canis was isolated from the feces of humans and dogs with diarrhea (Stanley et al., 1993) and more recently from a colony of diarrheic Bengal cats (Foley et al., 1999). The organisms are curved rods (0.25 μm × 4 μm), with occasional truncated ends (Fig. 11). Cells are motile and possess a single sheathed flagellum at each end. Colonies are pinpoint, translucent, and pigmented after 2 days growth on blood agar. Optimum growth occurs at 37°C under microaerobic conditions, with limited growth at 42°C.

All strains are oxidase positive and catalase and urease negative. They hydrolyze indoxyl acetate but do not reduce nitrate. Activity for alkaline phosphatase is detected. *Helicobacter canis* is sensitive to cephalothin and nalidixic acid but resistant to 1.5% bile and 5-fluorouracil. The G+C content is 48–49 mol%.

Insertion sequences (of 81–320 bp) have been detected in the 16S and 23S rRNA genes of some strains (Linton et al., 1994). Genetically *H. canis* shares detectable DNA-DNA hybridization levels with *H. fennelliae* and *H. cinaedi* (30 and 52%, respectively) and has approximately 98% 16S rRNA sequence similarity with *H. bilis* and "*H. rappini*."

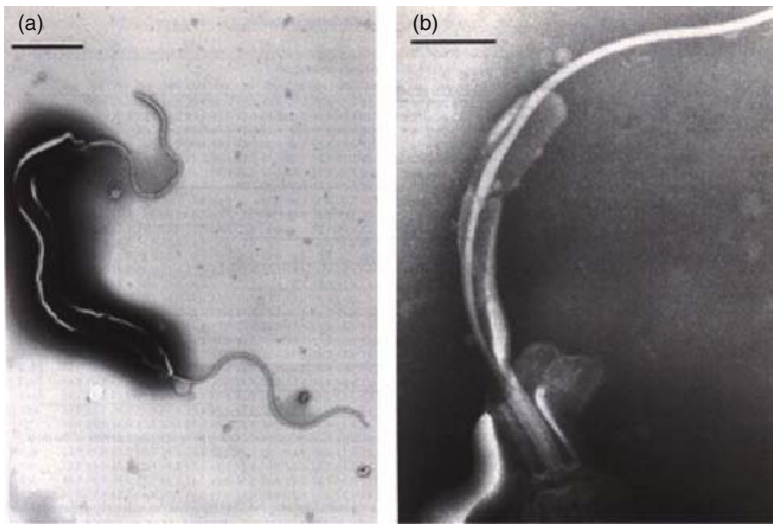

Fig. 11. Transmission electron micrograph of a negatively stained preparation of *Helicobacter canis* showing its S-shaped morphology and single, bipolar, sheathed flagella. Bar = 1 μm. (Reproduced with permission from Stanley et al., 1993.)

Fig. 12. Transmission electron micrograph of a negatively stained preparation of *Helicobacter hepaticus* showing its S-shaped morphology and single, bipolar, sheathed flagella. Bar = 0.5 μm. (Reproduced with permission from Fox et al., 1994.)

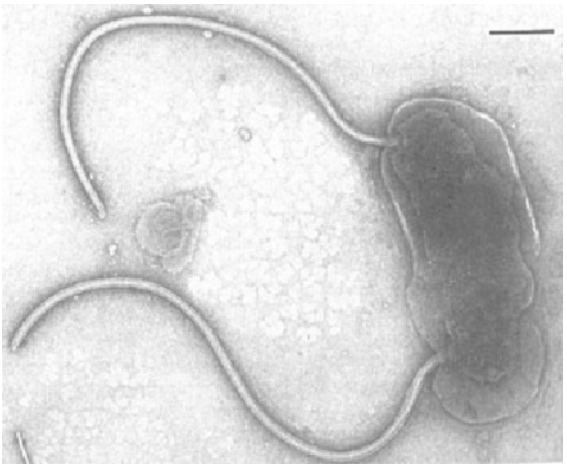

Fig. 13. Transmission electron micrograph of a negatively stained preparation of *Helicobacter pametensis* showing its curved rod morphology and single, bipolar, sheathed flagella. Bar = 0.3 μm. (Reproduced with permission from Dewhirst et al., 1994.)

Helicobacter hepaticus

Helicobacter hepaticus was isolated from the intestinal mucus and livers of mice (Fox et al., 1994). It is a Gram-negative, curved to spiral rod (0.2–0.3 μm × 1.5–5 μm; Fig. 12). Cells are motile and possess a single, bipolar, sheathed flagellum. The organism grows as a thin spreading film after 3–7 days on blood agar. Optimum growth occurs at 37°C under microaerobic conditions, with limited growth anaerobically and no growth at 42°C.

All strains are catalase, oxidase, and urease positive. They reduce nitrate and hydrolyze indoxyl acetate but not hippurate. *Helicobacter hepaticus* is sensitive to metronidazole and resistant to 1.5% NaCl, 1% glycine, cephalothin and nalidixic acid.

Helicobacter hepaticus is most closely related to *H. muridarum* by 16S rRNA sequence homology. The genomic diversity of *H. hepaticus* from four sources in the United States and three sources in Europe was determined by PFGE (Saunders et al., 1997). Three of the sites in the United States gave similar patterns. However, the fourth site and the three sites from Europe all gave different patterns, indicating significant genomic diversity among *H. hepaticus* strains. Sequencing of the complete *H. hepaticus* genome was recently reported in preliminary form (Suerbaum et al., 2001). The genome is 1.8 Mb with 1,800 open reading frames (ORFs). Notably absent were pathogenicity islands and orthologs of the *H. pylori* vacuolating cytotoxin (VacA), adhesins, and the Helicobacter outer membrane porin (HOP) family (Peck et al., 2001).

Helicobacter pametensis

Heliocbacter pametensis was isolated from tern, gull and swine feces with the species name derived from the origin of the isolates, the Pamet River in Truro, Massachusetts (Dewhirst et al., 1994). The organism is a small curved rod (0.4 μm × 1.5 μm), with rounded ends (Fig. 13). Cells are motile and possess a single sheathed flagellum at each end. The flagella are inserted subterminally, and occasional cells have a third flagellum adjacent to one of the others. Colonies are pinpoint to 0.5 mm in diameter, translucent, colorless and weakly hemolytic after 3 days growth on blood agar. Optimum growth occurs at 37°C under microaerobic conditions, with limited growth at 42°C or under anaerobic conditions.

All strains are catalase and oxidase positive and urease negative. They reduce nitrate but do not hydrolyze hippurate or indoxyl acetate. There is activity for alkaline phosphatase and arginine β-naphthylamide aminopeptidase, but not γ-glutamyl transpeptidase. *Helicobacter pametensis* is sensitive to 3.5% NaCl, nalidixic acid, and cephalothin, but resistant to 1% glycine. The G+C content is 38 mol%.

Helicobacter pullorum

Helicobacter pullorum was isolated from the ceca of asymptomatic broiler chickens, the livers and intestinal contents of hens exhibiting lesions suggestive of vibrionic hepatitis, and feces from patients with gastroenteritis (Stanley et al., 1994). The organism is a gently curved rod (0.3–

Fig. 14. Transmission electron micrograph of a negatively stained preparation of *Helicobacter pullorum* showing its curved rod morphology and single, monopolar, unsheathed flagella. Bar = 0.3 μm. (Reproduced with permission from Stanley et al., 1994.)

Fig. 15. Transmission electron micrograph of a negatively stained preparation of *Helicobacter trogontum* showing its tapered rod morphology with bipolar tufts of sheathed flagella and periplasmic fibers entwining the cell. Bar = 0.5 μm. (Reproduced with permission from Mendes et al., 1996b.)

0.5 μm × 3–4 μm), with a single unsheathed polar flagellum (Fig. 14). Colonies are pinpoint to 1 mm in diameter, translucent, watery and weakly α-hemolytic after 3 days growth on blood agar. All strains grow at 37 and 42°C under microaerobic conditions, but not anaerobically.

All strains are oxidase positive and urease negative. Most strains are catalase positive and are able to reduce nitrate. They do not hydrolyze hippurate or indoxyl acetate, and there is no alkaline phosphatase activity. *Helicobacter pullorum* is usually sensitive to 1% glycine, 2% NaCl, polymyxin B, and nalidixic acid. It is resistant to 1% bile, cefoperazone and cephalothin. The G+C content is 34–35 mol%.

Helicobacter trogontum

Helicobacter trogontum was isolated from the colonic mucosa of rats (Mendes et al., 1996b). It is a fusiform rod with tapered ends (0.6–0.7 μm × 4–6 μm; Fig. 15). It is motile by means of tufts of bipolar, sheathed flagella. Ultrastructurally the cells are characterized by the presence of periplasmic fibers coiled around the protoplasmic cylinder, giving a crisscross appearance to the bacterial surface. Bacteria initially grow as punctiform colonies and then as a fine spreading translucent film on moist blood agar plates after 3–5 days at 37 or 42°C under microaerobic conditions. No growth occurs at 25°C or under aerobic or anaerobic conditions.

All strains are urease, catalase and oxidase positive. They reduce nitrate but do not hydrolyze hippurate. Ornithine decarboxylase and γ-glutamyl transpeptidase activities are present, with variable activity for alkaline phosphatase. *Helicobacter trogontum* is resistant to nalidixic acid and cephalothin but sensitive to 1% glycine, 1.5% NaCl and metronidazole.

Helicobacter bilis

Helicobacter bilis was isolated from intestinal mucosa of mice and the bile and liver of mice with hepatitis (Fox et al., 1995). The organism has also been isolated from gastric mucosa in dogs (Eaton et al., 1996) and from the large bowel in a colony of male athymic nude rats (Haines et al., 1998). PCR evidence suggests the possibility that this bile-resistant *Helicobacter* species may also be associated with human diseases of the gallbladder (Fox et al., 1998a). *Helicobacter bilis* is a fusiform rod with tapered ends (0.5 μm × 4–5 μm; Fig. 16). It is motile by means of bipolar tufts of sheathed flagella. Ultrastructurally the cells are characterized by the presence of periplasmic fibers coiled around the protoplasmic cylinder, giving a crisscross appearance to the bacterial surface. Bacteria initially grow as punctiform colonies and then as a fine spreading translucent film on moist blood agar plates after 3–5 days at 37°C under microaerobic conditions. Microaerophilic growth occurs at 42°C but not 25°C.

All strains of *H. bilis* are urease, catalase and oxidase positive. They reduce nitrate but do not hydrolyze indoxyl acetate or hippurate. *Helicobacter bilis* is sensitive to 1.5% NaCl and metronidazole and resistant to 20% bile, 0.04% TTC, nalidixic acid and cephalothin. There is variable growth in the presence of 1% glycine.

Sequencing of the 16S rRNA gene revealed the presence of a 187-bp intervening sequence in *H. bilis*. The bacteria most closely related to *H. bilis* are *H. canis*, *H. cinaedi* and "*H. rappini*."

Helicobacter cholecystus

Helicobacter cholecystus was isolated from the gallbladders of Syrian hamsters with cholangiofibrosis and centrilobular pancreatitis (Franklin et al., 1996). It is a straight or curved rod (0.5–0.6 μm × 3–5 μm; Fig. 17). It is motile by means of a single, sheathed, polar flagellum. Colonies are pinpoint after 3 days incubation at 37°C

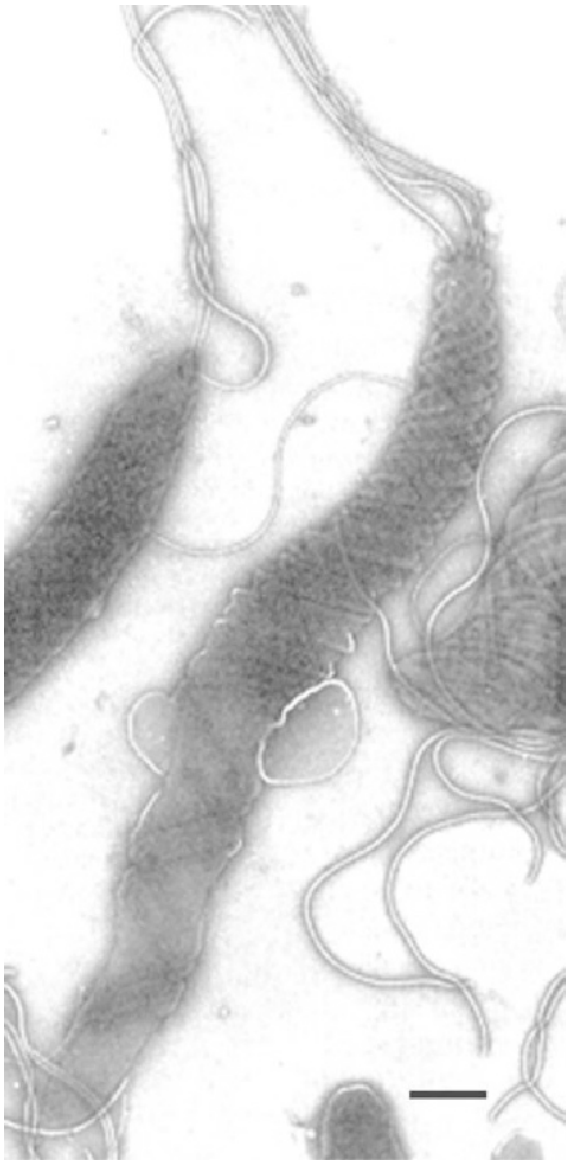

Fig. 16. Transmission electron micrograph of a negatively stained preparation of *Helicobacter bilis* showing its curved S-shaped morphology with bipolar tufts of sheathed flagella and periplasmic fibers entwining the cell. Bar = 0.35 μm. (Reproduced with permission from Fox et al., 1995.)

Fig. 17. Transmission electron micrograph of a negatively stained preparation of *Helicobacter cholecystus* showing its rod-like morphology and single, monopolar, sheathed flagellum. Bar = 1 μm. (Reproduced with permission from Franklin et al., 1996.)

under microaerobic conditions. Cells are also able to grow at 42°C and under anaerobic conditions.

All strains are catalase and oxidase positive and urease negative. They reduce nitrate but do not hydrolyze hippurate or indoxyl acetate. *Helicobacter cholecystus* exhibits activity for arginine aminopeptidase, alkaline phosphatase and L-arginine arylamidase but not γ-glutamyl transpeptidase, histidine aminopeptidase, or leucine aminopeptidase. *Helicobacter cholecystus* is sensitive to 1.5% NaCl but resistant to 5% bile and cephalothin. It exhibits intermediate sensitivity to nalidixic acid.

Helicobacter rodentium

Helicobacter rodentium was isolated from the intestinal mucosa and feces of mice (Shen et al., 1997). It is a curved or spiral rod (0.3 μm × 1.5–5 μm; Fig. 18). It is motile by means of single, bipolar, unsheathed flagella. Bacteria grow as a fine spreading translucent film on moist blood agar plates after 4–7 days incubation at 37°C under microaerobic conditions. Bacterial growth

Fig. 18. Transmission electron micrograph of a negatively stained preparation of *Helicobacter rodentium* showing its S-shaped morphology and single, bipolar, unsheathed flagella. Bar = 1 μm. (Reproduced with permission from Shen et al., 1997.)

also is seen when cells are incubated at 42°C or under anaerobic conditions.

Helicobacter rodentium is urease negative and exhibits weak catalase and oxidase activities. It reduces nitrate but does not hydrolyze indoxyl acetate or hippurate, and no γ-glutamyl transferase or alkaline phosphatase activity is detected. *Helicobacter rodentium* is able to grow in the presence of 1% glycine and 1.5% NaCl, and it is resistant to nalidixic acid and cephalothin.

Helicobacter mesocricetorum

Helicobacter mesocricetorum was isolated from feces of Syrian hamsters (Simmons et al., 2000). It is a spiral, curved rod without periplasmic fibers whose average size is 0.5 μm × 2.5 μm (Fig. 19). It is motile by means of single, bipolar, unsheathed flagella. Growth occurs as pinpoint colonies or as a thin spreading film at 42°C but not at 25°C. Growth is minimal to absent under anaerobic conditions and does not occur under aerobic conditions. *Helicobacter mesocricetorum* is positive for catalase and alkaline phosphatase, and it usually expresses nitrate reduction. It is negative for urease, γ-glutamyl transferase, and hippurate hydrolysis. No growth occurs with 1% glycine or 1.5% NaCl. *Helicobacter mesocricetorum* is resistant to cephalothin and generally sensitive to nalidixic acid. Like some other enterohepatic helicobacters, *H. mesocricetorum* has a 16S rRNA gene with an intervening sequence. The closest known relative is *H. rodentium*.

Helicobacter ganmani

Helicobacter ganmani was cultured during routine screening of intestinal scrapings from conventional and specific pathogen-free mice (Robertson et al., 2001). It is a curved to spiral rod measuring 0.3 μm × 2.5 μm with two turns per cell and single, unsheathed, bipolar flagella (Fig. 20). After 3–5 days incubation at 37°C on 5% horse blood, growth appears as a thin, transparent film. No growth occurs at 42°C. Single colonies, which are not usually seen, are irregular and less than 1 mm in diameter. *Helicobacter ganmani* is anaerobic, with no growth under microaerobic or aerobic conditions.

Helicobacter ganmani is urease negative but weak catalase activity is found in some strains. There is no alkaline phosphatase or indoxyl acetate hydrolysis. No growth occurs in the presence of 1% glycine, 2–4% NaCl, or nalidixic acid, but *H. ganmani* is resistant to cephalothin. The 16S

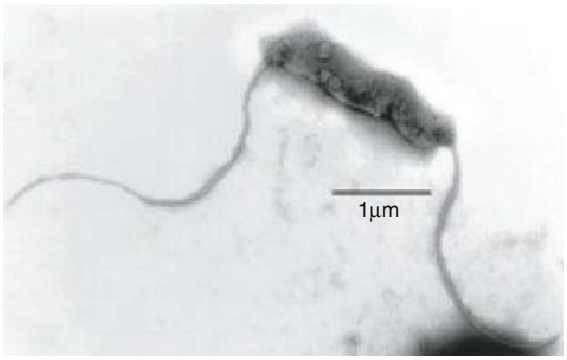

Fig. 19. Transmission electron micrograph of a negatively stained preparation of *Helicobacter mesocricetorum* showing its curved S-shaped morphology and single, bipolar, unsheathed flagella. Bar = 1 μm. (Reproduced with permission from Simmons et al., 2000.)

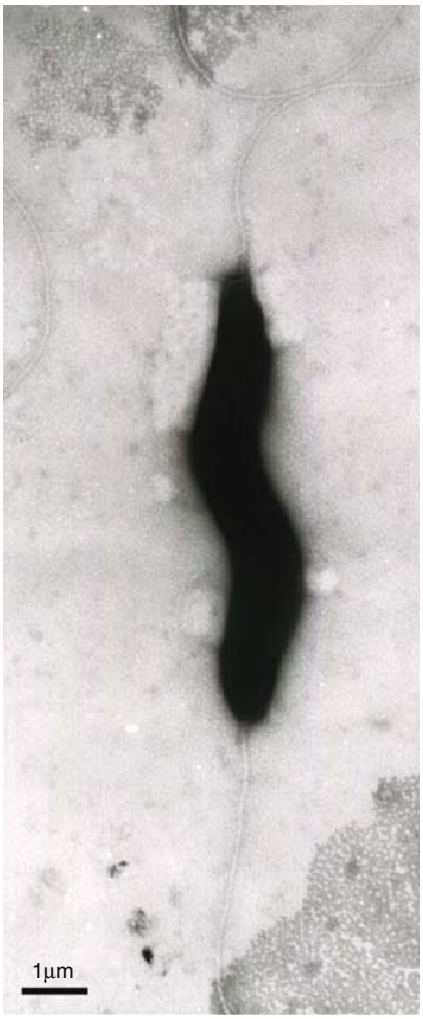

Fig. 20. Transmission electron micrograph of a negatively stained preparation of *Helicobacter ganmani* showing its S-shaped morphology and single, bipolar unsheathed flagella. Bar = 0.3 μm. (Reproduced with permission from Robertson et al., 2001.)

rRNA gene from *H. ganmani* is 98.2% similar to the type strain of *H. rodentium* and is identical to a sequence from an unnamed mouse isolate, *Helicobacter* sp. MIT 95-2011 (GenBank accession no. U96298).

Helicobacter canadensis

Some strains of *H. pullorum* identified by 16S rRNA sequence, fatty acid analysis, and restriction enzyme analysis were unexpectedly found to be indoxyl acetate positive, which had not been previously noted in *H. pullorum* (Gibson et al., 1999). Re-examination of four such isolates from patients with diarrhea showed that they differed biochemically from *H. pullorum* by their inability to hydrolyze indoxyl acetate and their resistance to nalidixic acid (Fox et al., 2000). Complete 16S rRNA sequence analysis indicated a 2% difference with *H. pullorum*, and these isolates were proposed as a novel species, designated *H. canadensis*. The ultrastructure of *H. canadensis* is very similar to that of *H. pullorum*, except that the unsheathed flagella are unipolar rather than bipolar. Growth occurs microaerobically at 37 and 42°C, but not under anaerobic or aerobic conditions. *Helicobacter canadensis* is urease, alkaline phosphatase, and γ-glutamyl transpeptidase negative but catalase and oxidase positive. Nitrate reduction is variable.

Fig. 21. Transmission electron micrograph of a negatively stained preparation of *Helicobacter aurati* showing its tapered rod morphology with bipolar tufts of sheathed flagella and periplasmic fibers entwining the cell. Bar = 0.5 μm. (Reproduced with permission from Patterson et al., 2000.)

Helicobacter aurati

Helicobacter aurati was cultivated from inflamed stomachs and ceca of adult Syrian hamsters (Patterson et al., 2000). They have a fusiform rod morphology (0.6 μm × 4–8 μm), with periplasmic fibers, and are motile by means of multiple, bipolar, sheathed flagella (Fig. 21). Growth on 5% sheep blood agar appears as a thin, spreading film without distinct colonies. Microaerobic growth occurs at 37 and 42°C. No growth occurs under anaerobic conditions or in the presence of 1–3% NaCl or 1% glycine. *Helicobacter aurati* is positive for urease, catalase, oxidase and γ-glutamyl transpeptidase activities and for indoxyl acetate hydrolysis. Nitrate reduction and alkaline phosphatase hydrolysis are absent. *Helicobacter aurati* is sensitive to nalidixic acid but resistant to cephalothin. By 16S rRNA sequence analysis, *H. aurati* is most closely related to *H. muridarum* and *H. hepaticus*.

Helicobacter typhlonius

A novel *Helicobacter* species was originally isolated from IL-10-deficient mice with colitis and typhlitis (Fox et al., 1999). An identical organism was subsequently cultivated from feces of BALB/c mice and the designation "*Helicobacter typhlonicus*" was proposed (Franklin et al., 1999). For grammatical reasons, this name was changed to *Helicobacter typhlonius* and has recently been included within the validated species (Franklin et al., 2001). It is a curved to spiral rod (0.3 μm × 2–5 μm), and it is motile by means of single, bipolar, sheathed flagella (Fig. 22). *Helicobacter typhlonius* grows as transparent, pinpoint colonies on blood agar under microaerobic conditions at 37°C, with no growth under aerobic or anaerobic conditions or at 25 or 42°C. It is oxidase and catalase positive but urease negative. *Helicobacter typhlonius* reduces nitrate but does not hydrolyze indoxyl acetate or hippurate. There is no alkaline phosphatase or γ-glutamyl transpeptidase activity. Growth occurs in the presence of 1.5% NaCl and 1% glycine. 16S rRNA sequence shows that *H. typhlonius* is most closely related to *H. hepaticus* and *H. muridarum* (97.5%). Similar to *H. bilis* and *H. canis*, there is a 164–166-bp intervening sequence in the 16S rRNA gene.

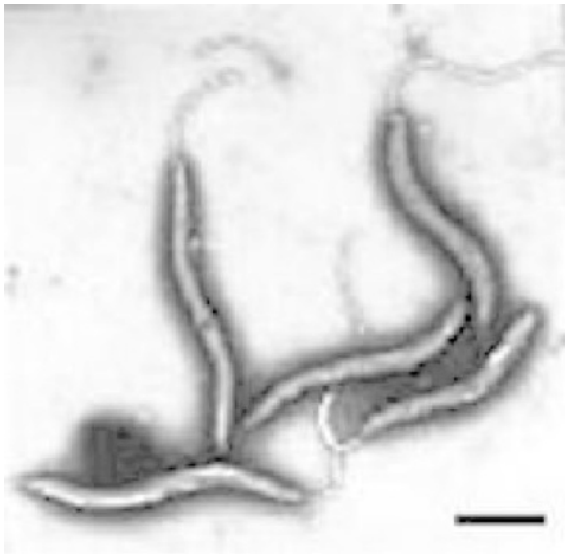

Fig. 22. Transmission electron micrograph of a negatively stained preparation of *Helicobacter typhlonius* showing its curved S-shaped morphology and single, bipolar, sheathed flagella. Bar = 1.5 μm. (Reproduced with permission from Fox et al., 1999.)

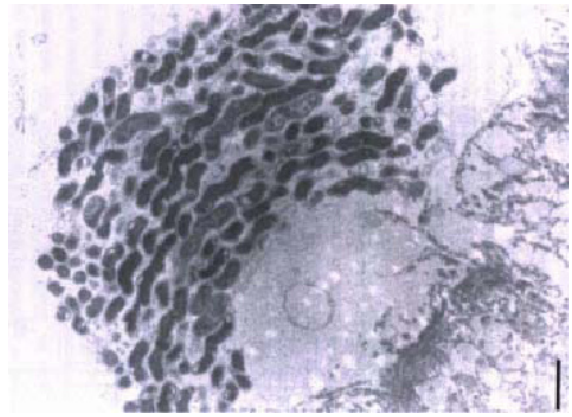

Fig. 23. Transmission electron micrograph of bovine gastric mucosa showing the S-shaped morphology of "*Candidatus Helicobacter bovis*." Bar = 1 μm. (Reproduced with permission from De Groote et al., 1999b.)

Candidate Unvalidated Species

In addition to the 22 validated *Helicobacter* species, a number of isolates currently do not fulfill criteria to be classified as novel species. In some cases the inability to culture the organisms in vitro has resulted in classification as *Candidatus* species. The International Committee on Systematic Bacteriology (Subcommittee on the Taxonomy of *Campylobacter* and Related Bacteria) has recently agreed upon the need for minimal standards for the description of new *Helicobacter* species (Dewhirst et al., 2000b). The category *Candidatus* was proposed and implemented to provide provisional status for incompletely described prokaryotes (Murray and Schleifer, 1994; Murray and Stackebrandt, 1995). In addition to DNA sequence data, a description of *Candidatus* species should include verification of localization in their natural niche by techniques such as in situ hybridization, as well as descriptive information relating to structure and metabolism so far as is available. Currently the *Helicobacter* genus includes two *Candidatus* species and numerous unvalidated species (Tables 4 and 5).

Candidatus Helicobacter bovis

Candidatus Helicobacter bovis is an uncultured bacterium found in the pyloric portion of the abomasum of calves and adult cattle (De Groote et al., 1999b). Gastric bacteria detected in the gastric crypts of the abomasal stomachs of healthy cattle crossreact with polyclonal antibody against *H. pylori*. Ultrastructural studies reveal the presence of large groups of multiple spiral bacteria with 1–3 turns (Fig. 23). The bacteria possess a Gram-negative cell wall and are 0.3 μm × 1.5–2.5 μm in size, with at least four flagella at one end. The presence or absence of a flagellar sheath was not determined. Pyloric biopsy samples were shown to be urease positive. Cloning and sequencing of the 16S rRNA gene from DNA obtained from seven different cattle showed they had a sequence homology of greater than 99%. The closest taxonomic relative was *H. bilis* (92.8%) as determined by a 16S rRNA similarity matrix. A "*Candidatus* Helicobacter bovis"-specific probe (5– AAT TGC GTT TGA AAC TAT CAT T –3) confirmed the presence of these bacteria in the cattle abomasum by in situ hybridization.

Candidatus Helicobacter suis

Candidatus Helicobacter suis is a urease-positive uncultivated bacterium identified in antral biopsies of healthy slaughterhouse pigs (De Groote et al., 1999a). Organisms (2.5–3.5 μm long × 0.6 μm wide) have a tightly coiled appearance with 1–5 bipolar flagella (Fig. 24). Polyclonal antisera against *H. pylori* crossreact with "*Candidatus Helicobacter suis*" and reveal the bacteria most commonly in superficial portions of the gastric crypts. Pairwise comparisons of 16S rDNA sequences obtained from five isolates showed a minimum of 97.7% similarity. The 16S rDNA sequence was 99.5% similar to that of "*H. heilmannii*" type 1 (Solnick et al., 1993), which has been found in humans, pigs, and nonhuman primates. Owing to precedence and nonspecific

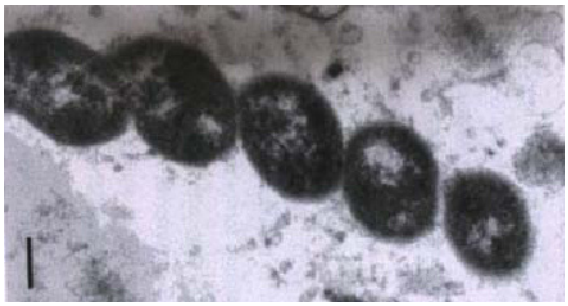

Fig. 24. Transmission electron micrograph of porcine gastric mucosa showing the tight helical morphology of "*Candidatus Helicobacter suis*." Bar = 0.3 µm. (Reproduced with permission from De Groote et al., 1999a.)

host range, it has been proposed that "*Candidatus Helicobacter suis*" be renamed "*Candidatus Helicobacter heilmannii*" (O'Rourke et al., 2001a).

Helicobacter heilmannii

Helicobacter heilmannii (Fig. 25) was initially proposed as the designation for an uncultivated urease-positive gastrospirillum identified in biopsies of human gastric mucosa (Solnick et al., 1993). The morphology is indistinguishable from that of "*Candidatus Helicobacter suis*" (Fig. 24). Since the16S rDNA sequence from the original two isolates differed by 3.5%, they were provisionally given the designation "*H. heilmannii*" type 1 and "*H. heilmannii"* type 2 (Solnick et al., 1993). Subsequent analysis based on both 16S rDNA and urease sequences confirmed that porcine, nonhuman primate, and some human isolates clustered closely together with the original "*H. heilmannii*" type 1 strain. It has been proposed that these strains be designated "*Candidatus Helicobacter heilmannii*," which would replace "*Candidatus Helicobacter suis*" (O'Rourke et al., 2001a). Another group of related strains identified in a tiger, wild dog, bobcat, and human are more closely related to the original "*H. heilmannii*" type 2 isolate and to other known species such as *H. felis* and *H. bizzozeronii*. In clinical gastroenterology, where only morphological data are available, these organisms are often collectively referred to as "*H. heilmannii*," a practice that is convenient but which obscures species differences.

Helicobacter sp. "flexispira"

A Gram-negative bacterium with a slightly spiral morphology, multiple periplasmic fibers, and bipolar tufts of sheathed flagella (Fig. 26) was originally isolated by Kirkbride from aborted

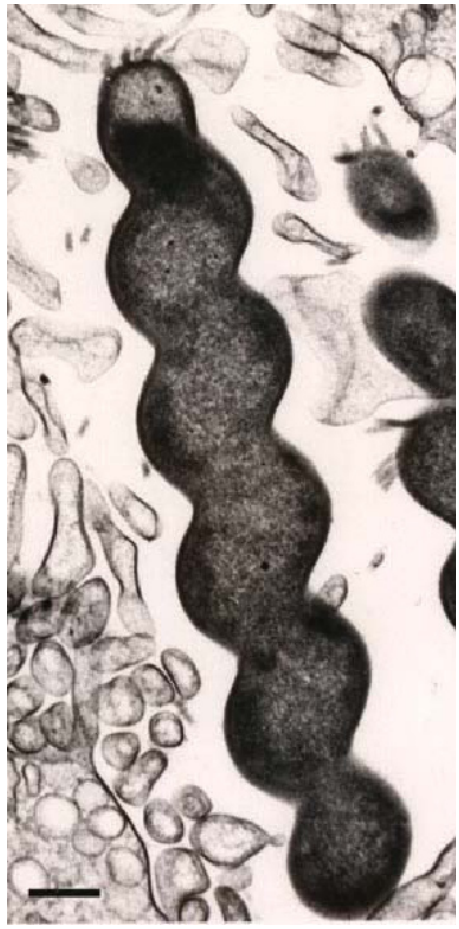

Fig. 25. Transmission electron micrograph of feline gastric mucosa showing the tight helical morphology of "*Helicobacter heilmannii*." Bar = 0.3 µm.

ovine fetuses (Kirkbride et al., 1985). Closely related organisms have subsequently been isolated from a broad range of animal hosts, as well as from normal and immunocompromised humans (Archer et al., 1988; Romero et al., 1988; Schauer et al., 1993; Tee et al., 1998). The original designation of "*Flexispira rappini*" has been abandoned in favor of *Helicobacter*, since several studies have shown that these organisms are members of this taxon (Vandamme et al., 1991a). Recent evidence suggests that this group of organisms contains at least 10 *Helicobacter* taxa, including the two named species, *H. bilis* and *H. trogontum* (Dewhirst et al., 2000a). It has been proposed that the designation "*Helicobacter rappinii*" be applied to strains referred to as *Helicobacter* sp. flexispira taxa 1, 4, and 5, which are closely related and include the original Kirkbride strain (Hänninen et al., 2001).

Helicobacter rappinii has urease, catalase, and γ-glutamyl transferase activity but does not reduce nitrate or produce alkaline phosphatase. Growth occurs as spreading colonies at 37 and

Fig. 26. Transmission electron micrograph of a negatively stained preparation of "*Helicobacter rapinni*" showing its tapered rod morphology with bipolar tufts of sheathed flagella and periplasmic fibers entwining the cell. Bar = 0.5 μm. (Reproduced with permission from Schauer et al., 1993.)

42°C. "*Helicobacter rappinii*" as represented by taxa 1, 4 and 5 grows under strictly anaerobic conditions, but other taxa (for example taxa 8, which includes the original human isolate) grow under microaerobic conditions. "*Helicobacter rappinii*" does not grow in the presence of 1% glycine, and it is resistant to nalidixic acid and cephalothin. By 16S rDNA sequence analysis, "*H. rappinnii*" is most closely related to *H. bilis*.

Helicobacter sp. strain "CLO-3"

Helicobacter sp. strain CLO-3 was one of three groups of *Campylobacter*-like organisms isolated from rectal cultures in homosexual males. The other two groups have subsequently been classified as *H. cinaedi* and *H. fennelliae* (Fennell et al., 1984; Totten et al., 1985; Vandamme et al., 1991a). *Helicobacter* sp. CLO-3 consists of only a single strain, which is a slender spiral rod (0.3–0.5 μm × 1.5–5 μm). It has rapid motility owing to the possession of single, polar, sheathed flagella. It grows as pinpoint, translucent colonies under microaerobic conditions at 37°C, with no growth aerobically or anaerobically. It is catalase positive, is urease negative, does not reduce nitrate, and weakly hydrolyzes indoxyl acetate. *Helicobacter* sp. strain "CLO-3" grows in the presence of 1% glycine and 0.04% TTC but not 2% NaCl. The G+C content is 45 mol%.

Helicobacter sp. "Bird-B" and "Bird-C"

Bacteria isolated from feces of wild terns, gulls, a house sparrow and swine were identified as three biotypes of *Helicobacter*, originally denoted *Helicobacter* sp. "Bird-A, -B and -C" (Seymour et al., 1994). The Bird-A isolate was subsequently classified as *H. pametensis* (Dewhirst et al., 1994). The other closely related organisms are not formally named and are still referred to as *Helicobacter* sp. "Bird-B and Bird-C" because they are represented by only two isolates for one species and one for the other (Dewhirst et al., 1994). Both organisms are slender Gram-negative, spiral rods (0.3–0.5 μm × 1.5–5 μm) and are motile by means of single, polar, sheathed flagella. They are distinguished from *H. pametensis* by their absence of urease activity and resistance to cephalothin. "Bird-C" is susceptible to nalidixic acid and "Bird-B" is moderately susceptible to nalidixic acid. The G+C content of "Bird-B" and "Bird-C" is 31 and 30 mol%, respectively.

Helicobacter suncus

Helicobacter suncus was isolated from the gastric mucosa of house musk shrews (*Suncus murinis*) with gastritis (Goto et al., 1998). It is a curved rod (0.5 μm × 3.55 μm) and is motile by means of bipolar, sheathed flagella (Fig. 27). Bacteria grow as transparent mucoid colonies on moist blood agar plates after incubation at 37°C under microaerobic conditions. Growth occurs under anaerobic, but not aerobic, conditions. Strains of "*H. suncus*" are catalase, oxidase and urease positive. They can reduce nitrate but do not hydrolyze indoxyl acetate or hippurate. "*Helicobacter suncus*" has alkaline phosphatase and arginine aminopeptidase activity but not γ-glutamyl transpeptidase. It is sensitive to tetracycline, erythromycin and chloramphenicol and resistant to nalidixic acid and cephalothin. Phylogenetically and biochemically "*H. suncus*" is most closely related to *H. mustelae* and the unnamed *Helicobacter* sp. "Bird-B and Bird-C."

Helicobacter colifelis

This organism was seen in fecal smears from an 8-week-old kitten with severe diarrhea (Foley et

al., 1998). Large numbers of spiral-shaped bacteria were seen in the crypts and surface mucus layer of the cecum and colon. The association with diarrhea was not proven since inoculation of pathogen-free cats with infected feces did not produce symptoms, although feces of the cats were positive by PCR using primers specific for the *Helicobacter* genus. Ultrastructurally "*H. colifelis*" is spiral shaped with two coils, 0.67 μm × 4–5.9 μm in size, with bipolar tufts of flagella that are connected to basal plates at the point of insertion (Fig. 28). Genetically "*H. colifelis*" is most closely related to *H. canis* (98.3%), *H. pullorum* (96.9–96.4%), *H. hepaticus* (96.7%) and *H. cinaedi* (96.5%). Since "*H. colifelis*" is currently uncultivated and was identified on the basis of 16S rRNA sequence from a single isolate, it remains unclear whether it represents a novel enterohepatic *Helicobacter* species.

Helicobacter sp. "Cottontop tamarin" (CTT)

An unnamed *Helicobacter* was isolated from fecal samples from Cotton-top tamarins with chronic colitis (Saunders et al., 1999). The organism is a fusiform rod (0.5 μm × 4–5 μm), with periplasmic fibers (Fig. 29). It is motile by means of 6–12 bipolar, sheathed flagella. The bacteria grow as a thin spreading film after 3–5 days growth under microaerobic conditions and are capable of growth at 37 and 42°C but not at 25°C. It is urease negative but positive for catalase and oxidase. Nitrate is not reduced, indoxyl acetate is not hydrolyzed, and no alkaline phosphatase occurs. "*Helicobacter* sp. CTT" is resistant to 1% glycine, nalidixic acid, cephalothin and trimethoprim-sulfamethoxazole. The 16S rRNA gene has a 350-bp intervening sequence and is most closely related to *H. canis* and *H. fennelliae*.

Helicobacter winghamensis

Helicobacter winghamensis was isolated from stools of children and adults with gastroenteritis (Melito et al., 2001). The organism is a curved to spiral rod (0.3–0.6 μm × 2 μm) that is motile by one or two bipolar, unsheathed flagella (Fig. 30). The absence of a flagellar sheath is uncommon

among helicobacters, but does occur in *H. pullorum*, *H. canadensis*, *H. mesocricetorum*, *H. ganmani*, *H. rodentium* and "*H. muricola*." Colonies on 10% sheep blood agar show a mixture of spreading and nonspreading morphology. Growth occurs under microaerobic conditions at 37°C but not at 42°C or in aerobic or anaerobic conditions. "*Helicobacter winghamensis*" is negative for urease and alkaline phosphatase activities, and it does not reduce nitrate. Catalase activity is also absent, which among helicobacters has only been described for *H. canis* and taxa 7 and 8 of *Helicobacter* sp. "*flexispira*" (Dewhirst et al., 2000a). "*Helicobacter winghamensis*" is bile tolerant, hydrolyzes indoxyl acetate, and is variably resistant to nalidixic acid and cephalothin. By 16S rRNA sequence analysis, "*H. winghamensis*" is most closely related to *Helicobacter* sp. "*flexispira*" taxon 1 and to *H. cholecystus*.

Helicobacter sp. "rhesus"

Microaerobic culture of colonic tissue from rhesus macaques revealed two novel *Helicobacter* biotypes that were isolated from clinically normal monkeys and monkeys with chronic idiopathic colitis, respectively (Fox et al., 2001b). Cells are spiral in shape, 0.2 μm × 2–3 μm in size, and motile by means of bipolar, sheathed flagella (Fig. 31). Both biotypes are oxidase positive and urease negative and grow at 37 or 42°C as pinpoint or spreading colonies. The two biotypes differ by catalase activity, ability to reduce nitrate, and sensitivity to cephalothin. By 16S rRNA sequence analysis, *Helicobacter* sp. "rhesus" type 1 is most closely related to a *Helicobacter* species isolated from a woodchuck and to *Helicobacter* sp. "Cottontop tamarin." *Helicobacter* sp. "rhesus" type 2 is most closely related to *H. fennelliae* and differs from type 1 by about 4%.

Helicobacter cetorum

Apparently novel *Helicobacter* species were identified by culture and PCR of gastric mucosa from the main stomach of stranded dolphins, *Lagenorhynchus acutus* and *Delphinus delphis* (Harper et al., 2000). Cultivated organisms had a fusiform to slightly spiral morphology and measured 4 μm by 0.6 μm, with laterally located, bipolar, sheathed flagella (Fig. 32). Organisms were positive for urease, catalase, oxidase and γ-glutamyl transpeptidase activity, but did not reduce nitrate or hydrolyze indoxyl acetate. Growth occurred at 42°C and with 1% glycine but not in the presence of nalidixic acid or cephalothin. 16S rDNA sequences from the dolphin isolates cluster with other gastric helicobacters and are most closely related to *H. pylori*. The

name "H. cetorum" has recently been proposed. These isolates represent the first helicobacters isolated from marine mammals. A closely related species was recently cultivated from feces of a beluga whale (Harper et al., 2002).

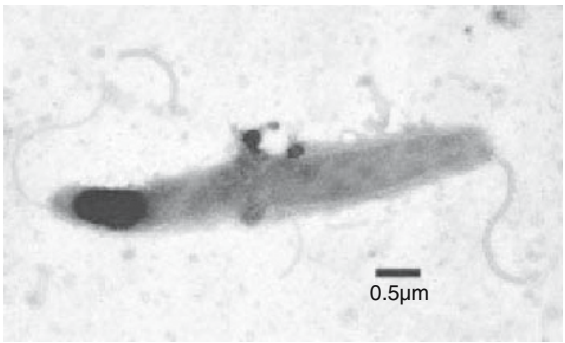

Fig. 32. Transmission electron micrograph of a negatively stained preparation of "*Helicobacter cetorum*" showing its fusiform to S-shaped morphology and bipolar, sheathed flagella. Bar = 0.5 µm. (Reproduced with permission from Harper et al., 2000.)

Helicobacter marmotae

Because woodchucks (*Marmota monax*) have a high incidence of hepatocellular carcinoma, which can be induced by *H. hepaticus* infection in mice, Fox et al. recently examined woodchuck livers to determine whether they were infected with *Helicobacter* species (Fox et al., 2002b). A novel helicobacter was isolated from a single woodchuck and also from the feces of four cats. The organism measures 0.2 by 5 µm, with bipolar, sheathed flagella similar to those of many other enterohepatic *Helicobacter* species. "*Helicobacter marmotae*" is positive for catalase and urease but negative for nitrate reduction, indoxyl acetate hydrolysis, and γ-glutamyl transpeptidase activity. Growth occurs in 1% glycine and in the presence of nalidixic acid and cephalothin, but not at 42°C. By 16S rDNA, "*H. marmotae*" clusters with *H. fennelliae* and with helicobacters isolated from rhesus monkeys and cotton-top tamarins. Whether "*H. marmotae*" promotes hepatocellular carcinoma in woodchucks or causes enterohepatic disease in cats is currently unknown.

Helicobacter muricola

Although Helicobacter species have been isolated from the intestinal tracts and hepatobiliary system of laboratory mice, helicobacters in wild mice have not been well described. Won et al. recently reported the isolation of a slowly growing species from the ceca and fecal pellets of Korean wild mice (Won et al., 2002). The organism measures 0.43–0.5 µm in width and 2.3–5.5 µm in length, with the same morphology as other enterohepatic helicobacters such as *H. typhlonius*, *H. hepaticus* and *H. rodentium*. Isolation required 7–15 days, which is longer than usual for most helicobacters. "*Helicobacter*

muricola" is catalase and urease positive but negative for alkaline phosphatase, γ-glutamyl transpeptidase activity and indoxyl acetate hydrolysis. No growth occurs in 1% glycine or at 42°C. "*Helicobacter muricola*" is sensitive to nalidixic acid but resistant to cephalothin. It is most closely related to another murine *Helicobacter* species, *H. muridarum* (96.7% similarity). Histopathologic evaluation of the gastrointestinal tract of infected mice revealed no abnormalities, so "*H. muricola*" is likely nonpathogenic in its natural host.

Helicobacter Infection and Disease

Helicobacter species are ubiquitous colonizers of the enteric mucosal surface of humans and other animals. In most cases, these bacteria do not appear to have a pathologic relationship with their host; however, there are important exceptions to this generalization, most notably *H. pylori*, which is associated with the development of peptic ulcers and gastric cancer in humans. Even with *H. pylori*, it should be remembered that the relationship between pathogen and host is complex, often commensal, and perhaps even beneficial in some cases (Blaser, 1999).

Human Medicine

H. PYLORI

Epidemiology The prevalence of *H. pylori* infection in developed countries increases with age to about 50% at age 50 years. In developing countries, the prevalence is higher and infection occurs at an earlier age, reaching 50% by age 5 years and increasing to 80% or more by adulthood (Mitchell et al., 1992; Bardhan, 1998; Brown, 2000; Everhart, 2000). *Helicobacterium pylori* infection is predominantly acquired in childhood (Mitchell et al., 1992; Parsonnet, 1995), which has led to the conclusion that the apparent association of *H. pylori* with age largely reflects a cohort effect. That is, infection is more common in older persons because they were born at a time when the prevalence was higher than it is currently. In the absence of effective antibiotic therapy, infection usually persists for decades, if not throughout the lifetime of the host, although some reports have suggested that loss of infection may be more common than previously thought (Klein et al., 1994; Malaty et al., 1999).

Transmission Helicobacter pylori is probably most often transmitted directly from person-to-person, which is suggested by case clustering in families and in institutionalized populations (Mitchell et al., 1989; Mitchell et al., 1993; Vincent et al., 1994; Rothenbacher et al., 1999) and by the fact that strains from family members are often genetically indistinguishable, while those from unrelated persons are usually unique (Wang et al., 1993). The mechanism of transmission is controversial, with evidence for and against gastro-oral, fecal-oral or oral-oral routes (Mitchell, 2001). Contaminated food and water have sometimes been implicated as a source for *H. pylori* infection, especially in developing countries (Klein et al., 1991; Goodman et al., 1996); however, the organism has never been cultivated from drinking water. Although *H. pylori* infection was identified in a single colony of laboratory cats (Handt et al., 1994) and is common among captive nonhuman primates (Dubois et al., 1995; Solnick et al., 1996), zoonotic transmission is unlikely. However, a recent report suggested that a potential zoonotic source may be sheep (Dore et al., 2001).

Associations with Disease Acute *H. pylori* infection rarely comes to clinical attention, but may be associated with self-limited epigastric pain and hypochlorhydria (Marshall et al., 1985; Morris and Nicholson, 1987). Chronic infection causes a histologic gastritis in all individuals that is usually asymptomatic, but may result in the development of duodenal or gastric ulcer. Most cases of peptic ulcer disease are now known to be caused by *H. pylori* infection (Dunn et al., 1997). This has prompted a National Institutes of Health (NIH) consensus recommendation that patients with peptic ulcer and *H. pylori* infection be treated with antibiotics in addition to the usual antisecretory agents (Anonymous, 1994). In some individuals, *H. pylori* infection leads to the development of atrophic gastritis, the histologic precursor to gastric cancer. Both epidemiological (Nomura et al., 1991; Parsonnet et al., 1991; Forman et al., 1993) and prospective studies (Uemura et al., 2001) now support the conclusion that chronic infection with *H. pylori* is associated with a significantly increased risk of developing gastric adenocarcinoma, which worldwide is the second most common cause of cancer morbidity and mortality. Chronic *H. pylori* infection may also cause gastric mucosa-associated lymphoid tissue (MALT) lymphoma, which is uncommon but of considerable interest because it is an antigen-driven tumor that, if detected early, can be cured with antibiotic therapy (Wotherspoon et al., 1991; Wotherspoon et al., 1993; Parsonnet et al., 1994; Roggero et al., 1995; Zucca et al., 1998; Isaacson et al., 1999).

Pathogenesis and Virulence A number of *H. pylori* genes are important in virulence, including those coding for urease and flagella, which are required for colonization (Dunn et al., 1997).

Nearly all strains of *H. pylori* express the VacA cytotoxin, which is an 87-kDa protein that causes vacuolization in cultured epithelial cells and is probably active in vivo (Reyrat et al., 1999). The *vacA* gene is highly polymorphic and particular alleles are more strongly associated with disease than others (Leunk et al., 1988; Atherton et al., 1995). About 60% of the United States strains have a 40-kb pathogenicity island, termed the "Cag PAI," which is more often found in strains isolated from patients with clinical disease (Censini et al., 1996). Six of the 27 genes on the Cag PAI have homology to components of the type IV secretion systems found in *E. coli*, *Agrobacterium tumefaciens*, *Bordetella pertussis* and others, which specialize in the transport of DNA and other macromolecules across the bacterial membrane or into other cells (Covacci et al., 1999). These and other genes on the Cag PAI are required for *H. pylori* to induce gastric epithelial cells to produce interleukin-8 (IL-8), which causes inflammation by recruitment of polymorphonuclear leukocytes (Segal et al., 1997; Crabtree et al., 1999; Li et al., 1999; Fischer et al., 2001). The CagA protein, itself, is also exported by the type IV apparatus and injected into the host cell, where it is tyrosine phosphorylated and likely interrupts eukaryotic signal transduction pathways (Segal et al., 1999; Odenbreit et al., 2000; Stein et al., 2000). Recent evidence suggests that at least one mechanism for this process is via formation of a physical complex between CagA and the SRC homology 2 domain (SH2)-containing tyrosine phosphatase, SHP-2 (Higashi et al., 2002).

Helicobacter pylori can survive over a pH range of 3.5–8 owing to the action of a highly adapted urease that permits maintenance of the proton motive force across the periplasmic membrane via production of ammonia, which eliminates excess hydrogen ions in the local acid milieu. Thus the energy supply to the cell is maintained (Meyer Rosberg et al., 1996). A critical gene for this acid resistance is *ureI*, which encodes a membrane protein that functions as an acid-activated urea transporter (Scott et al., 2000; Weeks et al., 2000). Variations in gastric pH caused by surgery, acid suppressive therapies, or host factors allow the bacteria to colonize different niches within the stomach environment, resulting in differing disease presentations. The location of the bacteria and its behavior at that site are a direct response to the local acid environment within the stomach. High acid output levels are associated with a predominately antral gastritis and increased risk of duodenal ulceration, whereas lower acid levels are associated with colonization through the entire stomach including the corpus mucosa, resulting in pangastritis, gastric ulceration, and gastric adenocarcinoma (Lee et al., 1995; Lee and Van Zanten, 1997; Van Zanten et al., 1999).

Diagnosis Endoscopic diagnosis of *H. pylori* infection is usually performed by histopathologic examination or rapid urease assay performed on gastric biopsies. Culture is not routinely performed in clinical practice, although in experienced laboratories, the sensitivity is probably greater than 95% and the specificity is 100% (Dunn et al., 1997). As *H. pylori* develops increasing antibiotic resistance, culture and sensitivity testing may play a greater role in diagnosis. Since the distribution of *H. pylori* infection is patchy, all endoscopic methods require examination of multiple biopsies, preferably at least three. Nonendoscopic diagnosis is most commonly performed by detection of serum IgG (Ho and Marshall, 2000), which if positive usually indicates active infection. There is currently no validated method for detection of acute *H. pylori* infection with IgM. Noninvasive diagnosis may also be performed using the urea breath test (Chey, 2000; Graham and Klein, 2000b) and stool antigen detection (Vaira et al., 2000).

Treatment Antibiotic therapy administered together with acid suppression using either a proton pump inhibitor or H2 blocker is effective in about 85% of patients, if administered for 7–14 days (Graham, 2000a). Combination of two or more antibiotics is required. Typical antibiotics commonly used are bismuth subsalicylate, tetracycline, and metronidazole administered four times daily or clarithromycin and either amoxicillin or metronidazole administered twice daily. The latter regimen is more expensive but also more convenient. Antibiotic resistance among *H. pylori* isolates is common and increasing, especially to metronidazole and clarithromycin (Meyer et al., 2002).

Prevention Currently, no vaccine is available for prevention of *H. pylori* infection. However, this is an area of active investigation (Del Giudice et al., 2001), and phase I clinical trials are currently underway.

Other *Helicobacter* Species

Gastric Infections Other than *H. pylori*, the only significant gastric *Helicobacter* seen in humans is "*Helicobacter heilmannii*," which has a prevalence of approximately 0.5% among patients undergoing endoscopy (O'Rourke et al., 2002). The low prevalence of "*H. heilmannii*" infections in humans means that a definite disease association is unlikely to be proven; however, it seems likely that this organism does cause gastritis, although the inflammation is generally less

aggressive than that seen with *H. pylori*, and may cause proportionately more cases of gastric MALT lymphoma (Stolte et al., 1997).

Enterohepatic Infections A growing number of enterohepatic *Helicobacter* species is being reported in association with gastroenteritis, hepatitis, and hepatobiliary diseases in humans (reviewed in O'Rourke et al. [2001b], Solnick and Schauer [2001], and Fox [2002a]). *Helicobacter cinaedi* and *H. fennelliae* may cause gastroenteritis, cellulitis, septic arthritis and bacteremia, most commonly but not exclusively in immunocompromised patients such as those infected with the HIV. *Helicobacter pullorum*, *H. canis*, *H. canadensis*, "*H. winghamensis*" and *Helicobacter* sp. "flexispira" may be associated with diarrhea, and *Helicobacter* sp. "flexispira" can also cause bacteremia. The association of *H. bilis* and other bile-tolerant species with hepatobiliary disease in humans is controversial but an area of active research (Fox et al., 1998a).

Veterinary Medicine

Helicobacter species are ubiquitous along the gastrointestinal mucosal surface of a broad range of domestic and feral animals. Nevertheless, there are very few well-documented instances in which infection of an immunocompetent, natural host results in clinical disease (Solnick and Schauer, 2001).

Gastric Infections

Gastric *Helicobacter* infections in animals are associated with a histologic gastritis that resembles that seen in humans, although the polymorphonuclear component is usually minimal or absent. The dominant pathology seen in cats and dogs is a mild chronic gastritis characterized by lymphocytic and lymphoplasmacytic infiltrates in the lamina propria with occasional formation of lymphoid follicles (Henry et al., 1987; Heilmann and Borchard, 1991; Geyer et al., 1993; Otto et al., 1994; Hermanns et al., 1995; Eaton et al., 1996; Happonen et al., 1996; Happonen et al., 1998; Neiger et al., 1998; Norris et al., 1999). A consensus statement by the American College of Veterinary Internal Medicine (ACVIM) concluded that most cats and dogs are infected with gastric bacteria irrespective of health status. Pathologic changes are detected but there is no simple association of bacteria with disease (Simpson et al., 2000).

Several studies have shown a significant increase in the prevalence of gastrospirilla in animals with ulceration of the *pars oesophagea* compared to animals with no ulcers (Barbosa et al., 1995; Queiroz et al., 1996; Roosendaal et al., 2000; Choi et al., 2001). It has been proposed that the bacteria may have an indirect effect on ulcer formation via induction of increased levels of acid secretion (Yeomans and Kolt, 1996). Some animal hosts are colonized by more than one *Helicobacter* species, such as *H. pylori* and *H. acinonychis* in cheetahs and *H. pylori* and "*H. heilmannii*" in nonhuman primates (Euler et al., 1990; Dubois et al., 1991; Dubois et al., 1994). In nonhuman primates, gastritis appears to be less severe in animals infected with gastrospirilla than in those infected with *H. pylori* (Dubois et al., 1991). Gastrospirilla are found intracellularly in parietal cells, which may be linked to increased acid output levels (Dubois et al., 1991; Dubois et al., 1994). Cheetahs that presented with chronic vomiting and weight loss had severe lymphocytic gastritis characterized by variable numbers of neutrophils, gland abscesses, lymphoid follicles and epithelial erosions (Eaton et al., 1991; Eaton et al., 1993b). A treatment study in cheetahs suggested that more severe pathology might be associated with *H. acinonychis* infection rather than with the other gastrospirilla (Wack et al., 1997).

Helicobacter mustelae is the natural colonizer of ferret gastric mucosa, where it is found in association with a diffuse antral chronic gastritis and gastric ulcers (Fox et al., 1986; Fox et al., 1990). The bacteria readily adhere to the epithelial surface, with evidence of endocytosis, a feature not commonly seen with other helicobacters except for *H. pylori* (O'Rourke et al., 1992). Inoculation of *H. mustelae* into uninfected ferrets results in an inflammatory response similar to that seen in naturally infected animals (Fox et al., 1991); however, an association between gastric ulcers and *H. mustelae* infection has not yet been documented.

Finally, experimental inoculation in some animal models may also reproduce pathologic evidence of malignancy. For example, experimental inoculation of *H. felis* in BALB/c mice or *H. pylori* in Mongolian gerbils can induce gastric MALT lymphoma or adenocarcinoma, respectively (Enno et al., 1995; Honda et al., 1998; Watanabe et al., 1998).

Enterohepatic Infection

Among the enterohepatic *Helicobacter* species, *H. hepaticus* infection in mice has been studied most extensively. This organism was first noted in an examination of A/JCr mice that exhibited an increased incidence of liver tumors (Fox et al., 1996a). The bacterium forms part of the normal microbiota of the lower bowel, with sporadic infection of the liver. Infection causes necrotizing hepatitis that commonly goes on to

preneoplastic hyperplasia and hepatocellular carcinoma. Infection of germ-free mice produces chronic hepatitis and hepatocellular carcinoma (Fox et al., 1996b); however, in immunocompetent mice there are no clinical signs of disease and no obvious reduction in breeding efficiency. *Helicobacter hepaticus* and other lower bowel helicobacters have been found in association with hepatitis or inflammatory bowel disease, but these were often in immunocompromised animals (Cahill et al., 1997; Shomer et al., 1997; Haines et al., 1998). "*Helicobacter rappinii*" was first isolated from aborted ovine fetuses and subsequently shown to cross the placenta in sheep, in which it induces abortion and hepatic necrosis in fetuses (Kirkbride et al., 1985; Bryner et al., 1987). These same diseases were induced in guinea pigs infected experimentally with "*H. rappinii*" (Bryner et al., 1987).

Conclusion

Members of the *Helicobacter* genus are ubiquitous colonizers of the enteric mucosal surface, which forms a critical interface between an organism and its environment. There are currently 22 formally named species (though *H. nemestrinae* is likely a junior heterotypic synonym for *H. pylori*). Many additional species have been provisionally named but not yet validated and others have been isolated but not yet named. The genus *Helicobacter* will undoubtedly continue to grow as these and other novel species are identified and characterized. Continued study of these organisms will likely yield new insights regarding the complex and dynamic host-pathogen relationship that occurs during chronic bacterial infections.

CHAPTER 3.5.3

The Genus *Wolinella*

JÖRG SIMON, ROLAND GROSS, OLIVER KLIMMEK AND ACHIM KRÖGER

Introduction

The genus *Wolinella* belongs to the family Helicobacteraceae (epsilon subclass of the *Proteobacteria*). There is only one species of the genus, *W. succinogenes*. The species formerly known as *W. recta* and *W. curva* have been re-classified as *Campylobacter rectus* and *C. curvus* (see [Phylogeny] and [Taxonomy]). *W. succinogenes* was isolated from bovine rumen fluid (see [Habitat and Isolation]) and can be identified and differentiated from other species by various morphological, biochemical and genetic methods (see [Identification]). The cells grow only by anaerobic respiration and do not ferment carbohydrates (see [Cultivation] and [Physiology]). Fumarate, nitrate, nitrite, nitrous oxide (N_2O), polysulfide or dimethyl sulfoxide (DMSO) can serve as terminal electron acceptor with formate as the electron donor. Molecular hydrogen and, at least in fumarate respiration, sulfide are alternative electron donor substrates. The electron transport enzymes and the mechanism for generating the electrochemical proton potential across the membrane are described in the section [Physiology]. Most of the genes encoding the electron transport enzyme complexes are known and a system for site-directed mutagenesis in *W. succinogenes* was established for both the operons coding for the subunits of fumarate reductase and hydrogenase (see [Genetics]).

Phylogeny

The overall phylogenetic position of *Wolinella* relative to other Gram-negative bacteria was determined from 16S rRNA sequencing. This indicated that the genus *Wolinella* falls in the family Helicobacteraceae, which belongs to the epsilon subclass of the *Proteobacteria* (Fig. 1). Other closely related bacteria are grouped within the family Campylobacteraceae, including the genera *Sulfurospirillum*, *Arcobacter* and *Campylobacter*.

Taxonomy

There is only one species of the genus, the type species *Wolinella succinogenes* (previously classified as *Vibrio succinogenes* by Wolin et al., 1961). Two oral species of *Wolinella*, *W. recta* and *W. curva* (Tanner et al., 1981), are now described as members of the genus *Campylobacter*, based on 16S rRNA sequence analysis (Paster and Dewhirst, 1988; Vandamme et al., 1991).

The type strain of *W. succinogenes* is ATCC 29543^T (FDC 602W; FDC: Forsyth Dental Center, Boston, MA, USA).

Habitat

Wolinella succinogenes was isolated from bovine rumen fluid (Wolin et al., 1961). Isolates resembling *W. succinogenes* have been isolated from sewage (Yoshinari, 1980; Tanner et al., 1984) and from humans (Radcliffe et al., 1979); however, no genetic information for these strains is available.

Isolation

Wolinella succinogenes was originally isolated from an inoculum of bovine rumen fluid after serial transfer in an anaerobic methanogenic enrichment medium containing formate, sulfide, and inorganic salts. Secondary enrichment was made in a broth medium containing formate and fumarate (Wolin et al., 1961). Additional strains of *W. succinogenes* were recently isolated using the same procedure except that the primary medium contained fumarate (A. Kröger, unpublished observation). These strains were virtually indistinguishable from the original Wolin strain with respect to their 16S rRNA sequence and their growth parameters. For isolation, bovine rumen fluid was passed through filter papers, and

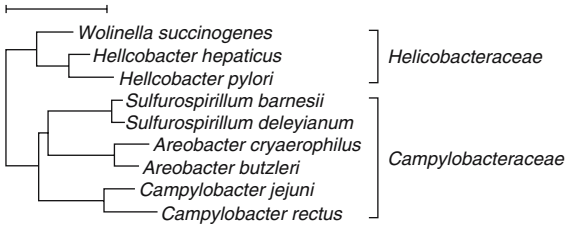

Fig. 1. Phylogeny of *Wolinella succinogenes* as derived from 16S rRNA sequences. The phylogenetic relationships of *Wolinella succinogenes*, the only member of the genus, compared to other members of the families Helicobacteraceae and Campylobacteraceae. Marker bar represents a 5% difference in nucleotide sequences.

Fig. 2. Electron photomicrographs of *Wolinella succinogenes*. (a) Negatively stained cells, strain ATCC 29543 (FDC 602W): a short curved rod with a typical Gram-negative cell wall surface and a single polar flagellum. Bar = 0.5 µm. (b) Transmission electron photograph showing the flagellar insertion (F). Bar = 0.2 µm.

the filtrate (250 ml) was centrifuged for 15 min at 10,000 × *g*. The sediment was resuspended in 200 ml formate/fumarate medium (Procedure 1). Centrifugation was repeated and the sediment was suspended in 200 ml Tris-buffer (50 mM, pH 8.0, 0°C). One volume of the suspension (a 5% inoculum) was added to nineteen volumes of the "culture medium," which was designed by Wolin et al. (1961) and prepared with tap water. The culture was kept for 24 h at 37°C. Using the same growth conditions, a 5% inoculum of the bacteria was transferred to formate/fumarate medium that contained 10 mM NH_4Cl instead of $(NH_4)_2SO_4$ and lacked acetate. Additionally, 2 mM Na_2S was added before inoculation. Further cultivation made use of the formate/fumarate medium (Procedure 1). Single strains were obtained by plating and picking of colonies (see [Cultivation]).

1. Minimal medium containing formate and fumarate for isolation and cultivation of *W. succinogenes*:

Tris	6.1 g
Fumaric acid	11.6 g
Sodium formate	6.8 g
Dipotassium hydrogen phosphate	3.5 g
Ammonium sulfate	0.7 g
Sodium acetate	2.7 g
Glutamic acid	0.2 g
Calcium/magnesium stock solution (see below)	1 ml
Trace element solution (see below)	0.2 ml
Distilled water	1000.0 ml

Calcium/magnesium stock solution:

Calcium chloride	0.74 g
Magnesium chloride	5.1 g
Distilled water	100.0 ml

Trace element solution:

Na_2 EDTA	5.2 g
$FeCl_2 \cdot 4H_2O$	1.5 g
$ZnCl_2$	70 mg
$MnCl_2 \cdot 4H_2O$	0.1 g
H3BO3	62 mg
CoCl2 ·6H2O	0.19 g
CuCl2 ·2H2O	17 mg
NiCl2 ·6H2O	24 mg
Na2MoO4 ·2H2O	36 mg
Distilled water	1000.0 ml

Combine the medium components and adjust the pH to 7.6–7.8 by addition of potassium hydroxide. Make the medium anoxic by alternate evacuation and flushing with N_2 using appropriate glassware, and sterilize by autoclaving.

Identification

Morphology

Cells of *Wolinella succinogenes* are non-spore-forming Gram-negative rods with a rapid, darting motility via a single polar flagellum. The cells are helical, curved, or straight, 0.5–1.0 µm in diameter and 2–6 µm in length, with rounded or tapered ends (Fig. 2). Colonies are pale yellow opaque to gray translucent with convex, pitting and spreading variants. When grown with nitrate as terminal electron acceptor, colonies appear reddish due to an increased cytochrome *c* content.

Biochemical Properties

Common characteristics for *W. succinogenes* are listed in Table 1. Cells of *W. succinogenes* grow at 37°C, demonstrate oxidase activity, and produce hydrogen sulfide, but are asaccharolytic

Table 1. Characteristics common to *Wolinella succinogenes*[a].

Common positive characteristics:	Gram-negative rods; actively motile via a single polar flagellum; growth in broth supplemented with formate and fumarate; growth in anaerobic and microaerophilic (5% O_2) atmospheres; reduction of nitrate, nitrite, neutral red, and benzylviologen; oxidase and benzidine positive; production of hydrogen sulfide, hydrogen, carbon dioxide and succinate; growth in the presence of Evans blue (0.05 g/liter), malachite green (0.02 mg/liter), brilliant green (0.0125 g/liter), and kanamycin (1, 2, or 4 μg/ml); arginine aminopeptidase positive in API An-Ident tests.
Common negative characteristics:	No growth in unsupplemented broth media or in media supplemented with only 0.2% nitrate; no growth on agar surfaces in air or in air containing 10% CO_2; no spores formed; not haemolytic; pH is not lowered when cells are incubated in formate- and fumarate-supplemented media with 1% adonitol, 1% amygdalin, 1% arabinose, 1% dextran, 1% dulcitol, 1% fructose, 1% galactose, 1% glucose, 1% glycerol, 1% glycogen, 1% inositol, 1% inulin, 1% lactose, 1% matose, 1% mannitol, 1% mannose, 1% melezitose, 1% melibiose, 1% raffinose, 1% rhamnose, 1% ribose, 1% salicin, 1% sorbitol, 1% sucrose, 1% trehalose, 1% xylose, 0.25% esculin, or 0.5% starch; catalase negative; lysine, ornithine, and arginine not decarboxylated; starch, dextran, esculin, casein, DNA, and gelatin not hydrolyzed; hydrogen peroxide, urease, lethicinase, lipase, indole, and acetylmethylcarbinol not produced; nitrous oxide, methane, formate, acetate, propionate, isobutyrate, butyrate, isovalerate, valerate, caproate, lactate, and pyruvate not detected; gas not formed under an agar layer over a broth culture; no growth in the presence of NaCl (20 or 40 g/liter) or penicillin (64 μg/ml); negative or weak reactions in API ZYM and API AN-Ident tests, except for arginine aminopeptidase.

[a] These characteristics are shared by *Campylobacter rectus* (formerly classified as *Wolinella recta*), *C. curvus* (formerly classified as *W. curva*), *C. gracilis*, *C. concisus*, and *C. sputorum*, except: *C. gracilis* has no flagellum and is not actively motile. Data from Tanner et al., 1981, 1984, 1985.

and are negative in many routine biochemical tests including enzyme substrate tests (Table 1). The cells contain *b*- and *c*-type cytochromes, whereas cytochromes of the *a*-, *d*-, and *o*-type are missing (Kröger and Innerhofer, 1976). Menaquinone-6 (2-methyl-3-farnesyl-farnesyl-1,4-naphthoquinone) and a methyl-substituted menaquinone-6 (2, [5 or 8]-dimethyl-3-farnesyl-farnesyl-1,4-naphthoquinone) have been reported as major respiratory quinones (Collins and Fernandez, 1984).

Differentiation of *Wolinella succinogenes* from Other Species

Cells of *W. succinogenes* have been difficult to differentiate from other species (e.g. from members of the Campylobacteraceae). *Campylobacter curvus* and *C. rectus* (formerly classified as *W. curva* and *W. recta*) share the common characteristics of *W. succinogenes* (Table 1). Characteristics that differentiate *W. succinogenes* from the *Campylobacter* species are shown in Table 2. Further differentiation is required from other non-fermentative species that either corrode agar (*Eikenella corrodens*) or demonstrate a formate- and fumarate-utilizing metabolism. *E. corrodens* (family Neisseriaceae) may be distinguished by its growth on agar surfaces in air with 10% carbon dioxide, growth in the presence of 4 μg/ml clindamycin, lack of active cell motility, lack of growth in media supplemented with formate and fumarate without nitrate, and by the presence of lysine and ornithine decarboxylases.

Nowadays, accurate species identification has become quite feasible using one or more of the following methods.

Elisa. Several antisera raised against subunits of *W. succinogenes* electron transport enzymes may be used for identification. However, the antiserum raised against the catalytic subunit (FrdA) of the fumarate reductase notably cross-reacted with the corresponding protein of *Helicobacter pylori* (Birkholz et al., 1994).

Gel Electrophoresis. Sonicated whole cell preparations of *W. succinogenes* and close relatives were run on SDS-polyacrylamide gels (Tanner, 1986). Each species demonstrated a different protein profile when gels were stained with a conventional silver stain (Fig. 3). Notably, *C. rectus* was most easily distinguished from the other species by the presence of yellow-staining bands at an approximate molecular weight of 25 kDa.

Profiling of Fatty Acids and Lipopolysaccharides. Differentiation of *W. succinogenes* from related species was accomplished by analysis of

Table 2. Characteristics that differentiate *Wolinella succinogenes* from various campylobacter species.

Characteristic	*Wolinella succinogenes*	*Campylobacter curvus*	*Campylobacter rectus*	*Campylobacter gracilis*	*Campylobacter concisus*
Source of isolation	Bovine rumen	Human clinical	Human clinical	Human clinical	Human clinical
Dominant cell shape	Helical	Curved	Straight[a]	Straight	Curved
Cells motile by flagellum	+	+	+	–	+
Double yellow bands in SDS-PAGE (20–25 kDa)	–	–	+	–	–
Growth on agar containing:					
NaF (0.5 g/liter)	+	–	–	+	+
Oxgall (10 g/liter)	+	+	–	V	+
Deoxycholate (1 g/liter)	+	+	–	+	+
Janus green (0.1 g/liter)	+	+	–	+	+
Basic fuchsin (0.032 g/liter)	+	+	–	+	+
Cystal violet (0.005 g/liter)	+	–	–	V	+
Indulin scarlet (0.5 g/liter)	–	+	–	–	–
Penicillin (4–16 µg/ml)	+	+	–	V	V
Polymixin B (2–4 µg/ml)	+	+	–	–	–

Data from Tanner et al., 1981, 1984; Tanner, 1986.
[a]*C. rectus* demonstrates an unusual ultrastructure, having hexagonal units in the cell wall.
+, positive feature; –, negative feature; V, variable feature.

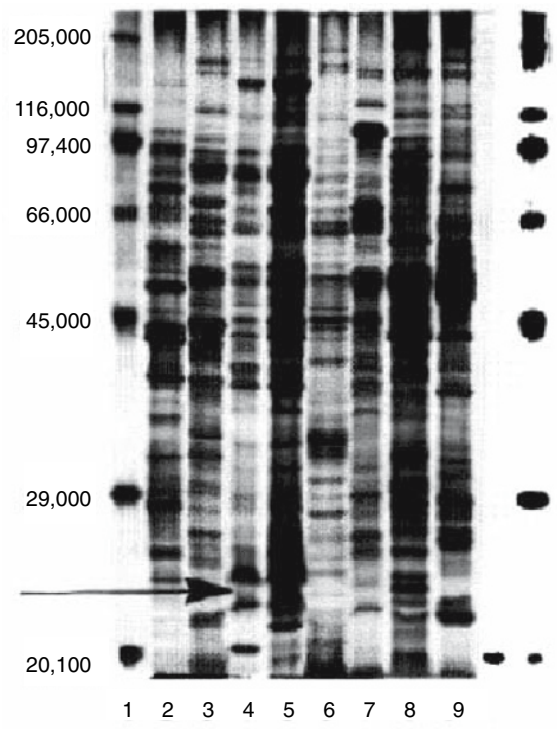

Fig. 3. Silver stained SDS-polyacrylamide gel of sonicated whole cells of species with a formate and fumarate metabolism. The running and stacking gels contained 14% and 4% acrylamide respectively. The current was run at 15 mA per 0.75 mm thick gel. The arrow indicates the level of yellow-staining bands of *Campylobacter rectus* isolates in lanes 4 and 5. Lane 1, high-molecular-weight standard mixture; lane 2, *Wolinella succinogenes* ATCC 29543^T; lane 3, *C. curvus* ATCC 35244^T; lanes 4 and 5, *C. rectus* strains ATCC 33238^T and FDC 267; lane 6, *C. concisus* ATCC 33237^T; lane 7, *C. sputorum* ATCC 35980^T (VPI S-17); lane 8, *C. gracilis* ATCC 33236^T; and lane 9, *Bacteroides ureolyticus* VPI 7815.

either cellular fatty acids (Brondz and Olsen, 1991) or lipopolysaccharides (Kokeguchi et al., 1991; Firoozkoohi et al., 1997). Fatty acids were identified and quantified by gas chromatography and gas chromatography-mass spectrometry. Lipopolysaccharides were extracted from cells by a hot phenol-water method and further purified by nuclease treatment and by repeated ultracentrifugation. Purified lipopolysaccharides were examined by SDS-PAGE and subsequent staining of the gel or by quantification of fatty acid and sugar composition.

Genetic Methods. *W. succinogenes* was discriminated from *Campylobacter* species by restriction fragment length polymorphism (RFLP) analysis of a PCR-amplified fragment of the gene encoding 16S rRNA (Cardarelli-Leite et al., 1996). Furthermore, specific DNA probes generated by PCR using nucleotide sequences of genes encoding electron transport enzymes may be applied for identification of *W. succinogenes* (see [Genetics]).

Cultivation

W. succinogenes can be cultivated using minimal media containing appropriate electron donor and electron acceptor substrates according to the various modes of anaerobic respiration (Table 3 and [Physiology]). The medium for growth with formate and fumarate is presented in the section [Isolation]. In this section, media are shown in which fumarate is replaced by either nitrate or polysulfide. For growth with H_2, formate is left out of the medium and the cultures are stirred

under an atmosphere of H_2 (150 kPa). Further media are described in the literature for growth with sulfide and fumarate (Macy et al., 1986), formate and DMSO (Lorenzen et al., 1994), formate and nitrite (Lorenzen et al., 1993), or formate and N_2O (Yoshinari, 1980). All media may be supplemented with 0.5% (w/v) yeast extract or 0.5% (w/v) brain-heart-infusion broth; this addition raises slightly the growth rate and the growth yield. The addition of brain-heart-infusion broth is recommended when the cells are cultivated on agar plates. The cells may be spread on an agar plate or, alternatively, may be mixed with medium containing 2.6% (w/v) brain-heart-infusion agar and the mixture poured into a Petri dish.

2. Minimal medium for growth with formate and nitrate.

Tris	6.1 g
Potassium nitrate	2.0 g
Sodium formate	5.4 g
Dipotassium hydrogen phosphate	0.2 g
Potassium sulfate	0.9 g
Disodium succinate	0.8 g
Glutamic acid	0.1 g
Cysteine	69 mg
Calcium/magnesium stock solution (see [Isolation])	4.0 ml
Trace element solution (see [Isolation])	0.2 ml
Distilled water	1000.0 ml

Combine the medium components and adjust the pH to 7.5. Make the medium anoxic by alternate evacuation and flushing with N_2 using appropriate glassware, and sterilize by autoclaving.

3. Minimal medium for growth with formate and polysulfide.

Bicine	9.0 g
Sodium acetate	2.4 g
Sodium formate	3.4 g
Dipotassium hydrogen phosphate	4.0 g
Ammonium chloride	0.6 g
Sodium sulfide	0.6 g
Glutamic acid	0.1 ml
Calcium/magnesium stock solution (see below)	1.0 ml
Trace element solution (see below)	0.4 ml
Distilled water	1000.0 ml

Sodium tetrathionate dihydrate stock solution:

Tetrathionate	30.6 g
Distilled water	100.0 ml

Sodium hydroxide stock solution:

Sodium hydroxide	8.0 g
Distilled water	100.0 ml

Combine the medium components and adjust the pH to 8.2. Sterilize the medium by autoclaving and make it anoxic by flushing with N_2 while stirring. After inoculation add 1 ml of the sodium tetrathionate stock solution and 1 ml of the sodium hydroxide stock solution. These additions are repeated after decolorization of the medium due to polysulfide reduction.

Preservation

W. succinogenes cells may be maintained in the laboratory by weekly transfer on the media described in the section [Cultivation]. Cells may be stored frozen either in liquid nitrogen or at –70°C. For longterm maintenance, cells are centrifuged and resuspended in 5% of the volume in the same medium. The suspension is mixed with the same volume of sterile glycerol (86%, v/v), incubated for 5 min at 37°C and stored in 1-ml portions in reaction tubes at –70°C. See The Anaerobic Way of Life in the second edition; anaerobism; ATP, electron acceptor; proton translocation; menaquinone; dicarboxylic acid.

Physiology

Energy Metabolism

W. succinogenes can grow only by anaerobic respiration and does not ferment carbohydrates (Wolin et al., 1961). Growth is sustained by the reduction of fumarate, nitrate, nitrite, N_2O, polysulfide ([S]), or dimethylsulfoxide (DMSO) as terminal electron acceptor and formate as electron donor (reactions a–f in Table 3). The stoichiometry of reactions (a), (b), (c), and (e) was confirmed experimentally with growing cultures, and cell formation was shown to be proportional to substrate consumption and product formation. Polysulfide is the actual terminal electron acceptor of sulfur respiration with *W. succinogenes*. Polysulfide is formed abiotically from elemental sulfur in sulfide solutions. Sulfate, thiosulfate, organic disulfides (R-S-S-R) and trimethylamine-N-oxide (TMAO) are not used as terminal electron acceptors. Growth is observed with fumarate, nitrate, polysulfide or DMSO when formate is replaced by H_2. *W. succinogenes* also can grow by fumarate respiration with sulfide as electron donor (reaction g; Macy et al., 1986).

The ATP required for growth is synthesized according to the mechanism of oxidative phosphorylation. Reactions (a)–(g) are envisaged to be coupled to the generation of an electrochemical proton potential (Δp) across the cytoplasmic membrane. In the second step, the free energy stored in the Δp is used for ATP synthesis from ADP and inorganic phosphate. The latter reaction is catalyzed by an ATP synthase. The ATP synthase of *W. succinogenes* is similar to those of aerobic or phototrophic bacteria (Bokranz et al., 1985a and b). When incorporated into liposomes, the isolated enzyme catalyzes ATP synthesis at the expense of an artificial Δp across the liposomal membrane. The measured Δp generated by reactions (a), (b), (c), (e) or (g) was 160–180 mV,

which is sufficient to drive ATP synthesis at a H^+/ATP ratio of 3 (Mell et al., 1986; Brune et al., 1987; Wloczyk et al., 1989; Hedderich et al., 1999; Simon et al., 2000).

Biosynthetic Metabolism

Fumarate can be used as the sole source of carbon during growth of *W. succinogenes* by fumarate respiration in a minimal medium (Bronder et al., 1982). Fumarate can be replaced by L-malate, L-aspartate, or L-asparagine (Wolin et al., 1961; Kafkewitz, 1975). Both the growth rate and yield of *W. succinogenes* cultivated in fumarate-containing medium nearly double when glutamate is present. The growth parameters in medium with yeast extract are slightly higher than they are in medium with glutamate. When grown in a minimal medium with nitrate, *W. succinogenes* required succinate as carbon source (Bokranz et al., 1983). Succinate could be substituted by malate, fumarate or L-asparagine, whereas oxaloacetate, pyruvate, bicarbonate, acetate, propionate, butyrate, L-glutamate, D-aspartate, or δ-aminolevulinic acid could not replace succinate (Niederman and Wolin, 1972). When polysulfide serves as terminal electron acceptor, acetate and glutamate are used as carbon sources in a minimal medium (Macy et al., 1986). While sulfate is used as the source of sulfur during growth with fumarate, either sulfide or cysteine has to be supplied for growth by nitrate respiration (Bokranz et al., 1983).

The biosynthetic metabolism of fumarate was elucidated using labeled fumarate (Fig. 4; Bronder et al., 1982). In addition, the specific activities of the key anabolic enzymes were measured. The synthesis of each aspartate and alanine residue of bacterial protein was found to be from one fumarate molecule, whereas the synthesis of each glutamate was found to be from two fumarate molecules, suggesting that glutamate is formed via citrate. In agreement with this view, *W. succinogenes* was found to contain citrate synthase; however, the specific activity was very low. During growth with glutamate and fumarate, *W. succinogenes* specifically incorporated the carbon of glutamate into the residues of the glutamate family (glutamate, glutamine, proline and arginine) of the bacterial protein. This suggests that growth in the absence of glutamate would be limited by glutamate biosynthesis. While approximately half of the added glutamate was incorporated into bacterial protein, the residual glutamate was oxidized to succinate. The reducing equivalents liberated in the latter process are used in biosynthesis. Hence, the catabolic electron donors H_2 or formate are not involved in biosynthesis, in agreement with the absence of enzymes catalyzing the reduction of NAD, NADP or ferredoxin by H_2 or formate. As an important consequence, *W. succinogenes* can be grown at limiting energy supply in continuous culture by making the concentration of formate in the medium growth limiting. Under these conditions, the growth yield was measured to be 43% higher than that during growth at limiting fumarate concentration (Mell et al., 1982).

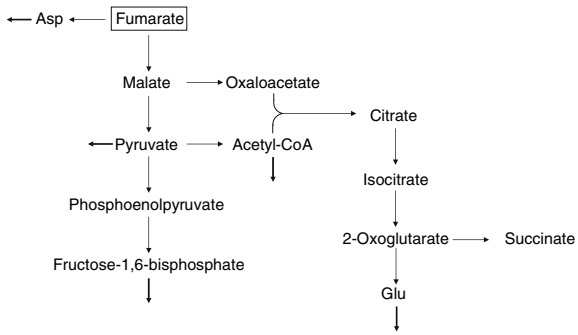

Fig. 4. Biosynthetic pathways of *W. succinogenes* growing with fumarate (boxed) as sole carbon source (Bronder et al., 1982). For details see subsection [Biosynthetic metabolism].

Electron Transport Enzymes

Fumarate reductase, hydrogenase, formate dehydrogenase, nitrite reductase, and polysulfide reductase are the key enzymes of anaerobic

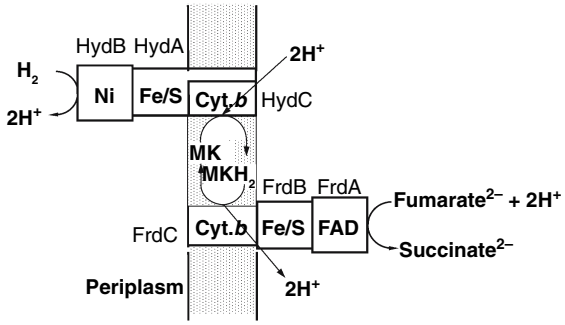

Fig. 5. Composition and orientation of hydrogenase (HydA, B, C) and of fumarate reductase (FrdA, B, C) in the membrane of *W. succinogenes*, and hypothetical mechanism of Δp generation by fumarate respiration with molecular hydrogen as electron donor. Hydrogenase is anchored in the membrane by its HydC subunit and the C-terminal hydrophobic region of HydA (Gross et al., 1998a). Ni, nickel ion; Fe/S, iron-sulfur centers; Cyt. *b*, diheme cytochrome *b*; MK, menaquinone.

fumarate respiration, nitrite respiration and polysulfide respiration, with molecular hydrogen or formate serving as electron donor (Table 3). These five enzymes are discussed below in more detail. Other electron transport enzymes have not been isolated, i.e., the nitrate reductase, the dimethylsulfoxide (DMSO) reductase, or the sulfide dehydrogenase that serves in fumarate respiration with sulfide as electron donor. The nitrous oxide reductase was isolated as a dimer with a molecular weight of 162,000 (Terguchi and Hollocher, 1989).

Fumarate Reductase Fumarate reductase catalyzes the reduction of fumarate by menaquinol (MKH_2; Unden et al., 1980; Unden and Kröger, 1982; Kröger et al., 1992). The enzyme consists of three different subunits and is anchored in the membrane by FrdC, a diheme cytochrome *b* that interacts with the quinol (Fig. 5; Unden et al., 1980; Körtner et al., 1990; Lauterbach et al., 1990). The crystal structure of *W. succinogenes* fumarate reductase has been solved at 2.2 Å resolution (Lancaster et al., 1999). The subunit FrdB carries three iron-sulfur centers and lies between FrdC and the catalytic subunit FrdA to which FAD is covalently linked. The fumarate catalytic site protrudes 40 Å into the cytoplasm. Fumarate is bound close to the flavin and is probably reduced by hydride transfer from N5 of reduced flavin. There is a pathway for single electron transfer extending from the heme groups via the iron-sulfur centers to the flavin. The [3Fe-4S] iron-sulfur center is closest to the heme group situated next to the cytoplasmic membrane surface, and the [2Fe-2S] center is closest to the flavin. Electron transfer between these two centers is mediated by the [4Fe-4S] center. When viewed along the membrane normal, the heme groups are on top of each other with their planes perpendicular to the membrane surface and with an interplanar angle of 95°. The centers of the heme groups are only 15.6 Å apart, suggesting a role in electron transfer for both heme groups. The site of quinol oxidation on FrdC is not seen. The structure of *E. coli* fumarate reductase is similar to that of *W. succinogenes* with respect to the hydrophilic subunits FrdA and FrdB (Iverson et al., 1999). The enzymes differ in their membrane anchor domains. The subunits FrdC and FrdD, which carry two menaquinone (MK) molecules but no heme, anchor the *E. coli* enzyme.

Hydrogenase Hydrogenase is bound to the membrane of *W. succinogenes* and catalyzes the reduction of menaquinone (MK) by H_2 (Fig. 5; Dross et al., 1992). The enzyme consists of three different subunits, HydA, B and C. The two hydrophilic subunits HydA and HydB are similar to the two polypeptides making up the periplasmic Ni (nickel)-hydrogenases with known crystal structures from two *Desulfovibrio* species (Volbeda et al., 1995; Higuchi et al., 1997). The larger subunit HydB carries the Ni/Fe catalytic center, and HydA carries three iron-sulfur centers. The structures suggest that H_2 is split into electrons and protons at the catalytic center. The protons are released on the surface of HydB through a proton pathway, while the electrons are guided by the three iron-sulfur centers to the binding site of the electron acceptor on the surface of HydA. Because nearly all the relevant residues are conserved in the membrane-bound Ni-hydrogenases, the same catalytic mechanism likely applies to these enzymes. In the enzyme of *W. succinogenes*, the electrons are transferred from HydA to the third subunit (HydC), a diheme cytochrome *b* that is integrated into the membrane and reacts with MK (Gross et al., 1998a; and 1998b). The catalytic subunit of HydB is oriented to the periplasmic side of the membrane. The subunit HydA carries a C-terminal hydrophobic helix that is integrated into the membrane. Such a hydrophobic C-terminus with a conserved histidine residue is predicted to occur in the HydA subunits of all membrane-bound Ni-hydrogenases and is missing in the periplasmic enzymes.

Formate Dehydrogenase Formate dehydrogenase catalyzes the reduction of menaquinone (MK) by formate (Unden and Kröger, 1982; Bokranz et al., 1991). The enzyme consists of two hydrophilic subunits, FdhA and FdhB, and of FdhC, a cytochrome *b* that is integrated into the membrane and reacts with MK (Fig. 6). The sub-

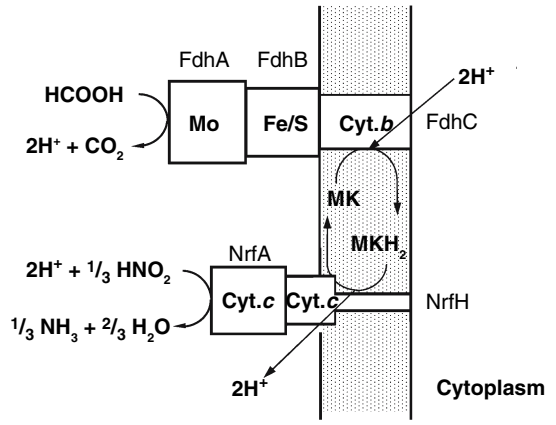

Fig. 6. Composition and orientation of formate dehydrogenase (FdhA, B, C) and of nitrite reductase (NrfA, H) in the membrane of *W. succinogenes*, and hypothetical mechanism of Δp generation by nitrite respiration with formate as electron donor. The substrates and products of nitrite reduction are drawn in their neutral forms for simplicity. Mo, molybdenum linked to molybdopterin guanine dinucleotide; Fe/S, iron-sulfur centers; Cyt. *b*, cytochrome *b*; Cyt. *c*, cytochrome *c*. (See The Dissimilatory Sulfate- and Sulfur-Reducing Prokaryotes in the second edition; elemental sulfur).

unit FdhC is similar to HydC of *W. succinogenes* hydrogenase and carries probably two heme B groups (Gross et al., 1998b). *W. succinogenes* contains a single formate dehydrogenase, but two gene loci code for the subunits of the enzyme (Lenger et al., 1997). These *fdh* operons differ in their promoter regions, but are nearly identical in their gene sequences. Deletion mutants lacking one of the operons still grow with formate as electron donor. The formate dehydrogenases of the mutants appear to be identical.

The catalytic subunit FdhA contains molybdenum ligated by molybdopterin guanine dinucleotide and is predicted to carry a tetranuclear iron sulfur center (Bokranz et al., 1991; Jankielewicz et al., 1994). The subunit FdhB is predicted to carry four tetranuclear or one trinuclear and three tetranuclear iron-sulfur centers. The sequence of FdhA is similar to those of several other molybdo-oxidoreductases whose crystal structures are known, including formate dehydrogenase H of *Escherichia coli* (Boyington et al., 1997). The structures of these enzymes share a deep crevice extending from the surface of the subunit to the molybdenum, the site of substrate conversion. In *E. coli* formate dehydrogenase H, an iron-sulfur center is localized at an appropriate distance to allow rapid electron transfer from the molybdenum site. This suggests that formate is split at the molybdenum site to yield two electrons, CO_2 and a proton. While the electrons are transferred to the iron-sulfur center, CO_2 and the protons probably leave the catalytic site via the substrate crevice. Therefore, the protons produced from formate are thought to be liberated at the surface of FdhA whereas the electron transfer from FdhA to FdhC is thought to be mediated by the iron-sulfur centers of FdhB (Fig. 6), similar to the mechanism proposed for hydrogenase (Fig. 5). The formate catalytic site of *W. succinogenes* formate dehydrogenase is exposed to the periplasm (Kröger et al., 1980).

Nitrite Reductase The nitrite reductase of *W. succinogenes* catalyzes the reduction of nitrite to NH_4^+ by menaquinol (MKH_2; Fig. 6; Simon et al., 2000). The enzyme consists of the hydrophilic catalytic subunit NrfA and the quinone reactive subunit NrfH that probably anchors the enzyme in the membrane by a single hydrophobic helix at its N-terminus. The subunit NrfH belongs to the *c*-type cytochromes of the NapC/NirT family (Roldán et al., 1998). Subunits NrfA and NrfH are predicted to carry five and four heme C groups, respectively. The subunit NrfA catalyzes nitrite reduction by reduced benzyl viologen, but NrfA does not react with quinols. NrfA-like nitrite reductases have been isolated from various bacteria, including *W. succinogenes*, *Escherichia coli* and *Sulfurospirillum deleyianum* (Liu et al., 1983; Schröder et al., 1985; Schumacher et al., 1994). The subunit NrfA of *W. succinogenes* is similar to NrfA of *S. deleyianum* (75% identity), whose crystal structure is known (Einsle et al., 1999). Four heme groups of this enzyme are bound to conventional CxxCH motifs. The fifth heme group is bound to a CxxCK motif and is localized near the substrate site of the enzyme.

Polysulfide Reductase Polysulfide reductase catalyzes the reduction of polysulfide by BH_4^- as well as sulfide oxidation to polysulfide by 2,3-dimethyl-1,4-naphthoquinone (Hedderich et al., 1999). The enzyme consists of two hydrophilic subunits (PsrA and PsrB) and a hydrophobic subunit (PsrC) that anchors the enzyme in the membrane (Fig. 7). The catalytic subunit (PsrA) is exposed to the periplasm (Krafft et al., 1995). Polysulfide reductase contains molybdenum and molybdopterin guanine dinucleotide (Jankielewicz et al., 1994). The sequences of PsrA and the catalytic subunits of the formate dehydrogenases (FdhA) of *W. succinogenes* and *Escherichia coli* are similar and have the cysteine residues that are typical for a tetranuclear iron-sulfur center (Krafft et al., 1992). The similarity of PsrA to the catalytic subunits of the formate dehydrogenases suggests similar catalytic mechanisms. The electrons for polysulfide reduction at the molybdenum site are probably provided via the iron-sulfur centers of PsrA and of PsrB (both are iron-sulfur proteins), while the protons

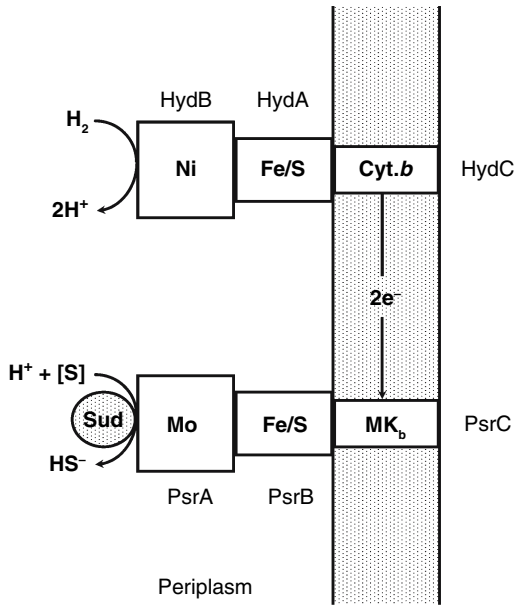

Fig. 7. Composition and orientation of Ni/Fe hydrogenase (HydA, B, C) and of polysulfide reductase (PsrA, B, C) in the membrane of *W. succinogenes*; the two enzymes make up the electron transport chain catalyzing polysulfide respiration with molecular hydrogen in *W. succinogenes*. Polysulfide-sulfur transferase (Sud) is described in subsection [Polysulfide respiration]. Mo, molybdenum linked to molybdopterin guanine dinucleotide; Ni, nickel ion; Fe/S, iron-sulfur centers; Cyt. *b*, cytochrome *b*; MK_b, menaquinone bound to PsrC.

required for HS^- formation enter the catalytic site via a channel in PsrA (Fig. 7). Bound menaquinone is assumed to serve as the prosthetic group of PsrC that accepts the electrons delivered by hydrogenase or formate dehydrogenase (Hedderich et al., 1999). The subunit PsrC does not carry heme.

In contrast to the wild-type strain, a mutant (Δ*psrABC*) lacking the *psrABC* operon does not catalyze polysulfide reduction by H_2 or formate when grown with fumarate as terminal electron acceptor (Krafft et al., 1995). Surprisingly, the mutant does grow with polysulfide, then forming a membrane-integrated enzyme that replaces polysulfide reductase. This enzyme has not been isolated as yet. Its properties appear to differ considerably from those of the polysulfide reductase enzyme. The enzyme does not cross-react with an antiserum raised against PsrA. Like polysulfide reductase, the enzyme catalyzes sulfide oxidation by 2,3-dimethyl-1,4-naphthoquinone. However, the apparent K_M values for sulfide differ drastically. The value measured with polysulfide reductase is 25 mM and that of the enzyme induced in the Δ*psrABC* mutant is approximately 1 mM (Klimmek, 1996). The enzyme present in the mutant is apparently absent from the wild-type strain, as suggested by this difference in the apparent K_M values.

Fumarate Respiration and Dicarboxylate Transport

The electron transport chain catalyzing fumarate respiration with H_2 consists of hydrogenase, menaquinone (MK) and fumarate reductase (Fig. 5). This was shown by restoring the activity of electron transport in liposomes containing the isolated enzymes (Graf et al., 1985; Kröger et al., 1992). Formate dehydrogenase replaces hydrogenase in the chain using formate as electron donor (Unden and Kröger, 1982). The electrochemical proton potential (Δp) is thought to be generated by the reduction of MK with H_2 (Fig. 5) or formate (according to Fig. 6; Kröger, 1978; Mell et al., 1986; Kröger et al., 1992; Geisler et al., 1994; Gross et al., 1998a). The protons generated from H_2 at the substrate site of the hydrogenase are released on the periplasmic side of the membrane, while the protons consumed by MK reduction are taken up from the cytoplasmic side. The oxidation of MKH_2 by fumarate does not contribute to Δp generation. The protons generated by MKH_2 oxidation via fumarate reductase are liberated on the cytoplasmic side, and the same number of protons are consumed by the reduction of fumarate, which also occurs on the cytoplasmic side of the membrane. Thus the Δp in fumarate respiration of *W. succinogenes* is generated by transmembrane electron transport without proton translocation.

The H^+/electron ratio postulated by the mechanism of Fig. 5 is consistent with the experimentally determined ratio of approximately one (Mell et al., 1986). The mechanism of Fig. 5 was confirmed by the observation that the reduction by H_2 of 2,3-dimethyl-1,4-naphthoquinone (DMN), a water-soluble MK analogue, is coupled to the generation of a Δp, whereas fumarate reduction by $DMNH_2$ is not (Geisler et al., 1994). Furthermore, coupled fumarate respiration was observed with liposomes containing hydrogenase, MK and fumarate reductase (A. Kröger, unpublished observation). Fumarate reduction by H_2 generated a Δp of approximately 100 mV across the liposomal membrane (positive outside). Only fumarate reductase molecules exposed to the outside of the liposomes are expected to participate in the electron transport because the permeation of fumarate across the liposomal membrane should be very slow. Thus the direction of the Δp appears to be independent of the orientation of fumarate reductase, in agreement with the mechanism of Fig. 5.

Because the substrate site of fumarate reductase faces the bacterial cytoplasm, fumarate and succinate have to be transported across the

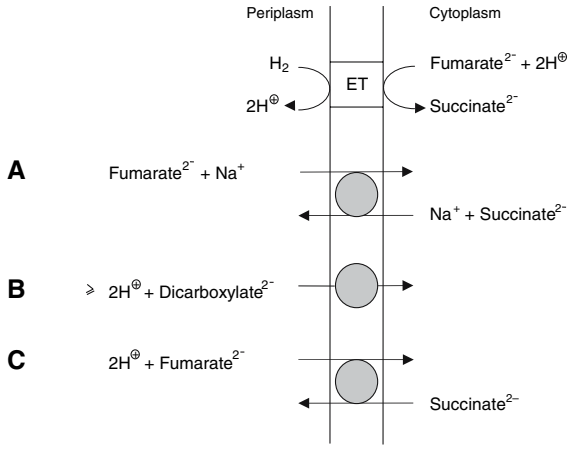

Fig. 8. Transport of fumarate and succinate across the membrane of *W. succinogenes*. (A) Na^+ dependent electroneutral antiport; (B) electrogenic uniport; (C) electrogenic antiport. ET, electron transport chain of fumarate respiration with molecular hydrogen as electron donor (see Fig. 5 for more detail).

membrane of *W. succinogenes* (Fig. 8). The fumarate that is converted to succinate in growing bacteria is taken up in exchange for succinate (Fig. 8A). This antiport process was found to be electroneutral in the presence of Na^+ (Ullmann et al., 2000). In the absence of Na^+, the cells take up fumarate in an electrogenic process according to the uniport (Fig. 8B) and the antiport (Fig. 8C) mechanism. The uniport process probably serves in the uptake of fumarate as a carbon source. In the absence of Na^+, the antiport process was found to dissipate the Δp generated by electron transport. This is probably the reason why *W. succinogenes* does not grow without Na^+ in the medium. In the absence of Na^+, resting cells catalyze fumarate reduction by H_2 or formate, but a Δp is not generated. In contrast, inverted membrane vesicles catalyze fumarate reduction with H_2 but generate a Δp in the presence or absence of Na^+. The transporters DcuA and DcuB of *W. succinogenes*, which are similar to the Dcu transporters of *Escherichia coli*, catalyze the transport of fumarate, succinate and other C_4-dicarboxylates (Six et al., 1994). A mutant of *W. succinogenes* that lacks both Dcu transporters does not grow by fumarate respiration, but the mutant still takes up dicarboxylates as a carbon source (Ullmann et al., 2000). (See The Dissimilatory Sulfate- and Sulfur-Reducing Prokaryotes in the second edition; elemental sulfur).

Nitrite Respiration

Liposomes containing formate dehydrogenase, menaquinone (MK) and nitrite reductase catalyze electron transport from formate to nitrite. This is coupled to the generation of an electrochemical proton potential (Δp) across the liposomal membrane (positive outside; Simon et al., 2000). The mechanism of Δp generation by nitrite respiration (Fig. 6) is envisaged to be similar to that of fumarate respiration (Fig. 5). The mechanisms differ in the orientation of the substrate sites of the reductases, nitrite reductase being exposed to the outside. The MK reduction with formate is thought to generate Δp, while MKH_2 oxidation by nitrite is assumed to be electroneutral (see [Fumarate respiration and dicarboxylate transport]). The protons produced by MKH_2 oxidation are thought to be liberated on the outside and to balance the protons consumed in nitrite reduction.

Polysulfide Respiration

The electron transport chain catalyzing polysulfide respiration with H_2 consists of hydrogenase and of polysulfide reductase (Fig. 7; Hedderich et al., 1999). Hydrogenase is replaced by formate dehydrogenase in the chain when formate is used as the electron donor. The two dehydrogenases are identical with those involved in fumarate respiration of *W. succinogenes*. The mechanism of electron transfer from the dehydrogenases to polysulfide reductase is not known. Electron transfer by menaquinone (MK) diffusion, as in fumarate respiration, appears to be unlikely because the standard redox potential of MK at pH 7.0 is more than 200 mV more electropositive than that of polysulfide. Experimental evidence suggests that electron transfer from the dehydrogenases to polysulfide reductase may require diffusion and collision of the enzymes within the membrane. The MK involved in polysulfide respiration is thought to be bound to PsrC (MK_b in Fig. 7). Bound MK probably serves as the prosthetic group of PsrC and as primary acceptor of the electrons delivered by HydC or FdhC. The mechanism of Δp generation in polysulfide respiration is not known. Possibly, protons are translocated by the redox reactions of the bound MK.

The K_M for polysulfide measured with intact cells of *W. succinogenes* grown with polysulfide (7 μM) is seven times lower than that measured with fumarate-grown bacteria or with the membrane fraction derived from bacteria grown under either condition (Klimmek et al., 1998). The lower K_M is caused by a polysulfide-sulfur transferase (Sud) that is induced during growth with polysulfide (Fig. 7). The Sud protein is localized in the periplasm; it consists of two identical subunits (14.3 kDa each) and does not contain prosthetic groups or heavy metal ions. The Sud protein binds sulfur from aqueous polysulfide solutions and probably transfers it to the cata-

lytic site of polysulfide reductase. Sulfur is covalently bound to the single cysteine residue of the Sud protein (Klimmek et al., 1999).

Genetics

Genetic Information

The G+C content of the DNA of *W. succinogenes* is 47 mol% (T_m); this number agrees well with the G+C contents of sequenced regions deposited in the data banks (47.6–50.0 mol%). A notable exception is the DNA of an insertion sequence (IS*1302*) whose G+C content is only 33.8 mol% (Simon and Kröger, 1998). IS*1302* is 1,306 bp in size, with 36-bp imperfect terminal repeats, and belongs to the IS*3* family of insertion sequences. As suggested by Southern-blot analysis, at least 13 copies are present in the genome. Insertion of IS*1302* resulted in a duplication of 3 bp of the target DNA. IS*1302* encodes a putative transposase whose predicted amino acid sequence is similar to those of transposases of various IS*3* family elements. IS*1302* may have been acquired from another organism inasmuch as the G+C contents of IS elements are usually in line with the G+C contents of the host DNA.

In recent years, a growing number of genes from *W. succinogenes* have been cloned and sequenced, including the operons encoding the subunits of fumarate reductase (*frdCAB*), of hydrogenase (*hydABC*), of polysulfide reductase (*psrABC*) and of nitrite reductase (*nrfHA*; Lauterbach et al., 1990; Körtner et al., 1990; Dross et al., 1993; Krafft et al., 1992; Simon et al., 2000). Lenger et al. (1997) detected two operons encoding the subunits of formate dehydrogenase (*fdhABC*); the operons differ in their promoter regions, but are nearly identical in their gene sequences. Other sequenced genes encode C_4-dicarboxylate transporters (*dcuA*, *dcuB*, *dctPQM*), L-asparaginase (*ansA*), L-aspartase (*aspA*), the two subunits of fumarase (*fumBα* and *fumBβ*), and the polysulfide-sulfur transferase (*sud*).

Genetic Manipulation

Transformation of *W. succinogenes* cells with plasmid DNA was achieved by electroporation under anaerobic conditions (Krafft et al., 1995; Simon et al., 1998). Cells were grown in media containing either fumarate or nitrate as terminal electron acceptor (see [Cultivation]) and were harvested in the exponential growth phase. The cells were washed with 0.3 M sucrose and suspended (10 g protein/liter) in growth medium. After addition of plasmid DNA (5–10 µg to 50 µl bacterial suspension), the mixture was subjected to electroporation in a 0.2-cm pathlength cuvette (25 µF capacity, 1.5 kV, 800 ω resistance). Anoxic growth medium (1 ml) was added; the bacteria were incubated for 2 h at 37°C and plated on agar medium containing an appropriate antibiotic.

Selection of transformants was accomplished using antibiotic resistance genes. The kanamycin resistance gene (*kan*) derived from the *Escherichia coli* plasmid pUC4K (Oka et al., 1981; Vieira and Messing, 1982) and the chloramphenicol resistance gene (*cat*) were obtained from the *E. coli* /*Helicobacter pylori* shuttle vector pDF4a (Haas et al., 1993). For selection, 25 µg/ml kanamycin or 12.5 µg/ml chloramphenicol is suitable.

Up to now, no plasmid replication was observed in *W. succinogenes*. Therefore, the generation of colonies on agar plates containing an antibiotic is dependent on recombination of the plasmid and the genome. Fragments of genomic DNA were replaced with a resistance gene by double homologous recombination. Using this method, various deletion mutants, each lacking, for example, an operon encoding an electron transport enzyme, were constructed. These strains comprise *W. succinogenes* Δ*frdCAB* (Simon et al., 1998), *W. succinogenes* Δ*hydABC* (Gross et al., 1998a), *W. succinogenes* Δ*psrABC* (Krafft et al., 1995), and mutants lacking either one of the two *fdh* operons (Lenger et al., 1997). The mutants *W. succinogenes* Δ*frdCAB* and *W. succinogenes* Δ*hydABC* were complemented by single crossover events of the mutant genome and plasmids carrying the entire *frdCAB* or *hydABC* operon (Simon et al., 1998; Gross et al., 1998a). This approach enabled the performance of site-directed mutagenesis of the two operons in *W. succinogenes*.

Applications

L-Asparaginase has been isolated from *W. succinogenes* (Kafkewitz and Goodman, 1974; Albanese and Kafkewitz, 1978). This enzyme inhibited growth of an in vitro culture of human pancreatic carcinoma cells (Wu et al., 1978) and was thus of particular interest for its potential antitumor activity. The crystal structure of *W. succinogenes* L-asparaginase, a homotetrameric enzyme, was determined (Lubkowski et al., 1996).

CHAPTER 4.1

Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta*

SUSAN LESCHINE, BRUCE J. PASTER AND ERCOLE CANALE-PAROLA

Introduction

The genus *Spirochaeta* includes anaerobic and facultatively anaerobic spirochetes that are indigenous to aquatic environments such as the mud and water of ponds and marshes. These spirochetes occur in nature as free-living forms; that is, their existence does not depend on physical associations with other organisms (Canale-Parola, 1984a).

Spirochaeta cells are helically shaped (Fig. 1–12) and possess the typical ultrastructural features of spirochetes (Canale-Parola, 1984b; Fig. 13). The outermost structure of the cells is an "outer membrane," or "outer sheath," which encloses the coiled cell body ("protoplasmic cylinder") consisting of the cytoplasm, the nuclear region, and the peptidoglycan-cytoplasmic membrane complex (Fig. 13). Organelles ultrastructurally similar to bacterial flagella are located in the area between the outer membrane and the protoplasmic cylinder (Fig. 13). These organelles are essential components of the motility apparatus of spirochetes (Paster and Canale-Parola, 1980) and are usually called "periplasmic flagella." Other names used to designate these motility organelles are "periplasmic fibrils," "axial fibrils," "axial filaments," and "endoflagella."

One end of each periplasmic flagellum is inserted near a pole of the protoplasmic cylinder, while the other end is not inserted (Fig. 13A). Individual periplasmic flagella extend for most of the length of *Spirochaeta* cells so that those inserted near opposite ends overlap in the central region of the organism (Fig. 13A). The *Spirochaeta* cell illustrated in Figure 13 has two overlapping periplasmic flagella, each inserted near a cell pole in a "1-2-1" arrangement. With one exception, all the known *Spirochaeta* species have two periplasmic flagella per cell. The exception is the large spirochete *Spirochaeta plicatilis*, which has as many as 18–20 periplasmic flagella inserted near each end of the protoplasmic cylinder (Blakemore and Canale-Parola, 1973).

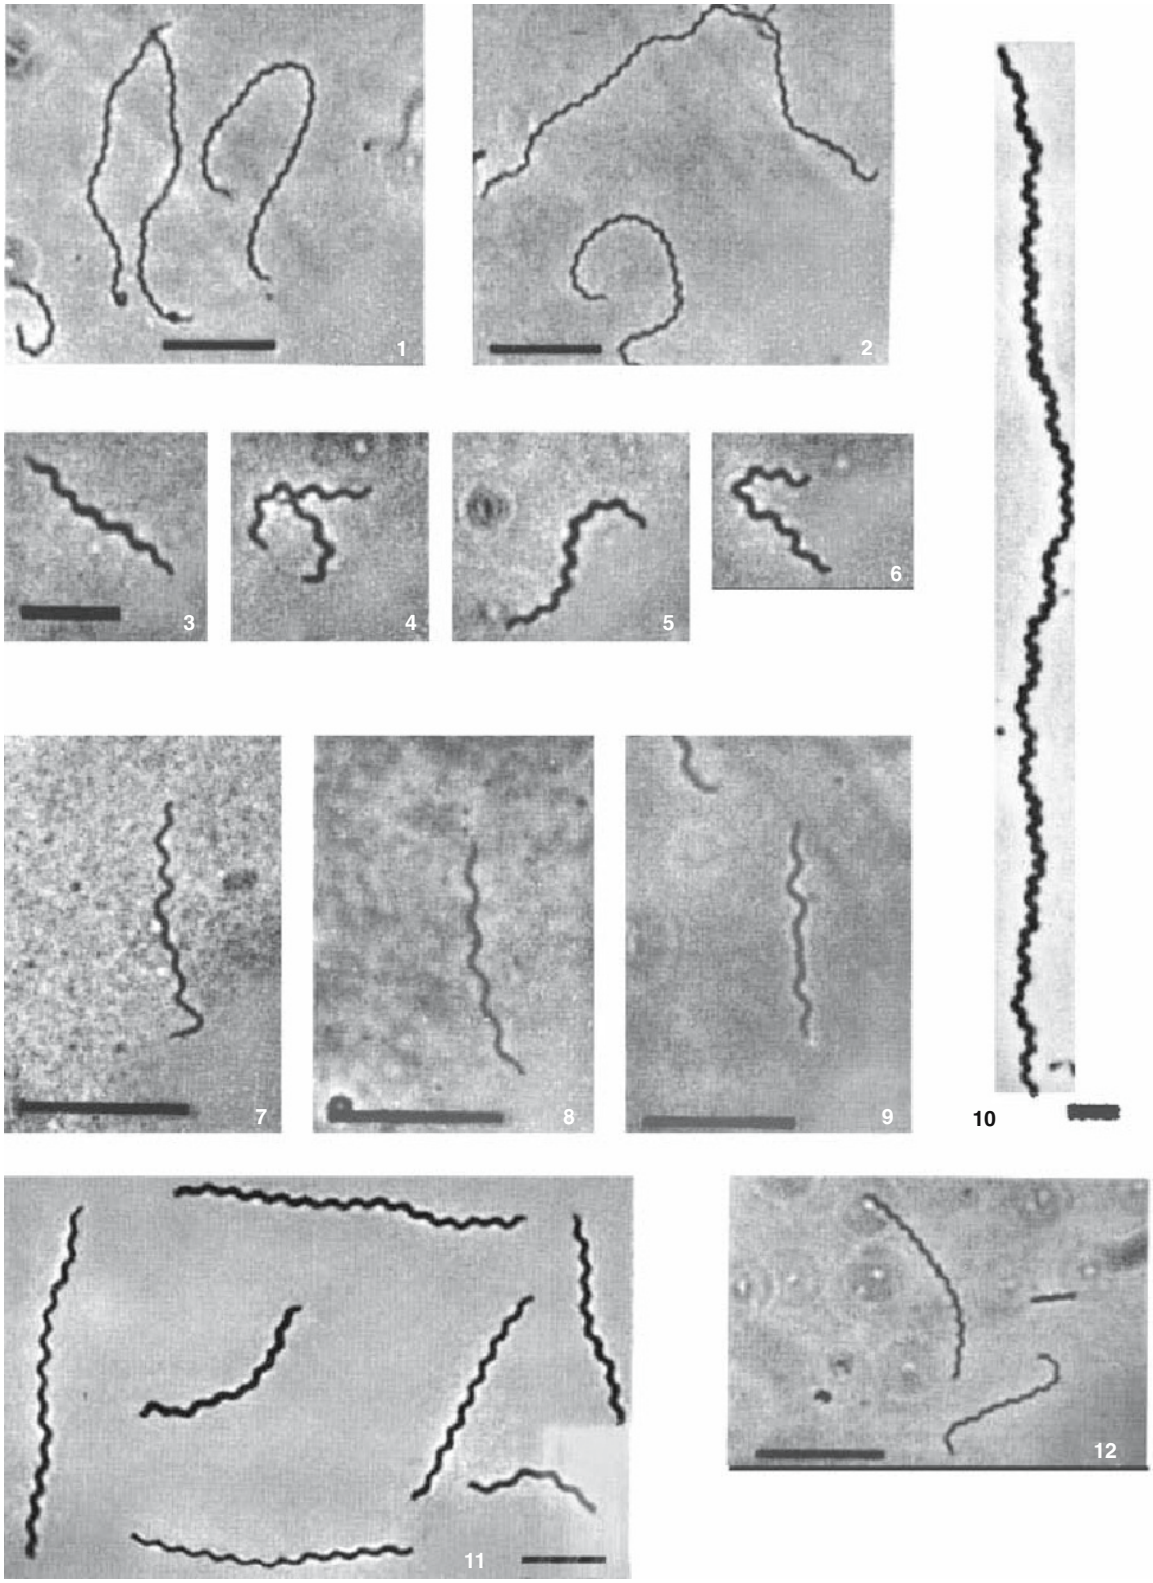
In contrast to flagella of other bacteria, the periplasmic flagella of spirochetes are permanently wound around the cell body and are entirely endocellular (Fig. 13B). Thus, the motility mechanism of spirochetes is different from that of other bacteria, which have flagella that function in direct contact with the external environment and are not wound around the cell body.

Phylogeny

Based on 16S rRNA gene sequence comparisons, most members of the genus *Spirochaeta* form one of the nine phylogenetic clusters of the spirochetes (Fig. 14). All spirochetes are presently classified in the class or phylum Spirochaetes in the order Spirochetales and are divided into three families. The first family, Spirochaetaceae, contains species of the genera *Borrelia*, *Brevinema*, *Cristispira*, *Spirochaeta*, "*Spironema*" and *Treponema*. The second proposed family, Serpulinaceae, contains the genus *Brachyspira* (*Serpulina*). The third family, Leptospiraceae, contains species of the genera *Leptonema* and *Leptospira*.

Novel *Spirochaeta* species, or phylotypes, which have not yet been cultivated in vitro, have been identified. For example, several phylotypes from sulfide-rich mud (Tanner et al., 2000) and one associated with the gutless marine oligochete *Olavius loisae* (Dubilier et al, 1999) clearly fall within the genus *Spirochaeta* (Fig. 14). Based on microscopic observations of aquatic and marine sediments, it is apparent that a significant population of additional "uncultivable" spirochetes, including the type species of the genus, *Spirochaeta plicatilis*, remains to be identified.

As shown in Fig. 14, the free-living, obligately anaerobic spirochetes from freshwater environments, *Spirochaeta stenostrepta*, *Spirochaeta zuelzerae* and *Spirochaeta caldaria*, are more closely related to members of the genus *Treponema* than to members of the genus *Spirochaeta*. The phylogenetic clustering of these species has been confirmed by single-base signature analysis, i.e., the sequences of these species possess more



Figs. 1–12. Phase contrast photomicrographs of living *Spirochaeta* cells. Wet mount preparations. Figs. 1 and 2, *Spirochaeta stenostrepta* strain Z1 (DSM 2028, ATCC 25083). Bars = 10 μm. (From Canale-Parola et al., 1968); Figs. 3–6, *Spirochaeta litoralis*, strain R1 (DSM 2029, ATCC 27000). Bar = 5 μm. (From Blakemore and Canale-Parola, 1973); Fig. 11, *Spirochaeta halophila*, strain RS1 (ATCC 29478). Bar = 5 μm. (From Greenberg and Canale-Parola, 1976); Fig. 12, *Spirochaeta zuelzerae*, strain ATCC 19044. Bar = 10 μm. (From Canale-Parola et al., 1968.)

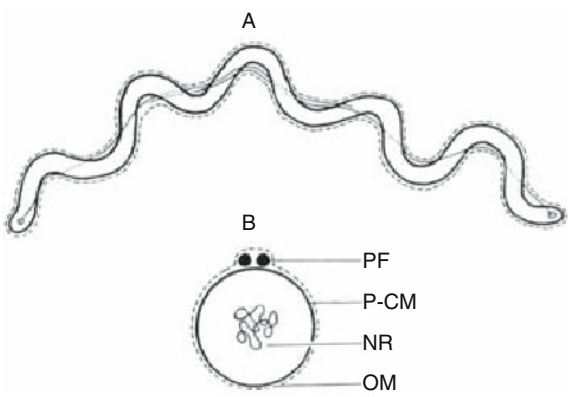


Fig. 13. (A) schematic representation of a *Spirochaeta* cell. The outermost broken line indicates the outer membrane (outer sheath). The protoplasmic cylinder is represented by the area delimited by the solid line adjacent to the outermost broken line. The cell has two periplasmic flagella indicated by the solid-dotted thin lines wound around the protoplasmic cylinder. The insertion points of the periplasmic flagella are represented by the small circles near the ends of the cell. (B) schematic representation of a cross section through a *Spirochaeta* cell. PF, periplasmic flagella; P-CM, peptidoglycan-cytoplasmic membrane complex; NR, nuclear region; OM, outer membrane (outer sheath).

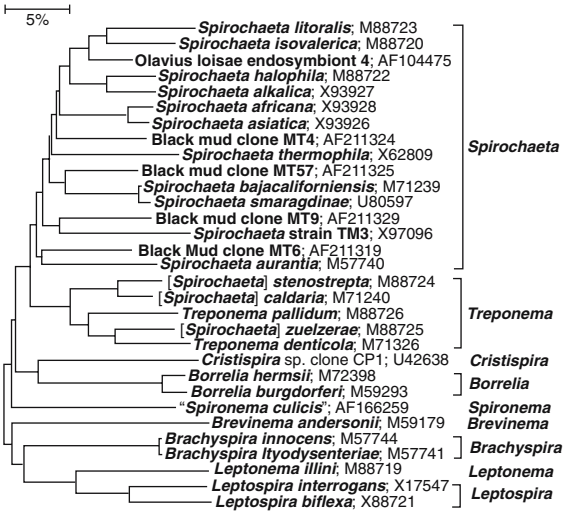

Fig. 14. Phylogeny of the genus *Spirochaeta*. The phylogenetic position of known species and phylotypes of *Spirochaeta* is shown relative to other genera of spirochetes as based on 16S rRNA gene sequence comparisons. GenBank accession numbers for the 16S rRNA sequences of the species tested are shown. Similarity matrices were corrected for multiple base changes by the method of Jukes and Cantor (1969). The neighbor-joining method (Saitou and Nei, 1987) was used for phylogenetic tree construction. TREECON,™a software package for the Microsoft Windows environment, was used for the construction and drawing of evolutionary trees (Van de Peer et al., 1994). The scale bar represents a 5% difference in nucleotide sequence determined by taking the sum of all of the horizontal lines connecting two species. Vertical distance has no meaning.

bases found in the sequences of the treponemes than in the sequences of *Spirochaeta* species (Paster et al., 1991). It was speculated that these "*Treponema*-like" free-living spirochetes might represent transitional species, i.e., descendants of the precursors to host-associated treponemes (Paster et al., 1991). However, it is possible that the source of these species may be hosts that release them with their feces. Consequently, it would be worthwhile to screen host environments for these species using specific DNA probes or oligonucleotide primers in polymerase chain reactions (PCRs).

Taxonomy

Fourteen species of *Spirochaeta* are presently known (Table 1). One of these, *Spirochaeta plicatilis*, has not been grown in pure culture, but its ultrastructure and some of its ecological characteristics have been described (Blakemore and Canale-Parola, 1973). Nine species (*Spirochaeta stenostrepta*, *Spirochaeta litoralis*, *Spirochaeta zuelzerae*, *Spirochaeta isovalerica*, *Spirochaeta bajacaliforniensis*, *Spirochaeta thermophila*, *Spirochaeta caldaria*, *Spirochaeta smaragdinae* and *Spirochaeta asiatica*) are obligate anaerobes, and two species (*Spirochaeta alkalica* and *Spirochaeta africana*) are aerotolerant anaerobes. Two other species, *Spirochaeta aurantia* and *Spirochaeta halophila*, are facultative anaerobes and characteristically produce carotenoid pigments when growing aerobically (see Identification). Most species of *Spirochaeta* are mesophilic, growing at optimum temperatures ranging from 15 to 40°C. However, the thermophilic species, *Spirochaeta thermophila* and *Spirochaeta caldaria*, both from thermal springs, have optimum growth temperatures of 66–68 and 48–52°C, respectively (Table 1).

Two subspecies of *Spirochaeta aurantia* are known (Table 1). One of these (subsp. *stricta*) is characterized by significantly narrower coils than the other (subsp. *aurantia*), and its DNA possesses a slightly lower G+C content (Breznak and Canale-Parola, 1975; Canale-Parola, 1984a).

Spirochaeta stenostrepta, *Spirochaeta zuelzerae*, *Spirochaeta caldaria* and *Spirochaeta aurantia* are freshwater species, whereas *Spirochaeta litoralis*, *Spirochaeta isovalerica*, *Spirochaeta bajacaliforniensis* and *Spirochaeta thermophila* are marine species (Table 1) and require sodium ion (Na^+) concentrations ranging from 200 to 480 mM for optimal growth (Aksenova et al., 1992; Fracek and Stolz, 1985; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970b). *Spirochaeta halophila* was isolated from a high-salinity pond and grows optimally when 750 mM NaCl, 200 mM $MgSO_4$

Table 1. Characteristics of the fourteen species of the genus *Spirochaeta*.

Species	Size[a] (μm)	Relationship to O_2	Optimum growth temperatures (°C)	Habitat	G+C content DNA (mol%)[b]
1. *Spirochaeta stenostrepta*	0.2–0.3 × 15–45	OA	30–37	Freshwater	60.2
2. *Spirochaeta litoralis*	0.4–0.5 × 5–7	OA	Near 30	Marine	50.5
3. *Spirochaeta zuelzerae*	0.2–0.4 × 8–16	OA	37–39	Freshwater	56.1
4. *Spirochaeta isovalerica*	0.4 × 10–15	OA	15–35	Marine	63.6–65.6
5. *Spirochaeta bajacaliforniensis*	0.1–0.2 × 15–45	OA	36	Marine (laminated sediment)	50.1
6. *Spirochaeta thermophila*	0.2–0.25 × 16–50	OA	66–68	Marine (hot springs)	52.0
7. *Spirochaeta caldaria*	0.2–0.3 × 15–45	OA	48–52	Freshwater (hot springs)	45.0
8. *Spirochaeta smaragdinae*	0.3–0.5 × 5–30	OA	37	Oil field, injection water	50.0
9. *Spirochaeta asiatica*	0.2–0.25 × 15–22.5	OA	35	Alkaline lake	49.2
10. *Spirochaeta alkalica*	0.4–0.5 × 9–18	AT	33–37	Alkaline lake	57.1
11. *Spirochaeta africana*	0.25–0.3 × 15–30	AT	30–37	Alkaline lake	56.1
12. *Spirochaeta aurantia*[c]					
subsp. *aurantia*	0.3 × 10–20	FA	25–30	Freshwater	62.2–65.3
subsp. *stricta*	0.3 × 10–20	FA	25–30	Freshwater	61.2
13. *Spirochaeta halophila*	0.4 × 15–30	FA	35–40	High salinity	62
14. *Spirochaeta plicatilis*[T]	0.75 × 80–250	Unknown	Unknown	Unknown	Unknown

Abbreviations: O_2, molecular oxygen; OA, obligate anaerobic; AT, aerotolerant; FA, facultative anaerobe; and [T], type species.
[a]Lengths indicated are of the majority of cells. Shorter and longer cells are also present in cultures.
[b]Buoyant density determinations, except for species 4, 6, 7, and 9–11 (determined by thermal denaturation method) and species 8 (determined using HPLC).
[c]Wavelength of the cell: subsp. *aurantia* cells, 2.0–2.8 mm; subsp. *stricta* cells, 1.1–1.5 mm.

and 10 mM $CaCl_2$ are present in the medium (Greenberg and Canale-Parola, 1976). Other halophilic species include *Spirochaeta asiatica*, *Spirochaeta alkalica* and *Spirochaeta africana*, which were isolated from the sediments of alkaline lakes and require Na^+ concentrations ranging from 850 to 1,200 mM for optimal growth (Zhilina et al., 1996). The latter three species are also alkaliphilic and growth does not occur below pH 8. *Spirochaeta smaragdinae*, isolated from a production water sample collected from an offshore oil field, requires at least 170 mM NaCl and grows optimally with 850 mM NaCl (Magot et al., 1997).

Habitat

Species of *Spirochaeta* occur, grow, and persist as free-living organisms in a variety of aquatic environments, such as the water, sediments, and muds of ponds, marshes, lakes, rivers, and oceans. Numerous strains of *Spirochaeta* have been isolated from various freshwater environments (Canale-Parola, 1984a; Pohlschroeder et al., 1994) and from marine muds collected in Pacific and Atlantic coastal regions (Aksenova et al., 1992; Fracek and Stolz, 1985; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970b). Using 16S rRNA phylogenetic analyses to investigate the microbial diversity of sulfur-rich black mud marine sediments, Tanner et al. (2000) reported the presence of several novel spirochete phylotypes in samples from hypersaline and brackish marshes. Moreover, Weber and Greenberg (1981) determined that *Spirochaeta* cells are present in salt marshes at densities ranging from 104 to 106 per gram (wet weight) of the top 1 cm of sediment.

Selective isolation procedures did not yield spirochetes from deep-sea sediments and water from the Sargasso Sea (3,630 m) and the Puerto Rico Trench (8,140 m; Harwood et al., 1982b). These results indicate that although anaerobic and facultatively anaerobic free-living spirochetes are common in marine coastal environments, they are not widely distributed in deep-sea regions. However, Harwood et al. (1982b) isolated an obligately anaerobic spirochete from a sample collected near a deep-sea (2,550 m) hydrothermal vent at the Galapagos Rift tectonic spreading center, and they observed bacteria with morphologies typical of spirochetes in surface scrapings from mussels present near a vent. The occurrence of spirochetes in this deep-sea region may be ascribed to vent area environmental conditions, which are favorable to the growth of various bacteria. Magot et al. (1997) isolated *Spirochaeta smaragdinae* from a production water sample collected from an offshore oil field of Congo, Africa, and speculated that this

spirochete might be indigenous to the deep subsurface waters of oil fields.

Three alkaliphilic *Spirochaeta* species have been isolated from the sediments of alkaline lakes, including *Spirochaeta alkalica* and *Spirochaeta africana* from Lake Magadi, East African Rift, Kenya, and *Spirochaeta asiatica* from Lake Khatyn in Tuva, Central Asia (Zhilina et al., 1996). These spirochetes grow at pHs of >9, and growth does not occur below pH 8. Moreover, these species are halophilic, requiring Na^+ concentrations ranging from 850 to 1,200 mM for optimal growth (Zhilina et al., 1996). Another halophilic species, *Spirochaeta halophila*, has been isolated from a high-salinity pond located on the Sinai shore of the Gulf of Aqaba (Greenberg and Canale-Parola, 1976).

Most species of *Spirochaeta* are mesophilic, growing at optimum temperatures ranging from 15 to 40°C (Canale-Parola, 1984a). However, thermophilic spirochetes have been isolated from various hot springs in geographically widely separated locations. Obligately anaerobic thermophilic spirochetes isolated from New Zealand thermal springs grow optimally at 45 to 50°C (Patel et al., 1985). Aksenova et al. (Aksenova et al., 1990; Aksenova et al., 1992), and Rainey et al. (1991) isolated (from a marine hot spring on the beach of Shiashkotan Island, Kuril Islands, Kamchatka, Russia, and a brackish hot spring on Raoul Island, Kermadec Archipelago, New Zealand) two strains of thermophilic cellulolytic spirochetes, which they named *Spirochaeta thermophila* (Aksenova et al., 1992). *Spirochaeta thermophila* type strain grew between 40 and 73°C with a growth optimum of 66 to 68°C. Strains of *Spirochaeta caldaria*, which were isolated from hot springs in Oregon and Utah, USA, grew optimally between 48 and 52°C (Pohlschroeder et al., 1994). In addition, based on 16S rRNA gene sequence analyses, spirochete phylotypes have been identified in samples from a hot spring (Octopus Spring) in Yellowstone National Park, USA (Weller et al., 1992). Thus, it is likely that thermophilic spirochetes are widely distributed in thermal spring waters.

Isolation

Selective Procedures

Anaerobic and facultatively anaerobic spirochetes are readily isolated from natural environments by means of selective procedures and usually grow abundantly in ordinary laboratory media. Anaerobic growth yields of the isolates range from 2×10^8 to approximately 10^{10} cells/ml, but commonly are 6×10^8 to 8×10^8 cells/ml (Breznak and Canale-Parola, 1975; Canale-Parola, 1973; Greenberg and Canale-Parola, 1976; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970a; Hespell and Canale-Parola, 1970b). Cell population doubling times in anaerobic cultures vary from 2.2 to 12 h, depending on the species and the growth conditions. Aerobically grown cultures yield from 0.7×10^9 to 1.2×10^9 spirochetes/ml, with doubling times of 2 to 4 h (Breznak and Canale-Parola, 1975; Canale-Parola, 1973; Greenberg and Canale-Parola, 1976).

A procedure in which the antibiotic rifampin (rifampicin) serves as a selective agent is quite effective for the isolation of free-living spirochetes (genus *Spirochaeta*) from natural environments (Harwood et al., 1982b; Patel et al., 1985; Stanton and Canale-Parola, 1979; Weber and Greenberg, 1981). This procedure, which is described below, is based on the observation that spirochetes in general are naturally resistant to rifampin (Leschine and Canale-Parola, 1986; Stanton and Canale-Parola, 1979). Thus, spirochetes such as *Spirochaeta stenostrepta* and *Spirochaeta aurantia* grow in the presence of as much as 100 to 200 μg of rifampin per ml of medium (Leschine and Canale-Parola, 1986), whereas the growth of many other bacteria is inhibited. The resistance of spirochetes to rifampin is probably due to the low affinity of their RNA polymerase for the antibiotic (Allan et al., 1986; Leschine and Canale-Parola, 1986).

Other enrichment procedures used in the isolation of *Spirochaeta* species are based either on one or both of the following selective factors: 1) the ability of spirochetes to pass through filters that retain most other bacteria, and 2) the migratory movement of spirochetes through agar media (Canale-Parola, 1973; Canale-Parola, 1984a). These selective procedures enrich for species of *Spirochaeta* measuring less than 0.5 μm in diameter (Table 1).

In the enrichment-by-filtration procedure, which is described in detail below, separation of *Spirochaeta* species from most of the microorganisms present in mud or water is achieved by techniques involving filtration through cellulose ester filter discs (e.g., Millipore filters) having an average pore diameter of 0.3 or 0.45 μm. Spirochetes pass through these filter discs because of their relatively small cell diameter (Table 1) and probably also because their motility apparatus enables them to swim freely in liquids as well as to move in contact with solid surfaces.

The enrichment-by-migration procedure uses the ability of spirochetes to move through agar gels or media containing as much as 1 to 2% (w/v) agar. This movement or migration occurs primarily within the agar gel, i.e., below the surface of the agar medium. In contrast, flagellated bacteria usually cannot carry out translational

movement through gels or media containing agar at the above-mentioned concentrations, although several exceptions have been reported (Greenberg and Canale-Parola, 1977b). Apparently, the cell coiling of spirochetes is important for their translational motion through agar gels, inasmuch as this type of movement is impaired in mutant spirochetes lacking the cell-coiling characteristic of the parental strain (Greenberg and Canale-Parola, 1977c).

Migration of spirochetes through agar media results from the unique motility mechanism of these bacteria (Canale-Parola, 1977; Canale-Parola, 1978), as well as from chemotaxis toward the energy and carbon source (Breznak and Canale-Parola, 1975; Greenberg and Canale-Parola, 1977a). The role of chemotaxis in the migration of saccharolytic spirochetes through agar media has been studied (Breznak and Canale-Parola, 1975). When these spirochetes are inoculated in the center of glucose-containing agar medium plates, they grow using this sugar as their energy source. Utilization of the sugar by the spirochetes gives rise to a glucose concentration gradient that moves away from the center of the plate as more of this carbohydrate is metabolized by the spirochetes. Because the spirochetes exhibit chemotaxis toward glucose and are able to move through the agar gel, they migrate into the areas of higher glucose concentration within the gradient. Thus, the spirochetal population follows the outward movement of the gradient and migrates toward the periphery of the plate. This behavior results in the formation of a growth "veil" or "ring" of spirochetes for which glucose serves both as the energy source for growth and as the chemoattractant (Breznak and Canale-Parola, 1975; Canale-Parola, 1973). The veil or ring increases continuously in diameter during incubation and may reach the outer edge of the plate. The migration rate of the spirochetal population is greatest in agar media containing low substrate concentrations (e.g., 0.02% glucose). In these media the substrate becomes rapidly depleted in the region where spirochetes are growing, and the spirochetal population moves toward the outer zone of higher substrate concentrations at a relatively fast rate (Breznak and Canale-Parola, 1975).

In procedures for the isolation of *Spirochaeta* species from natural environments, the chemotactic behavior and the ability of these bacteria to move through agar gels have important selective functions. In a typical isolation procedure, a small, shallow cylindrical hole is made through the surface of an agar medium containing a low concentration of carbohydrate. Rifampin may be included in the medium as an additional selective agent for spirochetes. The medium may be in a Petri dish or a small bottle. A tiny drop of pond water, or of any other material in which spirochetes have been observed, is placed within the hole. The chemotactic, saccharolytic spirochetes in the inoculum multiply and form a growth veil that extends outwardly through the agar medium. Thus, the spirochetes in the veil move away from contaminants, which remain mainly in the vicinity of the inoculation site. Spirochetal cells from the outermost edge of the veil are used to obtain pure cultures by conventional methods, such as streaking on agar medium plates. Isolation procedures involving chemotaxis and movement through agar gels are described below.

Selective isolation techniques have not been developed for the large *Spirochaeta* species, such as *Spirochaeta plicatilis*.

Enrichment by Migration

When other bacteria vastly outnumber spirochetes in the inoculum, it is advisable to begin the isolation procedure with an enrichment-by-migration step (the principle has been discussed above). A suitable medium (EBM agar medium) for this enrichment has the following composition in g/100 ml distilled water: yeast extract (Difco), 0.1; Trypticase (BBL Microbiology Systems), 0.1; L-cysteine, HCl, 0.05; resazurin, 10^{-4}; and agar (Difco), 1. For the enrichment and isolation of marine spirochetes, a mixture of seawater (70 ml) and distilled water (30 ml) is used instead of plain distilled water. The pH of the medium is adjusted to 7.2. After autoclaving, cellobiose is added as a sterile solution to a final concentration of 0.01 g/100 ml medium. Rifampin (filter-sterilized solution) may be used as a selective agent (0.5 mg per 100 ml of medium).

The medium is pre-reduced (Hungate, 1969) and is dispensed into narrow-necked 60-ml glass bottles. During this step and the steps that follow, the medium is maintained in an anaerobic atmosphere by delivering a stream of oxygen (O_2)-free nitrogen (N_2) into the bottles. The bottles containing the medium are sealed with neoprene rubber stoppers and are placed in a press to hold the stoppers in place during autoclaving. The sterilized medium is allowed to cool to approximately 50°C, and cellobiose and, if desired, rifampin are added. The complete medium is solidified at a 45° angle so that bottle slants are obtained. Then, a small (5-mm wide, 6-mm deep), cylindrical well is melted halfway down each slant by heating the tip of a thin metal rod and touching the agar with it. Alternatively, the well can be made by aspirating some of the agar medium with a sterile Pasteur pipette connected to a vacuum apparatus. All further manipulations are made either while maintaining an N_2 atmosphere within the bottles (Hungate, 1969)

or with the bottles placed within an anaerobic chamber and the rubber stoppers replaced by cotton stoppers.

Before inoculation, any liquid that oozed from the agar medium is removed by suction from the well and the lower part of each slant. The bottle slants are inoculated by carefully placing a small volume of inoculum (e.g., mud) into the well, and they are incubated at 30°C. In successful enrichments, the spirochetes form a characteristic, semitransparent growth veil that extends down into the agar medium and diffuses out toward the periphery of the slant, away from contaminating organisms growing in and near the well. The veil usually is visible after 4 to 7 days of incubation. Cells from the edges of the growth veil are used to obtain pure cultures of the spirochetes by means of a procedure involving serial dilutions in a rifampin-containing medium (see below).

Isolation in Rifampin-Containing Media

Serial dilutions in melted, rifampin-containing agar (RIM) medium can be used to isolate spirochetes from materials in which they are present in relatively large numbers (e.g., directly from mud or from the outer edges of growth veils in the bottle slants mentioned above). The spirochete-containing inoculum is serially diluted in tubes of melted (45°C), pre-reduced RIM medium. This medium is identical to the EBM agar medium described above except that the final concentration of cellobiose is 0.2% (w/v), rifampin (0.5 mg/100 ml of medium) is added, and the agar (Bacto, Difco) concentration is 0.8% (w/v). The medium is dispensed and sealed in anaerobic culture tubes containing an N_2 atmosphere (Hungate, 1969).

Spirochete colonies within the RIM agar medium are recognizable inasmuch as they are spherical and because, as a result of cell migration through the agar medium, they appear as "transparent bubbles," "veil-like growth with a dense center," or "cotton ball-like growth" (Paster and Canale-Parola, 1982; Stanton and Canale-Parola, 1979; Weber and Greenberg, 1981). To obtain pure cultures, the serial dilution step is repeated at least twice, using cells from spirochete colonies that developed within the RIM agar medium.

Procedures involving serial dilutions in rifampin-containing agar media have been used by Weber and Greenberg (1981) and by Patel et al. (1985) to isolate spirochetes from salt marsh sediments and hot springs, respectively.

Selective Enrichment by Filtration

A filtration technique has been used in the isolation of *Spirochaeta stenostrepta* (Canale-Parola et al., 1967; Canale-Parola et al., 1968), *Spirochaeta litoralis* (Hespell and Canale-Parola, 1970b), and the facultatively anaerobic *Spirochaeta halophila* (Greenberg and Canale-Parola, 1976). In all cases, the source of the spirochetes was black mud that had the characteristic smell of hydrogen sulfide (H_2S). *Spirochaeta stenostrepta* was isolated from a mud sample collected from a fresh-water pond, *Spirochaeta litoralis* from marine mud, and *Spirochaeta halophila* from the mud of Solar Lake, a high-salinity pond located on the Sinai shore of the Gulf of Aqaba. A filtration technique also was used in the isolation of the alkaliphiles, *Spirochaeta asiatica*, *Spirochaeta alkalica* and *Spirochaeta africana*, from the sediments of alkaline lakes located in the East African Rift region and central Asia (Zhilina et al., 1996).

Medium for Isolating *Spirochaeta stenostrepta*

Distilled water	875 ml
Glucose	5.0 g
Peptone	2.0 g
Yeast extract	0.3 g
Vitamin B_{12}	10^{-5} g
Phosphate solution	15 ml
Salts solution	100 ml
Sulfide solution	10 ml

The phosphate solution is prepared by dissolving 30 g of KH_2PO_4 and 70 g of K_2HPO_4 in 1,000 ml of distilled water.

To prepare the salts solution, 0.2 g of ethylenediamine tetraacetic acid are dissolved in 800 ml of distilled water by heating. The pH of the resulting solution is adjusted to 7.0 with 2.5% KOH. Then the following additions are made: $MgSO_4 7H_2O$, 2.0 g; $CaCl_2 2H_2O$, 0.75 g; $FeSO_4 7H_2O$, 0.1 g; trace elements solution (below), 5.0 ml. Finally, the volume of the salts solution is adjusted to 1,000 ml with distilled water. The sulfide solution (2 g of $Na_2S 9H_2O$/100 ml distilled water) is autoclaved separately and added shortly before inoculating the (precooled to 30–35°C) sterile medium. After sterilization by autoclaving, a precipitate is present in the medium, but it disappears as the medium cools. The final pH of the complete medium is 6.9–7.0.

Trace elements solution: a separate solution of each salt listed below, in the amount indicated. Heating may be required to dissolve some of the salts. The pH of the sodium molybdate and sodium vanadate (Na_2MoO_4 and $NaVO_3$) solutions is adjusted to a value below 7. The potassium iodide (KI) solution is added to the aluminum chloride ($AlCl_3$) solution and mixed by stirring. Then the other solutions are added, one at a time, to this mixture, with stirring, in the order in which they are listed below.

$AlCl_3 \cdot 6H_2O$	0.50 g
KI	0.25 g
KBr	0.25 g
LiCl	0.25 g
$MnCl_2 \cdot 4H_2O$	3.50 g
H_3BO_3	5.50 g
$ZnCl_2$	0.50 g
$CuCl_2 \cdot 2H_2O$	0.50 g
$NiCl_2 \cdot 6H_2O$	0.50 g
$CoCl_2 \cdot 6H_2O$	0.50 g
$SnCl_2 \cdot 2H_2O$	0.15 g
$BaCl_2 \cdot 2H_2O$	0.15 g
$Na_2MoO_4 \cdot 2H_2O$	0.25 g
$NaVO_3$	0.05 g

The volume of the final mixture is adjusted to 1,800 ml by adding distilled water and to pH 3–4 with HCl. A fine, white precipitate replaces a yellow precipitate after a few days. The solution should be mixed thoroughly immediately before it is used and may be stored at room temperature. This trace element solution is a modification of a solution described by Pfennig (1965).

Isolation of *Spirochaeta stenostrepta* (Canale-Parola et al., 1967) Black mud, from which a strong odor of H_2S could be detected, was suspended in aqueous sodium sulfide (0.02% Na_2S9H_2O). The slurry was filtered through Whatman No. 40 filter paper, and the filtrate was subjected to filtration through sterile cellulose ester filter discs (Millipore, pore diameter 0.45 μm). Each 1-ml aliquot of the resulting filtrate was added aseptically to a 60-ml glass stoppered bottle, half filled with sterile isolation medium. The bottles were then completely filled with medium, stoppered without trapping air bubbles, and incubated at 30°C (each bottle was covered with a sterile 50-ml beaker). After 5 to 7 d of incubation, the microbial population in many of the bottles consisted predominantly of thin spirochetes. Pure cultures were obtained by use of dilution shake cultures (the medium was covered with sterile paraffin) or by plating serial dilutions and incubating the plates in the absence of O_2 (Bray dishes). The isolation medium solidified with 1.5% agar was used. Spirochetal colonies appeared after 5 to 6 d. After isolation, the organisms were also grown in Florence flasks filled with a medium GYPT containing (g/100 ml distilled water): glucose, 0.5; yeast extract and peptone, 0.2 each; and sodium thioglycolate, 0.05. The pH of this medium was adjusted to 7.0–7.3 before sterilization. The spirochetes were maintained in paraffin-layered stab cultures of medium GYPT containing 1.5% agar at 5°C and transferred monthly. Subsurface colonies of *Spirochaeta stenostrepta* in agar media are white, spherical, and characteristically fluffy in appearance.

Spirochaeta litoralis and *Spirochaeta halophila* were isolated by a procedure similar to that used for *Spirochaeta stenostrepta*, except that different isolation media were used and the incubation temperatures were 22–23°C for *Spirochaeta litoralis* and 37°C for *Spirochaeta halophila* (Hespell and Canale-Parola, 1970b; Greenberg and Canale-Parola, 1976). Furthermore, one volume of the mud used as the source of *Spirochaeta litoralis* was suspended in five volumes of isolation medium before filtration through filter paper.

Isolation of *Spirochaeta litoralis* (Hespell and Canale-Parola, 1970b) The isolation medium for the marine spirochete included (g/100 ml of distilled water): tryptone (Difco), 0.3; yeast extract (Difco), 0.05; and NaCl, 2.0. To this mixture 2 ml of 1 M potassium phosphate buffer (pH 7.4) and 0.2 ml of a salt solution (see below) were added. The pH of the medium was adjusted to 7.3 with KOH before sterilization. Immediately before inoculation, the medium was supplemented with 2 ml of a sterile glucose solution (25 g per 100 ml distilled water) and with 0.5 ml of a sterile Na_2S9H_2O solution (10 g per 100 ml of distilled water). The final pH of the medium ranged from 7.4 to 7.5.

The salts solution contained (g/75 ml of distilled water): tetrasodium ethylenediamine tetraacetate, 1; $CaCl_22H_2O$, 3.75; $MgCl_26H_2O$, 12.5; and $FeSO_47H_2O$, 0.5. To 75 ml of this salt mixture, 25 ml of a trace elements solution (see Medium for Isolating *Spirochaeta stenostrepta*) was added.

After cloning, *Spirochaeta litoralis* was grown routinely in the isolation medium. Subsurface colonies of *Spirochaeta litoralis* in agar media are white to cream-colored and resemble those of *Spirochaeta stenostrepta*.

Maintenance procedures: Broth cultures of *Spirochaeta litoralis* in test tubes remained viable for 3 d at 30°C. Agar stabs grown at 30°C and then kept either at 5 or 30°C were no longer viable after approximately one week, whether they were layered with paraffin or not. Viable cells were not recovered from lyophilized preparations.

Spirochaeta litoralis was satisfactorily maintained by using "depression" cultures (Canale-Parola and Wolfe, 1960) prepared by using 1-liter Erlenmeyer flasks, each containing 800 ml of isolation medium to which 2 g of agar per 100 ml were added. These cultures, when incubated for 2 d at room temperature and then at 15°C, remained viable for at least three months.

Isolation of *Spirochaeta halophila* (Greenberg and Canale-Parola, 1976) The isolation medium contained 0.2 g of peptone (Difco) and 0.4 g of yeast extract (BBL) per 97 ml of an inorganic salt solution which had the

following composition: $CaCl_2 \cdot 2H_2O$, 0.04 M; NaCl, 0.85 M; and $MgSO_4 7H_2O$, 0.2 M. In preparing the salt solution, salts were added in the order in which they are listed to avoid formation of a precipitate. After adjusting the pH to 7.5 with KOH, the medium was sterilized by autoclaving. The volume of the medium was brought to 100 ml by adding separately sterilized solutions of glucose and $Na_2S 9H_2O$ to final concentrations of 0.5% and 0.05%, respectively.

Spirochaeta halophila was grown routinely at 37°C in ISM broth (Greenberg and Canale-Parola, 1975), which differed from the isolation medium because maltose replaced glucose, the $Na_2S 9H_2O$ was omitted, and the composition of the salt solution was changed (to $CaCl_2$, 0.01 M; NaCl, 0.75 M; and $MgSO_4$, 0.2 M). Furthermore, BBL yeast extract was replaced by Difco yeast extract, which supported higher growth yields of our isolate.

Spirochaeta halophila was maintained by storing ISM agar (ISM broth containing 0.75 g agar per 100 ml) plate cultures at 5°C. The cultures were transferred monthly.

Colonies of *Spirochaeta halophila* are pigmented when growing aerobically but lack pigmentation under anaerobic growth conditions. Colonies grown in air on ISM agar plates were red and appeared circular when viewed from above. A portion of each colony grew above the surface of the medium and part of the colony extended into the agar. Areas of diffuse growth were present at the periphery of the colonies. Generally, colonies measured 2–6 mm in diameter after 5 days at 35°C but were smaller or larger depending on the number of colonies on the plate and the length of incubation. Cells streaked on ISM agar plates and grown anaerobically in Bray dishes formed colonies that developed below the surface of the agar medium and were white, spherical and diffuse.

Cultivation of most of the anaerobic species of *Spirochaeta* described here does not require the use of stringent anaerobic procedures (e.g., the Hungate technique). Reducing agents, such as sodium thioglycolate or L-cysteine, are commonly added to the growth media, and other conventional techniques for the growth of anaerobes are used, as discussed elsewhere (Canale-Parola, 1973).

Enrichment by Filtration and Migration

Many strains of *Spirochaeta aurantia* have been isolated by means of a selective technique that combines filtration of the inoculum through a cellulose ester filter disk with migration of the spirochetes in agar media (Breznak and Canale-Parola, 1969; Canale-Parola, 1973; Breznak and Canale-Parola, 1975).

Isolation of *Spirochaeta aurantia* by Filtration and Migration

Ingredient	Medium HE	Medium PEP
Distilled water	50 ml	100 ml
Peptone	0.1 g	0.5 g
Yeast extract	0.1 g	0.05 g
K_2HPO_4	—	0.01 g
Hay extract	50 ml	—
Agar	1 g	1 g

The pH of medium HE is adjusted to 6.5 before sterilization. To prepare the hay extract, 0.5 g of dried barn hay are boiled in 100 ml of distilled water for 10 min. The boiled mixture is filtered using Whatman No. 40 filter paper. The filtrate is the hay extract.

The inoculum, consisting either of pond or marsh water or of a water-mud slurry, was prefiltered through Whatman No. 40 filter paper to remove large particles. Then, the enrichment cultures were prepared by depositing one or two drops of the filtrate near the center of each of a number of sterile cellulose ester filter disks (47-mm disk diameter, 0.3- or 0.45-μm pore diameter, Millipore) previously placed on the surface of isolation medium plates. One filter disk had been placed on each plate, approximately in the center. The cultures were incubated at 30°C for 12–24 h to allow spirochetes in the inoculum to move through the filter disk onto the surface of the medium. Then the filter disks were removed aseptically from the plates, and incubation of the plate cultures was continued. Spirochetes that had passed through the filter disks grew and migrated through the agar medium, forming semitransparent growth veils that diffused toward the edge of the plates. Spirochetal growth veils usually developed in 5–10 days.

Generally, 10–20% of the plate enrichments were successful (i.e., yielded growth veils) when spirochetes were present in the inoculum, as determined by light microscopy. Analyses showed (Breznak and Canale-Parola, 1975) that the total carbohydrate content of a batch of isolation medium HE was 40 mg/100 ml and the glucose content 5 mg/100 ml. Medium PEP contained 6 mg total carbohydrate and less than 1 mg glucose per 100 ml. As discussed previously, low carbohydrate concentrations, such as those in isolation media HE and PEP, are used to enhance the rate of spreading of the spirochetal growth veil through the agar medium.

It should be noted that bacteria other than spirochetes may form subsurface spreading growth veils in the enrichment plates. Most common among these veil-forming bacteria are *Aquaspirillum* (*Spirillum*) *gracile* (Canale-Parola et al., 1966) and *Serpens flexibilis* (Hespell, 1977). *Serpens flexibilis* cells are flexible, Gram-negative rods that have bipolar as well as lateral flagella.

Pure cultures of *Spirochaeta aurantia* are obtained by streaking cells from the outer edge of the growth veil onto isolation medium plates or growth medium plates.

A suitable growth medium for *Spirochaeta aurantia* contains (g/99 ml distilled water): glucose, 0.2; yeast extract, 0.2; and Trypticase (BBL), 0.5. The pH is adjusted to 7.5 before sterilization. When desired, agar (1 g) is added. After autoclaving and allowing the medium to cool, 1 ml of sterile 1 M potassium phosphate buffer (pH 7) is added.

Growth of some *Spirochaeta aurantia* strains is either partially or totally inhibited in media containing agar (Difco) concentrations higher than 1% (w/v). Thus, viable cell counts usually are higher when performed using plates of media containing 0.75 or 1% agar than when the cells are grown in media including agar at higher concentrations. *Spirochaeta aurantia* cells grown in media containing agar at concentrations higher than 1% frequently are aberrant in morphology. Many usually long, poorly coiled, filamentous cells are present, as well as an abundance of spherical bodies (Breznak and Canale-Parola, 1975).

Surface, aerobic colonies of *Spirochaeta aurantia* in growth medium (agar, 1%) are light orange to orange, round or nearly round, with slightly irregular edges, and measure 1–4 mm in diameter after 4–7 days at 30°C. The colonies grow mostly within the agar medium, just under the surface, but many have a slightly raised central portion. One strain (Vinzent strain) was found to produce both this type of colony and a "pinpoint" type of colony, measuring approximately 0.5 mm in diameter and growing primarily on the surface of the agar medium (Breznak and Canale-Parola, 1975).

Surface, anaerobic colonies of *Spirochaeta aurantia* (growth medium, 1% agar) are similar in morphology to the aerobic ones, but are not pigmented. Subsurface anaerobic colonies are white and spherical.

Spirochaeta aurantia may be maintained on slants of growth medium at 5°C. These stock cultures are transferred monthly.

Identification

At present, free-living, anaerobic and facultatively anaerobic, helical bacteria that possess the ultrastructural features typical of spirochetes (e.g., periplasmic flagella and outer sheath) are classified in the genus Spirochaeta. However, phylogenetic analyses have clearly indicated that some species identified as *Spirochaeta* using these criteria—namely, the free-living, obligately anaerobic spirochetes from freshwater environments, *Spirochaeta stenostrepta*, *Spirochaeta zuelzerae* and *Spirochaeta caldaria*—are more closely related to members of the genus *Treponema* than to other members of the genus *Spirochaeta* (see Phylogeny).

Differentiation among the obligately anaerobic species (Table 1, species 1–9; see Taxonomy) may be based, in part, on determinations of carbohydrate fermentation end products. *Spirochaeta stenostrepta*, *Spirochaeta litoralis*, *Spirochaeta isovalerica* and *Spirochaeta bajacaliforniensis* form acetate, ethanol, carbon dioxide (CO_2) and molecular hydrogen (H_2) as major products of glucose fermentation, whereas *Spirochaeta zuelzerae*, *Spirochaeta thermophila* and *Spirochaeta caldaria* produce acetate, lactate, CO_2, H_2, and, in some cases, small amounts of succinate (Aksenova et al., 1992; Canale-Parola, 1984a; Fracek and Stolz, 1985; Pohlschroeder et al., 1994). *Spirochaeta asiatica* produces acetate, ethanol, and lactate, but not H_2, during glucose fermentation (Zhilina et al., 1996). In addition, *Spirochaeta isovalerica* forms small amounts of isovalerate, 2-methylbutyrate and isobutyrate as fermentation end products when growing in media containing L-leucine, L-isoleucine and L-valine, as well as a fermentable carbohydrate (see Physiology; Harwood and Canale-Parola, 1983). *Spirochaeta smaragdinae* is the only species of *Spirochaeta* known to reduce thiosulfate or sulfur (but not sulfate) to H_2S and produces acetate, lactate, CO_2, and H_2S in the presence of thiosulfate and ethanol, lactate, CO_2, and H_2 in its absence (Magot et al., 1997).

Spirochaeta stenostrepta, *Spirochaeta zuelzerae* and *Spirochaeta caldaria* are freshwater anaerobes, whereas *Spirochaeta litoralis*, *Spirochaeta isovalerica*, *Spirochaeta bajacaliforniensis* and *Spirochaeta thermophila* were isolated from seawater environments and have salt requirements typical of marine bacteria (Aksenova et al., 1992; Fracek and Stolz, 1985; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970b; Pohlschroeder et al., 1994). Another anaerobic species, *Spirochaeta asiatica*, was isolated from the sediments of an alkaline lake and requires Na^+ concentrations ranging from 500 to 1,000 mM for optimal growth (Zhilina et al., 1996).

This latter species is also alkaliphilic, and growth does not occur below pH 8. *Spirochaeta smaragdinae*, an obligate anaerobe isolated from a production water sample collected from an offshore oil field, requires at least 170 mM NaCl and grows optimally with 850 mM NaCl (Magot et al., 1997). *Spirochaeta thermophila* and *Spirochaeta caldaria*, both isolated from hot springs, are thermophilic anaerobes with optimum growth temperature of 66–68 and 48–52°C, respectively (Aksenova et al., 1992; Pohlschroeder et al., 1994). Further characteriza-

tion of the obligate anaerobes should take into account interspecific differences in G+C content of the DNA and in cell size (Table 1).

Spirochaeta alkalica and *Spirochaeta africana* (Table 1, species 10 and 11) are aerotolerant species that survive two or three transfers in a glucose-containing medium incubated in air; however, aerobic growth is weak as compared to growth under anaerobic conditions (Zhilina et al., 1996).

These species may be distinguished by their ion requirements. *Spirochaeta africana* requires NaCl for growth, whereas *Spirochaeta alkalica* will grow in media supplemented with equimolar sodium carbonate and bicarbonate (Na_2CO_3 + $NaHCO_3$) in place of NaCl (Zhilina et al., 1996).

Salt requirements constitute an important basis of distinction between the facultative anaerobes *Spirochaeta aurantia* and *Spirochaeta halophila* (Table 1, species 12 and 13). The latter species is halophilic and has an absolute requirement for relatively high concentrations of Na^+, Cl^-, Ca^{++} and Mg^{++} (Greenberg and Canale-Parola, 1976), whereas *Spirochaeta aurantia* strains have been isolated only from freshwater environments and do not exhibit special salt requirements (Breznak and Canale-Parola, 1969; Breznak and Canale-Parola, 1975).

Pigment production is a characteristic of the aerotolerant and facultatively anaerobic species (Table 1, species 10–13). Zhilina et al. (1996) reported that the cell mass of the aerotolerant species *Spirochaeta alkalica* and *Spirochaeta africana* is orange. When growing aerobically, the facultative anaerobes *Spirochaeta halophila* and *Spirochaeta aurantia* produce carotenoid pigments. The major pigment of *Spirochaeta halophila* (strain RS1) is 4-keto-1′,2′-dihydro-1′-hydroxytorulene, whereas *Spirochaeta aurantia* (strain J1) produces mainly 1′, 2′-dihydro-1′-hydroxytorulene (Greenberg and Canale-Parola, 1975). Nonpigmented mutants of *Spirochaeta halophila* (Greenberg and Canale-Parola, 1976) and of *Spirochaeta aurantia* (B. J. Paster and E. Canale-Parola, unpublished data) have been isolated.

Cells of *Spirochaeta aurantia* subspecies *stricta* are more tightly coiled than those of *Spirochaeta aurantia* subspecies *aurantia* (Table 1, footnote c).

Criteria used for the identification of *Spirochaeta plicatilis* (Table 1, species 7) are its large size (Table 1) and its characteristic morphology and motility (Blakemore and Canale-Parola, 1973).

Preservation

Cells of *Spirochaeta* species can be preserved in a viable condition for several years by maintaining them at the temperature of liquid nitrogen. Conventional methods are used to prepare liquid nitrogen stock cultures of spirochetes (Canale-Parola, 1973).

Physiology

Motility and Chemotaxis

Three main types of motion are observed in species of *Spirochaeta*: 1) translational motion; 2) rotation of the cell around its longitudinal axis; and 3) flexing motion (Canale-Parola, 1978). In addition to swimming freely in liquid environments, some *Spirochaeta* are able to "creep" or "crawl" on solid surfaces, a movement resembling that of the gliding bacteria (Blakemore and Canale-Parola, 1973). Species of *Spirochaeta* retain their translational motion in environments of relatively high viscosity, e.g., 500 centipoise (Greenberg and Canale-Parola, 1977c). In comparison, flagellated bacteria, such as *Escherichia coli*, *Pseudomonas aeruginosa* and *Aquaspirillum serpens*, are immobilized at viscosities of or above 60 centipoise (Greenberg and Canale-Parola, 1977b).

The motility of a strain of *Spirochaeta aurantia* in liquid environments has been described as follows (Greenberg and Canale-Parola, 1977a; Greenberg et al., 1985): The spirochete usually swims in nearly straight lines (runs) and appears to spin about its longitudinal axis as it progresses through the liquid. From time to time the cell reverses swimming direction, the anterior end of the cell becoming the posterior end. Occasionally, the spirochete stops running, flexes, and then resumes its translational motion. However, upon resuming its translational motion, the spirochete usually alters the direction of its movement, and the previously leading cell end may or may not become the trailing cell end. Thus, *Spirochaeta aurantia* performs three kinds of behavior (runs, flexes, and reversals), in contrast to *Escherichia coli*, which performs two kinds (runs and tumbles). During runs, *Spirochaeta aurantia* cells have an average linear speed of approximately 16 μm/s (Fosnaugh and Greenberg, 1988). Flexes last from a fraction of a second to several seconds. The average frequency of reversals in cell populations is approximately 0.31 reversals/5 s (Fosnaugh and Greenberg, 1988).

A model that interprets the motile behavior of *Spirochaeta aurantia* has been proposed (Berg, 1976; Greenberg et al., 1985). According to this model, the two periplasmic flagella of *Spirochaeta aurantia* rotate, each driven by a motor at the insertion end. Rotation of the flagella in one direction (looking at the cell head on; see Fig. 13B, Introduction) causes the periplasmic cylin-

der and the outer membrane to move in directions opposite to each other. Owing to its helical shape, the cell rotates about its longitudinal axis and moves along it. Runs occur when the flagellar motor at one cell end rotates clockwise (CW) while the motor at the other cell end rotates counterclockwise (CCW). When both motors switch direction of rotation at the same time, a reversal takes place. A flex is generated during asynchronous switching, i.e., when only one motor switches direction so that both motors are rotating CW or CCW. Asynchronous switching causes the cell ends to twist in opposition to each other, and a flex occurs.

Spirochaeta aurantia exhibits chemotaxis toward D-glucose, D-xylose, cellobiose, and various other sugars, but not toward amino acids (Greenberg and Canale-Parola, 1977a). Many of the chemoattractants also serve as carbon and energy sources for growth of *Spirochaeta aurantia*. *Spirochaeta aurantia* cells grown in a chemostat at very low concentrations of an attractant that serves as a carbon and energy source exhibit an enhanced chemotactic response toward that attractant and are able to sense concentrations of the attractant much lower than those sensed by cells grown in the presence of excess attractant (Terracciano and Canale-Parola, 1984). Most likely, the ability to regulate its chemosensory system provides *Spirochaeta aurantia* with competitive advantages in natural environments deficient in nutrients.

Fosnaugh and Greenberg (1988) carried out an analysis of the motility and chemotaxis behavior of *Spirochaeta aurantia*. They observed that a population of *Spirochaeta aurantia* cells spent, on average, 66% of the time swimming smoothly (runs), 33% of the time flexing, and 1% of the time in reversals. After addition of an attractant (D-xylose, 10 mM final concentration), there was an increase in smooth swimming, a decrease in flexing, and a complete suppression of reversals. From 1.5 to 2 min after addition of the attractant, the population resumed its unmodified behavior. On the basis of their observations and of the above-mentioned motility model for *Spirochaeta aurantia*, Fosnaugh and Greenberg (1988) postulated that a mechanism for communication between the two flagellar motors is present in this spirochete and that a motor-switch-synchronizing device is also operating.

Fermentation Products and ATP-Yielding Pathways

Under anaerobic conditions, several species of *Spirochaeta* that have been cultured (Table 1, see Taxonomy) ferment carbohydrates with formation of acetate, ethanol, CO_2, and H_2 as major end products (Canale-Parola, 1984a; Fracek and Stolz, 1985; Harwood and Canale-Parola, 1983). *Spirochaeta zuelzerae*, *Spirochaeta thermophila* and *Spirochaeta caldaria* produce acetate, lactate, CO_2 and H_2 from carbohydrates (Aksenova et al., 1992; Canale-Parola, 1984a; Pohlschroeder et al., 1994), and *Spirochaeta zuelzerae* also produces small amounts of succinate (Canale-Parola, 1977; Canale-Parola, 1984a; Veldkamp, 1960). *Spirochaeta alkalica* and *Spirochaeta africana* produce acetate, ethanol, lactate and H_2, and *Spirochaeta asiatica* produces acetate, ethanol and lactate, but not H_2, during glucose fermentation (Zhilina et al., 1996). *Spirochaeta smaragdinae* is the only species of *Spirochaeta* that has been shown to reduce thiosulfate and sulfur to H_2S, producing acetate, lactate, CO_2 and H_2S in the presence of thiosulfate and producing ethanol, lactate, CO_2 and H_2 in its absence (Magot et al., 1997).

Spirochaeta isovalerica (Table 1) ferments (in addition to carbohydrates) L-leucine, L-isoleucine and L-valine, forming isovaleric, 2-methylbutyric and isobutyric acids, respectively, as end products (Harwood and Canale-Parola, 1983). However, *Spirochaeta isovalerica* requires a fermentable carbohydrate for growth. When *Spirochaeta isovalerica* is grown in medium containing both glucose and the three above-mentioned amino acids, only a relatively small fraction of the total amount of available amino acids is fermented (Harwood and Canale-Parola, 1981a; Harwood and Canale-Parola, 1981b). Under these growth conditions, the ATP derived from amino acid catabolism is estimated to be 4 to 5% of the total ATP formed. Fermentation of the amino acids in the absence of glucose does not support measurable growth of *Spirochaeta isovalerica*, but serves to generate ATP, which is utilized as a source of maintenance energy by the spirochete when fermentable carbohydrates are not available (Harwood and Canale-Parola, 1981a; Harwood and Canale-Parola, 1983). In addition to the branched-chain fatty acids, amino acid catabolism by *Spirochaeta isovalerica* yields small quantities of isobutanol and isoamyl alcohol (Harwood and Canale-Parola, 1981b; 1983).

All *Spirochaeta* species whose metabolic pathways have been studied (species 1, 2, 4, 6, 12 and 13 in Table 1; see Taxonomy) catabolize glucose to pyruvate via the Embden-Meyerhof pathway (Aksenova et al., 1992; Canale-Parola, 1984a; Harwood and Canale-Parola, 1983). Anaerobic metabolism of pyruvate yields acetyl-CoA, CO_2 and H_2 via a clostridial-type clastic reaction (Canale-Parola, 1977; Greenberg and Canale-Parola, 1976). Acetate is formed from acetyl CoA in reactions catalyzed by phosphotransacetylase and acetate kinase. A double reduction involving aldehyde and alcohol dehydrogenases

is responsible for ethanol production from acetyl CoA (Canale-Parola, 1977).

When growing aerobically, the two facultatively aerobic species (*Spirochaeta aurantia* and *Spirochaeta halophila*) oxidize glucose incompletely, with formation of CO_2 and acetate as major end products. Aerobically, both oxidative phosphorylation and substrate-level phosphorylation are utilized by the two species to generate ATP (Breznak and Canale-Parola, 1972b; Greenberg and Canale-Parola, 1976). The tricarboxylic acid cycle either is absent or plays a minor catabolic role in these two species.

Rubredoxin was detected in cell extracts of the obligate anaerobes *Spirochaeta stenostrepta* and *Spirochaeta litoralis* and of the facultative anaerobe *Spirochaeta aurantia* (Breznak and Canale-Parola, 1972a; Hespell and Canale-Parola, 1973; Johnson and Canale-Parola, 1973). Rubredoxin was isolated from extracts of both aerobically and anaerobically grown cells of *Spirochaeta aurantia*. Ferredoxin was present in cell extracts of anaerobically grown *Spirochaeta aurantia*, but was not found in aerobically grown cells of this bacterium (Johnson and Canale-Parola, 1973).

Ecology

Species of *Spirochaeta* are free-living bacteria indigenous to a variety of aquatic environments, such as the water, sediments and muds of ponds, marshes, lakes, rivers and oceans (Canale-Parola, 1984a). In these environments, *Spirochaeta* cells display a wide range of motility behaviors. When *Spirochaeta* cells swim through liquid environments, they may perform rotatory, locomotory and flexing movements (Canale-Parola, 1978). Also, spirochetes may move through environments of viscosity high enough to impede the progress of most flagellated bacteria (Harwood and Canale-Parola, 1984). Moreover, some *Spirochaeta* are able to move on solid surfaces by "creeping" or "crawling," a movement resembling that of the gliding bacteria (Blakemore and Canale-Parola, 1973). Complex physiological and behavioral adaptations, many of which involve one or more types of spirochaetal motility behavior, enable *Spirochaeta* species to persist in their environments and to compete successfully with other organisms for available nutrients (Harwood and Canale-Parola, 1984).

All species of *Spirochaeta* that have been cultivated are saccharolytic, and they usually lack the ability to utilize compounds other than carbohydrates as oxidizable substrates for growth. Various pentoses, hexoses, disaccharides and polysaccharides, such as starch, are used as carbon and energy sources (Aksenova et al., 1992; Canale-Parola, 1984a; Fracek and Stolz, 1985; Greenberg and Canale-Parola, 1976; Magot et al., 1997; Pohlschroeder et al., 1994; Zhilina et al., 1996). Even though free-living spirochetes are commonly observed in natural anaerobic environments in which plant material, containing cellulose and hemicelluloses, is biodegraded (Canale-Parola, 1978; Harwood and Canale-Parola, 1984; Leschine, 1995), only *Spirochaeta thermophila* has been reported to ferment cellulose and xylan (Aksenova et al., 1992). It may be inferred that, in their habitats, which frequently are rich in decaying plant material, *Spirochaeta* species usually ferment soluble sugars released into the environment by the enzymatic activities of other microorganisms that depolymerize plant polysaccharides. Pohlschroeder et al. (1994) reported that *Spirochaeta caldaria*, a thermophilic spirochete from a freshwater hot spring, forms stable, cellulose-degrading cocultures with the cellulolytic bacterium, *Clostridium thermocellum*. Cellulose is degraded more rapidly in cocultures than in monocultures of *Clostridium thermocellum*, suggesting that species of *Spirochaeta* may enhance cellulose breakdown in natural environments (Leschine, 1995).

Both facultatively and obligately anaerobic species of *Spirochaeta* grow abundantly when the energy source available to them is cellobiose, a major product of cellulose depolymerization, which is produced by the extracellular cellulase systems of some microorganisms (Breznak and Canale-Parola, 1969; Breznak and Canale-Parola, 1975; Greenberg and Canale-Parola, 1976; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970a; Hespell and Canale-Parola, 1970b; Leschine, 1995; Pohlschroeder et al., 1994). Furthermore, free-living spirochetes, such as *Spirochaeta aurantia*, exhibit a strong tactic response toward very low cellobiose concentrations (Greenberg and Canale-Parola, 1977a) and possess regulatory systems that enable them to enhance their chemotactic responses when attractants that serve as energy sources are present at very low concentrations in the environment (Terracciano and Canale-Parola, 1984). Inasmuch as cellobiose levels in environments in which cellulose is degraded are likely to be quite low (Smith et al., 1973), a strong tactic response to very low concentrations of cellobiose may confer an important selective advantage on the spirochetes among cellobiose-utilizing microorganisms.

In addition to their ability to regulate their chemosensory apparatus in response to low substrate concentrations, some species of *Spirochaeta* have developed other strategies to survive in environments lacking or nearly depleted of energy sources. One of these survival strategies

has been studied in *Spirochaeta isovalerica*, a saccharolytic anaerobe that does not utilize amino acids as fermentable substrates for growth, but catabolizes small amounts of L-leucine, L-isoleucine and L-valine with the formation of isovalerate, 2-methylbutyrate and isobutyrate, respectively, as end products (Harwood and Canale-Parola, 1981b; Harwood and Canale-Parola, 1983; Harwood and Canale-Parola, 1984). Although these amino acids are not used by *Spirochaeta isovalerica* as fermentable substrates for growth, their fermentation serves to generate ATP, which is utilized by the spirochetes as a source of maintenance energy. This process allows cells to survive during periods of growth substrate starvation (Harwood and Canale-Parola, 1981a; Harwood and Canale-Parola, 1981b; Harwood and Canale-Parola, 1982a). Other starvation-survival strategies utilized by *Spirochaeta* species may involve ATP generation through metabolism of endogenous RNA (Canale-Parola and Kidder, 1982; Harwood and Canale-Parola, 1984) or metabolism of intracellular polyglucose storage granules (Kropinski et al., 1988).

The large spirochete, *Spirochaeta plicatilis*, has been observed within masses of *Beggiatoa* trichomes in samples of black, sulfide-rich marsh mud covered with a layer of marsh water (Blakemore and Canale-Parola, 1973). In this study, the spirochetes were seen to swim freely among the tangled *Beggiatoa* trichomes, and they crept on or otherwise moved in contact with the surface of the trichomes. The close association with *Beggiatoa* suggested a chemotactic response by the large spirochete toward metabolites produced by the sulfur bacteria. As the level of sulfide generated by biological activities in the mud became low, gradual lysis of the *Beggiatoa* trichomes was observed. This lytic process coincided with a dramatic increase in the number of large spirochetes (Blakemore and Canale-Parola, 1973). Possibly, substances released by the lysing *Beggiatoa* were used as growth substrates for *Spirochaeta plicatilis*.

Applications

Thus far, few applications have been suggested for species of *Spirochaeta*. Pohlschroeder et al. (1994) reported that cellulose degradation by *Clostridium thermocellum* is enhanced in the presence of *Spirochaeta caldaria*, a thermophilic spirochete from a freshwater hot spring. Possibly, species of *Spirochaeta* might be employed in processes for the direct bioconversion of cellulose-containing wastes to fuels such as H_2 or ethanol.

CHAPTER 4.2

The Genus *Treponema*

STEVEN J. NORRIS, BRUCE J. PASTER, ANNETTE MOTER AND ULF B. GÖBEL

Introduction and Habitats

The genus *Treponema* (phylum Spirochaetes, order Spirochetales, family Spirochaetaceae) is composed of both pathogenic and nonpathogenic species indigenous to humans and animals. They are helical, tightly coiled, motile bacteria, ranging from 5–20 μm in length and 0.1–0.4 μm in diameter, and are best observed by dark-field microscopy (Fig. 1). The organisms stain poorly with the usual aniline dyes; however, those that are capable of aniline-dye uptake are Gram-negative. Staining can best be accomplished by the use of silver impregnation or immunofluorescent methods. The sequence of the genome of *Treponema pallidum* subsp. *pallidum*, the type species of the genus, was determined in 1998 (Fraser et al., 1998), and the sequence of the *Treponema denticola* genome is nearly completed. Information based on these genome sequences has been incorporated into sections of this chapter.

Several topics covered in this chapter have been reviewed previously, including procedures for propagation of pathogenic treponemes in laboratory animals (Turner and Hollander, 1957; Miller, 1971), clinical aspects and diagnosis of treponemal infections (United States Public Health Service, 1968; Larsen, et al., 1998, 1999), the endemic treponematoses (Antal et al., 2002), the phylogeny of spirochetes (Paster and Dewhirst, 2000), *T. pallidum* pathogenesis and immunology (Norris, 1988a; Radolf, 1994; Blanco et al., 1997; Radolf et al., 1999), and the biology and in vitro culture of *T. pallidum* (Cox, 1994; Norris et al., 2001). In addition, a book focused on current topics in spirochete biology was published in 2001 (Saier and Garcia-Lara, 2001). Portions of this chapter were modified from the previous version by Miller, Smibert, and Norris (Miller et al., 1990). The reader is referred to these previous reviews where they are applicable, and individual articles are cited where they are particularly pertinent.

The known frank pathogens of the genus *Treponema* are virtually identical organisms that are obligate parasites of humans or (in the case of one species) rabbits (Table 1). These organisms are morphologically indistinguishable and share extensive DNA homology and proteome similarity; in addition, they have not been cultured continuously in vitro. The four human pathogens and the diseases they cause are: *Treponema pallidum* subsp. *pallidum* (syphilis), *Treponema pallidum* subsp. *pertenue* (yaws), *Treponema pallidum* subsp. *endemicum* (nonvenereal endemic syphilis), and *Treponema carateum* (pinta). The reclassification of *T. pertenue* and *T. endemicum* as subspecies of *T. pallidum* (Smibert, 1984a) is supported by >95% DNA homology by hybridization (Fieldsteel, 1983) and the virtual identity of known sequences from this group of organisms. *Treponema carateum* cannot be propagated in small laboratory animals or in culture and is still classified separately owing to the lack of genetic information. *Treponema paraluiscuniculi* (venereal rabbit spirochetosis) is the only treponeme that has been established unequivocally as an animal pathogen (Bayon, 1913) and is also closely related to the *T. pallidum* subspecies (Baker-Zander and Lukehart, 1984; Centurion-Lara et al., 1997). Limited multiplication of *Treponema pallidum* subsp. *pallidum* has been accomplished in a tissue culture monolayer system (Cox, 1994).

The largest group of *Treponema* species identified thus far consists of oral spirochetes (Table 2). These include nine classified species and a large number of unnamed genospecies that have been identified by polymerase chain reaction (PCR) amplification of 16S rRNA sequences of gingival crevice specimens from patients with periodontal disease (Dewhirst et al., 2000). Periodontal disease is an important dental problem, resulting in inflammation of the gingival tissue, bone resorption, and tooth loss. A high proportion of oral treponemes are found in the flora of specimens from patients with acute necrotizing ulcerative gingivitis and other forms of periodontal disease, providing a strong association between these organisms and the disease process. In addition, oral *Treponema* species have

Table 1. Characteristics of pathogenic *Treponema* species.

Organism	Disease	Distribution	Predominant age of onset	Transmission	Congenital infection
T. pallidum subsp. *pallidum*	Venereal syphilis	Worldwide	Adolescents and adults	Sexual contact	Yes
T. pallidum subsp. *pertenue*	Yaws (frambesia, pian)	Tropical areas, Africa, South America, Caribbean, Indonesia	Children	Skin contact	No
T. pallidum subsp. *endemicum*	Endemic syphilis (bejel, dichuchwa)	Arid areas, Africa, Middle East	Children, adolescents and adults	Mucous membrane	Rarely
T. carateum	Pinta (carate, cute)	Semi-arid, warm areas, Central and South America	Children and adolescents	Skin contact	No
T. paraluis-cuniculi	Venereal spirochetosis of rabbits	Not applicable	Not applicable	Sexual contact	No

From Antal et al. (2002) and Larsen et al. (1999).

Fig. 1. Appearance of *Treponema pallidum* subsp. *pallidum* Nichols by darkfield microscopy.

been implicated in endodontic (tooth root) infection (Newman, 1984; Dahle et al., 1993a; Dahle et al., 1993b; Jung et al., 2000; Rupf et al., 2000; Siqueira et al., 2000a; Siqueira et al., 2000b; Sunde et al., 2000; Rocas et al., 2001) and atherosclerosis (Okuda et al., 2001), although additional studies are needed to determine whether the spirochetes play a causal role in these conditions. A recent report provides evidence against a previously proposed association between periodontal disease and diabetes (Yuan et al., 2001).

Skin-associated commensal spirochetes include *Treponema phagedenis*, *Treponema refringens*, and *Treponema minutum*. These organisms colonize smegma (desquamated epithelial cells and secretions) under the prepuce and other skin folds of the genitalia of humans, chimpanzees, and other animals. These skin-associated *Treponema*, some of which were initially thought to be avirulent forms of *T. pallidum* subsp. *pallidum*, are morphologically and genetically distinct from *T. pallidum* (Miao and Fieldsteel, 1978; Fieldsteel, 1983; Smibert, 1984a) and are not known to cause disease.

Recently, the anaerobic spirochetes that colonize termite guts were shown on the basis of 16S rRNA homology to be related to the genus *Treponema* (Paster et al., 1996; Lilburn et al., 1999). These organisms, which have not been classified as yet, are the subject of the chapter Termite Gut Spirochetes in this Volume.

Some organisms of the genus *Brachyspira*, including *B. hyodysenteriae* and *B. innocens*, were initially characterized as *Treponema* species; however, these intestinal spirochetes were reclassified, first as *Serpulina* then as *Brachyspira* (Ochiai et al., 1997), on the basis of dissimilar DNA homology and %G+C with *Treponema* species, as well as relatedness to *Brachyspira aalborgii* (Hovind-Hougen et al., 1982). The genus Brachyspira in this Volume is described in another chapter.

Well-defined, cultivable species of treponemes have been found in the oral cavity, intestinal tract, and/or genitalia of chimpanzees, pigs and dogs, as well as in the rumen of cattle (Pindak et al., 1965; Socransky et al., 1969; Zymet, 1969; Hanson, 1970; Leach et al., 1973; Holdemann et al., 1977; Cwyk and Canale-Parola, 1979; Stanton and Canale-Parola, 1979; Wojciechowicz and Ziolecki, 1979; Ziolecki, 1979; Stanton and Canale-Parola, 1980; Ziolecki and Wojciechowicz, 1980; Paster and Canale-Parola, 1982; Paster and Canale-Parola, 1985). In addition, spirochetes resembling treponemes have been observed in the intestinal tract of horses, mice, rats, guinea pigs, opossums, insects and termites and in the tissues of brine shrimp (Osborne and Bain, 1961; Breznak, 1973; McLeod et al., 1977;

Table 2. Other *Treponema* species associated with mammalian hosts.

Lee and Philips, 1978). Although many of these anaerobic and putative microaerophilic host-associated treponemes have been cultured in vitro and subsequently characterized, microscopic and PCR analyses of animal and human tissues, exudates, and normal flora suggest that other species have yet to be isolated (Dewhirst et al., 2000). Whether these spirochetes, alone or in combination with other organisms, can be implicated as the cause of oral, genital, or gastrointestinal disease remains uncertain.

In humans, as in animals, treponemes are found as part of the normal oral, intestinal, and genital flora (Parr, 1923; Rosebury and Foley, 1941; Shera, 1962; Hanson and Cannefax, 1964; Harland and Lee, 1967; Lee et al., 1971; Takeuchi et al., 1974; Ruane et al., 1989). Most of the organisms associated with human intestinal spirochetosis are *Brachyspira* species (Duhamel, 2001), although *Treponema* species are part of the normal flora of the human gastrointestinal tract (Table 2). *Treponema* is the predominant genus of spirochetes in the oral cavity. Although these organisms are part of the normal flora in the gingival crevices, *Treponema* are more prevalent in persons with periodontal disease and gingivitis than in people with a healthy gingiva (Moore and Moore, 1994; Moter et al., 1998b; Dewhirst et al., 2000). It is estimated that approximately 80 different phylotypes of *Treponema* are present in the oral cavity, only 10 of which have been speciated (Dewhirst et al., 2000).

Phylogeny/Taxonomy

On the basis of comparative analysis of 16S rRNA gene sequences, members of the genus *Treponema* form one of the nine phylogenetic clusters (genera) of spirochetes (Fig. 2). According to the most recent taxonomic outline of the prokaryotic genera in *Bergeys Manual of Systematic Bacteriology*, 2nd edition (Garrity, 2001), all spirochetes are classified in the phylum Spirochaetes in the order Spirochetales and are divided into three families. The first family, Spirochaetaceae, contains species of the genera *Borrelia*, *Brevinema*, *Cristispira*, *Spirochaeta*, "*Spironema*," and *Treponema*. Other spirochaetal genera, such as *Pillotina*, *Clevelandina*, *Hollandina* and *Diplocalyx*, are included in this family, but 16S rRNA sequences of these not-yet-cultivated species from the termite hindgut are not available to determine their true phylogenetic position. The second proposed family, "Serpulinaceae," or "Brachyspiraceae," contains the species of the genus *Brachyspira* (*Serpulina*). The third family, Leptospiraceae, contains free-living or pathogenic species of the genera *Leptonema* and *Leptospira*.

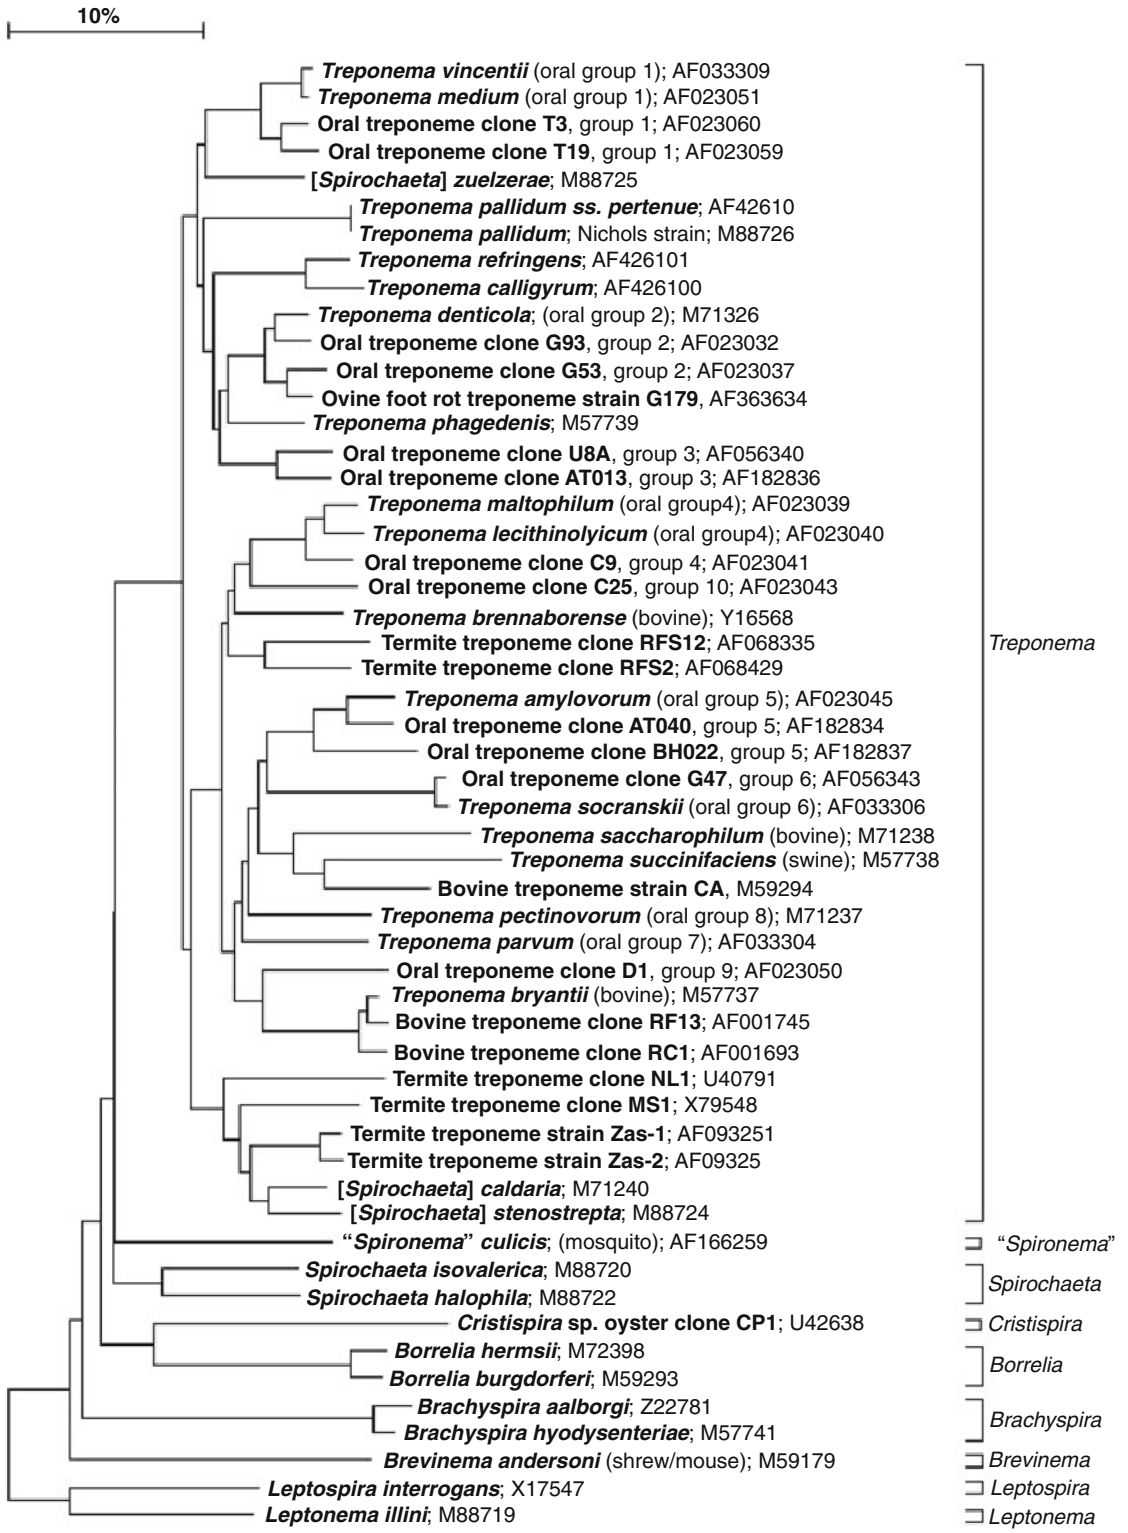

Fig. 2. Phylogeny based on 16S rRNA gene sequence comparisons of members of the genus *Treponema*. The phylogenetic position of known species and phylotypes of *Treponema* is shown relative to other genera of spirochetes. GenBank accession numbers for the 16S rRNA sequences of the species tested are shown. Previously unpublished 16S rRNA gene sequences of *T. refringens*, *T. calligyrum* and *T. pallidum* subsp. *pertenue* are reported here for the first time. Similarity matrices were corrected for multiple base changes by the method of Jukes and Cantor (1969). The neighbor-joining method (Saitou and Nei, 1987) was used for phylogenetic tree construction. TREECON, a software package for the Microsoft Windows environment, was used for the construction and drawing of evolutionary trees (Van de Peer and De Wachter, 1994). The scale bar represents a 10% difference in nucleotide sequence determined by taking the sum of all of the horizontal lines connecting two species. Vertical distance has no meaning.

Members of the genus *Treponema* and three species of the free-living *Spirochaeta*, namely *S. stenostrepta*, *S. zuelzerae* and *S. caldaria*, form a coherent phylogenetic cluster, referred to as the treponemes (Fig. 2). In addition to known species of *Treponema*, novel phylotypes, i.e., species that have not yet been cultivated in vitro, have been identified by analysis of 16S rRNA genes of DNA isolated from host-associated sources, such as the human oral cavity (Choi et al., 1994; Dewhirst et al., 2000; Paster et al., 2001), the hindgut of the termite (Lilburn et al., 1999), and the bovine rumen (Tajima et al., 1999). Representatives of each of these phylotypes are included in Fig. 2. In the human oral cavity, the diversity of treponemes is extensive. There are approximately 60 oral species of *Treponema*, of which 50 are presently represented only as phylotypes (see expanded phylogenetic trees in Dewhirst et al. [2000] and Paster et al. [2001]). These oral treponemes have been divided into 10 phylogenetic groups (Dewhirst et al., 2000; Paster et al., 2001). An equally impressive diversity of treponemes has been observed in the termite hindgut (Lilburn et al., 1999; Ohkuma et al., 1999) and is described in detail in a separate chapter.

Three species of the free-living *Spirochaeta*, namely *S. stenostrepta*, *S. zuelzerae* and *S. caldaria*, fall within the *Treponema* cluster rather than within the cluster of other free-living *Spirochaeta* (Fig. 2). The phylogenetic clustering of these species has been confirmed by single-base signature analysis, i.e., the sequences of these species possess more characteristic bases found in the sequences of the treponemes than in the sequences of *Spirochaeta* species (Paster et al., 1991). It has been speculated that these free-living spirochetes might represent transitional species, i.e., descendants of the precursors to host-associated treponemes (Paster et al., 1991). However, it is possible that these species may have originated from the host and were disseminated via fecal contamination.

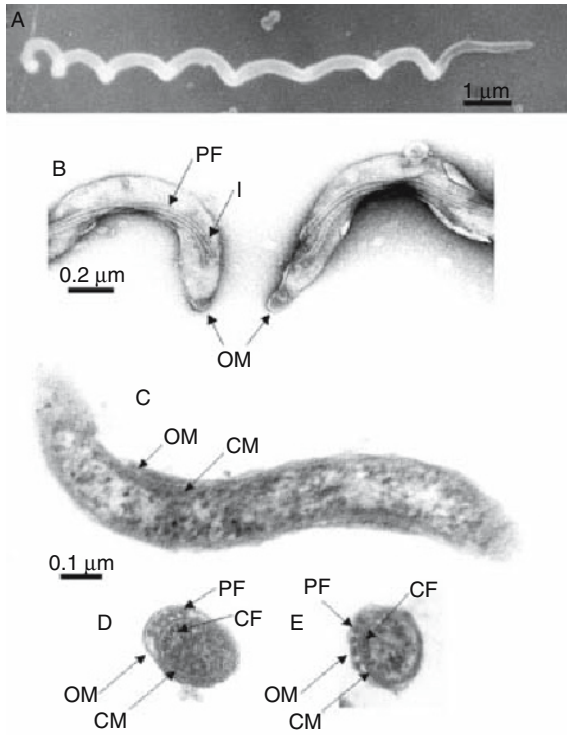

Fig. 3. Ultrastructure of *Treponema pallidum* subsp. *pallidum* Nichols. A) Scanning electron micrograph of an intact spirochete. B) Negatively stained, intact organisms examined by transmission electron microscopy, showing the periplasmic flagella (PF) and the flagellar insertion points near the end of the cell (I). The outer membrane can be seen extruding from the ends of the cells. C-E) Transmission electron microscopy of ultrathin longitudinal and cross sections. The locations of the PF, cytoplasmic membrane (CM), outer membrane (OM), and cytoplasmic filaments (CF) are indicated by arrows. The PF are located in the periplasmic space and extend from the ends of the cell toward the middle. The CF are ribbon-like structures (composed of an 80-kDa protein) found only in *Treponema* or related spirochetes (e.g., *Spirochaeta zuelzerae*) and run parallel to the PF in the cytoplasm of the cell; they are seen here in cross-section.

Morphology and Structure-Function Relationships

Selected General Characteristics

Treponemes, like all spirochetes, are composed of an outer membrane (OM) that delimits the outer cellular surface of the organisms, a cytoplasmic membrane (CM) that encloses the protoplasmic cylinder, and flagella that lie in between the two membranes (Johnson et al., 1973; Hovind-Hougen, 1976; Canale-Parola, 1977; Holt, 1978; Hovind-Hougen, 1983; Walker et al., 1989; Fig. 3). Unlike the flagella of members of other bacterial genera, spirochetal flagellar organelles lie entirely within the periplasmic space between the inner membrane (IM) and CM and are commonly referred to as periplasmic flagella (PF); other names for PF are endoflagella and axial filaments. The PF attach at either pole of the organism through basal body structures and wrap around the helical protoplasmic cylinder (Hovind-Hougen, 1976; Canale-Parola, 1977; Holt, 1978). The number of PF and the wavelength of the helix differ among members of this diverse group of organisms. *Treponema pallidum* and several other treponemes have been shown to possess cytoplasmic filaments, thin filaments which run the length of the organism just under the cytoplasmic membrane

(Hovind-Hougen and Birch-Andersen, 1971; Eipert and Black, 1979; Hovind-Hougen, 1983; You et al., 1996; Izard et al., 1999).

Outer Membrane Structure

The OM of *Treponema pallidum* subsp. *pallidum* and *pertenue* differs significantly from that of other organisms in its strikingly low number of intramembranous membrane particles when examined by freeze fracture microscopy (Radolf et al., 1989; Walker et al., 1989; Walker et al., 1991). In contrast, the free-living *Spirochaeta aurantia* has a number of OM intramembranous particles similar to that of *Escherichia coli*, and *T. phagedenis* Reiter and *T. denticola* have intermediate quantities (Radolf et al., 1989; Walker et al., 1989). This observation indicates a relatively low abundance of integral membrane proteins in the OM of *T. pallidum*.

Concerted efforts to identify the OM proteins of *T. pallidum* have been inconclusive. Treponemal rare outer-membrane proteins (TROMP) 1 and 2 were identified on the basis of their presence in preparations enriched for OM by Blanco et al. (1994). TROMP1 has been characterized as an OM porin that forms a trimeric structure (Blanco et al., 1995; Blanco et al., 1996; Blanco et al., 1997; Blanco et al., 1999; Zhang et al., 1999). However, sequence analysis and three dimensional structure determinations indicate that this protein (also called TroA) is the periplasmic protein of an ATP-binding cassette (ABC) transporter involved in Zn^{++} transport (Hardham et al., 1997; Lee et al., 1999; Lee et al., 2002). TROMP2 has sequence similarity to the *T. pallidum* flagellar sheath protein FlaA, but the recombinant form is associated with the OM of *E. coli* following heterologous expression (Champion et al., 1997). Other proteins, including glycerophosphodiester phosphodiesterase (GlpQ) and the *T. pallidum* repeat (Tpr) protein, TprK, have been identified as OM protein candidates, but have yielded conflicting data (Shevchenko et al., 1997; Shevchenko et al., 1999; Cameron et al., 1998; Centurion-Lara et al., 1999; Hazlett et al., 2001). It has been hypothesized that the relatively low abundance of OM proteins in *T. pallidum* may provide an antigenically inert surface and thus promote evasion of the immune response (Penn et al., 1985b; Stamm et al., 1987; Radolf, 1994; Blanco et al., 1997).

Another difference between the OMs of Gram-negative bacteria and *T. pallidum* is the apparent lack of lipopolysaccharide (LPS) in *T. pallidum* subsp. *pallidum* (Penn et al., 1985a; Radolf and Norgard, 1988a). Both *T. phagedenis* and *T. denticola* have been shown to contain material extractable with phenol-chloroform that has properties similar to those of LPS (Cockayne et al., 1989; Yotis et al., 1995; Dahle et al., 1996; Schultz et al., 1998). A recent analysis of phenol/water extracts from *T. maltophilum* and *T. brennaborense* cells revealed novel glycolipids consisting of a diacylglycerol-lipid anchor, a core region, and carbohydrate repeating units that interact with LPS-binding protein (LBP), CD14, and toll-like receptors TLR2 or TLR4, respectively (Schröder et al., 2000).

Subsurface Structures

Treponemal subsurface structures are defined as those molecules that lie beneath the OM. The most prominent structures are the PF, which mediate the striking translational and axial motility common to all spirochetes (Charon et al., 1992; Li et al., 2000). Members of the genus *Treponema* contain two to nine PF inserted into each end of the cell (Smibert, 1984a). An unusual feature of treponemal PF is that they are composed of multiple polypeptide subunits, as reviewed previously (Norris and Treponema pallidum Polypeptide Research Group, 1993; Li et al., 2000). Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis has shown that *Treponema pallidum* subsp. *pallidum* PF is composed of at least four polypeptides with molecular weights of 37, 34.5, 33, and 31 kDa, while the PF of *Treponema phagedenis* biotypes Reiter and Kazan 5 are made up of four polypeptides with similar molecular weights (Sand-Peterson et al., 1981; Limberger and Charon, 1986; Radolf et al., 1986; Blanco et al., 1988; Norris et al., 1988b). FlaB1 (34.5 kDa), FlaB2 (33 kDa), and FlaB3 (31 kDa) are closely related to one another and to the flagellins of other bacteria (Pallesen and Hindersson, 1989; Champion et al., 1990) and comprise the central core of the flagella (Cockayne et al., 1987). Interestingly, the predicted products of the three encoding genes are all ~31,000 Da; the differences in electrophoretic mobility may be due to glycosylation (Norris and Treponema pallidum Polypeptide Research Group, 1993; Wyss, 1998). FlaA forms a sheath on the outer surface of the flagellar shaft and is expressed as a precursor protein with a signal sequence (Cockayne et al., 1987; Isaacs et al., 1989; Isaacs and Radolf, 1990). The flagella of the other members of the genus *Treponema* examined thus far have a similar protein content and structure (Limberger and Charon, 1986; Norris et al., 1988b; Ruby et al., 1997).

Additional motility-related operons encoding basal body and accessory proteins have been characterized in *T. pallidum* (Limberger et al., 1996; Fraser et al., 1998), *T. denticola* (Heinzerling et al., 1997; Stamm and Bergen, 1999; Stamm

and Bergen, 2001), and *T. phagedenis* (Limberger et al., 1996). These loci are highly conserved relative to the motility operons of Gram-positive and Gram-negative bacteria.

In addition to the proteins that make up the PF subunit structures, several antigenic polypeptides from *Treponema pallidum* subsp. *pallidum* and *pertenue*, ranging in molecular weights from 12 to 190 kDa, have been identified by immunoprecipitation, crossed immunoelectrophoresis, and western blot analysis (reviewed by Norris et al. [1987] and Norris and the Treponema pallidum Polypeptide Research Group [1993]). Characterization of *Treponema pallidum* subsp. *pallidum* by two-dimensional electrophoresis has revealed at least 78 antigenic polypeptides (Norris and Sell, 1984; Norris et al., 1987; Norris and Treponema pallidum Polypeptide Research Group, 1993). Phase partitioning with the nonionic detergent Triton X-114 has resulted in identification of several *Treponema pallidum* subsp. *pallidum* antigenic polypeptides in the hydrophobic phase with molecular weights of 14–57 kDa (Cunningham et al., 1988; Radolf et al., 1988b; Norris and Treponema pallidum Polypeptide Research Group, 1993). The majority of these antigens are, in fact, lipoproteins, which anchor to the CM or OM by means of their covalently attached fatty acids (Chamberlain et al., 1989a; Chamberlain et al., 1989b; Swancutt et al., 1990). Three of these lipoproteins, the pathogen-specific 47-, 34-, and 15-kDa antigens (Radolf and Norgard, 1988a), stimulate immobilizing antibody (47 and 34 kDa), treponemicidal antibody (47 kDa), and lymphocyte proliferative responses (15 kDa; Robertson et al., 1982; Jones et al., 1984; Baker-Zander et al., 1988). Immunofluorescent studies indicate that the major lipoproteins are anchored to the outer leaflet of the CM, and little if any of these antigens is expressed on the OM surface (Cox et al., 1995). Many genes expressing *T. pallidum* subsp. *pallidum* antigens were cloned, expressed in *E. coli* and sequenced in the late 1900s (reviewed by Norris and the Treponema pallidum Polypeptide Research Group, 1993), and several of these have been identified as useful serodiagnostic antigens (Larsen et al., 1999).

Masuda and Kawata (1989) initially isolated and characterized the cytoplasmic filaments (CF) of *T. phagedenis* and other treponemes; they found that these structures were comprised of a single major 80-kDa polypeptide. The genes encoding the 80-kDa subunit called "CfpA" of *T. pallidum* subsp. *pallidum* and *pertenue*, *T. phagedenis*, *T. denticola* and *T. vincentii* have since been cloned and characterized (You et al., 1996; Izard et al., 1999). Izard et al. (2001) constructed a targeted disruption mutant of *cfpA* in *T. denticola*, which resulted in loss of the cytoplasmic filaments. They found that the mutation had pleiotropic effects, including an abnormal condensation of chromosomal DNA and incomplete cell division. These effects suggest that the cytoplasmic filaments are involved in DNA segregation and/or cell division (Izard et al., 2001).

The major 60-kDa polypeptide of *Treponema pallidum* subsp. *pallidum* has been shown to be the subunit of a multimeric protein homologous to the *groEL* chaperonin protein of *E. coli* (Houston et al., 1990). These chaperonins are found in all prokaryotes and eukaryotes and apparently are involved in protein folding and assembly. Similar proteins exist in the other treponemes.

Isolation, Identification, and Characterization

Human Treponemal Pathogens

Methods of Isolation and Cultivation Limited multiplication of *Treponema pallidum* subsp. *pallidum* has been obtained in a tissue culture system (Fieldsteel et al., 1981), as reviewed previously (Cox, 1994; Norris et al., 2001). However, continuous in vitro culture has not been achieved, thus precluding the use of this procedure for isolation and identification. *Treponema pallidum* subsp. *pallidum*, *pertenue* and *endemicum*, along with the rabbit pathogen *Treponema paraluis-cuniculi* can be isolated by inoculation of infectious tissue or exudates into adult male rabbits by either the intratesticular or intradermal routes. *Treponema carateum* is isolated by the intradermal inoculation of chimpanzees or other primates (see Table 1 for animal susceptibility to cutaneous lesions). Detailed procedures for the preparation of suspensions and methods of inoculation, and accepted criteria for determining infectivity, and identification by dark-field microscopy have been described by Turner and Hollander (1957) and Miller (1971). The development of lesions in these animals characteristic for each species and subspecies of *Treponema* (Turner and Hollander, 1957; Miller, 1971), as well as the pattern of lesion development in human disease (see Table 1 and Miller, 1987), are useful criteria for identification. Several isolates of *Treponema pallidum* subspecies continue to be propagated by intratesticular passage in rabbits. The Nichols strain of *Treponema pallidum* subsp. *pallidum* has been passaged continuously by this route since 1912. It has been studied more extensively than any other isolate and is the strain used in the preparation of treponemal antigens for immunologically specific serodiagnostic assays.

The in vitro multiplication of *T. pallidum* subsp. *pallidum* in a tissue culture system was first described by Fieldsteel et al. (1981). Treponemes extracted from infected rabbit tests are inoculated into cultures of Sf1Ep rabbit epithelial cells (American Type Culture Collection [ATCC], Rockville, MD, USA). The medium used is a modification of Eagle's minimal essential medium with Earl's salts, containing 13.9 mM D-glucose, 0.63 mM dithiothreitol, 31.3 mM HEPES (*N*-2-hydroxyethylpiperizine-*N*′2-ethane sulfonic acid) buffer (pH 7.4), resazurin (0.126 mg/ml), and 20% fetal bovine serum or calf serum inactivated at 56°C for 30 min. Optimal conditions for growth consist of incubation at 33–35°C in an atmosphere containing 1.5–5% O_2, 5% CO_2, and the balance N_2 (Fieldsteel et al., 1982). *Treponema pallidum* subsp. *pallidum* attaches to the Sf1Ep cells and multiplies on the mammalian cell surface (Fieldsteel et al., 1981; Konishi et al., 1986). Under these conditions, the Nichols strain of *Treponema pallidum* subsp. *pallidum* can increase in numbers up to 100-fold and maintain viability and infectivity for rabbits for 12–15 days. Although several strains of *T. pallidum* subsp. *pallidum* multiply in this system, isolates of *T. pallidum* subsp. *pertenue* and *endemicum* fail to grow (Cox et al., 1984). Attempts to extend multiplication by subculture have thus far been unsuccessful (Norris and Edmondson, 1986a; Norris et al., 2001). Enhanced multiplication of *T. pallidum* subsp. *pallidum* can be achieved in a modified medium (*T. pallidum* Culture Medium or TPCM) that contains the additives cobalt chloride, cocarboxylase, mannitol, histidine, superoxide dismutase and catalase (Cox et al., 1990; Cox, 1994). These agents help to scavange reactive oxygen intermediates and hence reduce oxygen toxicity.

Little is known about the growth requirements of *Treponema pallidum*. Treponemal multiplication does not occur in the absence of mammalian cells; the reason for this dependence has not been determined. The requirement for serum is stringent, and the required components are associated with the protein fraction (Norris and Edmondson, 1986b). Inasmuch as only certain lots of fetal bovine or calf sera are effective in maintaining growth, serum lots must be prescreened for this activity. Human serum inactivated at 56°C for 30 min can also fulfill the serum requirement (Norris and Edmondson, 1986b). Optimal multiplication at 1.5–5% O_2 (Fieldsteel et al., 1982; Cox et al., 1990) and metabolic and survival studies (reviewed by Cox [1983], Jenkin and Sandok [1983], Sell and Norris [1983], and Norris et al. [2001]) provide evidence that *Treponema pallidum* subsp. *pallidum* is microaerophilic. Optimal growth of *Treponema pallidum* subsp. *pallidum* (Nichols) at 33–35°C (Fieldsteel et al., 1982) in vitro mirrors its in vivo growth, as seen in rabbits where infection is enhanced in cooler regions of the body, such as the testes and exposed areas of the skin (Turner and Hollander, 1957; Miller, 1971).

Identification in Exudates and Tissues The restrictions of in vitro cultivation, together with the impracticability of animal inoculation, preclude the use of these isolation procedures in the diagnosis of treponemal disease. At present, the identification of treponemes in lesion exudates from patients with early-acquired treponemal disease or early congenital syphilis is usually attempted by dark-field microscopy and is based upon the demonstration of characteristic morphology and motility. Unfortunately, the use of dark-field microscopy for the identification of *T. pallidum* and diagnosis of syphilis and other treponemal infections has several limitations:

1. *Treponema pallidum* identification can be difficult because of the potential presence of host indigenous, nonpathogenic treponemes with similar morphology and motility characteristics in the oral cavity, genitalia, and gastrointestinal tract, precluding an unequivocal identification from these sites. Indeed, dark-field examination of lesions within the oral cavity and the anal region is most often contraindicated due to the potential presence of nonpathogenic spirochetes.

2. Prepared slides must be examined rapidly. The relatively rapid loss of motility in the presence of atmospheric O_2 necessitates that slide specimens be examined within a short period of time after preparation (15–30 min) to ensure the observation of characteristic movement. This restriction not only reduces the chances for accurately identifying organisms in the exudate but also reduces the probability of observing the treponemes that might be present.

3. Sensitivity is relatively poor. Dark-field examination of lesion exudates from patients with early treponemal disease may be negative, despite the presence of *Treponema pallidum*. This lack of sensitivity is not surprising. Dark-field examination of *Treponema pallidum* suspensions containing 10^6 organisms per ml would present as 2 organisms per high dry field (HDF) and 10^3 treponemes per ml of lesion exudate (a significant number of organisms) would present as 2 organisms per 1,000 HDFs and would not be detectable.

4. A specially equipped microscope is required, as well as personnel with considerable training, experience, and expertise. This combination is generally not available at most health care facilities. As a result, dark-field examination may not be done or may be performed incorrectly. Again, because antibody may be lacking

or its presence is inconclusive, this creates a serious problem for both physicians and health care officers responsible for controlling spread of the disease.

The limitations associated with dark-field examination have been recognized since the procedure was first described, and as might be expected, attempts have been made to develop a more efficient method. One such assay utilizes direct immunofluorescence and is referred to as the "Direct Fluorescent Antibody Test for *T. pallidum*" (DFA-TP; Larsen et al., 1998, 1999). With this procedure, lesion material or tissue sections are fixed to a microscopic slide and combined with fluorescein isothiocyanate-labeled rabbit, anti-*Treponema pallidum* immunoglobulin conjugate previously absorbed with crossreacting nonpathogenic treponemes to render it specific for *T. pallidum*. Following a 30-min incubation and washing, the slide is examined for the presence or absence of treponemes by fluorescence microscopy. This immunological procedure provides the opportunity to examine accurately not only smears from oral and anal lesions, but also tissue sections for the presence of treponemes. In addition, the organisms need not be motile, thus eliminating the need for immediate examination. The use of adequate controls with this assay is essential because conjugates of poor specificity due to incomplete absorbance of crossreacting antibodies may give misleading results.

A modification of this procedure (DFAT-TP) can be used for identification of *T. pallidum* in tissue sections (Larsen et al., 1998).

Silver impregnation methods have proven valuable in the identification of treponemes in tissues. However, their technical difficulty, poor reproducibility, and presence of artifacts resembling treponemes often make identification difficult. The modified Krajian procedure is one of many available silver impregnation methods and is described in detail by Miller (1971), along with techniques for tissue fixation, embedding and sectioning. A method in which the tissue sections are heated in a microwave oven (Swisher, 1987) provides more rapid and reproducible staining.

Another method that has been developed for the detection of *T. pallidum* in recent years has been PCR (reviewed by Larsen et al., 1999). New procedures permit not only the detection of *T. pallidum*, but also the identification of subspecies (Centurion-Lara et al., 1998) or even the direct detection and delineation of *T. pallidum* subsp. *pallidum* strains during syphilis outbreaks, using lesion exudates or blood (Pillay et al., 1998; Sutton et al., 2001).

A discussion of nontreponemal and treponemal tests in the serological diagnosis of treponemal infection is beyond the scope of this chapter. However, detailed presentations of the principles, procedures, interpretations of results, precautions, and potential problems associated with these serological assays are available (Larsen et al., 1998, 1999).

Oral Spirochetes

Isolation and Preservation

General Comments Owing to their fastidious nature, most oral treponemes cannot be cultured on a routine basis. Their isolation requires complex media and microaerophilic or strictly anaerobic growth conditions rendering their cultivation laborious, time-consuming, and often frustrating. Oral treponemes were first cultured by Noguchi in 1912 using a medium containing sheep serum and kidney tissue or rabbit or sheep testicle. A routine method for culturing small oral treponemes was published by Hampp and Bethesda (1943), and since then, media have been supplemented with a variety of components such as serum, volatile fatty acids, vitamins, carbohydrates or sterilized body fluids. However, because nutritional needs of oral treponeme species vary as much as their diversity, there is no single medium optimal for the recovery of all oral treponemes. Addition of up to 10% inactivated animal serum has been used successfully for cultivation of many species. However, some fermentative treponemes, e.g., *T. maltophilum* and *T. lecithinolyticum*, were found to be inhibited by serum (Koseki et al., 1996b; Wyss et al., 1996, 1999). Systematic studies on essential nutrients and environmental growth factors are scarce. Fiehn investigated nine oral, small-sized spirochete strains (Fiehn, 1989). These strains grew in the absence of rabbit serum. Human globulin and certain carbohydrates stimulated growth, while bovine albumin and long-chain fatty acids inhibited growth. The pH optimum was 7.5. Changes by only one half of a pH unit resulted in approximately 50% growth reduction.

Atmospheric Requirements In general, oral treponemes are sensitive to oxygen. In the study mentioned above, spirochetes tolerated 3% oxygen, but strictly anaerobic culturing conditions gave the highest average cell yields. Handling of cultures under aerobic conditions decreased cell counts (Fiehn, 1989). Therefore culturing can be accomplished with an anaerobic chamber, anaerobic jars, or roll tubes. The gas mixture used in an anaerobic jar with palladium catalyst can be either a hydrogen-generating system, such as GasPac (BBL) envelope, or a tank gas mixture containing H_2 and CO_2, e.g., 95% H_2-5% CO_2. Handling of cultures in an anaerobic glove

box is of help, and prereduction of growth media prior to inoculation of the sample in anaerobic jars is advantageous. The plate-in-bottle method (Umeda et al., 1990) has been developed to produce strict anaerobic conditions. Autoclaved steel wool (1.0 g) was activated by an acidic copper sulfate solution and placed quickly in a stainless steel pan inside a glass bottle that contained growth medium. All steps were carried out under anaerobic conditions by flushing with 100% CO_2 gas. This technique yielded a higher recovery of oral treponemes from subgingival plaque than the anaerobic chamber yielded (Koseki et al., 1996a).

Growth Media and Microscope Observation Treponemes can be cultured in semisolid or liquid media either in roll tubes or on agar plates. Observations of growth, size, purity of strains, multiplication and motility should be conducted by dark-field microscopy every 3–8 days. The media most commonly used are as follows.

GM-1 and NOS Medium The GM-1 and new oral spirochete (NOS) medium supplemented with rifampicin as selective agent both resulted in high recovery of oral spirochetes (Blakemore and Canale-Parola, 1976; Leschine and Canale-Parola, 1980). Gingival crevice material was collected with sterile toothpicks and subsequently placed in tubes with prereduced medium. Tubes were gently shaken for 2 hours and serially diluted into tubes of melted GM-1 or NOS agar. After incubation at 37°C, spirochete colonies appeared as "cotton balls" or "transparent bubbles" within the agar. They were removed with sterile Pasteur pipettes for successive transfer in agar medium. NOS-medium has been used to isolate various species, e.g., *T. denticola*, *T. vincentii*, *T. socranskii* and *T. phagedenis* and, supplemented with pectin, the treponemes from the Smibert collection (Chan et al., 1993a; Paster et al., 1998). For enumeration of colony forming units, NOS medium was solidified by the addition of agarose (NOS-A), gelatin/Noble Agar (NOS-GN) or gelatin/Bacto agar (NOS-GB; Chan et al., 1993b; Chan et al., 1997; Qiu et al., 1994). NOS medium was used also to study the growth requirements of nine small-sized oral spirochetes by varying oxygen content, pH or nutrient factors (Fiehn, 1989). For details of the formula, see ATCC medium (http://www.atcc.org/) no. 1357 and no. 1494.

OTI Medium The oral treponeme isolation medium (OTI) contains pectin, clarified rumen fluid, yeast autolysate and serum. It was first used to culture treponemes from young human adults with experimental gingivitis (Moore et al., 1982). For isolation of treponemes, authors used the membrane technique described below. This way *T. pectinovorum*, *T. socranskii* subsp. *socranskii*, *T. socranskii* subsp. *buccale* and *T. socranskii* subsp. *paredis* were isolated from periodontitis patients for the first time (Smibert and Burmeister, 1983; Smibert et al., 1984b). For the formula, see ATCC medium (http://www.atcc.org/) no. 1367.

(M)TYGVS Medium TYGVS is modified Laughon medium (Laughon et al., 1982) and has been used for enzyme analyses of *T. denticola* (Otha et al., 1986) and quantitative recovery of spirochetes from subgingival plaque (MTYGVS; Salvador et al., 1987). Combined with the filter technique, this medium allowed the isolation of treponemes from different clinical sources, including the novel species *T. medium* (DiRienzo et al., 1991; Nakazawa et al., 1997; Umemoto et al., 1997; Sato and Kuramitsu, 1999).

Medium 10 Medium 10 (M10), a medium without serum and rumen fluid, was originally designed for nonselective enumeration and cultivation of rumen bacteria (Caldwell and Bryant, 1966). It was later successfully used to isolate treponemes from plaque samples of periodontitis patients. While well suited for primary isolation of treponemes, it could not be used for maintaining the strains. The authors later developed enriched medium10, containing trypticase peptone, yeast extract, glucose and volatile fatty acids (Koseki et al., 1996b).

OMIZ-Pat To develop a chemically defined medium for culturing a wide range of oral anaerobes, Wyss (1992) described the OMIZ-W1, containing more than 80 components. This medium is laborious to prepare. However, using this mixture supplemented with asialofetuin, a methanol soluble fraction of yeast extract, neopeptone and some carbohydrates, a number of new oral treponeme species were cultivated (Wyss et al., 1996). This complex medium was called "OMIZ-Pat." For isolation of new strains, antibiotics rifampicin and phosphomycin were added and a limiting dilution technique in 96-well plates was performed. This technique succeeded in the isolation of *T. maltophilum* (Wyss et al., 1996); supplemented with human serum, *T. amylovorum* (Wyss et al., 1997); prepared without dipalmitoyl phosphatidylcholine, *T. lecithinolyticum* (Wyss et al., 1999); and supplemented with serum, polymyxin and nalidixic acid, *T. parvum* (Wyss et al., 2001). For the formula, see ATCC medium (http://www.atcc.org/) no. 2131.

Systematic comparisons of different growth media are rare. The detection frequency and recovery of oral treponemes from subgingival plaque in different cultivation media were inves-

tigated (Koseki et al., 1995; Koseki et al., 1996a). The authors used M10, M10 supplemented with rumen fluid, serum or rifampicin, NOS, NOS with rifampicin, altered oral treponeme isolation medium (aOTI) and enriched trypticase soy agar. NOS yielded the highest detection frequency of treponemes in all samples tested, whereas M10 with 10% rabbit serum showed the highest number of colony-forming units of treponemes in the positive samples. Therefore, the authors recommended M10 combined with the plate-in-bottle technique for high recovery of oral treponemes from subgingival plaque. However, cultivation bias may be significant as serum-free M10 selected mainly saccharolytic strains such as *T. socranskii* or related species (Koseki et al., 1995; Koseki et al., 1996a).

Techniques for Isolation of Treponemes from Clinical Samples It is difficult to obtain pure subcultures of treponemes from highly contaminated primary cultures. Because of bacterial coaggregation in subgingival plaque, it is necessary to disrupt the biofilm to obtain single species colonies; however, care should be taken not to harm the fragile treponemes by the procedures used. This issue has been addressed by Salvador et al. (1987) in studying the quantitative recovery of oral spirochetes after sonification, mechanical mixing, and homogenization of plaque samples, the latter technique being the most suitable one.

Though most media for isolation of treponemes are highly enriched, long cultivation periods up to two weeks may be required. Most isolation techniques rely on treponeme motility. In solid or semisolid media, treponeme colonies appear hazy, like cotton balls or nearly transparent bubbles within the agar (Paster and Canale-Parola, 1982). Colonies can be removed using sterile Pasteur pipettes and can be cloned by several rounds of subcultivation to obtain isogenic colonies.

Well-Plate Method This method uses agar plates containing a thick layer of solid medium with a well cut into the center of the plate (Rosebury and Foley, 1941; Hampp and Bethesda, 1943). Clinical samples are placed into agar wells and incubated anaerobically. Treponemes appear as a white haze growing out from the well into the agar and away from contaminants. Agar plugs of the leading haze are cut with sterile glass pipettes and transferred into agar wells of fresh agar plates. This procedure was used successfully to isolate *Treponema medium* (Umemoto et al., 1997).

Membrane-Filter Methods These techniques rely on the ability of treponemes to pass through pores of membrane filters that hold back most other bacteria. These methods are limited, therefore, to the isolation of treponemes smaller than other bacteria. Samples are inoculated onto membrane filters placed on top of agar media with a pore size ranging from 1.5–100 μm. A sterile O-ring sealed to the filter with 3% agar can help to keep the sample in place. This prevents other bacteria from swarming or being washed off and growing on the agar medium (Loesche and Socransky, 1962; Moore et al., 1982). Motile treponemes migrate through the pores of the filter and grow into the agar medium. After 2 days to 2 weeks, filters are removed and agar plates are further incubated and observed for the development of colonies that can be picked and subcultured. This technique allowed the isolation of *T. denticola*, *T. pectinovorum* and *T. socranskii* spp. (Smibert and Burmeister, 1983; Smibert et al., 1984b; Chan et al., 1993a).

Serial Dilutions Treponemes can be isolated using the limiting dilution assay in liquid media (Wyss et al., 1996). *Treponema maltophilum* was isolated by ten-fold dilutions of selective medium with subgingival plaque in 96-well plates. After anaerobic incubation of plates, dilutions of 10^{-5} to 10^{-7} resulted in growth in about 50% of the wells. After 10 days, wells were examined for growth of spirochetes, and respective samples were subcultured on solid media for further isolation.

U-tube Method Patient samples also can be incubated in U-tubes containing pectin medium (Dahle et al., 1995). In these U-tubes, the "bacterial sample side" and the "sterile medium side" are separated by a membrane filter and an agar plug at the caudal part of the tube. The bacterial sample is placed on the agar-plug side of the tube, whereas fresh medium is added on the other side. The U-tube is then incubated for 4 days. The sterile medium side is examined daily for viable treponemal cells by aspirating a drop of culture with a needle and observation in a dark-field microscope. Motile treponemes start to migrate through the agar-plug and the membrane immediately after being transferred to the U-tube. Using this technique, the authors managed to isolate treponemes from all 51 clinical samples investigated.

Selective Media While most conventional isolation techniques depend upon the migration of treponemes, therefore selecting for highly motile or slender treponemes, selective media allow isolation independent of motility or size. Treponemes are resistant to a number of antimicrobial agents (Abramson and Smibert, 1971). Rifampicin, phosphomycin and polymyxin have

been used to suppress contaminating oral flora, allowing the isolation of slowly growing spirochetes. Addition of rifampicin significantly increased the numerical ratio of spirochete colonies to other oral species (Leschine and Canale-Parola, 1980; Koseki et al., 1996a), thus facilitating the isolation and enumeration of spirochetes. On the other hand, addition of antibiotics strongly reduced the absolute number of spirochete colony forming units (Koseki et al., 1996a). Antibiotics have successfully been used in combination with various media: NOS was supplemented with rifampicin (4 mg/liter) (Chan et al., 1993a) or with rifampicin (1 mg/liter) plus phosphomycin (100 mg/liter; Chan et al., 1997); M10 was supplemented with rifampicin (5 mg/liter; Koseki et al., 1996a); OTI with rifampicin (2 mg/liter) plus polymyxin (800 U/ml; Smibert et al., 1984b); and OMIZ-Pat with rifampicin (1 mg/liter) plus phosphomycin (100 mg/liter; Wyss et al., 1996).

Subcultivation and Preservation of Cultures

The isolation procedures described above select treponemes from other bacteria, but not from different species of treponemes. Isolated colonies from mixed treponemal cultures must, therefore, be streaked and subcultured several times. Fiehn et al. used a dilution technique for subcultures. An agar plug with colony material was transferred to liquid medium. After 4 days of growth, a 10-fold serial dilution of the culture was re-streaked on solid media and incubated for a 14-day period again to obtain single-species colonies (Fiehn et al., 1995). Pure-culture isolates must be identified to the species level and must be fully characterized prior to conduct of further studies. As treponemes do not typically form colonies on the surface, but rather migrate into solid media, the agar should be softer than usual to allow treponemes to migrate. Concentrations of 1.25–1.3% Bacto-agar or Noble agar are therefore recommended. All cultures must be examined by dark-field microscopy (magnification at least 1000×) to determine purity.

Depending on the species, treponemes are transferred to a suitable medium every 3–7 days for experimental use. For preservation of treponeme cultures over several months or years, cryoprotective agents such as 10–15% glycerol or 3% dimethylsulfoxide (DMSO) are added to the liquid cultures. Aliquots are prepared in sterile cryotubes that are gassed with N_2 until the top is closed and stored in liquid nitrogen or a freezer at –70 or –80°C. To recover the cultures, aliquots are removed from storage, thawed to room temperature, transferred to fresh, pre-reduced medium, and incubated at 37°C until growth is observed.

Digital Dermatitis Spirochetes

Digital dermatitis is a condition occurring in ungulates, including cattle and sheep, in which ulcers or papillomatous lesions occur either in the pastern region or between the hooves (Cheli and Mortellaro, 1974; Blowey and Sharp, 1988; el-Ghoul and Shaheed, 2001). Although the lesions represent a polymicrobial infection, treponemes are prominent constituents (Blowey et al., 1994; Walker et al., 1995; Borgmann et al., 1996; Dopfer et al., 1997; Demirkan et al., 1999; Mumba et al., 1999b; Collighan et al., 2000). At least five different phylotypes of *Treponema* can be present (Choi et al., 1997), including organisms with rDNA sequences resembling those of *T. denticola*, *T. vincentii* and *T. maltophilum*. Fluorescence in situ hybridization with rDNA probes (Fig. 4) indicates that, as in periodontal plaque (Moter et al., 1998a), the microbial flora in bovine digital dermatitis are stratified with different treponemal phylotypes occupying different layers of the biomass (Moter et al., 1998b). On the basis of PCR results, topical antibiotic treatment reduces, but does not appear to eradicate, the treponemal infection (Mumba et al., 1999a). Thus far, only one isolate has been speciated and was provided the name *Treponema brennaborense* (Schrank et al., 1999); this organism was isolated using the OMIZ-Pat medium described above. Two treponemal isolates have been obtained from a condition called "severe virulent ovine foot rot" (SVOFR; Naylor et al., 1998; Demirkan et al., 2001), which appears to be distinct from the interdigital infection in which *Dichelobacter nodulans* and other bacteria are the primary causative agents. In one of these studies, immunomagnetic separation using magnetic beads coated with anti-treponemal antibodies was employed as a novel approach to enriching for spirochetes prior to culture. The spirochetes from SVOFR cases were cultured using Oral Treponema Enrichment Broth (OTEB; Anaerobe Systems, Morgan Hill, CA, USA) supplemented with rifampicin (5 mg/liter) and nalidixic acid (500 mg/liter) to inhibit growth of other bacteria.

Skin Commensal Spirochetes

Treponema phagedenis, *T. refringens* and *T. minutum* are spirochetes that can be isolated from human sebaceous secretions and desquamated epithelial cells in skin folds of the genital region. Specimens can be collected using moistened sterile swabs, and the organisms can be cultured readily under anaerobic conditions at 37°C in thioglycollate medium with 10% heat-inactivated rabbit serum (or a variety of other serum-containing media). Rifampin (2 μg/ml)

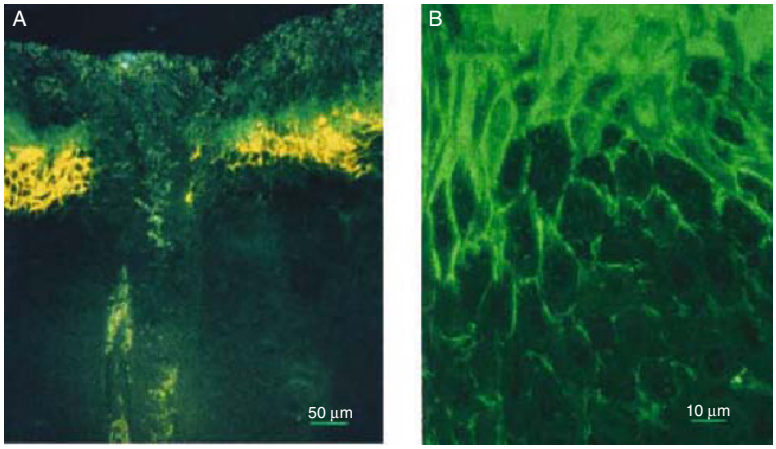

Fig. 4. Treponemes in a bovine digital dermatitis biopsy, as shown by fluorescence in situ hybridization (FISH). A) Simultaneous hybridization with EUB338FITC and DDK4Cy3, a probe specific for treponemes associated with digital dermatitis. Note the stratification with EUB338-positive bacteria (green) predominantly on the outer surface and DDK4-positive treponemes (yellow) within the stratum corneum and the stratum spinosum. B) High-power view. Single spirochetes seem to invade the tissue through the intercellular spaces in the stratum corneum (top) and the stratum spinosum (bottom). Epidermal cells exhibiting weak autofluorescence with black nuclei allow orientation within the tissue. From Moter et al. (1998b), with permission.

and polymyxin (800 µg/ml) can be added to inhibit the growth of other bacteria.

Genetics

The genome of *Treponema pallidum* subsp. *pallidum* Nichols was sequenced in 1998 (Fraser et al., 1998) and consists of a single circular chromosome of 1,138,006 bp. The G+C content of 52.8 mol% is considerably higher than that of *T. denticola* (~37%), *T. phagedenis* (38–39%), and *T. refringens* (41.5%; Miao and Fieldsteel, 1978), consistent with the evolutionary distance between the noncultivated, pathogenic treponemes and the cultivable *Treponema*. The pathogenic *Treponema* (Table 1) are essentially a clonal population. By all indications, this group of organisms have essentially identical genomes that differ by only a few base pairs concentrated in a relatively small number of repetitive genes or sequences (Miao and Fieldsteel, 1980; Fieldsteel, 1983; E. Sodergren, unpublished data). The regions flanking *tpp15*, encoding a 15-kDa lipoprotein, contain heterogeneous sequences and have been utilized to devise PCR, sequencing, and restriction fragment length polymorphism (RFLP) techniques for distinguishing *T. pallidum* subspecies and strains (Centurion-Lara et al., 1998). A set of 12 related *T. pallidum* repeat (*tpr*) genes constitute "hot spots" of recombination in *T. pallidum*, and the resulting heterogeneity represents a major portion of the genetic differences between strains (Centurion-Lara et al., 2000a; Centurion-Lara et al., 2000b; Stamm and Bergen, 2000; E. Sodergren, unpublished data). Recently, Pillay et al. devised a system utilizing a combination of PCR and RFLP of *tpr* genes and the acidic repeat protein gene (*arp*) to distinguish between *T. pallidum* subsp. *pallidum* strains in skin lesions or blood from syphilis patients (Pillay et al., 1998; Sutton et al., 2001). It should be emphasized, however, that nearly all other sequences examined have been identical in *T. pallidum* strains, and the overall genome arrangement appears to be invariant among the *T. pallidum* strains and subspecies.

The *T. pallidum* subsp. *pallidum* Nichols genome encodes ~1,040 open reading frames, which have been evaluated in some detail in other publications (Fraser et al., 1998; Radolf et al., 1999; Norris et al., 2001). The resulting information has been incorporated in the Physiology section and elsewhere in this chapter.

The *T. denticola* ATCC 35405 genome is also being subjected to sequence analysis, and at the time of this writing, the sequence is nearly completed. The genome is a single circular chromosome approximately 2.8 million base pairs (Mb) in size; a similar size of 3.0 Mb was determined previously by physical mapping of *T. denticola* ATCC 33520 (MacDougall and Saint Girons, 1995). In addition, *T. denticola* and other oral treponemes have been found to contain circular plasmids ranging in size from 2.0 kb to 4.2 kb (MacDougall et al., 1992; Chan et al., 1996). The 4.2-kb plasmid, pTS1, was present in several different periodontal isolates, including clones of *T. denticola* and *T. socranskii* (Chan et

al., 1996); in addition, transfer of a plasmid from *T. denticola* to *Streptococcus gordonii* has been demonstrated in broth and artificial biofilm cultures (Wang et al., 2002). These results suggest that genetic transfer can occur both among *Treponema* strains and between *Treponema* and other bacteria in the oral microbiological environment.

Treponema pallidum is not amenable to genetic manipulation because it has not been cultured continuously in vitro. *Treponema denticola* has become the model for gene disruption and other forms of genetic manipulation of the genus *Treponema*. Several genes of *T. denticola* have been inactivated by targeted insertional mutation with suicide vectors containing an erythromycin resistance gene (Li et al., 1996; Kataoka et al., 1997; Ruby et al., 1997; Fenno et al., 1998; Li et al., 1999). In addition, heterologous expression and complementation have been achieved using a shuttle vector with a coumermycin A1-resistance marker (Chi et al., 1999; Chi et al., 2002; St. Girons et al., 2000). Thus the combination of the availability of the *T. denticola* genomic sequence and genetic manipulation tools promises to be of value in determining the functions of *Treponema*-specific genes.

Physiology

The physiology of *T. pallidum* has been discussed in other articles (Cox, 1983; Fraser et al., 1998; Radolf et al., 1999; Subramanian et al., 2000; Norris et al., 2001) and will not be described in detail here. Briefly, the *T. pallidum* genome sequence has confirmed previous indications that the organism has extremely limited metabolic capabilities. Genes corresponding to biosynthetic pathways are virtually nonexistent, indicating a profound dependence on the human host for provision of amino acids, cofactors, fatty acids, and nucleic acid precursors. In addition, the glycolytic pathway is the only form of ATP production identified thus far, in that the tricarboxylic acid cycle and elements of electron transport systems are absent. As discussed above, *T. pallidum* is microaerophilic and requires small quantities of oxygen for optimal survival and multiplication in vitro; however, the mechanism of oxygen utilization has not been determined. Genes for reduced nicotinamide adenine dinucleotide (NADH) oxidase (*nox*), alkyl hydroperoxidase (*ahpC*), and neelaredoxin (TP0823) are present in the *T. pallidum* subsp. *pallidum* genome (Fraser et al., 1998); the catalysis of superoxide anion-hydrogen peroxide conversion has been demonstrated with recombinant *T. pallidum* neelaredoxin (Jovanovi'c et al., 2000). These enzymes may provide some measure of protective activity against reactive oxygen intermediates. Overall, the apparent loss of genes encoding activities not required in the mammalian tissue environment explains the highly fastidious nature of *T. pallidum* and indicates an extreme adaptation to obligate parasitism.

All members of the genus *Treponema* appear to require fatty acids in some form. Albumin serves as a detoxifying carrier for fatty acids in cultures of *T. denticola* and *T. vincentii* (Van Horn and Smibert, 1982; Van Horn and Smibert, 1983). The albumin fraction of serum also replaces the serum requirement of *T. pallidum* in culture, suggesting that fatty acids associated with albumin are required for multiplication in this system (Norris and Edmondson, 1986b). Fatty acids are incorporated in an unmodified form into membrane lipids by *T. pallidum* (Schiller and Cox, 1977) and may be assimilated into the outer membrane directly from the host milieu (Cox and Radolf, 2001). Fermentative treponemes isolated from subgingival plaque require *iso*-butyric acid, 2-methylbutyric acids and/or *iso*-caproic acid for optimal growth in M10 medium, substituted for the rumen fluid commonly used in culture media (Livermore and Johnson, 1975; Koseki et al., 1996b). Although most *Treponema* species appear to lack LPS, recent studies have indicated that the outer membrane of *T. denticola* contains an LPS-like substance (Dahle et al., 1996; Schultz et al., 1998; Walker et al., 1999).

Epidemiology

Syphilis is a sexually transmitted disease, whereas yaws, endemic syphilis, and pinta are all transmitted by direct skin-to-skin contact, usually during childhood and adolescence. Syphilis is still a common disease in many areas of the world, with an estimated 12 million new cases occurring per year (World Health Organization, 2001). In the United States, the annual reported incidence of syphilis was at its highest point in 1946 (963,647 reported cases), just after World War II and prior to the widespread availability of penicillin. During the 1950s, syphilis cases dropped dramatically, leading to hopes of eradication of the disease. However, the rates again increased in the 1960s and 1970s. Following an epidemic that peaked in 1990, the reported incidence of syphilis has dropped to historic lows (Fig. 5); a total of 31,575 cases was reported in 2000. The reasons for this decrease are unclear, in that incidence of other sexually transmitted diseases (e.g., chlamydia infections) have remained high. The Centers of Disease Control

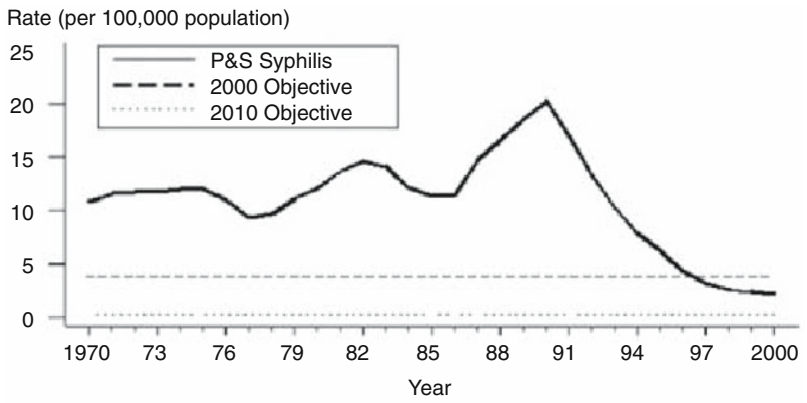

Fig. 5. Annual reported incidence per 100,000 population of primary and secondary syphilis in the United States, 1980–2000. Target objectives for 2000 and 2010 are shown. From United States Centers for Disease Control and Prevention.

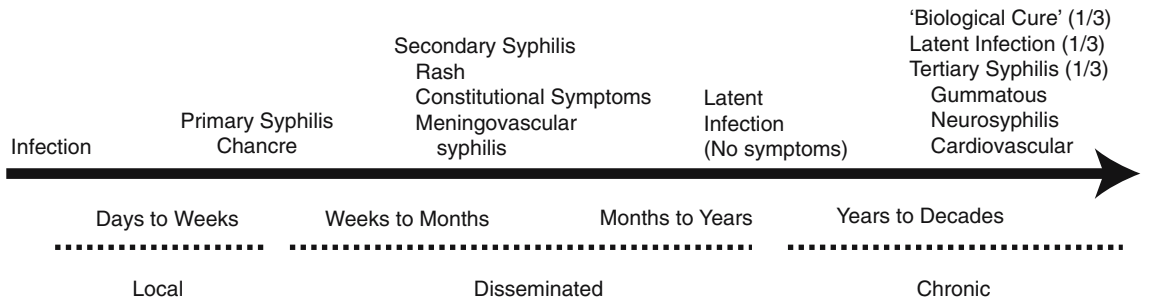

Fig. 6. Clinical course of syphilis.

and Prevention and the National Institutes of Health have established a program for the elimination of Syphilis in the United States (http://www.cdc.gov/stopsyphilis/).

The endemic treponematoses (yaws, endemic syphilis, and pinta) are restricted to certain geographic regions, and incidence is related to both socioeconomic conditions and climate (Table 1). Yaws and pinta are found predominantly in rural, tropical rain forest areas, whereas endemic syphilis may occur also in arid regions and some temperate areas (Antal et al., 2002). In 1950, the worldwide incidence of yaws alone was estimated to be 50 million cases. A global endemic treponematoses control program was initiated by the World Health Organization in 1949, and approximately 160 million people were treated between 1952 and 1964 (Antal et al., 2002). The collective incidences of these diseases was estimated to be 2.5 million cases in 1998 (World Health Organization, 1998). Foci of yaws are still found in Africa, Central and South America, Southeast Asia, and some Pacific Islands, and endemic syphilis is present in the Near East. Pinta is restricted to regions in or near the Amazon basin (Antal et al., 2002).

Disease

Thorough descriptions of syphilis and the other treponematoses can be found in infectious disease textbooks and other sources (United States Public Health Service, 1968; Larsen et al., 1999) and will not be covered in detail here. Briefly, syphilis is a multistage, invasive infection with local, disseminated, and chronic manifestations (Fig. 6). Infection occurs when viable organisms from an infectious lesion enter through a fissure in the epidermis or a mucous membrane. *Treponema pallidum* multiplies locally and causes a characteristic painless, ulcerative lesion called a "chancre." At the same time, treponemes disseminate through the bloodstream or lymphatics and can infect almost any organ or tissue. Secondary syphilis lesions may occur weeks to months after infection and signify the disseminated stage of the disease. They consist of multiple maculopapular lesions that may occur preferentially on the palms of the hands and soles of the feet or appear throughout the torso and extremities. Both primary and secondary lesions contain large numbers of *T. pallidum* and represent the infectious stage of the disease. All

untreated patients enter a period of latent infection, in which manifestations of the disease are not evident; the only indications of infection are positive serologic tests. Disease of approximately two-thirds of patients is diagnosed during this stage, and diagnosis is based solely on patient history and reactive serologies. Infection with *T. pallidum* may last the lifetime of the individual in untreated cases and can result in debilitating or life-threatening disease years to decades after the initial infection. Late syphilis manifestations occur in roughly one-third of untreated patients, according to records from the early 1900s (Gjestland, 1955). These consist of granulomatous lesions called "gummas," cardiovascular manifestations such as aortic aneurysm, or neurosyphilis, including infection of the brain (paresis) or of the sensory ganglia and spinal cord (tabes dorsalis). Some forms of neurosyphilis, such as meningovascular syphilis, can occur at earlier stages. Congenital syphilis results from transplacental transmission of *T. pallidum* from the mother during the infectious stage, usually in the first year of maternal infection; it can cause abortion, stillbirth, fulminant infection and destructive lesions at the time of birth or latent infection that results in manifestations later in childhood, including bone and tooth deformation, interstitial keratitis (clouding of the cornea), deafness, and intellectual deficits. Late syphilis has become virtually nonexistent in the United States (owing in part to coincidental treatment of other infections), but continued surveillance is needed to minimize the occurrence of congenital syphilis.

Yaws, endemic syphilis, and pinta each have cutaneous manifestations, but have progressively less internal organ involvement (Antal et al., 2002). The initial lesion of yaws ("mother yaw") usually occurs on the legs, feet or buttocks and consists of a raised papule containing large numbers of *T. pallidum* subsp. *pertenue*. Secondary lesions may occur as long as two years after infection and are also highly infectious. Late manifestations are typically restricted to the skin, subcutaneous tissue, cartilage and bone. Hypopigmented areas and gummas may occur in the skin, and painful bone and cartilage deformations result in curvature of the tibia, destruction of the nose and palate (gangosa), or nodules in the facial bones or near joints. In endemic syphilis, the primary lesion is usually not evident and may involve the oral mucosa. Secondary lesions consist of papules, typically in the mouth or warm, moist areas of the skin. Gummas again occur in later stages in skin and bone, causing deformities similar to those seen in yaws. Pinta ("spot") is a skin disease that results in hyper- or hypopigmented lesions, desquamation, or erythematous rashes over a period of several years; it does not involve internal organs. Neurologic involvement is nonexistent in the endemic treponematoses; congenital transmission may occur rarely in yaws, but has not been observed in endemic syphilis or pinta. Penicillin remains the treatment of choice for *T. pallidum* infections.

Periodontal disease represents a spectrum of polymicrobial infections of the gingival crevice, which in its various forms can cause gum inflammation, expansion of the gingival pocket, bone resorption, and tooth loss (Moore and Moore, 1994). It is estimated that over 80% of adults in the United States have experienced some form of periodontal disease. Dental plaque is essentially a complex, stratified biofilm (Fig. 7). If it is not removed by brushing and flossing, gum inflammation and the progressive changes associated with periodontal disease will result from both preferential outgrowth of subsets of anaerobic organisms (including oral spirochetes) within the deep layers of the biofilm and prolonged exposure to the bacteria and their products. At least part of this effect appears to be due to the production of inflammatory cytokines by host cells in response to bacterial products. The lack of effective animal models and the poly-

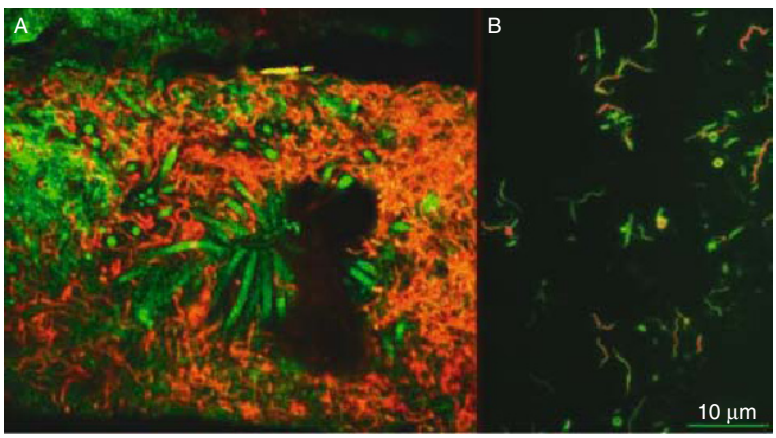

Fig. 7. Fluorescent in situ hybridization (FISH) on subgingival biofilm (plaque) from a human subject. A section of a fixed and sectioned region of the biofilm A) and a smear B) are shown. Probes used were the general eubacterial 16S rDNA oligonucleotide EUB338FluoX (green) and the 16S rDNA probe TRE ICy3 (red) for the detection of phylogenetic group I treponemes, most of which are yet uncultured. The results show the high proportion of treponemes involved in biofilm formation. A) is from Wecke et al. (2000), with permission, and B) was provided by A. Moter.

microbial nature of periodontal disease have complicated the assessment of the role of oral spirochetes and other bacteria in its pathogenesis.

CHAPTER 4.3

The Genus *Borrelia*

MELISSA CAIMANO

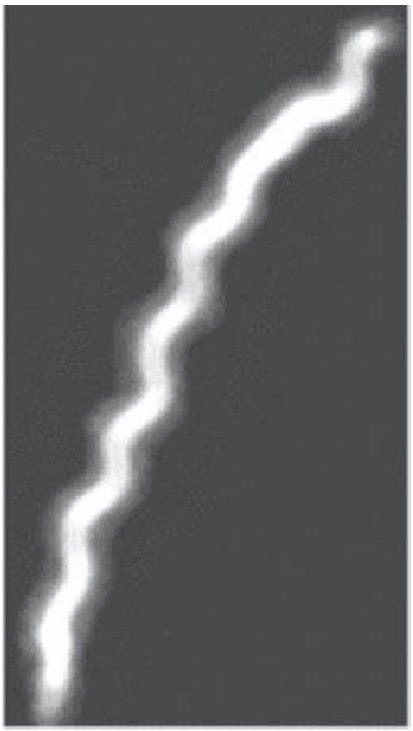
Phylogeny

The inability to cultivate many spirochetes, including the borreliae, at one time significantly hindered the placement of these organisms into a taxonomic scheme based on traditional biochemical methodologies. As a result, these organisms were initially grouped based primarily on their common helical or spiral shape (Fig. 1). The advent of contemporary ribosomal RNA cataloging has facilitated the division of the spirochetes into three phylogenetic families, the Spirochaetaceae (including the genera *Borrelia*, *Brevinema*, *Cristispira*, *Spirochaeta*, *Spironema* and *Treponema*), the Brachyspiraceae (including the genus *Brachyspira* [*Serpulina*]), and the Leptospiraceae (including the genera *Leptospira* and *Leptonema*; Thomas et al., 2001). All species in the genus *Borrelia* are transmitted to vertebrates by hematophagous (blood-feeding) arthropods. In most cases, the differentiation of borreliae species was based on 1) identification of the specific vector that transmits the spirochete, 2) the vertebrate host (humans, animals or birds), and 3) the variable infectivity of isolated borreliae for different species of laboratory animals (Davis, 1956; Felsenfeld, 1971; Burgdorfer, 1976a; Table 1). To date, thirty species of *Borrelia* have been recognized (Thomas et al., 2001). The principal species of *Borrelia* and their primary vectors are listed in Table 1. Additional information on *B. burgdorferi* sensu lato strains is also available: (http://www.pasteur.fr/recherche/borrelia/Bb_ strains_alphabetic.html.) With the exception of louse-borne relapsing fever, all of the borrelioses are zoonoses.

Borreliae, like most spirochetes, were historically considered to be Gram negative because of their double-membrane structure (Fig. 6), but as stated above, genetic analyses have placed them, along with the other spirochetes, into a separate eubacterial phylum (Paster et al., 1991). Ultrastructural (*Borrelia* Molecular Architecture), molecular, and biochemical studies also have emphasized the wide taxonomic gap between spirochetes and Gram-negative bacteria. Most notably, *Borrelia burgdorferi*, and presumably all *Borrelia* spp., does not contain lipopolysaccharide (LPS; Takayama et al., 1987). In addition to lacking LPS, borrelial outer membranes differ from those of Gram-negative bacteria in that they 1) exhibit considerably greater fluidity, 2) are more susceptible to physical manipulations (i.e., centrifugation, washing and resuspension; Brusca and Radolf, 1994; Cox et al., 1994; Cox et al., 1996), 3) are more easily solubilized in very dilute detergents than are the membranes of Gram-negative bacteria (Barbour and Hayes, 1986b; Brusca and Radolf, 1994; Cox et al., 1994; Cox et al., 1996), and 4) have a much lower density of transmembrane proteins (Walker et al., 1991; Radolf et al., 1994b; Radolf et al., 1995b). (For excellent reviews of *Borrelia* morphology and ultrastructure, see Hovind-Hougen, 1976, Barbour, 1989, Hayes and Burgdorfer, 1993, and Radolf, 1994a.)

Habitat

All known *Borrelia* species have an inherent requirement for a competent (often genospecies-specific) arthropod vector and vector-suitable mammalian host(s) to be maintained in their natural enzootic cycles (Table 1). Three types of arthropod vectors have been associated with transmission of *Borrelia*: the human body louse (Fig. 2), the argasid or soft tick (Fig. 3), and the ixodid or hard tick (Fig. 4). Numerous mammalian hosts appear to be involved in maintaining *Borrelia* within a population, with the primary reservoir usually being a small mammal. The coincident geographic distribution of both of these elements is thought to be foremost in establishing and perpetuating a given *Borrelia* species within a locale. This point is clearly demonstrated by Lyme borreliosis; the geographic distribution of its two arthropod vectors (Fig. 15), *Ixodes scapularis* and *I. pacificus*, closely mirrors that of the disease (Orloski et al., 2000; Fig. 16).



Darkfield Image of Spirochete

Presence in Lice

Borrelia recurrentis is the etiological agent of louse-borne (epidemic) relapsing fever and is the only species of borreliae that is louse-transmitted (Table 1). The human is the only known reservoir of this spirochete. The human body louse, *Pediculus humanus* subsp. *humanus* (Fig. 2), becomes infected after feeding on a spirochetemic individual and remains infected during its life span of approximately 10–61 days. The ingested borreliae enter the louse's midgut where, within several days, they penetrate the gut epithelium to gain entrance to the hemolymph where they multiply. Infection of the mammalian host is thought to occur when spirochetes, liberated when the lice are crushed on the skin by scratching, enter abraded skin or mucous membranes. Since body lice prefer normal body temperature to the higher temperatures of patients with acute relapsing fever, they are predisposed to seek an afebrile person after feeding on a febrile individual. This behavior results in the rapid transmission of infection during epidemics.

Fig. 3. Soft tick (*Ornithodoros* spp.). Image kindly provided by Julie Rawlings, MPH, Texas Department of Health (http://www.tdh.state.tx.us/yellow/r.htm).

Presence in Soft Ticks

All of the other pathogenic borreliae are parasites of either soft or hard ticks (Table 1). All tick-borne borrelial infections, with the possible exception of infections by *Borrelia duttonii*,

Table 1. Characteristics of *Borrelia* species of medical and veterinary significance.

Species	Vector	Animal Reservoir	Disease	Geographic distribution
B. recurrentis	*Pediculus humanus* subsp. *humanus*	Humans	Louse-borne relapsing fever	Worldwide
B. duttonii	*Ornithodoros moubata*	Humans	Old World tick-borne relapsing fever	Central, eastern and southern Africa
B. hispanica	*O. marocanus*	Rodents	Old World tick-borne relapsing fever	Spain, Portugal, Morocco, Algeria, Tunisia
B. crocidurae, *B. merionesi*, *B. microti*, *B. dipodilli*	*O. erraticus*	Rodents	Old World tick-borne relapsing fever	Northern and eastern Africa, Near and Middle East, southeastern Europe
B. persica	*O. tholozani*	Rodents	Old World tick-borne relapsing fever	Middle East, Greece, Central Asia, Russia, western China
B. caucasica	*O. verrucosus*	Rodents	Old World tick-borne relapsing fever	Iraq, eastern Europe
B. latyschewii	*O. tartakowskyi*	Rodents	Old World tick-borne relapsing fever	Iraq, Iran, Afghanistan, Russia
B. coriaceae	*O. coriaceus*	Rodents	Epizootic bovine abortion	California
	Alectorobius sonrai		Tick-borne relapsing fever	Western Africa
B. hermsii	*O. hermsi*	Rodents, chipmunks, tree squirrels	New World tick-borne relapsing fever	Canada, western USA
B. turicatae	*O. turicata*	Rodents	New World tick-borne relapsing fever	Southwestern USA
B. parkeri	*O. parkeri*	Rodents	New World tick-borne relapsing fever	Western USA
B. mazziottii	*O. talaje (O. dugesi)*	Rodents	New World tick-borne relapsing fever	Southwestern USA, Mexico, Central and South America
B. venezuelensis	*O. rudis*	Rodents	New World tick-borne relapsing fever	Central and South America
B. venezuelensis	*O. rudis*	Rodents	New World tick-borne relapsing fever	Central and South America
B. burgdorferi sensu lato	*Ixodes scapularis*	Rodents, Lagomorpha, Deer, Fowl	Lyme (borreliosis) disease	Midwestern and eastern USA
	I. pacificus			Western USA
	I. ricinus			Europe
	I. persulcanis			Asiatic Europe, China, Japan
B. lonestari	*Amblyomma americanum*	Rodents	Lyme disease-like illness	Southern USA
B. theileri	*Rhipicephalus evertsi*, *Boophilus microplus*, *B. annulatus*, *B. decoloratus*	Cattle, Horses, Sheep	Bovine borreliosis	South Africa, Australia, Brazil, Mexico
B. anserina	*Argas persicus* and other *Argas* spp.	Fowl	Avian borreliosis	Worldwide

Image of Hard Ticks

Fig. 4. From left to right: The deer tick (*Ixodes scapularis*) adult female, adult male, nymph, and larva on a centimeter scale. Image taken from the Centers for Disease Control and Prevention (CDC) Lyme Disease Home Page (http://www.cdc.gov/ncidod/dvbid/lymeinfo.htm).

involve humans as an accidental host. In East Africa, *B. duttonii* is carried by the domestic soft tick, *Ornithodoros moubata*, and the reservoir for this spirochete appears to be the human population. The relapsing fever spirochetes are the primary borreliae transmitted by the soft tick (Fig. 3). The numerous species of *Borrelia* are responsible for the tick-borne relapsing fevers and are distributed worldwide in both tropical and temperate climates (Table 1). Soft ticks of the genus *Ornithodoros* serve as the primary vectors of these relapsing fever spirochetes, with wild rodents being the major reservoir. Occasionally, lizards, toads, turtles and owls can also serve as competent reservoirs for these spirochetes.

Soft ticks become infected while obtaining a blood meal from a spirochetemic animal. Following ingestion of a blood meal on an infected mammal, *Borrelia* rapidly multiply within the tick. Within hours, a generalized infection ensues such that spirochetes can be found in a variety of tissues, including the salivary glands, the coxal glands on the legs, and the ovaries. Consistent with the presence of spirochetes in the ovaries, the female *Ornithodoros* spp. tick, unlike the body louse, can transmit borreliae transovarially to their progeny. Humans and animals become infected while the tick is feeding, through infectious saliva, excrement, and/or coxal fluid entering via the bite wound or skin. The presence of the *Ornithodoros* spp. vector on humans often goes unnoticed since this vector 1) typically feeds at night, 2) usually completes its feeding in 5 to 20 minutes, and 3) does not cause pain. Soft ticks are particularly durable vectors as they are able to survive for months to years without a blood meal. The spirochetes are similarly able to survive in the ticks for extended periods of time. In addition, the spirochetes can be maintained within the vector during the transition from one developmental stage to another (e.g., larva to nymph to adult).

Presence of *Borrelia* in Hard Ticks

The Ixodidae (hard) ticks are the primary vectors of *B. burgdorferi*, the etiological agent of Lyme disease (Table 1). The association between *B. burgdorferi* and *I. scapularis*, the vector in the northeastern and north-central United States (Fig. 4), has been studied extensively (Burgdorfer et al., 1982; Burgdorfer et al., 1989b; Spielman et al., 1984; Benach et al., 1987; Ribeiro et al., 1987; Piesman, 1989; Dolan et al., 1998; Humair and Gern, 2000). This relationship is similar to that occurring between the European Lyme disease (Table 5) spirochetes and ticks of the *Ixodes ricinus* complex. The larval and nymphal forms of *I. scapularis* commonly become infected with *B. burgdorferi* when obtaining a blood meal from infected rodents, with the white-footed mouse, *Peromyscus leucopus*, being the primary reservoir (Table 2). A variety of birds, in addition to small mammals, may also serve as a reservoir for the Lyme disease spirochete (Anderson and Magnarelli, 1984). One recent study suggests that latent *Borrelia burgdorferi* sensu lato infection in migratory birds (i.e., redwing thrush) may be reactivated by the stress associated with migration. Many of these birds are infested with ixodid ticks and, subsequently, may serve as an efficient mechanism of spreading ticks carrying this pathogen over long distances (Gylfe et al., 2000).

Recent studies using *B. burgdorferi*-infected *I. pacificus* nymphs fed on the western fence lizard (*Sceloporus occidentalis*) suggest that lizard serum contains a thermolabile, borreliacidal factor, probably a protein, that destroys spirochetes in the midgut of feeding *I. pacificus* ticks. The presence of lizards in the enzootic cycle may help to reduce the force of transmission of *B. burgdorferi* by diverting a competent vector tick from an alternative reservoir-competent host (i.e., the dusky-footed wood rat or the California kangaroo rat; Lane and Quistad, 1998).

In contrast to the soft tick- (see Presence in Soft Ticks) and louse-borne (see Presence in Lice) relapsing fever *Borrelia* spp., *B. burgdorferi* remains in the midgut of the hard tick (Fig. 4) until the next blood meal (Ribeiro et al., 1987; Burgdorfer, 1989a), at which time it penetrates the basal membrane of the midgut, invades the hemolymph and various tissues, including the salivary glands, and is transmitted to the host via infectious saliva (Schwan, 1996). Recent studies suggest that the differential expression of lipo-

[b]The name has been corrected from *B. turdae* (Fukunaga et al., 1996) by International Union of Microbiological Societies (1998).

proteins (see Differential Gene Expression) on the surface of the spirochete in response to the blood meal facilitates migration from the midgut to the salivary glands and subsequent transmission to the mammalian host (Schwan et al., 1995; de Silva et al., 1996; Ohnishi et al., 2001). Transovarial transmission by *Ixodes* spp. ticks is thought to occur infrequently. For a review comparing spirochete transmission by hard and soft ticks, see Schwan (1996).

Isolation

The study of *Borrelia* was greatly facilitated by the development of a culture medium by Kelly that would support the growth of the spirochetes (Kelly, 1971). In 1982, Stoenner enriched this formulation by adding yeast extract and tissue culture medium (referred to as "fortified Kellys medium"; Stoenner et al., 1982). Subsequent modifications by Barbour (1984a) resulted in Barbour-Stoenner-Kelly (BSK I) medium, which has allowed the isolation of borreliae from a variety of sources (Barbour, 1986a). For historical reviews of the cultivation of *Borrelia* spp., see Barbour and Hayes (1986b), Barbour (1984a), and Anderson and Magnarelli (1992). The successful cultivation of *Borrelia* spp. is usually dependent on the quality of the animal serum or albumin used in the preparation of the medium (Callister et al., 1990). These reagents are thought to provide necessary long-chain fatty acids, but other, as yet unidentified, trace components may also be important. A commercial source for this medium has now become available (http://www.sigma-aldrich.com, Sigma-Aldrich, BSK [catalog # B 8291]). Semisolid medium is prepared by the addition of 100 ml of sterile 1.89% agarose (dissolved in boiling water) to the BSK I recipe given above to yield BSK II. The agarose solution (cooled to 55°C) is added just prior to dispensing medium. Several methods have been described for plating *Borrelia* as a surface lawn (Kurtti et al., 1987) or by subsurface plating (Samuels et al., 1994a).

Isolation of *Borrelia* from Ticks

The hemolymph and most tissues of *Ornithodoros* spp. ticks can be used as a source of the relapsing fever borreliae and *B. coriaceae*. In contrast, *B. burgdorferi* is usually restricted to the midgut in flat (unfed) *Ixodes* ticks. *Borrelia burgdorferi* has been successfully cultured from the midguts of live, infected *Ixodes* nymphs and adults by crushing the entire contents of the midgut in a sterile Petri dish or on a glass slide, mixing the contents with a small amount (0.5 ml) of BSK II (Table 3) medium, transferring the contents to a sterile screwcap microcentrifuge tube containing an additional 1 ml of BSK II medium and then incubating at 30–35°C for 7–21 days. Cultures should be checked every sev-

Table 3. Liquid BSK II medium for growth of *Borrelia* spp. (Barbour, 1984a).

1. To 900 mls of glass-distilled water, add the following:	
HEPES (Sigma)	6.0 g
Neopeptone (Difco)	5.0 g
Sodium citrate	0.7 g
Glucose	5.0 g
Sodium bicarbonate	2.2 g
TC Yeasolate (Difco)	2.5 g
Sodium pyruvate	0.8 g
N-acetyl glucosamine (Sigma)	0.4 g
Bovine serum albumin, fraction V	50.0 g
2. Adjust pH of medium at room temperature to 7.6 with 1N NaOH.	
3. Sterilize by filtration (0.2 μm).	
4. Add 100 mls of sterile 10× CMRL 1066 without glutamine (Gibco/BRL).	
5. Add 200 mls of sterile 7% gelatin (Difco), which has been dissolved in boiling water.	
6. Add 64 mls of sterile, heat-inactivated rabbit serum (Pel-Freeze Biologicals, Inc).	
7. Dispense to glass or polystyrene tubes or bottles.	
8. Fill to 90% capacity and cap tightly.	
9. Store complete medium at 4°C.	

eral days for spirochetes by microscopy. Owing to their slender shape, they are best visualized by darkfield microscopy (Fig. 1). *Borrelia* also can be isolated from *Ornithodoros* spp. and *Ixodes* spp. tick tissues using BSK II (Table 3) medium.

Isolation of *Borrelia* from Patient Specimens

The *Borrelia* strains causing relapsing fever (Table 1) are typically present in high numbers circulating in the blood of patients during acute (febrile) phases of this disease. The tick-borne relapsing fever spirochete, *B. hermsii*, is readily cultivated from patient samples, primarily blood. Several reports also have described the cultivation of the louse-borne relapsing fever spirochete, *B. recurrentis* (Cutler et al., 1997; Cutler et al., 1999), and the tick-borne relapsing fever spirochete, *B. duttonii* (Cutler et al., 1999), from the blood of spirochetemic patients. Both of these types of relapsing fever spirochetes may be isolated from blood by inoculating one to two drops per 10 ml of liquid or semisolid BSK II (Table 3) media. Cutler et al. (1999) suggest that the critical factor in determining the success of cultivation of *B. duttonii* is the quality of the albumin used in preparation of the BSK II (Table 3) medium; over two-thirds of the batches of this critical medium ingredient tested were rejected because they failed to support growth of the relapsing fever spirochete. Larger tissue and organ samples (bladder, heart, spleen and joint) can be cultured by homogenization in liquid BSK II (Table 3) medium (10% wt/vol) with a Stomacher Lab Blender (Tekmar, Cincinnati, OH). Larger debris is allowed to settle and serial dilutions (10-fold) of the supernatant are made in the semisolid BSK II (Table 3) medium. Cultures are incubated at 30–35°C and examined by darkfield microscopy for spirochetes at weekly intervals.

In contrast to in relapsing fever patients, relatively low densities of spirochetes are present in the blood and tissues of Lyme disease patients. Nevertheless, numerous laboratories have reported the successful isolation of *B. burgdorferi* from skin, blood and other tissues obtained from Lyme disease patients. Spirochetes are most readily cultured from biopsy specimens of the skin lesion of erythema migrans (EM; Fig. 20) and acrodermatitis chronicum atrophicans (ACA; Berger et al., 1985; Berger et al., 1992; Schwartz et al., 1992; van Dam et al., 1993; Nadelman et al., 1996; Picken et al., 1998). *Borrelia burgdorferi*, however, has been isolated and subcultured from the blood and plasma of Lyme disease patients (Benach et al., 1983; Nadelman et al., 1989; Berger et al., 1994; Wormser et al., 1998; Wormser et al., 2000). Significantly improved rates of spirochete cultivation were obtained when plasma (instead of serum or blood) and/or large sample sizes (up to 9 ml of whole blood or 3 ml of serum) were used to inoculate BSK II (Table 3) medium (Wormser et al., 1998; Wormser et al., 2000). Although spirochetes have been isolated and cultured from the cerebrospinal fluid (CSF) of patients exhibiting neurological symptoms (Steere et al., 1983; Nocton and Steere, 1995), attempts to recover spirochetes from this tissue are usually not productive. Although this fastidious organism is clearly difficult to cultivate in vitro, the lack of successful cultivation of spirochetes from CSF may be more a reflection of the limited invasion of the central nervous system by *B. burgdorferi* (Steere et al., 1983; Barthold et al., 1991; Estanislao and Pachner, 1999; Cadavid et al., 2000).

Isolation of *Borrelia* from Animal Tissues

The most common method of cultivating *Borrelia* spp. from field-caught or experimentally infected animals is by inoculation of BSK II (Table 3) medium with several drops of blood (relapsing fever) or by ear punch biopsy (Lyme borreliosis; Sinsky and Piesman, 1989). For ear punch biopsy, a small sample of skin tissue (3 mm) may be taken from an infected animal's ear using a punch tool (available from most biological and veterinary suppliers) or by using fine point scissors to excise a 3-mm long "pie cut" from the animal's ear. The entire ear biopsy is placed in a small volume (1–2 ml) of liquid BSK

II (Table 3) medium. In this case, use of antibiotic additives (rifampicin [5 mg/ml], phosphomycin [2 mg/ml], and amphotericin B [250 mg/ml]), commercially available as a cocktail from Sigma-Aldrich Chemical Corp. (http://www.sigma-aldrich.com) (catalog # A 1956), is recommended to reduce the risk of contamination with animal and/or environmental flora. Although borreliae usually can be detected in culture medium within one to three weeks of incubation, some isolates may not be visible for several months. *Spirochetes* also may be cultured from other animal tissues, including heart, bladder and joint (Anderson et al., 1986; Schwan et al., 1988a; Sinsky and Piesman, 1989; Anderson and Magnarelli, 1992; Pachner et al., 1993).

Uncultivatable *Borrelia* spp.

Despite the successful use of artificial media in cultivating spirochetes from both ticks and mammalian tissues, several examples of uncultivatable *Borrelia* spp. have been reported. Anda et al. (1996) described the isolation of a new relapsing fever *Borrelia* following isolation of this agent from the blood of three febrile patients. Although refractory to in vitro cultivation attempts using numerous BSK II (Table 3) formulations and growth conditions, this organism can be passaged in mice. In addition to being visible in the blood of infected mice, spirochetes were also detected in liver and spleen by Dieterle stain 15 days post-inoculation (Anda et al., 1996). A second notable example of an uncultivatable *Borrelia* spp. is the *Amblyomma americanum* spirochete, *Borrelia lonestari* (*B. barbouri*). This spirochete is thought to be responsible for a tick-associated Lyme disease-like illness in the southern United States (Barbour et al., 1996a). Although immunological and molecular reagents have been developed to detect and partially characterize this spirochete using field-collected tick specimens (Barbour et al., 1996b; Rich et al., 2001), it has yet to be successfully cultivated in vitro using media that support the growth of *B. burgdorferi* (i.e., BSK; Table 3). The inability to cultivate this spirochete (Barbour et al., 1996a) from patient samples and distinguish it from the closely related *B. burgdorferi* may result in the true incidence of *B. lonestari* borreliosis being significantly underestimated. This is a particular concern in areas where the vectors of both spirochetes coexist and coassociate with the human population. In such areas, *B. lonestari*-associated borreliosis could result in physician-diagnosed or -suspected Lyme disease that could be both culture-negative and seronegative. In addition, coinfection with both species of spirochetes may also go undetected.

Use of PCR for Detection of *Borrelia* in Tissues

In addition to the complex media requirements and the fastidious nature of *Borrelia*, several additional factors, including the low density of spirochetes in blood and other tissues during infection, the large volume of sample required, and the expertise needed to biopsy skin and other tissues (i.e., cerebrospinal fluid [CSF] and synovial fluid [SF]) from Lyme disease patients, have made clinical diagnosis based on spirochete isolation unreliable. The development of assays based on the sensitive polymerase chain reaction (PCR), however, has made the detection of *Borrelia* within relatively small samples of blood and other tissues feasible. PCR-based assays have been used to detect spirochetes in EM skin lesions (Fig. 20) and lesion exudate (Melchers et al., 1991; Schwartz et al., 1992), ACA lesions (Moter et al., 1994), plasma (Goodman et al., 1995; von Stedingk et al., 1995), blood (Guy and Stanek, 1991), urine (Lebech and Hansen, 1992; Huppertz et al., 1993; Liebling et al., 1993; Priem et al., 1997), CSF (Keller et al., 1992; Lebech and Hansen, 1992; Huppertz et al., 1993; Liebling et al., 1993; Nocton et al., 1994; Nocton et al., 1996; Priem et al., 1997), and SF (Liebling et al., 1993; Bradley et al., 1994; Nocton et al., 1994; Jaulhac et al., 1996; Priem et al., 1997). Although these studies demonstrate that PCR-based methodologies can successfully detect *Borrelia* spp. from a variety of tissues, the clinical utility of these detection methods, however, has not been fully established. For a comprehensive review of PCR-based detection of *Borrelia*, see Schmidt (1997).

Culture Bias

The application of culture-independent techniques (i.e., direct PCR-amplification) has revealed that sequences retrieved from bacteria cultured from tick and patient samples often do not fully reflect the degree of sequence diversity present in the uncultured sample. This phenomenon, called "culture bias," is thought to result from the preferential growth of one genetically distinct subpopulation present within a sample such that it outgrows other members within the population. One of the first examples of borrelial culture bias was discovered during a comparative analysis of cultured and uncultured (i.e., PCR-amplified directly) tick samples collected from an area of the country (Colorado) where Lyme disease is not endemic (Fig. 16). In these studies, Norris et al. (1997) demonstrated that the genetic diversity of alleles at three different loci (*flaB* [see "Flagella"], *p66* [*Borrelia* Molecular Architecture], and *ospA* [see "Reciprocal

Expression of OspA and OspC"]) was consistently lower in cultured spirochetes, suggesting that culturing of *B. burgdorferi* in BSK-H medium may select for specific genotypes. In addition, some alleles were restricted to either cultured organisms or ticks alone (Norris et al., 1997). The potential clinical relevance of culture bias became evident when a similar study was performed using samples from Lyme disease patients (Liveris et al., 1999). In this study, DNA from in vitro-cultivated *B. burgdorferi* or from blood and tissue biopsy samples obtained from Lyme disease patients was characterized by restriction length polymorphism (RFLP) typing of the 16S-23S ribosomal DNA intergenic spacer region. The RFLP diversity seen by direct tissue analysis was significantly greater than that present in the cultured samples. These results are consistent with the conclusions drawn from the Colorado tick study cited above. The combined results of these studies suggest that the diversity of genotypes present within either tick or human populations may be significantly underestimated if based on in vitro cultivation or direct PCR-amplification alone.

Preservation

Borreliae are best preserved by the addition of glycerol (final concentration, 10–15%) to blood or plasma from infected animals (relapsing fever borreliae), or to culture medium, and stored at –70°C or in liquid nitrogen. Spirochetes may be recovered from glycerol stocks by the addition of a small amount (0.5 ml) of BSK II (Table 3) medium to the top layer of the frozen culture, pipetted several times, removed, and transferred to a sterile test tube containing an additional 1–3 ml of BSK II (Table 3) medium. The "resurrected" spirochetes should be visible by darkfield microscopy within 1–2 weeks.

Physiology

The publication of the *Borrelia burgdorferi* genome (The *B. burgdorferi* Genome Sequence) has vastly increased our understanding of the physiology of this *Borrelia* species. For a complete outline of the results of this project, visit The Institute for Genome Research (TIGR)). A survey of the *B. burgdorferi* genome revealed a paucity of genes associated with the biosynthesis of amino acids, fatty acids, enzyme cofactors, and nucleotides (Fraser et al., 1997). The absence of genes involved in fatty acid synthesis is in agreement with the biochemical evidence that 1) borreliae are unable to elongate or beta-oxidize fatty acids (Livermore and Johnson, 1978; Belisle et al., 1994) and 2) the fatty acid composition of borrelial cells reflects that of the growth medium (Livermore and Johnson, 1978; Belisle et al., 1994). These findings are thought to explain, at least in part, the fastidious nature of this organism and the requirement for serum-supplemented mammalian tissue culture medium (i.e., CMRL; see Table 3). Genes encoding all of the enzymes of the glycolytic pathway were identified (Fraser et al., 1997). Work by Gebbia et al. (1997) identified the glycolytic enzyme operons in *B. burgdorferi* and *B. hermsii*, and as expected, these loci exhibit very high sequence identity and similar orientations on the linear chromosomes of both organisms. Analysis of the metabolic pathways identified suggests that glucose serves as the major energy source (Fraser et al., 1997). Consistent with the microaerophilic nature of borreliae, genes involved in the conversion of pyruvate (pro-

duced by glycolysis) to lactate were identified (Fraser et al., 1997). This finding also is supported by biochemical studies that identified lactic acid as the predominant metabolic end product of glucose utilization (Kelly, 1976). None of the genes encoding proteins of the tricarboxylic acid cycle or oxidative phosphorylation were identified. These findings, along with the lack of the necessary components of a respiratory transport chain, may explain the slow growth rate (12–30-hour doubling time) of this organism. Analysis of the genome also revealed genes involved in the utilization of glycerol, glucosamine, fructose and maltose, suggesting that the bacterium may also use these substrates as alternative carbon sources (Fraser et al., 1997). Although primarily serving as a component of the cell wall, genes (*N*-acetylglucosamine-6-phosphate deacetylase [BB0151] and glucosamine-6-phosphate isomerase [BB0152]) were identified which would allow *N*-acetylglucosamine (NAG) to be used as an alternative carbon source. The NAG is a necessary additive to BSK II (Table 3) medium and is required for growth of *B. burgdorferi* (Kelly, 1971; Barbour and Hayes, 1986b). Additionally, a model has been proposed for the potential utilization of the tick cuticle component chitin (composed primarily of NAG) as an alternative carbon source for *Borrelia*, which may be contained within the midgut of the tick for extended periods of time (months to a year) between feeding and subsequent transmission to a new mammalian host (Fraser et al., 1997). Support for this hypothesis is provided by the identification of a phosphotransferase system (PTS) cellobiose transporter operon (BBB04, BBB05, and BBB06) that could possibly transport chitobiose (di-*N*-acetyl-D-glucosamine), a molecule with structural similarity to NAG, and a gene product with sequence similarity to chitobiase BBB02, which may convert chitobiose to NAG (Fraser et al., 1997).

The genes encoding essential transcription (sigma factors σ70, σ54, and *rpoS*, translation *nusA*, *nusB*, *nusG*, *rho*, and 31 tRNAs), and DNA replication and repair machinery (DNA pol III, ligase, gyrase, *uvrA-D*, and *recA*) were identified, along with the chromosomal origin of replication (*ori*; Fraser et al., 1997; Picardeau et al., 1999a). In addition, two independent studies have examined the effect of DNA replication and transcription on triplet codon usage for *B. burgdorferi* (McInerney, 1999; Lafay et al., 1999). These studies suggest that evolutionary pressures have resulted in an enrichment for highly expressed genes on the leading strand during the asymmetrical replication of this organism's linear chromosome.

Growth of *Borrelia burgdorferi*: No Iron Requirement

A common theme in microbial pathogenesis is a requirement for iron during growth within a mammalian host. For reviews, see Payne (1993), Litwin and Calderwood (1993), Vasil and Ochsner (1999), and Ratledge (2000). The level of free iron present within human serum and/or tissues is well below that required for growth of many microorganisms. This level is further limited by the production and secretion of the iron-binding protein lactoferrin by the human host during infection. To overcome this host limitation, many bacteria have evolved specialized systems for the acquisition and assimilation of iron in vivo. A recent survey of the *Borrelia* genome suggests that this bacterium has overcome iron limitation within the human host by dispensing with those proteins that utilize iron as a cofactor (i.e., catalase, peroxidase, cytochromes, respiratory proteins, and metalloenzymes; Fraser et al., 1997; Posey and Gherardini, 2000). In support of this hypothesis, Posey and Gherardini (2000) demonstrated that 1) *Borrelia* were able to grow normally in iron-limited medium and 2) the level of iron (either free or bound to proteins) detected in *B. burgdorferi* cell lysates was well below a physiologically relevant concentration. The genes encoding a number of metal-requiring proteins, however, were identified within the *Borrelia* genome, including superoxide dismutase, RNA polymerase and DNA polymerase (Fraser et al., 1997). Although the metal requirements of these putative borrelial metalloenzymes have not been determined, it has been suggested that these proteins may have evolved to utilize alternative metal ions (i.e., manganese and zinc; Posey and Gherardini, 2000).

Borrelia Molecular Architecture

Borrelia share the same basic ultrastructural features as other members of the Family Spirochaetaceae. These features include an outer membrane that encloses a protoplasmic cylinder encased within a cytoplasmic membrane (Fig. 6). Although similar to Gram-negative bacteria in possessing both cytoplasmic and outer membranes, several fundamental differences in the outer membranes of these two types of bacteria have been revealed using combined molecular, ultrastructural and immunological methods. The outer membranes of Gram-negative bacteria characteristically contain a high density of proteins with extensive β-pleated sheet structure (i.e., porins) and no or only rare surface-exposed lipoproteins (Lugtenberg and van Alphen, 1983; Pugsley, 1993). In addition to a

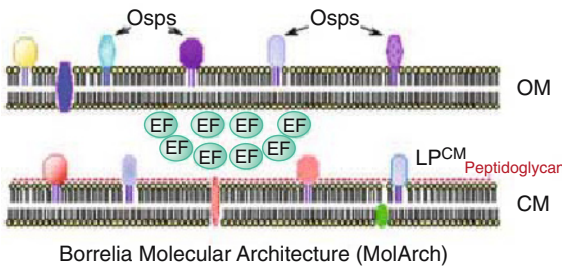

Fig. 6. *Borrelia burgdorferi* molecular architecture. The outer membrane (OM) of *B. burgdorferi* contains a limited number of integral membrane proteins (outer surface proteins or Osps). The majority of proteins within borrelial outer (OM) and inner cytoplasmic (CM) membranes are lipoproteins, anchored via associated lipid moieties. Lipoproteins (LP) anchored to the periplasmic leaflet of the CM are in close association to the peptidoglycan layer. Endoflagella (EF; see "Flagella") are located in the periplasmic space.

significantly lower protein-to-lipid ratio, *B. burgdorferi* outer membranes, in contrast to Gram-negative membranes, contain predominantly lipoproteins (many of which are lipid-anchored to the periplasmic face of the cytoplasmic membrane) and relatively small amounts of proteins with transmembrane (membrane-spanning) domains (Walker et al., 1991; Radolf et al., 1994b; Radolf et al., 1995b; Jones et al., 1995). In concert with the spirochete's ability to alter its outer membrane composition (see "Antigenic Variation") during the course of infection, these two characteristics of the borrelial membrane may help to explain the Lyme disease spirochete's ability to avoid host clearance mechanisms and establish persistent infection. In addition, *Borrelia* spp. have the potential to differentially express (see "Differential Gene Expression") (i.e., downregulate) many of their surface-exposed lipoproteins, thereby further limiting the ability of the host immune system to recognize these immunogens.

One of the most striking characteristics of spirochetal outer membranes, particularly those of *B. burgdorferi* and *Treponema pallidum* (see The Genus *Treponema* in this Volume), is their lability. As a result, the outer membranes of these organisms are often disrupted during routine experimental manipulations (i.e., centrifugation), initially leading some investigators to conclude (using immunofluorescence) that a number of borrelial lipoproteins (i.e., outer surface protein OspA [see "Reciprocal Expression of OspA and OspC"] and OspB) were exclusively surface-exposed (Barbour et al., 1983; Barbour et al., 1984b; Luft et al., 1989). Later studies, using techniques that do not disrupt the spirochetal outer membrane prior to analysis (immunocryoultramicrotomy, Brusca et al., 1991, and immunofluorescence using spirochetes encapsulated within agarose beads, Cox et al., 1996) demonstrated that most of the cell's complement of OspA and OspB is located in the periplasmic space. A similar localization pattern has now been established for a third lipoprotein, OspC (Cox et al., 1996; see "Reciprocal Expression of OspA and OspC"). The presence of some lipoproteins simultaneously in both the inner and outer membranes suggests that the content of borrelial membranes is dynamic (Brusca et al., 1991; Cox et al., 1996). This hypothesis is further supported by a recent study in which exogenously provided recombinant lipoproteins were shown to be incorporated into the outer membranes of viable spirochetes (Bunikis et al., 2001). It is tempting to speculate whether *Borrelia* spp. use the inner membrane as a "holding depot" for lipoproteins that may eventually be transferred to the outer membrane and bacterial surface as the organism encounters different environmental/growth conditions.

A second class of proteins within the outer membranes of *Borrelia* is the membrane-spanning proteins. To date, only a handful of such proteins have been identified. Of these, P66 has attracted the most attention. This 66-kDa protein was identified as a component of borrelial membrane-enriched cell fraction (Barbour et al., 1984b; Bunikis et al., 1995) and also, by an independent group, using a protease screening assay (Probert et al., 1995). Computer analyses predict that, in addition to having an N-terminal signal peptidase I cleavable leader peptide, P66 contains a C-terminal intramembranous domain (amino acid residues 498–597) composed of two transmembrane-spanning hydrophobic α-helices (Bunikis et al., 1998). This prediction is supported by experimental studies, immunoelectron microscopy (Bunikis et al., 1995) and protease (trypsin and proteinase K) sensitivity (Probert et al., 1995), which identified a small (~5 kDa) flexible loop fragment near the C-terminus. This 5-kDa loop domain appears to be the only portion of P66 that is exposed on the spirochetal surface (Bunikis et al., 1996; Bunikis and Barbour, 1999). Recent evidence suggests that P66 is physically associated with OspA and that OspA may shield P66 from proteolytic attack (Bunikis and Barbour, 1999). Consistent with its having surface-exposed epitopes, mice immunized with recombinant P66 were partially protected against *B. burgdorferi*-challenge (Exner et al., 2000). Antibodies against P66 also were readily detectable in immune sera from human Lyme disease patients (Sadziene et al., 1993; Bunikis et al., 1996; Ntchobo et al., 2001), confirming that this protein is expressed during infection.

Two different functions have been proposed for P66. Coburn et al. (1999) reported that recombinant P66 binds to β_3 chain integrins, whereas Skare and coworkers (Skare et al., 1997) reported that the recombinant protein has porin-like activity in planar lipid bilayers. While neither of these functions is mutually exclusive, they are problematic, however, when viewed against the topological analyses indicating that P66 has only limited surface exposure. The P66 integrin-binding domain was mapped to a region that does not appear to be surface-exposed (Coburn et al., 1999). Porins typically contain multiple membrane-spanning domains (Nikaido, 1996). Further work will be needed to resolve these ostensible discrepancies.

Two other membrane-spanning proteins identified in *B. burgdorferi* are *Borrelia* glycosaminoglycan (GAG)-binding protein (Bgp) and an outer membrane-spanning protein, Oms28, with an observed mass of 28 kDa. The Bgp protein was identified from membrane-enriched extracts of *B. burgdorferi* on the basis of its glycosaminoglycan-binding and hemagglutination activities (Parveen and Leong, 2000). Indirect immunofluorescence and Western blotting of purified outer membrane vesicles (both with anti-Bgp antiserum) were used to localize this protein to the spirochetal surface. Purified recombinant Bgp also was shown to inhibit attachment of *B. burgdorferi* to the surface of several different mammalian cell lines (293, Vero and C6), a result consistent with this protein being present on the surface of spirochetes (Parveen and Leong, 2000). The GAG-binding specificity of Bgp, however, has not been determined. The Oms28 protein was identified in *Borrelia burgdorferi* outer membrane preparations based on its porin activity; this activity was demonstrated in a planar lipid bilayer assay using *Escherichia coli* overexpressing recombinant Oms28 (Skare et al., 1996).

Peptidoglycan

The peptidoglycan of *Borrelia* spp. is responsible for imparting structural stability to the protoplasmic cylinder of the spirochete and is the primary component of the bacterial cell wall (Beck et al., 1990; Fig. 6). Additional data demonstrating a structural role of the borrelial peptidoglycan were reported by Charon and coworkers (Motaleb et al., 2000); spirochetes with their outer membranes removed were readily lysed by the addition of the peptidoglycan-degrading enzyme streptozyme (Motaleb et al., 2000). Muramic acid (Ginger, 1963) and ornithine (Klaviter and Johnson, 1979) have been identified as components of the peptidoglycan in relapsing fever *Borrelia*. Although biochemical analyses of the peptidoglycan of other *Borrelia* have not been performed to date, it is likely that both of these components are present in all borrelial cell walls.

Flagella

Spirochetes are unique in that their organelles of motility are located beneath their surface (Fig. 6). For detailed reviews of spirochetal and borrelial flagella ultrastructure, see Holt (1978) and Barbour and Hayes (1986b), respectively. For a comprehensive contemporary review of spirochete flagella and motility, see Li et al. (2000a). Encased between the outer and cytoplasmic (inner) membranes are the periplasmic flagella, also referred to as "endoflagella" (Fig. 6); in this respect, spirochetes are distinct from other bacteria in having their organelles for motility reside inside the cell within the periplasmic space. The number of periplasmic flagella in borreliae varies depending on the species, as well as within the same strain; the relapsing fever spirochetes generally have between 15 and 30 flagella per cell end, whereas Lyme spirochetes have from 7 to 11 per end (Hovind-Hougen, 1976; Barbour and Hayes, 1986b). The periplasmic flagella are composed of two classes of proteins, FlaB, core protein, flagellin, and FlaA (a possible sheath protein, with FlaB being the major constituent). Although the periplasmic flagella of other spirochete species (i.e., *Brachyspira*) have been shown to be composed of at least three core proteins (FlaB1, FlaB2 and FlaB3) and two sheath proteins (FlaA1 and FlaA2; Li et al., 2000b), the periplasmic flagella of *Borrelia burgdorferi* have been shown to be composed of only one each of these two types of proteins (Ge and Charon, 1997a; Fraser et al., 1997; Ge et al., 1998). In addition, the relatively low abundance of FlaA in *B. burgdorferi* suggests that it is unlikely to form a sheath along the entire flagellar length (Li et al., 2000a). A comparison of the periplasmic flagella proteins shows a high degree of conservation (immunological crossreactivity and sequence similarity) within the spirochete phylum (Limberger and Charon, 1986; Cockayne et al., 1987; Norris et al., 1988; Koopman et al., 1992; Trueba et al., 1992; Limberger et al., 1993; Ruby et al., 1997; Ge et al., 1998).

The flagella of *Borrelia* spp. have been shown to be 1) inserted subterminally and bipolarly, 2) wrapped around the protoplasmic cylinder, and 3) overlapping in the middle of the protoplasmic cylinder (Holt, 1978). Electron microscopy studies revealed that the periplasmic flagella form a bundle and are not dispersed around the cell in the periplasmic space (Hovind-Hougen, 1984). Purified periplasmic flagella have been shown to be left-handed with a defined helix pitch and

diameter. These dimensions, however, are dramatically altered when measured in situ (i.e., in association with the protoplasmic cylinder; Goldstein et al., 1996). The helical shape of the flagella, wrapped in a bundle around the peptidoglycan-encased protoplasmic cylinder, imparts to the spirochete a flat-wave morphology (Motaleb et al., 2000; Fig. 7). Charon and coworkers (Motaleb et al., 2000) hypothesize that the outer membrane juxtaposes the peptidoglycan and periplasmic flagella so that these structures can optimally interact with one another to promote cell motility. The dynamics of *Borrelia* spp. motility also have been examined (Goldstein et al., 1994). These studies have demonstrated that, in contrast to their helical shape, translating (i.e., moving) spirochetes swim with a planar waveform similar to that of eukaryotic flagella and propagate backward moving spiral waves. The waves on individual spirochetes were observed to gyrate in a counterclockwise direction (Goldstein et al., 1994; Fig. 7). In addition, periplasmic flagella, inserted at opposite ends of the protoplasmic cylinder, were shown to rotate in opposite directions around one another, causing the cell to bend or exhibit characteristic "flexing" morphology (Goldstein et al., 1994). This rotation, however, was not required for the spirochetes to maintain their helical morphology (Motaleb et al., 2000). The contribution of the periplasmic flagella to both motility and cell morphology has been confirmed using both a spontaneous *Borrelia* mutant (Sadziene et al., 1991) and a *flaB* mutant strain created by allelic exchange (Motaleb et al., 2000). In both studies, the spirochetes not only were nonmotile, but also exhibited a long, straight, rod-shaped morphology. The periplasmic flagella also help the cells maintain their motility in environments of relatively high viscosity (Berg and Turner, 1979; Kimsey and Spielman, 1990; Goldstein et al., 1994). Although borreliae are extracellular parasites, this vigorous form of motility has also been implicated in the spirochete's ability to invade and infect various tissues (including connective tissue and extracellular matrix) and to traverse endothelial cell junctions (Comstock and Thomas, 1989; Comstock and Thomas, 1991; Szczepanski et al., 1990; Sadziene et al., 1991; Klempner et al., 1993).

The 35 genes encoding the proteins required for the synthesis of the complete flagellar organelle are grouped into seven clusters (Fig. 8) on the *B. burgdorferi* chromosome (Li et al., 2000a). Promoter analyses of the *B. burgdorferi* *flaA* and *flaB* genes revealed a striking difference between the regulation of flagellin gene (*flaB*) expression in this spirochete and in other bacteria; transcription of the *flaB* gene in *B. burgdorferi* appears to be initiated by the housekeeping transcription factor, σ 70. This is in contrast to the flagellin genes, *flaB* and *fliC*, in other spirochetes and bacteria, respectively, which are known to be or thought to be controlled by the alternative σ factor, σ 28 (Li et al., 2000b). These data also are consistent with the absence of 1) σ 28 promoter recognition sequences, 2) a σ 28-encoding gene, and 3) a gene encoding the anti-σ factor, FlgM, within the *B. burgdorferi* genome sequence (Fraser et al., 1997; Li et al., 2000a). Interestingly, transcription of the *flaB* gene from *T. pallidum* (the only other sequenced spirochetal genome) does appear to be initiated by σ 28, and a gene encoding this σ factor was identified within this treponemal genome.

Lipoproteins

The study of borrelial lipoproteins has long been a focus of research involving this bacterium. For a recent review, see Haake (2000). Borrelial lipo-

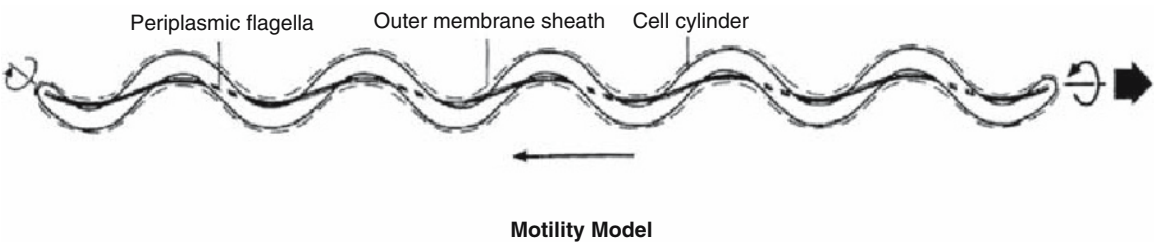

Fig. 7. Proposed model of *Borrelia burgdorferi* motility translating toward the right (wide arrow). The ridge, which is composed of the periplasmic flagella, extends down the length of the cell, and is left-handed with respect to the cell axis. The periplasmic flagella rotate counterclockwise (CCW) as viewed from the back of the cell (thin arrow at anterior end). This rotation causes waves to move from the anterior to the posterior ends of the cell (center arrow). Concomitant with this rotation, the cell rolls clockwise (CW) about the body axis (thin arrow at the posterior end). Image taken from Li et al. (2000b), with permission of Horizon Scientific Press.

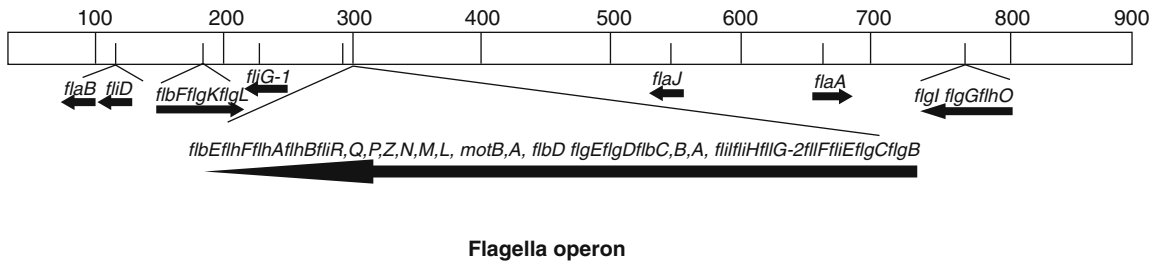

Fig. 8. Organization of the motility genes of *B. burgdorferi* (Fraser et al., 1997; Ge and Charon, 1997a; Ge and Charon, 1997b). Black arrows indicate direction of transcription of genes, and promoters have been identified by primer extension and operons by RT-PCR (Ge and Charon, 1997a; Ge and Charon, 1997b). Gray stippled arrows indicate presumed promoters, operons, and direction of transcription based solely on sequence analysis. Adapted from Li et al. (2000b), with permission of Horizon Scientific Press.

proteins are of interest for several reasons: 1) they are often found at the interactive surface (*Borrelia* Molecular Architectiture) between the spirochete and its growth environment, 2) many have been shown to be differentially expressed (see "Differential Gene Expression") depending on the growth environment, with some being preferentially expressed within either the arthropod or mammalian host, 3) some have assigned physiological roles (see "Differential Gene Expression"), 4) they may serve as potential protective immunogens (see "Lyme Disease Vaccine"), and 5) they are potent proinflammatory agonists (Lipoproteins and the Innate Immune Response). The significance of this class of membrane proteins is highlighted by the large number of putative lipoproteins identified (>150 on the linear chromosome and the plasmids) in the *Borrelia burgdorferi* genome, comprising nearly 10% of the total coding region (Fraser et al., 1997; Casjens et al., 2000). Not surprisingly, the majority of borrelial membrane proteins were found to be typical bacterial lipoproteins, possessing consensus lipoboxes (leader peptides required for lipid modification and transport to the membrane; Fraser et al., 1997). As also would be expected, genes encoding the necessary enzymes for lipid modification (prolipoprotein diacylglycerol transferase *lgt* and prolipoprotein signal peptidase *lsp*) also were identified. A gene encoding the enzyme (Lnt) responsible for the next step in lipoprotein biosynthesis, transfer of a fatty acid from a membrane phospholipid to the N-terminal cysteine of the mature polypeptide, however, was not identified. Since this activity has been shown by biochemical and structural analyses to exist in *Borrelia* (Brandt et al., 1990; Belisle et al., 1994; Beermann et al., 2000), it is presumed that the organism contains a novel form of this enzyme.

Transporters

A number of genes thought to be involved in the transport of solutes and small molecules (Fig. 9) were identified within the *B. burgdorferi* genome; the linear chromosome encodes 46 ORFs and the plasmids of an additional six ORFs related to the transport and binding of proteins. The combined ORFs form 16 distinct membrane transporters of amino acids (i.e., glycine/betaine/L-proline and oligopeptides), carbohydrates (i.e., methylgalactoside, ribose, galactose, fructose, glucose and maltose), small molecules (glutamate, chromate and spermadine/putrescine), anions (i.e., phosphate), and cations (i.e., magnesium and potassium; Fraser et al., 1997). The majority of these transport systems are members of the family of ATP-dependent, multi-subunit ABC-transporters, with many exhibiting broad substrate specificity (Fraser et al., 1997). The ability of *Borrelia* to transport a wide variety of solutes is thought to compensate for this organism's restricted coding potential and its inability to synthesize amino acids de novo. A survey of the genome sequence failed to identify transport systems for nucleotides, nucleosides, NAD/NADH, or fatty acids, although proteins responsible for these functions are likely to be present (Fraser et al., 1997).

The oligopeptide transporters (Opp) are the best studied of the *Borrelia* transporter families. This family is composed of 1) five peptide-binding proteins, OppA1, OppA2, OppA3, OppAIV, and OppAV (all thought to be lipoproteins, but lipid modification has only been confirmed for OppA-1, OppA-2 and OppA-3; Kornacki and Oliver, 1998); 2) two transmembrane proteins (OppB and OppC); and 3) two ATPases (OppD and OppF, Fraser et al., 1997; Bono et al., 1998). OppA1, OppA2 and

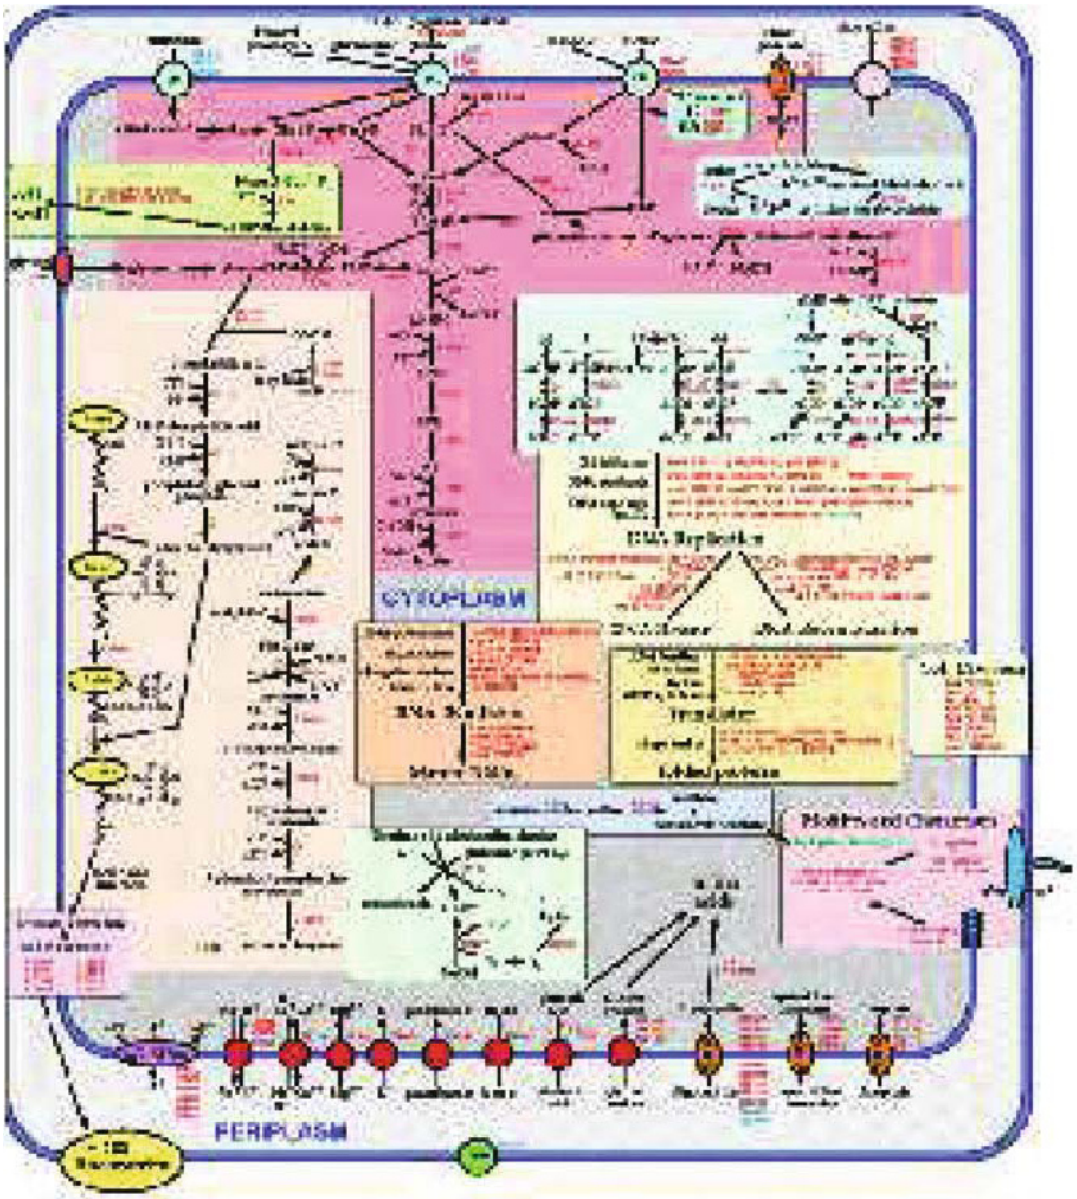

Fig. 9. Solute transport and metabolic pathways in *B. burgdorferi*. A schematic of a *B. burgdorferi* cell, providing an integrated view of the transporters and the main components of the metabolism of this organism, as deduced from the genes identified in the genome. The ORF numbers correspond to those listed in Table 2 of Fraser et al. (1997). Red indicates chromosomal and blue indicates plasmid ORFs. Presumed transporter specificity is indicated. Yellow circles indicate places where particular uncertainties exist as to the substrate specificity, subcellular location, direction of catalysis, or absence of expected activities. Taken from Fraser et al. (1997) and www.nature.com (http://www.nature.com/cgi-taf/DynaPage.taf?file=/nature/journal/v390/n6660/full/390580a0_fs.html) and reprinted by permission from Nature (http://www.nature.com), © 1997 Macmillan Magazines Ltd.

OppA3, along with OppB-F, are encoded in tandem on the chromosome, whereas OppAIV and OppAV are encoded on a circular (cp26) and linear (lp54) plasmid, respectively (Bono et al., 1998). This genetic organization is unique among oligopeptide transporters, which typically are present at a single chromosomal locus. Paralogs of these genes have also been identified in the *B. burgdorferi* sensu lato strains, *B. hermsii* and *B. afzelii* (Kornacki and Oliver, 1998).

The putative physiological roles for this, and other oligopeptide transporters, include sensing pertinent environmental signals and nutrient uptake (by recycling cell wall and external peptides; Bono et al., 1998). The OppA (OppA-1, OppA-2, OppA IV and OppAV) proteins were able to function as substrate binding proteins by complementation of an *opp*$^{-}$ *E. coli* strain (Lin et al., 2001). To explore the role of this oligopeptide permease in the transmission and adaptation of *B. burgdorferi* between the arthropod and mammalian environments, an *oppAIV* mutant was created by insertion inactivation; this mutant did not show impaired growth in BSK II medium (Bono et al., 1998; Table 3). Unfortunately, the current state of borrelial genetics did not allow for this mutation to be constructed in an infectious *Borrelia* strain, and therefore its ability to cycle between the tick and mammalian host could not be determined. A *B. burgdorferi* strain N40 containing a spontaneous truncation in *oppA2*, however, was successfully maintained in the tick-mammal infectivity cycle. This latter observation may be due to functional redundancy among the five OppA peptide-binding proteins, or this system is not essential for maintenance of the enzootic cycle.

Genetics

The organization of the *Borrelia* genomes is unique within the Family Spirochaetaceae and perhaps among the prokaryotes. Most significantly, the chromosome is linear in nature, having single-stranded hairpin loops at each termini, resembling telomeres, a form of DNA thought to be restricted to eukaryotes and viruses (Barbour and Garon, 1987; Baril et al., 1989; Ferdows and Barbour, 1989; Hinnebusch et al., 1990; Bergstrom et al., 1992; Casjens and Huang, 1993; Casjens et al., 1997a; Casjens, 1999; Casjens et al., 2000; Volff and Altenbuchner, 2000). Borrelial DNA has a G+C content of ~29 mol%, which is lower than that (www.tigr.org) reported for *Treponema pallidum* and *Leptospira* (Hyde and Johnson, 1984; Fraser et al., 1997; Fraser et al., 1998). The chromosome copy number of one borrelial species, *B. hermsii*, was determined to be 16 copies per cell (Kitten and Barbour, 1992). These data were also supported using individual agarose-embedded spirochetes (*B. burgdorferi* and *B. hermsii*) labeled in situ and visualized directly by epifluorescence microscopy (Hinnebusch and Bendich, 1997). This number is significantly higher than that of the prototypic bacterial species, *E. coli*, which when actively growing, has an average of 6.5 chromosomal origins per cell (Bremer and Dennis, 1987). In situ visualization of the bacterial nucleoids of *E. coli* and *Borrelia* spp. by fluorescence microscopy also suggests that the *Borrelia* spp. chromosome is not organized into the tightly packed, or condensed, nodes found in *E. coli*, but instead consists of a loose meshwork of DNA strands that lack a central organizing node (Hinnebusch and Bendich, 1997).

The putative origin of replication (*ori*) of the *B. burgdorferi* chromosome was recently mapped using a combination of theoretical (GC skew analysis) and molecular (nascent DNA strand analysis) methodologies (Picardeau et al., 1999b). Analysis of the GC skew pattern identified a region in which there was a switch in polarity from positive to negative at the middle of the chromosome. A cumulative GC skew diagram of complete series of *B. burgdorferi* gene sequences showed a minimum between the *dnaA* and *dnaN* genes, analogous to the position of *oriC* in an identical analysis of *E. coli*. Further analysis of this region, however, failed to identify other sequences (DnaA initiator protein-binding sites and AT-rich regions) characteristic of both Gram-negative and Gram-positive origins (Picardeau et al., 1999a). The identification of a DnaA ortholog in *B. burgdorferi* suggests that this protein may bind to a unique site within the origin (Fraser et al., 1997).

Plasmids of *Borrelia*

In addition to containing linear chromosomes, any one spirochete may contain 21 or more different extrachromsomal elements (plasmids), ranging in size from 5–56 kb, in either linear or supercoiled circular forms (Fraser et al., 1997; Casjens et al., 2000; Fig. 11). Linear plasmids also have covalently closed termini similar to those on the linear chromosome. The unusual linear plasmids were first described in *B. hermsii*, but multiple linear and circular plasmids have also been described for many other *Borrelia* including *B. hermsii*, *B. parkeri*, *B. turicatae*, *B. crocidurae*, *B. burgdorferi*, *B. coriaceae* and *B. anserina* (Hyde and Johnson, 1984; Barbour, 1988; Goodman et al., 1991; Kitten and Barbour, 1992; Xu and Johnson, 1995; Marconi et al., 1996a; Barbour et al., 1996b; Stevenson et al.,

2000a; Stevenson et al., 2000b; Hendson and Lane, 2000).

The only fully sequenced, and therefore the best characterized, genome is that of *B. burgdorferi* (The *B. burgdorferi* Genome Sequence). In this species, the full complement of linear and circular plasmids comprises approximately one-third of the total genomic content (Fraser et al., 1997; Casjens et al., 2000). Studies examining the copy number of *Borrelia* plasmids indicate that the linear and circular plasmids are closely maintained at approximately one plasmid copy per chromosome in a population of cells (Kitten and Barbour, 1992; Hinnebusch and Barbour, 1992; Casjens and Huang, 1993). This tight control of plasmid copy number suggests that replication of these extrachromosomal elements may be controlled by a mechanism similar to that of chromosomal replication. It has been proposed that the *Borrelia* linear plasmids are actually "minichromosomes" (Casjens, 1999; Barbour, 1993). The mechanism by which the linear and circular plasmids are replicated is currently a matter of much speculation, although recent data would suggest that the linear plasmids initiate replication at their centers and that replication in both types of plasmids proceeds in a bidirectional manner (Picardeau et al., 1999b; Casjens, 1999; Casjens et al., 2000). In proposed models (Fig. 12), the *Borrelia* linear plasmids are thought to use a circular intermediate for replication; circular replication intermediates have been isolated from some *Borrelia* spp. (Ferdows et al., 1996). The formation of covalently closed hairpin loops (telomeres) and the initiation of DNA replication near the center of the chromosome and linear plasmids present, however, a dilemma for the cell. How does the cell resolve two parental strands that are covalently joined at the telomeres, but destined to end up in different

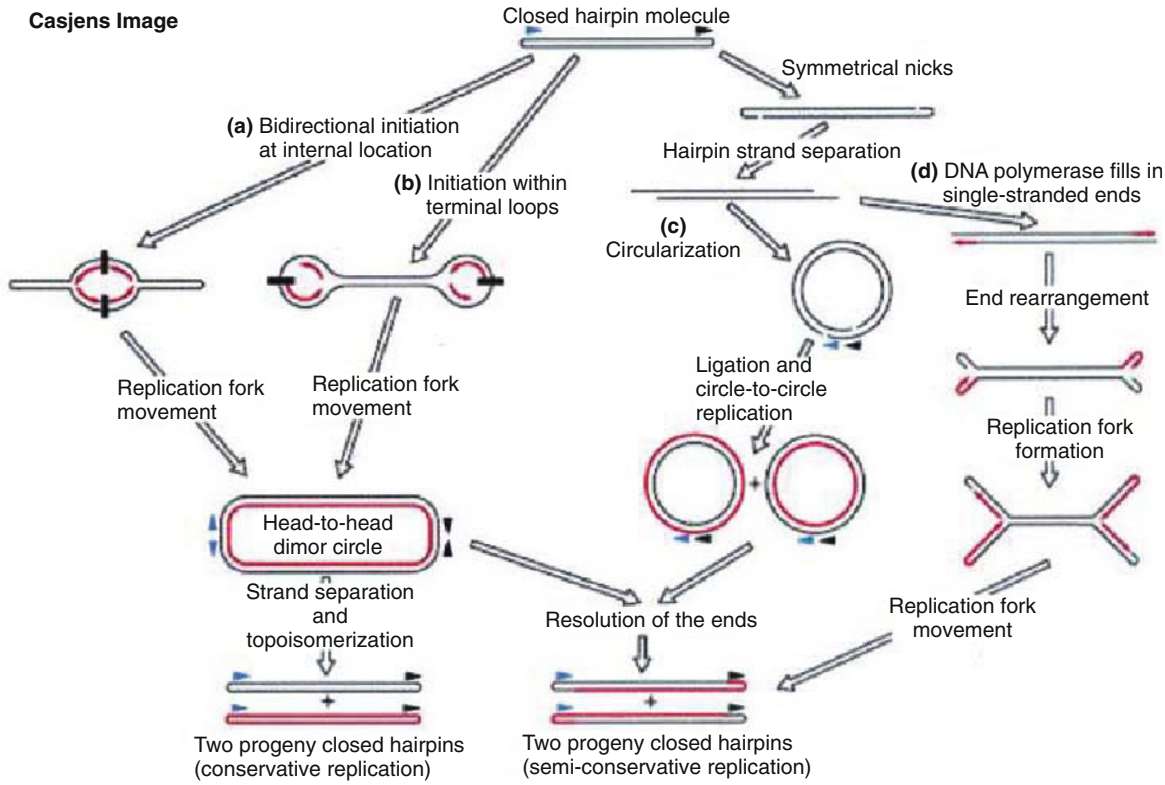

Fig. 12. Four strategies to replicate linear DNAs with covalently closed hairpin telomeres. In scheme (a), bidirection initiation of replication occurs near the center of the chromosome, whereas in scheme (b), initiation occurs within the terminal loops. In both (a) and (b), replication is followed by strand nicking and reassortment during end resolution (semiconservative replication) or strand separation and topoisomerization (conservative replication). In scheme (c), strand nicking occurs both during circularization and after replication. In scheme (d), strand nicking precedes duplication. Red lines indicate newly synthesized strands; black bars indicate replication origins on an unbroken template strand; the black and blue arrowheads indicate different sequences near the two telomeres to indicate the head-to-head and tail-to-tail joints in the possible dimer circle intermediate and the head-to-tail joints in the possible monomer circle intermediate. These strategies need not be mutually exclusive; for example, strategies (a) and (d) could combine to replicate the bulk and ends of the DNA, respectively. Reprinted from *Current Opinion in Microbiology*, 2, Casjens, S., Evolution of the linear DNA replicons of *Borrelia burgdorferi*. pp. 529–534, © 1999, with permission from Excerpta Medica, Inc. (Casjens, 1999).

daughter cells? Several mechanisms of strand resolution have been proposed, each utilizing a strand breakage to allow for segregation of the two parental strands, and also may involve the use of specific proteins, (i.e., transposases, integrases and telomerases). Recent studies by Chaconas et al. (2001) have proposed a model by which the hairpin telomeres are processed during replication. According to this model, the final step in the replication of linear replicons is a site-specific DNA breakage and reunion event to regenerate covalently closed hairpin ends. For recent reviews of *B. burgdorferi* DNA replication, see Casjens (1999) and Garcia-Lara et al. (2000).

The origin of linear DNA hairpin telomeres in *Borrelia* is also a matter of much speculation. Hinnebusch and Barbour (1991) noticed a low level of sequence similarity between the *Borrelia* telomeres and the hairpin ends of the iridopoxvirus African swine fever virus (ASFV). One very interesting hypothesis suggests that if a linear ASFV-like element had integrated into an ancestral *Borrelia* circular DNA element, it could have generated a linear DNA molecule and brought along with it the necessary machinery for end-resolution. Although no convincing DNA similarities were detected between *Borrelia* and poxvirus genes, most of the poxvirus genome could have been lost during evolution, leaving only the end-resolution apparatus required for the replication of the linear DNA molecules. This scenario is made more plausible by the fact that both *Borrelia* and ASFV are transmitted by arthropods; *Ornithodoros moubata* (Table 2) is known to transmit both *B. duttonii* and ASFV. This colocalization within an arthropod vector brings these very distinct

phyla into close enough proximity of each other to allow for genetic exchange (Casjens, 1999).

Plasmids and *Borrelia* Virulence

Shortly after the discovery of *Borrelia* plasmids, it was noted that this bacterium will often lose plasmids as a result of continuous in vitro cultivation (Barbour, 1988). It also was demonstrated that a loss of plasmid content was often associated with changes in protein profile and/or a reduction of infectivity (Schwan et al., 1988b; Persing et al., 1994; Golde and Dolan, 1995; Norris et al., 1995; Xu et al., 1996; Busch et al., 1997; Zhang et al., 1997; Anguita et al., 2000; Purser and Norris, 2000; Labandeira-Rey and Skare, 2001). Two recent studies have more fully characterized the relationship between plasmid content and infectivity in *B. burgdorferi* using clones with their plasmid content fully (Purser and Norris, 2000) or partially (Labandeira-Rey and Skare, 2001) characterized. Both of these studies demonstrated that the loss of one or more linear plasmids can be correlated with a reduction or loss of infectivity. While both of these studies represent a significant step towards furthering our understanding of the role of plasmid-encoded genes in borrelial virulence, the contribution of many of the circular plasmids could not be assessed because 1) they were not lost spontaneously during the isolation of clones (Purser and Norris, 2000), or 2) they were not included in the test panel to determine plasmid content (Labandeira-Rey and Skare, 2001). These data are, however, consistent with the notion that one possible role for the plasmids of *Borrelia* spp., like the virulence-associated plasmids of many bacteria (i.e., *Salmonella* spp, *Shigella flexneri*, *Bacillus anthrasis* and *Agrobacterium tumefaciens*), is to encode proteins that enable this bacterium to survive in vastly different environmental conditions and hosts. Also consistent with this hypothesis is the presence of genes that are expressed preferentially within either of these different host environments. To date, all of the differential gene expressions described have been localized to the linear and circular plasmids, further supporting a significant role for plasmids in the biology of these spirochetes (Wallich et al., 1993; Champion et al., 1994; Akins et al., 1995; Akins et al., 1999; Schwan et al., 1995; Stevenson et al., 1995; Stevenson et al., 1998a; Suk et al., 1995; Porcella et al., 1996; Lahdenne et al., 1997; Cassatt et al., 1998; Fikrig et al., 1999; Yang et al., 1999; Caimano et al., 2000; Miller et al., 2000; Hefty et al., 2001).

The *Borrelia burgdorferi* Genome Sequence

One of the most significant recent developments in borrelial research was the publication of the complete DNA sequence of the *B. burgdorferi* chromosome (Fig. 5) and associated plasmid elements (Fraser et al., 1997; Casjens et al., 2000; Fig. 11). The *B. burgdorferi* strain chosen for this project was the type strain B31 (ATCC 35210), an isolate obtained from an *I. scapularis* tick caught on Shelter Island, New York (Burgdorfer et al., 1982; Johnson et al., 1984). Prior to beginning the sequencing project, the American Type Culture Collection (ATCC) isolate was cloned by limiting dilution to yield an isolate now referred to by many as "B31-MedImmune" (B31-MI; Fraser et al., 1997). While this isolate has been minimally passaged in vitro, B31-MI is missing three circular plasmids (cp32-2, cp32-5 and cp9-2) as compared to the original isolate (Stevenson et al., 1998c; Miller et al., 2000). Briefly, the data from this project revealed that the *B. burgdorferi* linear chromosome is approximately 911 kb and is predicted to encode 853 open reading frames (ORFs). Biological roles were assigned to 59% of these ORFs. Of the remaining ORFs, 12% matched hypothetical coding sequences of unknown function from other organisms, and 29% were unique to *B. burgdorferi* (Fraser et al., 1997). In addition to the large linear chromosome, 12 linear and 9 circular extrachromosomal elements (plasmids) were also sequenced, totaling an additional 611 kb (Fraser et al., 1997; Casjens et al., 2000). In contrast to the ORFs encoded on the chromosome, greater than half of the ORFs contained on the plasmids did not have significant database matches to organisms other than *Borrelia*.

In the pre-genomic era, a number of laboratories had published reports calling attention to the fact that *B. burgdorferi* contains a large number of "repeated" sequences (i.e., related sequences present in multiple copies per genome; Simpson et al., 1990; Zückert et al., 1994; Zückert et al., 1999; Marconi et al., 1996b; Porcella et al., 1996; Zückert and Meyer, 1996; Fraser et al., 1997; Stevenson et al., 1997; Stevenson et al., 2000a; Carlyon and Marconi, 1998a; Carlyon et al., 1998b; Caimano et al., 2000; Carlyon et al., 2000), reviewed in Casjens et al. (2000). The full extent of this sequence redundancy has become apparent with the availability of the complete genomic sequence (Fraser et al., 1997; Casjens et al., 2000). One hundred and fifty-six paralogous families have been identified, with each paralogous family having at least two and up to 42 members. Although biological roles have been assigned to some of these paralogous families (e.g., ABC transporters [PF4, PF37,

PF41, PF105], methyl-accepting chemotaxis proteins [PF13], and plasmid partitioning [PF32, PF49]), the majority represent proteins with no known function. The large number of paralogous families is strong evidence that recombinatorial processes have conferred a remarkable degree of plasticity upon the *B. burgdorferi* genome, presumably in the context of enhancing its adaptation to diverse ecological niches.

The cp32 Family of Supercoiled Circular Plasmids

One of the best characterized examples of genetic redundancy in *Borrelia* is the family of 32- and 18-kb supercoiled circular plasmids (cp32s; Zückert et al., 1994; Zückert and Meyer, 1996; Casjens et al., 1997b; Stevenson et al., 1997; Stevenson et al., 1998c; Stevenson et al., 2000b; Akins et al., 1999; Caimano et al., 2000; Casjens et al., 2000). *Borrelia burgdorferi* sensu stricto isolates may contain up to 9 different cp32 plasmids (Fig. 11), each encoding *ospE*/*ospF*/*elp*/*erp* loci (Akins et al., 1995; Akins et al., 1999; Stevenson et al., 1996; Stevenson et al., 1997; Stevenson et al., 1998c; Casjens et al., 1997a; Caimano et al., 2000; see "OspE/OspF/Elp Lipoproteins"), as reviewed in Stevenson et al. (2000b). Each member of this plasmid family shares a high degree of similarity throughout its sequence, with only limited regions of sequence heterogeneity observed. Interestingly, the three regions, which are variable between members of this plasmid family, contain loci thought to be involved in the stable maintenance and partitioning of these plasmids and two paralogous families of differentially expressed lipoproteins (the Mlp Lipoproteins and OspE/OspF/Elp lipoproteins; Porcella et al., 1996; Stevenson et al., 1996; Stevenson et al., 1998c; Stevenson et al., 2000a; Akins et al., 1999; Yang et al., 1999; Caimano et al., 2000). Evidence has been presented that suggests these latter two variable regions represent sites of extensive recombination during the molecular evolution of this plasmid family (Stevenson et al., 1998c; Akins et al., 1999; Caimano et al., 2000). In addition, the presence of "unique" sequences downstream of some of the OspE/OspF/Elp loci suggests that *B. burgdorferi* may be capable of acquiring and incorporating exogenous DNA (Caimano et al., 2000). The relatively high density of spirochetes in the tick midgut, compared to the density within mammalian tissues, makes the midgut the most likely milieu in which this recombination occurs.

Linear forms of cp32-related plasmids have been described in *B. burgdorferi* (lp56) and *B. parkeri* (Fraser et al., 1997; Casjens et al., 2000; Stevenson et al., 2000b). An analysis of one linear plasmid, lp56, revealed that it contains within it an essentially intact copy of a cp32-like plasmid. The region of lp56 that is cp32-like appears to have resulted from an integration event (by an unknown mechanism) between a progenitor cp32-like plasmid and an unique linear plasmid. Although the inserted cp32-like progenitor shares a higher degree of homology with several cp32s (cp32-4, cp32-6 and cp32-9), it is not identical to any of the seven known cp32 plasmids and therefore potentially represents an eighth member of this family (Casjens et al., 2000). A second example of recombination between the linear and circular plasmids is evident on lp54 (Casjens et al., 2000; Caimano et al., 2000; Fig. 13). This plasmid is notable because it encodes the *ospA/B* (see "Reciprocal Expression of OspA and OspC") operon and the decorin-binding protein operon *dbpBA* (see "Decorin- and Fibronectin-binding Proteins"); both of these operons have been shown to be differentially expressed (*ospA/B* is downregulated, whereas *dbpBA* is upregulated in the mammalian host). The linear lp54 plasmid contains several stretches with high degrees of homology to paralogs which are otherwise exclusively encoded on cp32 plasmids (Fraser et al., 1997; Caimano et al., 2000; Casjens et al., 2000; Fig. 13). The presence of subsequent insertions and replacements within the region of cp32-like sequence suggests that the recombinatorial event(s) responsible for shaping lp54 is likely to have occurred much earlier in the evolution of the *Borrelia* plasmid complement than the event that resulted in the lp56 plasmid (Casjens et al., 2000).

Two different types of recombinatorial events are thought to have occurred within the cp32 family of plasmids (Caimano et al., 2000). The first involved exchanges between these plasmids and the bacterium's other genetic elements. This process appears to have been relatively unrestricted in that it utilized diverse donor sequences and recipient sites; its principal constraint is that it was limited to sequences already present within the borrelial genome. One of its primary functions appears to have been plasmid building (Fig. 13), that is, generating the scaffolding or framework needed to assemble novel genetic elements. The second type of recombinatorial event, in contrast, was confined to relatively small regions of the cp32 plasmids but was less restrictive in that it utilized nonparalogous DNAs, including what may be exogenous genes (i.e., the unique sequences downstream of some of the OspE/OspF/Elp lipoproteins loci). A major consequence of this second type was to individualize plasmids via the variable regions.

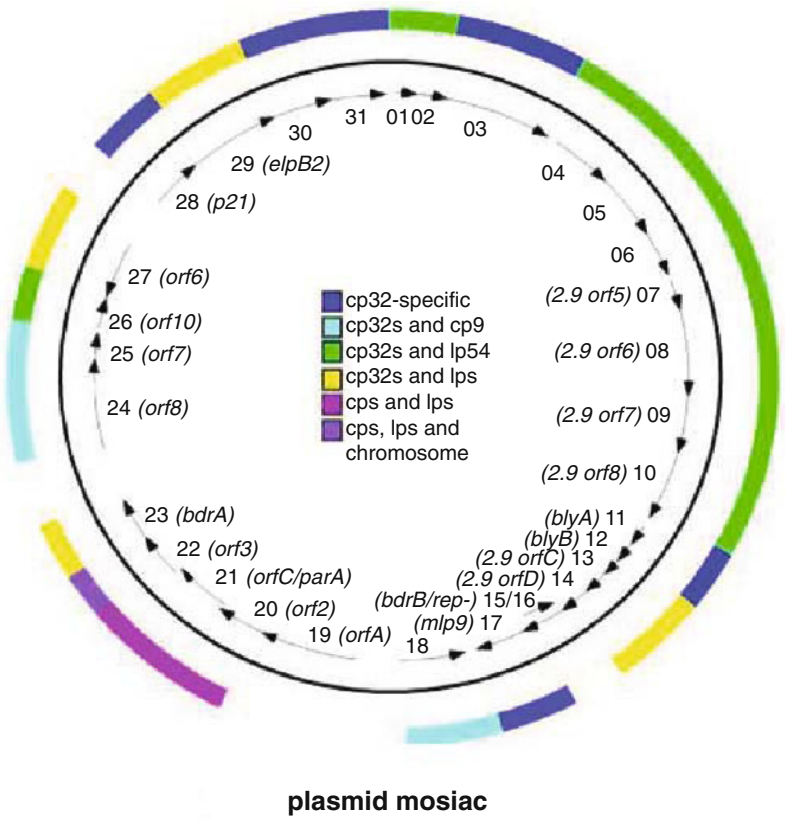

Fig. 13. *Borrelia burgdorferi* strain 297 cp18-2. Representative depiction of the mosiac nature of the cp32/18 plasmid family. Taken from Caimano et al. (2000), with permission of American Society of Microbiology (ASM) Press (http://www.journals. asm.org).

Recently, members of the cp32 family were also described in the relapsing fever spirochete, *B. hermsii* (Stevenson et al., 2000a). Although this plasmid contains many of the sequences that typify the cp32 family of plasmids (i.e., Mlp Lipoproteins, two Bdr paralogs, and partitioning loci (PF32 and PF50 paralogs), it does not contain an OspE/OspF/Elp (Erp) lipoprotein (Stevenson et al., 2000b; OspE/OspF/Elp Lipoproteins). Even more striking, however, is that the position of the Mlp Lipoproteins on the *B. hermsii* plasmid is in the position normally occupied by the *ospE*/*ospF*/*elp*/*erp* (see "OspE/OspF/Elp Lipoproteins") locus. An analysis of the *B. hermsii* genome by Southern hybridization did not reveal any sequences that hybridized with a *B. burgdorferi ospE*/*ospF*/*elp*/*erp* probe (Stevenson et al., 2000a), suggesting that the relapsing fever spirochete lacks homologs of these lipoproteins, or if they are present, their sequences are divergent beyond detection at the level of stringency used. The *B. hermsii* cp32 also encodes a novel protein, Bhm, a putative nucleotide methylase (Stevenson et al., 2000b).

Borrelia Pseudogenes

In addition to the duplications and rearrangements identified in the *B. burgdorferi* genome, a significant proportion of the genome was found to contain a large number of mutationally damaged genes and/or genes thought not to be expressed due to frameshift, inframe stop codons, and fused or truncated genes (pseudogenes; Casjens et al., 2000). In some instances, the majority of a plasmid's copy capacity is comprised of pseudogenes; for example, lp28-1 encodes 36 pseudogenes (78% of its total coding capacity), lp21 encodes 6 pseudogenes (50% of its coding capacity), and lp56 encodes 22 pseudogenes (61% of its total coding capacity; Casjens et al., 2000). In total, 670 potentially functional (non-pseudo)genes and 167 pseudogenes were identified on the 21 plasmids sequenced (Fraser et al., 1997; Casjens et al., 2000). Interestingly, ten of the strain B31 plasmids (lp5, lp17, lp21, lp25, lp28-1, lp28-3, lp28-4, lp36, lp38 and the non-cp32-like portion of lp56) contain 87% of the pseudogenes and have a total non-pseudogene coding capacity of only 41%, with the majority (43%) of these encoding genes ≥300 bp in length (Casjens et al., 2000). It has been hypothesized that the large number of pseudoegenes present on some borrelial plasmids may represent remnants of genes that are no longer useful but have not yet been completely eliminated from the genome (Casjens et al., 2000). Two recent publications may help explain why at least two of the pseudogene-rich plasmids are

consistently maintained in the *B. burgdorferi* genome: 1) the localization of a locus, *vlsE* (*B. burgdorferi* vls Locus), thought to be responsible for antigenic variation in *B. burgdorferi* to lp28-1 (Zhang et al., 1997), and 2) lp28-1 and lp25 were both correlated with infectivity in mice (Purser and Norris, 2000; Labandeira-Rey and Skare, 2001).

Bacteriophage of *Borrelia*

Bacteriophage-like particles have been described for a number of spirochetes, including *Borrelia*, *Treponema* (see The Genus *Treponema* in this Volume), *Leptonema*, *Leptospira* and *Brachyspira* (see review by Eggers et al., 2000). Hayes and coworkers (Hayes et al., 1983) identified the first bacteriophage-like particles in *B. burgdorferi* in 1983. Two similar phage-like particles were described from a human isolate of *B. burgdorferi*, but differed (at the ultrastructural level) from those particles reported by Hayes and co-workers. These data suggest that borreliae may harbor more than one type of bacteriophage (Neubert et al., 1993; Schaller and Neubert, 1994). Recently, Eggers and coworkers have characterized a bacteriophage ΦBB-1 (Fig. 14) from *B. burgdorferi* stain CA-11.2A (Eggers and Samuels, 1999) and demonstrated that phage particles could be produced spontaneously or by the use of a DNA alkylating compound (MMNG, 1-methyl-3-nitro-nitrosoguanidine) as an inducing agent. A molecular characterization of ΦBB-1 revealed that the phage heads were packaged with a discrete piece of linear, double-stranded DNA molecule 32 kb in size as its genome. These linear molecules lack the covalently closed ends characteristic of the linear plasmids typically found in *Borrelia*. Further analyses demonstrated that the prophage form of ΦBB-1 is maintained as one or more members of the cp32 plasmid family and that genes present on these plasmids (BBP41 to BBP26) most likely constitute the genes necessary for a phage late regulon (Eggers et al., 2000). Eggers and coworkers have also been able to use ΦBB-1 as a tool for transduction (the transfer of DNA between bacteria using bacteriophage) by transferring an antibiotic-resistance marker (*kan*^{r}) between cells of different *B. burgdorferi* strains (Eggers et al., 2001).

Fig. 14. *Borrelia burgdorferi* phage ΦBB-1. Samples were collected from polyethylene glycol (PEG)-precipitated cell-free supernatants of a *B. burgdorferi* culture, stained with phosphotungstic acid, and viewed by transmission electron microscopy. The contractile tail is either extended (left) or contracted (right). Image taken from Eggers et al. (2001), with permission of ASM Press (http://www.journals.asm.org).

Genetic Transformation of *Borrelia*

The inability to introduce exogenous (borrelial or non-borrelial) DNA into *Borrelia* spp. had long been a hindrance to using molecular biology techniques (i.e., transformation, gene inactivation, and transfection/transduction) that have become routine in most other well-characterized bacterial strains such as *E. coli*, *Bacillus subtilis* and *Streptococcus pneumoniae*. This was due in part to both the difficulties associated with the development of a method for the introduction of exogenous DNA into *Borrelia* spp. and the lack of a suitable cloning (shuttle) vector; these two basic elements are necessary to perform many of the classical molecular genetics experiments. Recent work on *B. burgdorferi*, however, has demonstrated that both of these hurdles may soon be cleared (see review by Tilly et al., 2000). One of the first major advances in molecular genetics was the demonstration of transformation of *B. burgdorferi*. In this pioneering experiment, Samuels and co-workers (Samuels et al., 1994b) were able to introduce a genetic marker (coumermycin A_1 resistance [*gyrB*^{r}]) into *Borrelia* using electroporation. This methodology, combined with a solid medium plating technique, allowed for the isolation of single colony isolates of transformed bacteria (Samuels and Garon, 1993; Samuels et al., 1994a; Samuels et al., 1994b; Samuels et al., 1995). These studies were soon followed by the first allelic exchange studies using targeted insertions of borrelial

genes (Rosa et al., 1996; Tilly et al., 1997). A number of additional borrelial genes involved in peptide transport (*oppAIV*), nucleotide biosynthesis (*guaB*), and environmental sensing and / or virulence (*ospC*, see "Reciprocal Expression of OspA and OspC") have since been mutated by gene inactivation and their phenotypes examined (Tilly et al., 1997; Tilly et al., 1998; Bono et al., 1998). The limitations of using coumermycin soon necessitated the development of tools for the introduction of heterologous (foreign) DNA to monitor gene expression without antibiotic selection (Stevenson et al., 1998b). The most recent breakthrough came with the development of the first extrachromosomal cloning vector system for *B. burgdorferi*. In this system, a broad-host range vector, pGK12 (containing replication functions from *Lactococcus lactis* and erythromycin- and chloramphenicol-resistance markers from *Staphylococcus aureus*), was used to transform *B. burgdorferi* and confer resistance to erythromycin. This plasmid was shown to replicate autonomously in strain B31 and conferred resistance to erythromycin to these transformed bacteria. These studies permitted the development of a reporter plasmid containing enhanced green fluorescent protein (EGFP) under the control of a borrelial promoter (Saratokova et al., 2000). These combined studies represent major steps toward furthering our understanding of borrelial genomics, particularly the regulation of gene expression and function. The majority of this work was performed using noninfectious strains of *B. burgdorferi*. To fully realize the potential of these molecular tools, methods for the transformation of infectious strains of *Borrelia* will need to be developed. Towards that end, recent studies by Stewart et al. (2001) have reported the isolation of a circular plasmid region from a *B. burgdorferi* circular plasmid (cp9) that is capable of autonomous replication and represents the first shuttle vector based on a borrelial origin of replication and plasmid partitioning. Stewart and co-workers also were able to demonstrate that this cp9-based shuttle vector can be electroporated into an infectious strain of *B. burgdorferi* (Stewart et al., 2001). One notable consequence of this transformation, however, was the rapid displacement of the endogenous cp9 plasmid of the recipient strain N40, a phenomenon almost certainly related to a plasmid compatibility issue between the shuttle vector (containing the cp9 replication region) and the endogenous cp9. While this displacement event did not affect the ability of the bacterial transformants to grow in culture medium, it does present a significant limitation of using this and similar shuttle vectors in a genetic background containing the full genetic complement of borrelial plasmids, whose roles in bacterial physiology and/or pathogenesis have not been fully determined.

Epidemiology

Relapsing Fever

Two major forms of relapsing fever have been described, epidemic (louse-borne) and endemic (tick-borne). During large epidemics of louse-borne relapsing fever (LBRF), millions of people have been infected. The last large outbreak of epidemic relapsing fever occurred during and following World War II in the Mediterranean region, North Africa, and the Middle East (Felsenfeld, 1965; Bryceson et al., 1970; Cadavid and Barbour, 1998). Current outbreaks of LBRF are primarily reported from African countries, particularly Ethiopia and Sudan (Cadavid and Barbour, 1998), with some outbreaks occurring in the South American Andes.

Endemic tick-borne relapsing fever (TBRF), transmitted by soft ticks of the genus *Ornithodoros* (Table 1), is more sporadic in occurrence than LTRF. TBRF is endemic in the western United States, southern British Columbia, the plateau regions of Mexico, and Central and South America, the Mediterranean, Central Asia, and throughout most of Africa. In the United States, the environment in which a human host comes into contact with a tick vector is largely determined by the geographical location. In Texas, in the relapsing fever spirochete, *B. turicatae*, TBRF is transmitted by *O. turicatae* and is primarily acquired by residents or tourists cave exploring. In most other western states and southern British Columbia, *B. hermsii* is transmitted by *O. hermsi* and primarily acquired at higher elevations by visitors of rustic cabins that may house rodent nests. A recent outbreak of TBRF (due to *B. hermsii*) in Colorado was associated with a visit by vacationers from Nebraska and Kansas to a rustic cabin in Colorado (Trevejo et al., 1998). In this report, 11 out of 23 family members vacationing at one rustic cabin developed symptoms suggesting TBRF, and although no spirochetes were visible in the case-patients blood smears, *B. hermsii* was cultured from the blood of one case-patient and two chipmunks trapped near the cabin (Trevejo et al., 1998). A survey of previous visitors to that same cabin identified five additional persons from Nebraska, Kansas, Florida and Texas who had developed similar symptoms following their visit. A recent review by Dworkin et al. (1998), however, identified 133 confirmed cases and 49 probable cases in northwestern United States and southwestern Canada. Confirmed cases were defined as both a febrile illness and detection

of spirochetes by microscopic examination of peripheral blood smears. A probable case was defined as a typical clinical history and either an exposure associated with a confirmed case or a positive serology test or enzyme-linked immunosorbent assay (ELISA) confirmed by Western blot. The distribution of these cases was primarily in Washington (33%), Oregon (25.3%), Idaho (22%), and British Columbia (14.3%), with the remaining cases in Montana (0.5%) or not specified (4.9%). The majority of these cases were thought to be acquired by visiting rural cabin dwellings or homes (76.3%), often located on or near a body of water. Potential rodent reservoirs (mice, squirrels, chipmunks and rats) were also present at the exposure sites. The median elevation at which exposure occurred in 89 of the 182 cases was 2,131 feet (range, 100–6,436 feet). The most frequent months of onset were the summer months (July and August), but cases were identified in all months except November. The cases were fairly evenly distributed among the sexes (male, 57.1%; female, 42.9%), but a higher number of cases were seen in children younger than 5 (6%) or under 18 years of age (28.9%). Four women (11.4%) pregnant during their illness were included in the review, one of whom gave birth to an infected infant. Many cases in the southern United States (i.e., Texas) are often associated with cave exploration. In this region, the tick vector (*O. turicata*) of the relapsing fever spirochete, *B. turicatae*, is found in burrows made by cave-dwelling rodents, owls and snakes (Goubau, 1984). TBRF in the southern United States exhibits a different seasonality from TBRF in the northwestern areas, with the majority of cases having a late fall, early winter month of onset (Burgdorfer, 1976b).

Unlike Lyme disease (see "Epidemiology"), TBRF is not a nationally reportable communicable disease and is likely to be underreported. TBRF also may be incorrectly identified as Lyme disease owing to false positivity in Lyme disease serological diagnostic testing (Dworkin et al., 1998). Unless a patient history of wilderness exposure or camping in rodent-infected areas is given and the patient is aware of a tick bite, the illness is usually not suspected during the initial period of fever (Fihn and Larson, 1980).

Lyme Disease

According to the Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov/ncidod/dvbid/lymeinfo.htm), Lyme disease is the most common vector-borne infection in the United States. According to surveillance data submitted to the CDC between 1992 and 1998, a total of 88,967 cases of Lyme disease were reported by 49 states, the District of Columbia, and Guam (2 cases), with a mean annual average of 5.1 reported cases/100,000 persons/year (Orloski et al., 2000; Fig. 17). Of the total cases reported nationwide, the majority were from only four Northeastern states, New York (32.8%), Connecticut (17.4%), Pennsylvania (14.6%), and New Jersey (12.2%; Orloski et al., 2000). The reported incidence of Lyme disease (Fig. 16), when plotted by county, closely mirrors the regional distribution of the arthropod vector (Fig. 15) *Ixodes scapularis* in the Northeast and Midwest and *Ixodes pacificus* in the pacific northwest United States (Orloski et al., 2000). Cases have also been reported in most European countries where the Lyme spirochete is transmitted by *Ixodes ricinus*. In addition, the disease has been reported in China, Japan, Africa and Australia (Table 2).

In the United States, Lyme disease is a reportable disease, and epidemiological data are collected and cataloged by the CDC (http://www.cdc.gov/ncidod/dvbid/lymeinfo.htm). Lyme disease in Europe are not reportable, and therefore the epidemiological features of borreliosis in this region are often limited. An extensive epidemiologic study of Lyme disease in Europe, however, was performed in southern Sweden in 1996 by Berglund et al. (1995). This study, conducted over a one-year period, used case definitions that generally corresponded to those used by the CDC for surveillance purposes (clinically diagnosed erythema migrans or one or more clinical manifestations of disease plus serological confirmation) to include a total of 1,471 patients with Lyme disease, with *B. afzelii* being the causative agent in all cases. This number reflects an overall annual incidence of 69 cases per 100,000 inhabitants, a number similar to that of endemic areas in the United States (24.2/100,000 and 98/100,000 in New York and Connecticut, respectively). As with cases in the United States, the incidence varied markedly according to geographic region, and the disease was widely prevalent in several areas, with incidences ranging between 26 per 100,000 to as high as 160 per 100,000 (Berglund et al., 1995). While no differences were observed in the number of cases between men and women, incidence in children (5–9 yrs old) and the elderly (60–74 yrs old) was higher (Berglund et al., 1995; Fig. 18).

In the northeastern United States, the onset of Lyme disease is greatest during the months of June, July and August (Orloski et al., 2000). The European study also reported a similar seasonality to Lyme disease, with tick bites being most frequent in July and the highest number of erythema migrans cases occurring in August and September (Berglund et al., 1995). These months coincide with the questing (feeding) period of the *Ixodid* nymph (Fig. 4), the life

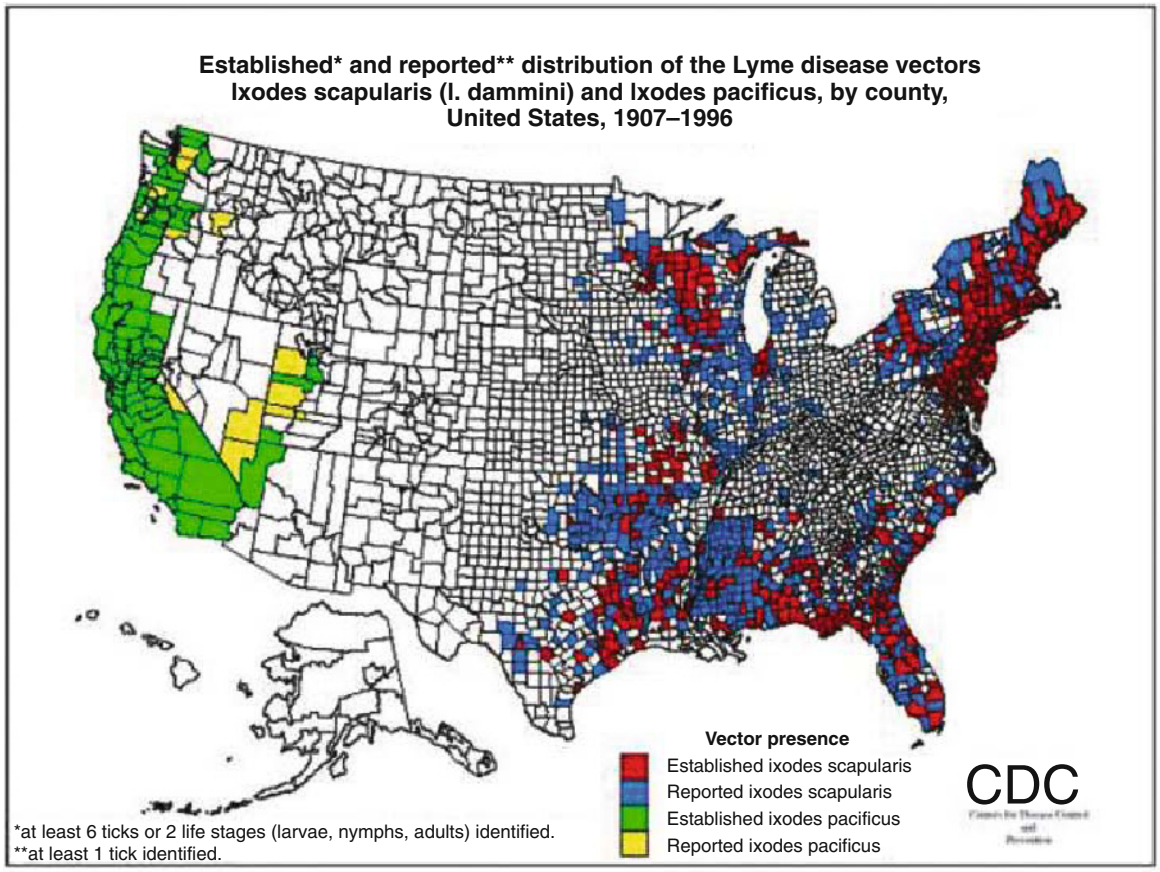

Fig. 15. Geographic distribution of *Ixodes* spp. Image adapted from the CDC (http://www.cdc.gov/ncidod/dvbid/lymeepi.htm).

stage primarily responsible for the transmission of *B. burgdorferi*. In addition, these months are often associated with increased outdoor activities, such as walking and hiking, which bring humans into closer proximity to the arthropod vector habitat.

Recent reports have described a Lyme disease-like illness in the south-central and southeastern United States in patients who have no known exposure to the Lyme disease vector, *Ixodes scapularis* (Barbour et al., 1996a; Fig. 15). In these cases, a skin rash resembling erythema migrans (EM; Fig. 20) has been associated with bites by the hard tick, *Ambylomma americanum*, the Lone Star tick. *Amblyomma americanum* has not been shown to be a competent vector for *B. burgdorferi* (Piesman and Happ, 1997; Dolan et al., 1998) and the infectious agent, *Borrelia lonestari* (*B. barbouri*), thought to be responsible for this Lyme disease-like illness (Barbour et al., 1996b) has yet to be cultivated (Uncultivatable *Borrelia* spp.).

Of mice and moths .... One interesting study by Jones et al. (1998) described a chain reaction of events beginning first with the level of acorns in a wooded area determining the winter survival, reproduction, and the resulting density of mice (both a predator of gypsy moth pupae and a reservoir of the Lyme disease spirochete, *B. burgdorferi*) in the oak forests of the eastern United States. Second, the relationship between mouse and moth densities can either suppress or increase subsequent acorn densities (i.e., high gypsy moth populations can result in deforestation and reduced acorn crops, whereas high mouse populations can result in increased pupae predation and increased acorn crops). Third, the location of high autumnal acorn density determines the next summer's larval tick densities by effecting the use of oak forests by deer (used by

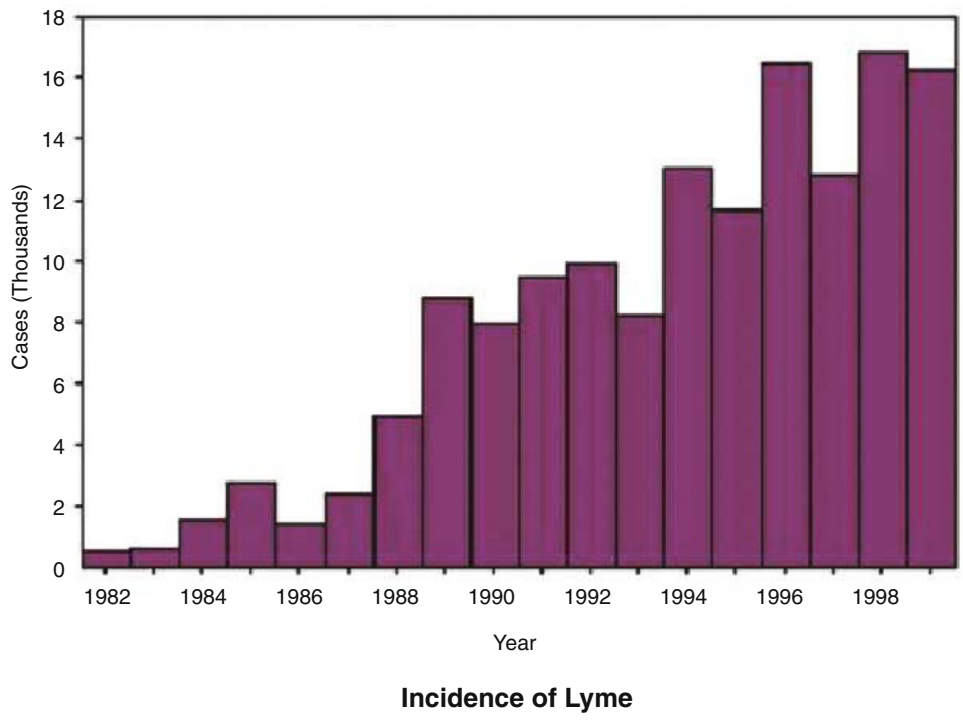

Fig. 17. Incidence of Lyme disease, by year—United States 1982–99 (http://www.cdc.gov/ncidod/dvbid/images/ld_case_barchart.gif). Taken from Orloski et al. (2000), with permission.

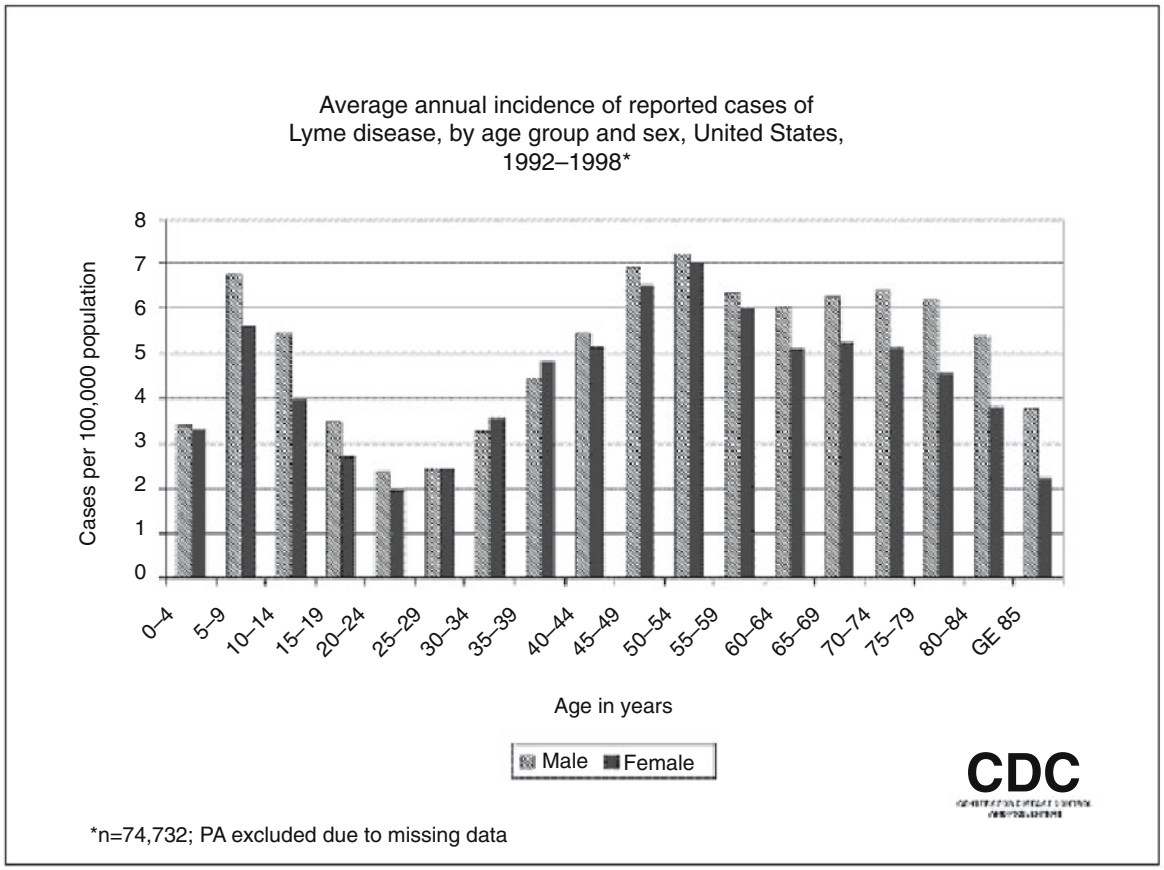

Fig. 18. Average annual incidence of reported cases of Lyme disease (http://www.cdc.gov/ncidod/dvbid/images/ld_case_barchart.gif), by age group and sex in the United States during 1992–1998 (http://www.cdc.gov/ncidod/dvbid/lyme/92-98agesex.htm).

adult ticks for mating); this situation in turn results in high densities of uninfected larval ticks and nymphal ticks questing when and where potentially spirochete-infected mice are most abundant. The authors suggest that it may be feasible to predict the risk of contracting Lyme disease from infected nymphal ticks in oak forests on the basis of autumnal acorn crops (masting), with the risk being greatest two years after an abundant acorn crop (Jones et al., 1998).

Pathogenicity

Relapsing Fevers

Two major forms of relapsing fever have been described, epidemic (louse-borne) and endemic (tick-borne; Table 1). For recent reviews of relapsing fever, see Dworkin et al. (1998) and Cadavid and Barbour (1998). In either of these forms, the relapsing fever borreliae gain access to the mammalian blood and lymph following transmission from an infected arthropod. After an incubation period of 4–18 days and after the spirochetes have multiplied to levels of 10^6–10^8 cells per ml of blood, the illness begins abruptly with shaking chills, fever, headache and fatigue, which persist for 3–7 days. Following an afebrile period of 5–10 days, a second symptomatic episode may occur. Additional relapses of decreasing time and intensity are characteristic of the tick-borne disease but are uncommon in the louse-borne disease. In either case, the relapses are the result of antigenic variation, where the spirochetes are able to undergo a number of cyclic antigenic variations (see "Antigenic Variation"). When antibodies to the prevailing antigenic type appear, organisms "disappear" from the peripheral blood and are replaced by a different antigenic variant within a few days. If the host is untreated, this process may be

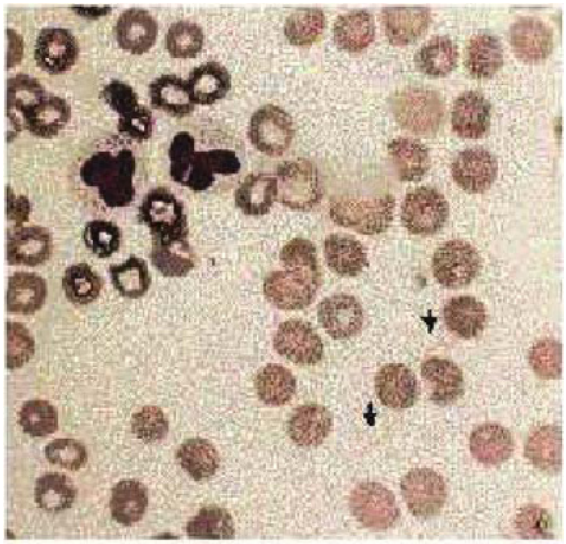

Fig. 19. Relapsing fever. A Wright's-stained peripheral-blood smear contains two borrelia spirochetes isolated from a patient with recurring fever (arrows) (http://www.nejm.org/content/1996/0335/0016/1197.asp). Taken from Newton and Pepper (1996).

Relapsing fever

repeated several times, depending upon the infecting strain of *Borrelia*. During the acute phases of the illness, borreliae may be seen in blood smears stained with Giemsa or Wright stain (Fig. 19) and counterstained with crystal violet (Felsenfeld, 1971). The mortality rate in louse-borne relapsing fever ranges as high as 40% in untreated cases, but can be less than 5% following antibiotic treatment. For a recent excellent review of the clinical manifestations and pathology of tick-borne relapsing fever, see Cadavid and Barbour (1998).

Relapsing fever is well recognized as an infection of the blood, but a number of other tissues also may be involved (Felsenfeld, 1965; Barbour and Hayes, 1986b; Pachner, 1986; Garcia-Monco and Benach, 1995). In this respect, the multisystemic nature of the relapsing fevers is similar to infections with other pathogenic spirochetes (i.e., *B. burgdorferi*, *Treponema pallidum* (see The Genus *Treponema* in this Volume), and *Leptospira interrogans* (see The Genus *Leptospira* in this Volume). Patients with TBRF may exhibit symptoms of ocular involvement, including iritis, cyclitis, choroiditis and optic neuritis (Falcone, 1952; Cadavid and Barbour, 1998). In such cases, vision can rapidly deteriorate, leaving most patients with residual visual defects (Quin and Perkins, 1946; Bergeret and Raoult, 1948). Ocular disease has also been associated with relapse episodes (Hamilton, 1943; Falcone, 1952). Ocular complications are most frequently associated with relapsing fevers due to *B. duttonii*, *B. hispanica* and *B. turicatae* (Cadavid and Barbour, 1998).

The frequency of neurological involvement (i.e., lymphocytic meningitis and peripheral facial palsy, crossing of the blood-brain barrier, and persistence in brain tissue) in this disease is similar to that of Lyme disease (Reik et al., 1979; Pachner et al., 1989; Cadavid and Barbour, 1998; Table 4). Spirochetes have been observed by silver stain within the cerebral microvasculature and interstitial spaces and between neurons and glia of autopsied TBRF patients (Buschke and Kroo, 1922; Martínez-Báez and Villasana, 1945). No spirochetes were observed within the brain cells themselves (Lavaditi et al., 1929), a finding which is consistent with the extracellular nature of these pathogens. The relapsing fever spirochetes, however, have differing abilities to invade and persist in brain tissue. *Borrelia duttonii*, *B. crocidurae* and *B. hispanica* were able to infect the brains of all mammalian hosts examined (Cadavid and Barbour, 1998). In contrast, *B. recurrentis* infected the brains of primates (Garnham et al., 1947), but not the brains of mice (Sparrow, 1956). These differences may be due, in part or in whole, to the expression of particular variable membrane proteins (i.e., VspA, see "Antigenic Variation"), some of which have been associated with the increased central nervous system (CNS) involvement and neuroborreliosis (Cadavid et al., 1997; Cadavid and Barbour, 1998).

Although neurological involvement is rare during LBRF, edema and subarachnoid and parenchymal brain hemorrhages were consistently observed during the autopsy of patients who succumbed to infection (Belezky and Umanskaja, 1930; Anderson and Zimmerman, 1955; Judge et al., 1974; Salih et al., 1977; Ahmed et al., 1980). No ocular involvement has been reported in patients with LBRF.

As the geographical distribution of cases of TBRF and Lyme disease (Fig. 15) begin to over-

EM Lesions Images

Fig. 20. Examples of early erythema migrans (EM). Left, an example of a typical EM rash with a central zone of clearing (visible 18 cm in cross diameter) was present on the right iliac crest of a 25-year-old Connecticut man. Image was taken 10 days after initial detection. Image kindly provided by Juan Salazar, M.D., University of Connecticut Health Center. Right, an example of an intensely erythematous rash (15 cm in cross diameter) over the dorsum of the right thigh of a 32-year-old Texas man who most likely contracted Lyme disease while on vacation in Connecticut. The image shown was taken 4 days after initial detection. Image kindly provided by Timothy Sellati, Ph.D., University of Connecticut Health Center.

Table 4. Comparison of tick-borne relapsing fever (TBRF), louse-borne relapsing fever (LBRF), and Lyme disease.

Characteristics	TBRF	LBRF	Lyme disease
Agent	Several species	*B. recurrentis*	*B. burgdorferi* sensu lato[a]
Vector	*Ornithodoros* spp. (soft tick)	*Pediculus humanus* (human body louse)	*Ixodes* spp. (hard tick)
Usual reservoir	Rodents[b]	Humans	Rodents
Epidemiology	Endemic	Epidemic	Endemic
Distribution	Tropical and temperate regions	East Africa[c]	North America, Eurasia
In vitro cultivation	Yes	Yes[d]	Yes
Fever (temperature ≥39°C)	Common	Common	Rare
Fever relapses	Multiple	Few	None
Neurological involvement	Common[e]	Rare	Common
Local skin rash	No	No	Common (EM[f])
Arthritis	No	No	Common
Spirochetes on blood smear	Yes	Yes	No
Serological assay specificity	Fair to poor	Fair to poor	Good to excellent
Antibiotic therapy	Several doses	Single or few doses	Several doses
Jarisch-Herxheimer reaction	Moderate	Moderate to severe	Mild

[a]Included are *B. burgdorferi* sensu stricto, *B. afzelii*, and *B. garinii*.
[b]The reservoir for *B. duttonii* in some locations may be humans.
[c]LBRF has a potential worldwide distribution because of association with human body louse.
[d]*In vitro* cultivation of *B. recurrentis* has been reported (Cutler et al., 1999).
[e]Common in >10% of patients with disseminated disease.

lap, an underappreciation of the frequency of neurological (and ocular) involvement during TBRF could result in this disease being misdiagnosed as Lyme disease, or vice versa, in areas where both diseases are found (Barbour et al., 1996a). These two diseases, however, may be readily distinguishable in some cases by the presence of spirochetes at a density sufficiently high enough as to be visible in the blood during a febrile episode or by a temperature above 38°C (hallmarks of relapsing fever) or by the presence of a localized EM lesion (a hallmark of early Lyme (Borreliosis) Disease; Fig. 20). Molecular and serological techniques can be used to definitively differentiate between these *Borrelia* spp.

Lyme (Borreliosis) Disease

Lyme disease is a multisystem illness that primarily affects the skin, nervous system, heart and joints (Steere, 1989). The hallmark skin lesion of Lyme disease, erythema migrans, was first described in Europe in 1908 (Afzelius, 1921) and in the United States in 1969 (Scrimenti, 1970). The disease was brought to the attention of the medical community in the United States as the result of an outbreak of arthritis in adults and children in Lyme, Connecticut, United States, and the adjacent communities of Old Lyme and East Haddam. The resulting epidemiological and clinical investigations led to the identification of a new disease entity, Lyme disease (Steere et al., 1977). The causative agent of Lyme disease was first described by Willy Burgdorfer and colleagues in 1982, and the species bears his name, *Borrelia burgdorferi* (Burgdorfer et al., 1982; Burgdorfer et al., 1991; Burgdorfer et al., 1993). For an excellent review of Lyme borreliosis, see Steere (1998a).

Lyme disease can be divided into early and late infection (Table 5). Approximately seven to nine days following the initial tick bite, the early (localized) infection is marked by the pathognomonic skin lesion, erythema migrans (in 60–90% of patients; Fig. 20), and is accompanied by fever, regional lymphadenopathy, or minor constitutional symptoms (Steere, 1989).

The EM lesions (Fig. 20) usually fade within three to four weeks, even when untreated, but they may recur at secondary sites coincidental or distal to the initial EM lesion. Weeks to months later (disseminated disease), patients may develop meningoencephalitis, Bell's palsy, myocarditis, migrating musculoskeletal pain and intermittent attacks of arthritis, especially in the large joints such as the knee. As the infection progresses (late or persistent infection), the episodes of arthritis last for months rather than weeks. Also, syndromes of both the central and peripheral nervous system may occur more than a year after the initial infection. Persistent infections in Lyme disease may also develop as acrodermatitis chronicum atrophicans (ACA), the late skin manifestation of the disease, which has primarily been observed in Europe (Asbrink and Hovmark, 1988; Kaufman et al., 1989). The skin lesion typically begins as a bluish-red discoloration of swollen skin on an extremity. This lesion may occur at an earlier site of EM. The inflammatory stage of ACA may persist for years or decades and may lead to atrophy of the skin. Transplacental transmission of *B. burgdorferi* has been reported; however, congenital infection with adverse outcome, such as perinatal death, appears to be unusual (Schlesinger et al., 1985; Weber et al., 1988).

Since Lyme disease is not a notifiable disease in Europe, the knowledge of the epidemiological features of this illness in this region is limited. One extensive study of Lyme borreliosis in southern Sweden, however, does represent an excellent source for reliable epidemiologic (see Epidemiology) and clinical data for this disease (Berglund et al., 1995). The most frequent clinical manifestation (Table 5) was EM (seen in 77% of all cases; Fig. 20), followed by neuroborreliosis (16%) and arthritis (7%). With the exception of a slightly lower rate of carditis (0.5–4%), the pattern of disease found in this study was similar to that reported in the United States.

After the first several weeks of infection, most patients have a positive antibody response to the spirochete. The specific immunoglobulin (Ig)M response is detectable after the third week and peaks after 6–8 weeks (Steere et al., 1983). The *B. burgdorferi*-specific IgG response peaks during the second to third month of infection and may persist for years. Since the direct visualization and culture of *B. burgdorferi* from patient specimens are difficult, serologic determinations are currently the most practical mode of laboratory diagnosis. False negative results occur early in the disease, whereas false positives may occur in patients with a variety of other diseases, including syphilis, Rocky Mountain spotted fever, autoimmune disease, and neurologic disorders. Differential diagnosis is most often made using the CDC surveillance case definition (http://www.cdc.gov/ncidod/dvbid/casedef2.htm) as a guide. If Lyme disease is suspected in an endemic area, patients are often started on antibiotic therapy based solely on the presence of an EM rash (5 cm in diameter; Fig. 20) and/or a history of a recent ixodid tick bite accompanied by one or more of the early Lyme disease symptoms outlined by the CDC surveillance case definition.

Borrelia Genotype and Pathogenesis

Currently, all borreliae capable of causing Lyme disease are members of the *B. burgdorferi* sensu lato complex that is comprised of ten different *Borrelia* genospecies (Wang et al., 1999; Table 2). North American isolates are limited primarily to *B. burgdorferi* sensu stricto, whereas *B. garinii* and *B. afzelii* isolates, in addition to *B. burgdorferi* sensu stricto, are responsible for the majority of cases of Lyme disease in Europe (Table 2). These latter genospecies are more often associated with neuroborreliosis (*B. garinii*; van Dam et al., 1993; Lebech et al., 1994; Wilske et al., 1996; Marconi et al., 1999; Cauwels et al., 2001) and chronic skin manifestations (i.e., ACA; *B. afzelii*; van Dam et al., 1993; Wienecke et al., 1994; Strle et al., 1996; Picken et al., 1998;

Table 5. Major clinical manifestations of Lyme borreliosis in North America and Europe.

Stage[a]	Clinical feature[b]	Incidence in: North America[c]	Incidence in: Europe[d]
I	*Early local infection*		
	EM	Common (60–90%)	Common (~77%)
	Tick bite recalled	25%	64%
	Central clearing of EM	35%	68%
	Systemic symptoms	50–69%	38–51%
II	*Early disseminated infection*		
	Multiple EM	Common (≥18%)	Unusual (6%)
	Neuroborreliosis	Common (10–20%)	Common (16–80%)
	Meningoradiculitis	3–21%	37–61%
	Meningitis	2–17%	4–27%
	Carditis	0.5–10%	0.5–4%
	Borrelial lymphocytoma	Rare	Well documented (3%)
III	*Late LB*		
	Lyme arthritis	Common (51–57%)	Uncommon (~7%)
	ACA	Rare	Well documented (3%)
	Peripheral neuropathy	30–70% late NB	40–63% ACA patients
	CNS involvement	Well documented	<9%
	Encephalomyelitis	Rare (0.1%)	4–6%
	Menigencephalitis	9%	0.5–4%

[a]Stages of the clinical features are those of Steere (Steere, 1989, ID: 185).

[b]NB, neuroborreliosis; CNS, central nervous system.

[c]Data were mainly on an earlier report by the Centers for Disease Control and Prevention on LB surveillance from 1984–1986 (Ciesielski, Markowitz, et al., 1989, ID: 4217) and a population-based study in children in Southern Connecticut (Gerber, Shapiro, et al., 1996, ID: 11924), except for those indicated specifically.

[d]Data were based mainly on a population-based study in Southern Sweden (Berglund, Eitrem, et al., 1995, ID: 9264), except for those indicated specifically.

[e]Data were based on 76 American (Nadelman, Nowakowski, et al., 1996, ID: 12196) and 231 European (Strle, Nelson, et al., 1996, ID: 19085) culture-confirmed patients with EM.

[f]NB patients were used as denominator to calculate the relative prevalence. European data were based on data from 330 NB cases from Germany (Oschmann, Dorndorf, et al., 1998, ID: 19084) and 176 NB cases from Denmark (Hansen & Lebech, 1992, ID: 6973).

[g]A recent population-based study showed that only 7% of children with LB developed Lyme arthritis (Gerber, Shapiro, et al., 1996, ID: 11924). About 10% of patients with Lyme arthritis may develop chronic antibiotic treatment-resistant arthritis (Gross, Forsthuber, et al., 1998, ID: 14570).

Cauwels et al., 2001). Lyme arthritis, first described in the United States, is still more commonly reported in North American cases of Lyme disease (Steere et al., 1983; Table 5), where the causative agent is *B. burgdorferi* sensu stricto isolates, than in European cases, where Lyme disease is attributed to the much more heterogeneous *B. burgdorferi* sensu lato complex. The reverse, however, is true for ACA, which is fairly common in Europe, but rarely seen in North America (Table 5).

For Lyme disease in North America, a correlation between *B. burgdorferi* sensu stricto genotypes and clinical manifestations is not as clear as it is for *B. afzelii* (ACA) and *B. garinii* (neuroborreliosis) in Europe. Two recent studies present evidence suggesting that genetic heterogeneity within *B. burgdorferi* sensu stricto isolates in North America may influence invasiveness and pathogenicity. In the first study, Seinost et al. (1999) examined 140 *B. burgdorferi* strains isolated from primary EM lesions, blood and CSF from patients seen at the Lyme Disease Center at Stony Brook, New York, the Lyme Disease Diagnostic Center at New York Medical College, or at local private physicians. Strains were genotyped according to their *ospC* alleles using a combination of PCR and cold single-strand conformation polymorphism (SSCP) analysis, a method that gave 100% sensitivity and specificity when comparing alleles. Additional samples were obtained by analyzing spirochetes present in locally collected *I. scapularis* ticks. Twenty-two additional alleles were added from sequences present in GenBank. The authors concluded 1) that some *B. burgdorferi* sensu stricto isolates rarely, if ever, cause disease in humans, 2) that some *B. burgdorferi* sensu stricto isolates cause a local infection at the tick bite site but not systemic disease, and 3) that systemic *B. burgdorferi* sensu stricto infections are associated with four *ospC* groups. It is not clear, how-

ever, whether *ospC* is directly influencing pathogenicity or serving as a marker for other, probably unlinked, determinants of invasiveness. Independent work by Baranton et al. (2001), examining genetic diversity of *ospC* loci in European isolates of *B. afzelii* and *B. garinii*, also came to a similar conclusion.

The second study (Wormser et al., 1999) examined the correlation between genetic subtypes and hematogenous dissemination in 104 untreated patients with EM. In this study, the authors used restriction length polymorphism (RFLP) methodology to compare the *B. burgdorferi* sensu stricto 16S-23S rDNA spacer region of spirochetes cultured from EM skin biopsies, whole blood, serum and plasma. Results from this study suggest that the genetic subtype of the infecting strain in the skin is a major determinant of the risk for hematogenous dissemination. The continued characterization of genetic markers associated with different subtypes of *B. burgdorferi* sensu stricto is likely to further our understanding of the relationship between genotype and the clinical presentations of patients with Lyme disease. Additionally, a clearer understanding of the genotypes responsible for disseminated infection in humans may facilitate the selection of novel vaccine candidates by identifying antigenic targets common to these isolates that might be essential to their survival and maintenance in the mammalian host.

Differential Gene Expression in *Borrelia*

To be maintained in its enzootic life cycle, borreliae must adapt to two strikingly different environments, the arthropod vector and the mammalian host. It is, therefore, not surprising that this bacterium undergoes extensive changes in protein composition as it cycles between these two hosts (de Silva and Fikrig, 1997). An extensive amount of work during the past several years has been devoted to elucidating the phenomenon of differential gene expression.

Reciprocal Expression of OspA and OspC

The best studied example of differential gene expression by *B. burgdorferi* involves the synthesis of outer surface protein A (OspA) and C (OspC) during tick feeding. In a pioneering study (http://www.niaid.nih.gov/dir/labs/lmsf.htm), Schwan et al. (1995) observed that *B. burgdorferi*, when present in the midguts of unfed ticks, expressed large amounts of OspA and little to no OspC. When infected ticks were allowed to feed on a suitable mammalian host (i.e., mice), spirochetes within the tick midgut downregulated the expression of OspA and expressed substantial amounts of OspC. Although increased temperature (tick versus mammal) has been shown to be involved in this expression-pattern (see "Environmental Signals as Gene Regulators"), upregulation of OspC independent of temperature was recently demonstrated by the in vitro incubation of spirochetes at 28°C in the presence of tick hemolymph plasma (Johns et al., 2000), suggesting that expression of OspC is enhanced by, but does not require, increased temperature. These data are supported by studies examining the expression of *ospA* and *ospC* mRNA by RT-PCR (Montgomery et al., 1996) and the production of antibodies against OspA and OspC during early murine (Montgomery et al., 1996) and human Lyme borreliosis.

Recent advances in elucidating the potential roles for OspA and OspC in Lyme disease pathogenesis were provided by the publication of the crystal structures (Fig. 21) of these lipoproteins (Li et al., 1997; Eicken et al., 2001; Kumaran et al., 2001). These structures are also of particular interest as OspA is the antigen on which the current Lyme disease vaccine is based, while OspC is considered a highly promising candidate for the next generation of Lyme disease vaccine. The OspA protein displays an unusual, elongated fold composed of 21 consecutive antiparallel β-strands connected by turns or short loops followed by a single short α-helix (Fig. 21). The presence of a cavity and partially buried charged residues with the cleft suggests that the C-terminal domain of OspA might be a binding site for a negatively charged or hydrophobic ligand, small peptide, linear polysaccharide, or exposed protein loop (Li et al., 1997). In contrast to OspA, OspC is comprised of four long helices plus a short fifth helix (Eicken et al., 2001; Kumaran et al., 2001; Fig. 21). An elongated, kidney-shaped OspC dimer (Fig. 21) is thought to form through hydrophobic interactions primarily between the α1 and α1' helices on two OspC monomers. While OspA has no known structural homologs, OspC has similarity to the periplasmic domain of the *Salmonella* aspartate receptor (AR), which is also a dimer. Interestingly, when the crystal structures (Fig. 21) of the OspCs from the HB19 and B31 (both invasive strains) were used to model the structures of noninvasive isolates (Seinost et al., 1999), notable differences were detected in the electrostatic surface potential of the region of OspC furthest away from the surface of the membrane; the surface potential is highly negative in the invasive strains, but not so for the noninvasive strains (Kumaran et al., 2001). The authors speculate that this region's interaction with a positively charged ligand, such as fibronectin (see "Decorin- and Fibronectin-binding Proteins") or a similar molecule, might play a role in the pathogenesis of Lyme disease

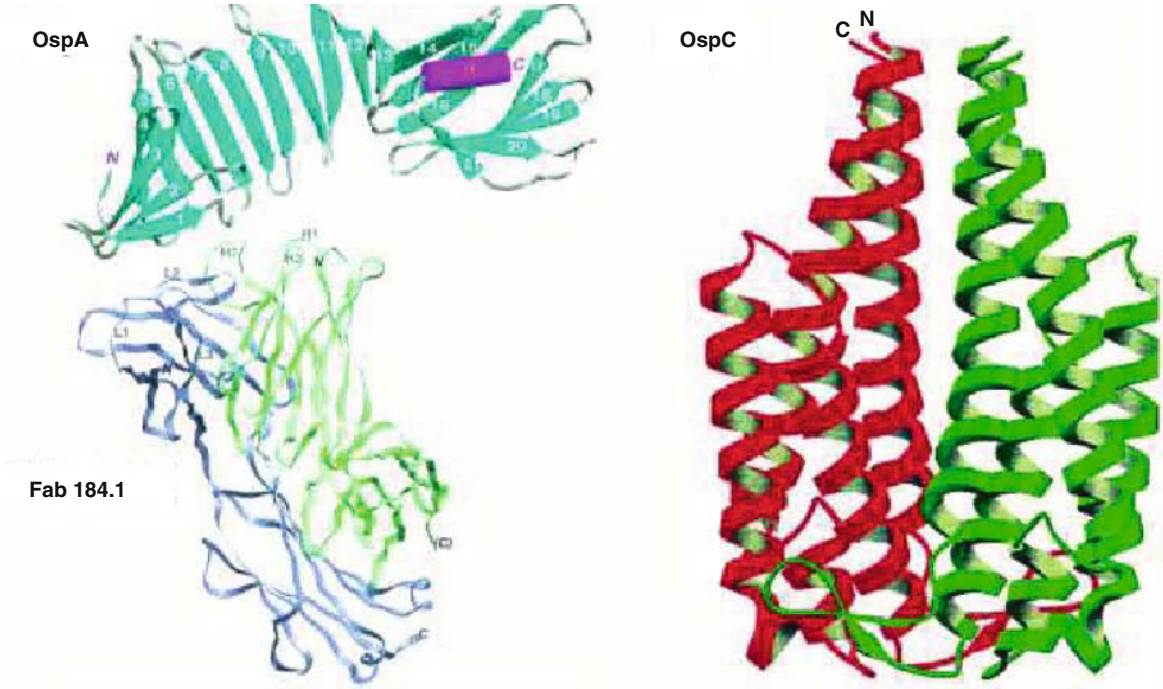

Fig. 21. Crystal structure of OspA and OspC. Left, schematic view of the OspA-Fab 184.1 complex. OspA is displayed with its secondary structural elements, β-strands (cyan, numbered 1–21) and α-helix (magenta, labeled), connected by gray turns or loops. The front face of the central sheet is seen in this view. Fab 184.1 is represented by violet and green ribbons for the light and heavy chains, respectively. The three complementarity determining region (CDR) loops on each chain are displayed as thin ropes and labeled (e.g., L1 for CDR1 of the light chain). Image was taken from Li et al. (1997), © 1997, National Academy of Sciences, with permission. Right, RIBBONS representation of the OspC-HB19 dimer. The two monomers are colored red and green, respectively. The close proximity of the two innermost helices indicates that it is a tight dimer. Image taken from Kumaran et al. (2001) and reproduced by permission of Oxford University Press.

(Kumaran et al., 2001). This finding also has significant implications for the development of an OspC-based vaccine, which is tailored towards recognition of those (invasive) strains that are more likely to cause disseminated disease (see "Lyme Disease Vaccine").

Both OspA and OspC are thought to play critical roles in the transmission of *B. burgdorferi* from the tick to the mammalian host. Two domains within the N40 OspA (amino acids [aa] 85–103 and aa 229–247) were recently identified and proposed to contain functional binding sites responsible for the adherence of spirochetes to the tick midgut (Pal et al., 2000). Consistent with this proposed binding activity, the location of one of these domains (229–247) is predicted by the OspA crystal structure (Fig. 21) data mentioned above to be within the putative ligand binding domain. The role of OspC in the transmission process is unclear. A recent study suggests that this lipoprotein plays a role in the transmission of spirochetes from tick to mammal, but not from mammal to tick (Schwan and Piesman, 2000). A second report demonstrated that immunization with OspC significantly reduced the migration of *Borrelia* from the midgut to the salivary glands of infected *I. scapularis* ticks (Gilmore and Piesman, 2000). These data are consistent with numerous studies demonstrating a role for OspC antibodies in the protection of laboratory animals against tick transmission using both passive and active immunization (Gilmore et al., 1996; Mbow et al., 1999; Zhong et al., 1999).

Recent work by Ohnishi and coworkers (Ohnishi et al., 2001), in which the authors examined the temporal expression patterns of OspA and OspC in both ticks and the skin adjacent to the feeding site in a murine model of Lyme disease, suggests that the relationship between OspA and OspC expression patterns is perhaps even more complex than initially envisioned. Results from these studies demonstrate that the complete downregulation of OspA and the expression of OspC are not required for migration of spirochetes from the midgut to the salivary glands. In fact, OspC was not expressed by a significant percentage of spirochetes in the salivary glands until feeding had progressed for >61 hours. This coincided with the time required to consistently transmit the spirochetes and establish infection. The authors also noted that

early during transmission, mice with spirochetes detectable in the skin directly adjacent to the bite site, expressing mostly OspA compared to OspC, failed to develop infection. In contrast, those mice that had spirochetes expressing higher levels of OspC and reduced OspA consistently became infected. From these data (combined with other studies described above), Ohnishi et al. suggest a model by which spirochetes are retained in the midgut by OspA-mediated adherence until such time as they are adequately "adapted" for migration from the gut lumen to the hemocele and salivary glands by an OspC-facilitated process. Once they have exited the midgut, spirochetes appear to downregulate the expression of OspC, as well as continue to downregulate OspA. In some instances, however, spirochetes ($OspA^+/OspC^-$) are apparently "mislocalized" to the salivary glands and/or prematurely transmitted to the host before being fully "adapted"; these spirochetes fail to establish infection in the mammalian host. This model also suggests that the transmission of *B. burgdorferi* from the arthropod to mammalian host may occur in a steady wave of spirochetes over an extended period (days). These studies also demonstrate that the signal(s) responsible for the temporal expression patterns of OspA and OspC (and most likely other Osps) are clearly complex and likely to include stimuli from both the arthropod and mammalian hosts.

OspE/OspF/Elp Lipoproteins

In addition to the *B. burgdorferi* OspA and OspC lipoproteins (see "Reciprocal Expression of OspA and OspC"), a second group of differentially expressed proteins, the OspE/OspF/Elp lipoproteins, has garnered much interest in the *Borrelia* field. For a recent review of this family of cp32-encoded lipoproteins, see Stevenson et al. (2000a). These lipoproteins were once all considered as one large group of related lipoproteins and referred to by a generic term, "Erp" (OspE/F-related proteins), in the B31 strain (Stevenson et al., 1996; Casjens et al., 2000). A more comprehensive analysis has revealed that the similarities among these proteins are largely restricted to their leader peptides, whereas the mature portions of the polypeptides actually fall into three evolutionary distinct groups: 1) OspE-related orthologs, 2) OspF-related orthologs, and 3) Elps, which contain OspE/F-like leader peptides, but are otherwise unrelated to both OspE and OspF (Akins et al., 1999; Caimano et al., 2000). It is likely that this family of lipoproteins arose from a series of gene fusion events in which a common N-terminus was fused upstream of otherwise unrelated sequences. The resulting fusions formed the progenitors for each of the three groups of OspE, OspF, and Elp lipoproteins, each of which underwent subsequent genetic polymorphisms to form the family of lipoproteins (Fig. 22). In addition to their group designations, members of this larger family of lipoproteins have been referred to by a variety of names in the literature, including p21, pG, BbK2.10, BbK2.11, and "upstream homology box" (UHB) lipoproteins (Lam et al., 1994; Akins et al., 1995; Akins et al., 1999; Suk et al., 1995; Wallich et al., 1995; Marconi et al., 1996a).

The genes encoding all members of this family are encoded on 32- or 18-kb supercoiled circular plasmids (referred to collectively as "cp32s"; see "The cp32 Family of Supercoiled Circular Plasmids") as either mono- or bicistronic operons. The first member of this family shown to be differentially expressed was the p21 lipoprotein, identified within a *Borrelia* expression library as an antigen recognized by sera from infected mice but not by sera from mice immunized with in vitro-cultivated, killed spirochetes (Suk et al., 1995). A number of additional proteins within this family, pG, BbK2.10 and ElpA1, from several different strains have since been characterized as "in vivo-expressed" antigens (i.e., proteins selectively expressed during infection but not by spirochetes grown in artificial medium; Akins et al., 1995; Wallich et al., 1995; Hefty et al., 2001). The remaining OspE/OspF/Elp lipoproteins have all shown to be expressed both in vitro and within the mammalian host (Akins et al., 1995; Akins et al., 1998; Stevenson et al., 1998a; Hefty et al., 2001). Recently, Hefty et al. (2001) performed a comprehensive study of the OspE/OspF/Elp family in *B. burgdorferi* strain 297, which suggested that the differential patterns of antigen expression observed during tick feeding and mammalian infection might represent a temporal hierarchy in which proteins are expressed sequentially as the spirochetes adapt in preparation for the transmission from arthropod to mammal. An examination of the upstream promoter regions has revealed that although this region (upstream homology box, UHB) is highly conserved among all of the *ospE*/*ospF*/*elp*/*erp* genes (Marconi et al., 1996b; Hefty et al., 2001), sequence polymorphisms (insertions/deletions and transitions/transversions) were present (Fig. 23). The majority of these differences were in the putative -10 and -35 hexamers and spacer region between (Hefty et al., 2001); these regions are all known to be critical for RNA polymerase recognition and binding in prokaryotes. A comparative (phylogenetic) analysis of the *ospE*/*ospF*/*elp*/*erp* promoter regions (Fig. 23) demonstrated that these regions do not segregate according to their polypeptide-encoding regions, but instead

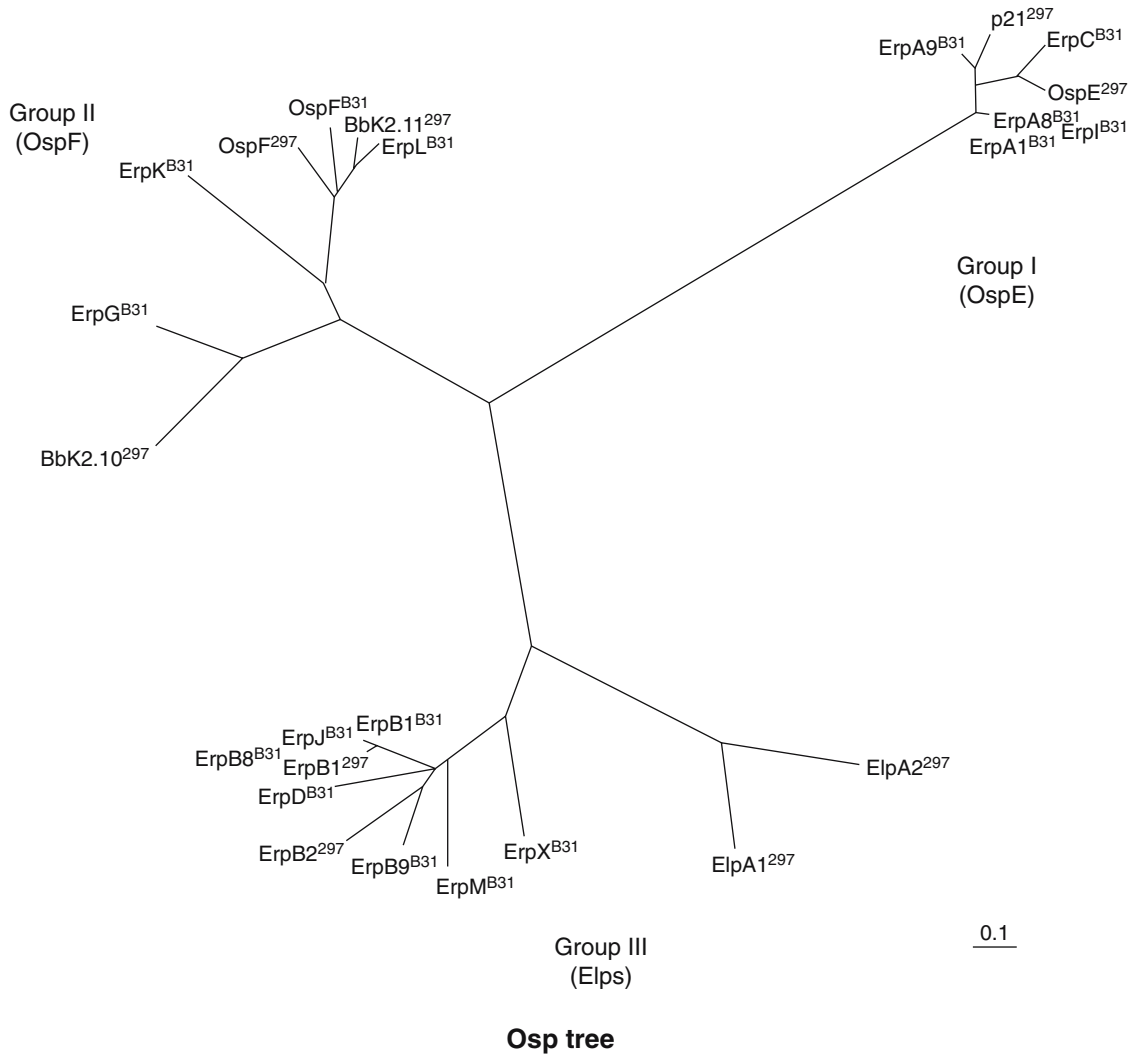

Fig. 22. Unrooted neighbor-joining phylograms of the *B. burgdorferi* strains 297 and B31 OspE/OspF/Elp/Erp lipoproteins. Taken from Caimano et al. (2000), with permission of ASM Press (http://www.journals.asm.org).

appear to segregate according to their temporal expression pattern. These data suggest that minor sequence differences between the promoters may result in altered affinity of RNA polymerase and/or altered expression under different environmental conditions (Hefty et al., 2001).

Mlp Lipoproteins

In addition to the *ospE*/*ospF*/*elp*/*erp* loci (see "OspE/OspF/Elp Lipoproteins"), the cp32/18 family of circular plasmids encodes a second variable lipoprotein family, the *mlp* loci (Porcella et al., 1996; Yang et al., 1999; Porcella et al., 2000; Stevenson et al., 2000b). This family is comprised of two evolutionarily distinct classes that possess highly similar N-termini but divergent C-termini (Caimano et al., 2000; Fig. 24). The recombinatorial process that resulted in the formation of these two lipoprotein classes is likely to be mechanistically similar to that of the process responsible for the formation of the OspE/OspF/Elp family (see "OspE/OspF/Elp Lipoproteins") of lipoproteins (Caimano et al., 2000). Four of the strain 297 Mlps (Mlp7A, Mlp7B, Mlp9 and Mlp10) were shown to be preferentially expressed within a mammalian model (Akins et al., 1998; Yang et al., 1999). Immunoblotting using antiserum from tick-infected C3H/HeJ mouse serum suggests that the strain 297 Mlp lipoproteins are not all expressed early in infection, but may be turned on in a temporal pattern as the spirochetes transition from the arthropod vector to first the skin and then other tissues of the mammalian host (Yang et al., 1999). Preliminary protection studies using a multivalent for-

mulation of the Class 2 Mlps from strain 297 as the immunogen gave rise to 80% protection of mice (Yang et al., 1999). Immunoblotting using sera from Lyme disease patients also confirms that members of this family are expressed during human infection (Porcella et al., 2000). While preliminary, these data suggest that this family of lipoproteins may have some vaccinogenic potential that warrants further consideration (Yang et al., 1999).

Decorin- and Fibronectin-binding Proteins

The mechanism(s) by which borreliae are able to disseminate following transmission from the arthropod vector to cause a multisystemic infection in the mammalian host remain largely unknown. The recent identification of two *B. burgdorferi* proteins, DbpA and DbpB, which have the ability to bind decorin (a collagen-associated extracellular matrix proteoglycan found in skin and other tissues), represented a significant step towards characterization of the early stage of Lyme disease (Table 5), as the spirochete first enters the mammalian host through the site of tick feeding (Cassatt et al., 1998; Hagman et al., 1998; Hanson et al., 1998). Based on their ability to interact specifically with extracellular matrix components, these molecules have been placed within a class of cell surface adhesins designated "MSCRAMMs" (microbial surface components recognizing

adhesive matrix molecules; Patti et al., 1994). Interestingly, neither *dbpA* nor *dbpB* was detected in *B. hermsii*, *B. turicatae* or *B. coriaceae* by Southern hybridization (Roberts et al., 1998). Data from proteinase K sensitivity assays (DbpA and DbpB) and immunoelectron microscopy (DbpA) suggest that these proteins are surface-exposed, a location consistent with their putative role in adherence to basement membrane (Hagman et al., 1998; Hanson et al., 1998). Brown et al. (1999) have identified three highly conserved lysine residues (Lys-82, Lys-163 and Lys-170), found in all DbpA polypeptide sequences examined, and all appear to be critical for association with decorin. Several studies have shown that immunization with DbpA, but not DbpB, protects mice against syringe inoculation (Cassatt et al., 1998; Feng et al., 1998; Hagman et al., 1998; Hanson et al., 1998), although DbpA-immunized mice were not protected when inoculated by tick infestation (Hagman et al., 2000). A role for decorin in Lyme disease pathogenesis was recently demonstrated using a decorin-deficient transgenic mouse (Brown et al., 2001). In these studies, decorin-deficient mice were more resistant to infection with *B. burgdorferi* (i.e., fewer spirochetes were found in joints) and showed lower incidence and severity of arthritis than either wildtype or heterozygotes.

A second differentially expressed protein with a potential role in spirochetal attachment to extracellular matrix (Probert and Johnson, 1998) is the fibronectin-binding protein, BBK32; this protein has also been referred to as P35 and P47 (Fikrig et al., 1997; Fikrig et al., 2000; Probert and Johnson, 1998). The BBK32 protein was initially thought to be expressed only within the mammalian host (Fikrig et al., 1997), but this later was shown to be a stain-specific phenomenon, with some *B. burgdorferi* sensu lato isolates (B31, 297, ACA1 and IP3) expressing detectable amounts of BBK32 when cultivated in BSK II (Table 3) medium (Probert and Johnson, 1998). A comprehensive analysis of *bbk32* expression in *B. burgdorferi* strain N40 (which preferentially synthesizes BBK32 during murine and human Lyme disease) was performed by Fikrig et al. (2000) to elucidate what, if any, role this protein plays in tick transmission and/or mammalian infection. The results from these studies demonstrated that 1) BBK32 was not detectable by immunofluorescence on spirochetes within flat ticks, but was present on spirochetes within the engorged ticks, 2) *bbk32* mRNA was first detected two days following syringe inoculation and was maximal at 30 days postinfection, 3) *bbk32* message was detectable in all tissues tested (skin, joints, heart, spleen and bladder) at 14 days postinfection and remained detectable for 60 days, albeit at a significantly reduced level, and 4) BBK32 antibodies provided partial protection from tick infection with *B. burgdorferi* (in a guinea pig model) by killing the spirochetes within the engorged tick, thereby inhibiting the transmission of spirochetes to an immunized animal host (Fikrig et al., 2000).

Environmental Signals as Gene Regulators

A major theme in microbial pathogenesis is the effect of environmental signals on bacterial gene expression. To be maintained within its enzootic cycle, borreliae must possess the ability to adapt to growth within two strikingly different milieus, the arthropod vector and the mammalian host. During this cycle, the spirochete is likely to encounter differences in, among other things, nutrients, temperature and pH. One of the best-studied environmental conditions is temperature. Increased temperature has been associated with increased expression of OspC (see "Reciprocal Expression of OspA and OspC"), OppAV (Bono et al., 1998; see "Transporters"), and the OspE/OspF/Elp (Stevenson et al., 1995; Stevenson et al., 1998a; Hefty et al., 2001; see "OspE/OspF/Elp Lipoproteins") and Mlp (Porcella et al., 2000; Yang et al., 2000; see "Mlp Lipoproteins") lipoprotein families. Several lines of evidence, however, suggest that temperature alone is not solely responsible for the increased expression of these lipoproteins. The incubation of unfed *B. burgdorferi*-infected *I. scapularis* nymphs at 37°C for 24, 72 or 144 hours did not stimulate expression of OspC (Schwan et al., 1995). In addition, the expression of OspC has been shown to wane with continued passage in vitro at 37°C (Schwan and Piesman, 2000). Similarly, a number of observations have been made on the expression of the OspE/OspF/Elp lipoproteins: 1) expression in a mammalian host-adaptation model is significantly greater than the levels observed in spirochetes cultivated in vitro following a temperature shift from 23 to 37°C (Akins et al., 1998), 2) the p21 lipoprotein (see "OspE/OspF/Elp Lipoproteins"), which is not expressed in vitro following temperature shift, is readily detected in a mammalian host-adaptation model (Akins et al., 1998), and 3) animals infected by either tick- or needle-inoculation with *B. burgdorferi* produce antibodies against p21 (see "OspE/OspF/Elp Lipoproteins") and BbK2.10 early during infection, but these sera fail to detect these lipoproteins in spirochetes cultivated in vitro following temperature shift (Wallich et al., 1993; Akins et al., 1995; Akins et al., 1998; Suk et al., 1995; Das et al., 1997). The expression pattern of the Mlp lipoproteins family has been examined in two strains, B31 and 297. Using Northern analyses (Porcella et al., 2000)

and RT-PCR (Yang et al., 1999), little or no *mlp* expression was seen at 23°C, whereas all were shown to be upregulated in response to temperature. A number of environmental factors other than temperature also have been shown to result in differential gene expression in *B. burgdorferi*. Alban et al. (2000) examined the effects of serum starvation in *B. burgdorferi* (grown in RPMI). This study reported that growth of *Borrelia* under this fatty acid- and lipid-limited growth condition resulted in the formation of cysts-like "starvation" forms containing nonmotile, but otherwise intact and viable spirochetes, which rapidly revert to a "vegetative" form when transferred to BSK II (Table 3) medium. In addition, the expression of approximately 20 proteins was induced during growth in RPMI as compared to *B. burgdorferi* grown in BSK II (Table 3) medium. It is intriguing to speculate whether some of these "starvation-induced" proteins are involved in the ability of these bacteria to withstand the extended periods of nutrient limitation they undoubtedly experience in the arthropod host (Alban et al., 2000). Carroll et al. (1999) identified at least 37 changes within borrelial membrane preparations by two-dimensional nonequilibrium pH gradient gel electrophoresis (2D-NEPHGE) in response to changes in pH (pH 6.0 vs 7.0 vs 8.0). In these studies, outer surface protein C (OspC, see "Reciprocal Expression of OspA and OspC") was shown to be decreased at the higher pH, whereas a second unidentified protein was shown to be increased at pH 8.0 (Carroll et al., 1999). Two studies examining spirochetes cultivated in BSK-H (Table 3) medium demonstrated that increased cell density (at constant pH) resulted in increased expression of both *ospC* (see "Reciprocal Expression of OspA and OspC") and *mlp8* (Indest et al., 1997; Ramamoorthy and Philipp, 1998; Mlp Lipoproteins). Although a protein with homology to a quorum-sensing autoinducer synthetase (AI-2) has been identified within the *B. burgdorferi* genome (BB0377; Surette et al., 1999), it has yet to be determined whether a quorum-sensing autoinducer synthetase-like mechanism is responsible for cell-density mediated gene expression. The contribution of growth phase has also been examined. These studies identified a number of protein bands in sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gels (including P35, BmpD and P7.5), which were upregulated between 2- to 66-fold as the spirochetes in BSK II (Table 3) medium transitioned from mid-log to stationary phase (Ramamoorthy and Philipp, 1998). Using a combination of Northern analyses and immunoblotting, Yang et al. (2000) furthered these studies by examining the interdependence of pH, temperature and cell density on spirochetes cultivated in vitro in BSK-H medium. In these studies, a decrease in pH, in conjunction with an increase in temperature and cell density, acted interdependently, resulting in the reciprocal expression of *ospC* and *ospA* (see "Reciprocal Expression of OspA and OspC"). Examination of other environmentally regulated genes identified patterns of expression that fall roughly into two groups, group I (*ospC*-like) and group II (*ospA*-like). In the proposed model, the group I genes (i.e., *ospC*, *ospF* and *mlp8*) exhibit reduced expression when the concentration of spirochetes and environmental temperature are low, whereas the pH is relatively high. This condition is thought to represent the microenvironment of the unfed tick midgut. The group II genes (i.e., *ospA/B*, *p22* and *lp6.6*) behave in a reciprocal manner and exhibit increased expression under these same conditions. Yang et al. (2000) also propose a role for the alternative σ factor *rpoS* (Fraser et al., 1997; Elias et al., 2000) in the regulation of the group I genes. One group I gene, *dbpA*, did not fit the proposed model; unlike *ospC*, expression of *dbpA* was substantially reduced at pH 6.8 (relative to 7.5; Yang et al., 2000). This result is, however, consistent with the recent finding that DbpA (see "Decorin- and Fibronectin-binding Proteins") is not expressed by *B. burgdorferi* in the midguts of fed *I. scapularis* ticks (Hagman et al., 2000). While these studies represent significant steps toward understanding the complex interplay between multiple environmental factors, each of the above-mentioned studies involves the characterization of spirochetes cultivated in vitro using artificial medium and therefore needs to be seen as suggestive. The development of a tick cell culture model for cultivating *B. burgdorferi* and the demonstration that the reciprocal expression of *ospA* and *ospC* (see "Reciprocal Expression of OspA and OspC") can be modulated by temperature using this model offer an exciting potential for further environmental studies that more closely reflect the arthropod phase of growth (Obonyo et al., 1999).

While alterations in temperature, medium composition and pH are undoubtedly important, mammalian host-derived signals also play a role in inducing dramatic changes in gene and protein expression. The preferential expression of genes in the mammalian host is considered to be indicative of a role in virulence, although this role has not always been readily apparent. The identification and characterization of borrelial genes preferentially expressed in the mammalian host, however, is stymied by the inability to genetically manipulate these organisms and the paucity of organisms found in tissues during infection, particularly in Lyme disease. As a consequence, borrelial gene expression studies have had to rely on

more conventional molecular and immunological assays, examining the expression of only a limited number of genes within a given sample. Ideally, however, one would want to examine the simultaneous expression of multiple genes and the polypeptides they encode in the context of mammalian infection. Towards this end, several recent developments have significantly advanced the field towards overcoming the abovementioned limitations and allowed for the application of more contemporary methodologies. These developments include 1) the development of an electroporation protocol for the introduction of genetic material into *Borrelia burgdorferi* (Genetic Transformation of *Borrelia*), 2) the development of at least two published *Borrelia* shuttle vectors (Genetic Transformation of *Borrelia*), and 3) the development of new animal models for the isolation of spirochetes in a "host-adapted" state. The first two developments are covered elsewhere in the chapter. Animal models for the isolation of spirochetes in a more mammalian host-adapted state were developed by several independent research groups and include the transplantation of skin containing *B. burgdorferi* from infected animals to naive animals developed for either a murine (Barthold et al., 1995) or rabbit (Shang et al., 2000) model of Lyme disease and the cultivation of spirochetes with dialysis membrane chambers (DMC) implanted into the peritoneal cavities of rats (Akins et al., 1998) and subsequently rabbits (Sellati et al., 1999). Future studies utilizing these methodologies will undoubtedly provide insights into both spirochetal and mammalian factors and stimuli involved in the pathogenesis of Lyme disease.

Antigenic Variation in *Borrelia*

VMP LIPOPROTEINS Antigenic variation, a mechanism of immune evasion often employed by bacterial pathogens (Borst, 1991; Donelson, 1995; Deitsch et al., 1997), has been defined as the changes in the structure or expression of antigenic proteins that occur at a frequency greater than the usual mutation rate (Seifert and So, 1990). The best example of antigenic variation in the borreliae is that of the variable major proteins of the relapsing fever spirochetes. One of the hallmarks of relapsing fever is the periodic cycling of acute and afebrile episodes. The acute febrile episodes are characterized by the presence of a large number of spirochetes in the bloodstream of the infected mammal or patient (spirochetemia) and are followed by a change in the serotype and major lipoproteins associated with the bacterial membrane. Multiphasic antigenic variation was first described in the relapsing fever spirochete *B. hermsii* (Barbour et al., 1982; Stoenner et al., 1982) and was associated with a family of lipoproteins, collectively named the "variable major lipoproteins" (VMPs). The VMPs were later shown to be composed of two multigene families, the *vsp* (variable small protein) family, which encodes lipoproteins 20–23 kDa in size, and the *vlp* (variable large protein) family, which encodes lipoproteins 36–40 kDa in size (Barstad et al., 1985; Restrepo et al., 1992; Cadavid et al., 1997; Hinnebusch et al., 1998). The *vlp* family can further be divided into four subfamilies (α, β, γ and δ; Hinnebusch et al., 1998). These proteins share several features of the variant surface glycoproteins (VSGs) responsible for antigenic variation in African trypanosomes, including the post-translational addition of a lipid moiety that mediates attachment to the cell membrane and similar secondary structures of the mature polypeptides (Burman et al., 1990). In addition, these two organisms use a similar recombinatorial mechanism for the genetic exchange of DNA during antigenic variation (Kitten and Barbour, 1990; Donelson, 1995). The mechanism for the conversion of VMP types (and related VMP-like proteins) has been described for several *Borrelia* strains, but here *B. hermsii* will be used as the prototype. Briefly, 28–32-kb linear plasmids of *B. hermsii* have greater than 30 silent copies of serotype-specific variable major protein genes (*vsp* and *vlp*; Meier et al., 1985; Kitten and Barbour, 1990; Barbour, 1993). These silent loci were originally named by variable major protein designations (*vmp1*, *vmp2*, *vmp3*, etc.), but have since been renamed by either *vsp* or *vlp* family designations (Cadavid et al., 1997). The expression locus containing a promoter sequence and the active copy of either a *vsp* or *vlp* is located on the same or a different 28–32-kb linear plasmid (Fig. 11) adjacent to the covalently closed telomeric end (Kitten and Barbour, 1990; Plasterk et al., 1985). Only one *vmp (vsp/vlp)* gene present at one telomere end of the single linear expression plasmid is expressed in each organism (Kitten and Barbour, 1990; Barbour et al., 1991a). Antigenic variation (switching) occurs at a frequency of 10^{-3} to 10^{-4} per generation (Stoenner et al., 1982) and results from the recombination of one of the silent (archival) genes into the telomeric expression locus through inter- and intraplasmic recombination (Plasterk et al., 1985; Barbour et al., 1991b; Restrepo et al., 1994b). This recombination, which is thought to utilize homologous sequences present within the 5′ and 3′ ends of all silent and expressed *vmp* loci, results in the partial or complete replacement of the former VMP serotype with a new serotype. In some instances, incomplete recombination has resulted in the formation of chimeric expression loci containing partial or complete copies of

more than one *vmp* gene (Kitten et al., 1993; Restrepo et al., 1994b). Additional sequence heterogeneity is provided by the introduction of point mutations post-switch (Restrepo and Barbour, 1994a).

Two Vsp serotypes, VspA and VspB, also have been described in relapsing fever agent *B. turicatae* (Cadavid et al., 1997; Pennington et al., 1999a). The Vsp system in *B. turicatae* differs most significantly from the VMPs of *B. hermsii* in that the archival silent loci and the expressed locus are both located near the center of 37–50-kb linear plasmids and not near the telomeres (Pennington et al., 1999b). The silent and expressed loci are, however, encoded on different linear plasmids (Pennington et al., 1999a). The antigenic switching mechanism in *B. turicatae* occurs when a silent *vsp* locus and downstream 3′ sequence (totaling approximately 13–14 kb) are duplicated at a unique expression site, replacing the existing expressed copy and its corresponding downstream sequence (Pennington et al., 1999a). As with the VMPs of *B. hermsii*, only one Vsp serotype is expressed at a time in *B. turicatae*. Vsp/Vlp-related sequences have also been described in *B. parkeri*, *B. crocidurae* and *B. coriaceae* (Hinnebusch et al., 1998).

Antigenic switching of the VMPs has been shown to occur both during in vitro cultivation and during infection of the mammalian host (Stoenner et al., 1982; Schwan and Hinnebusch, 1998). During infection of a mammalian host, each acute relapse episode is predominated by an almost entirely new serotype (Stoenner et al., 1982), presumably allowing evasion from the mammalian adaptive immune response. Until recently, it was not known whether a similar switch occurred as the spirochete passaged from the arthropod-vector to the mammalian host during tick feeding, but a recent study by Schwan and Hinnebusch (1998), using *O. hermsi* infected with either of two distinct *B. hermsii* VMP serotypes, demonstrated that the *vmp* gene present at the telomeric expression site did not change during passage through ticks.

While there are now extensive data on the mechanisms of *vmp*/*vls* serotype switching in borreliae, much less is known about the contribution of these lipoproteins to pathogenesis. Recent studies with *B. turicatae* using a mouse model of Lyme disease demonstrated that organisms expressing the VspA lipoprotein have more extensive CNS involvement, whereas organisms expressing the VspB lipoprotein exhibit more severe arthritic manifestations (Cadavid et al., 1994). In addition, Pennington and coworkers (Pennington et al., 1997) demonstrated that mice infected with the VspB-expressing serotype showed increased numbers of spirochetes in their joints and blood than did mice infected with serotype A. Magoun and co-workers (Magoun et al., 2000) provided further evidence for a possible role of the VMPs in virulence and/or differences in tissue tropism by demonstrating that VspB, but not VspA, mediated attachment of *B. turicatae* to cultured mammalian cells through an interaction with cell-associated glycosaminoglycans (heparin and dermatan sulfate).

Vsp-OspC Lipoprotein Family A third type of variable major protein serotype was also described in *B. hermsii* by Stoenner et al. (1982) and designated "serotype C." This serotype was of interest due to its tendency to predominate in serially passaged populations of *B. hermsii* (Barbour et al., 1982; Stoenner et al., 1982). Once it was determined that antibodies specific for serotype C were directed against a variable small lipoprotein (Vsp), the designation was later changed to "Vsp33" in keeping with the established nomenclature of VMP serotypes (Carter et al., 1994). The *vsp33* gene differs from the other *vsp* and *vlp* genes in that 1) it is expressed from a site distinct from that of the telomeric site typically used by the *vsp/vlp* genes (Barbour et al., 2000), and 2) the *vsp33* promoter is more closely related to the promoter for the *ospC* gene of *B. burgdorferi* than the promoters for the *vsp/vlp* genes of *B. hermsii* (Barbour et al., 1991a; Pennington et al., 1999b).

Phylogenetic analyses of Vsp33 from *B. hermsii* with the other small Vsps of the relapsing fever *Borrelia* spp., a Vmp from *B. miyamotoi* (Fukunaga et al., 1995), and the OspCs (see "Reciprocal Expression of OspA and OspC") from *B. burgdorferi* sensu lato isolates suggest that these proteins form a family of related proteins, termed "the Vsp-OspC family" (Carter et al., 1994; Cadavid et al., 1997). These data are supported by recent structural studies (circular dichroism) comparing the *B. turicatae* VspA with three related proteins, VspB of *B. turicatae*, Vsp26 of *B. hermsii* and OspC (see "Reciprocal Expression of OspA and OspC") of *B. burgdorferi* strain B31. Results from these studies suggest that 1) despite as little as 40% identity in primary sequence, these proteins share a common highly α-helical secondary structure predicted to form a four-helix bundle (Fig. 21), 2) non-conservative amino acid changes, insertions and deletions could potentially affect secondary structure cluster in regions outside the predicted helices, and 3) a common secondary structure results in the formation of similarly sized protease-resistant cores (Zückert et al., 2001). In addition, each of the proteins examined had the ability to dimerize in solution (Zückert et al., 2001). Further structure-function analyses of the Vsp-OspC family of lipoproteins will likely increase our understanding of the role of these

proteins in antigenic variation, facilitating transmission from the arthropod vector, and mammalian infection, particularly the establishment of tissue-specific niches.

Although they share some sequence similarity in their promoter regions and plasmid origins (Barbour et al., 2000), *vsp33* from *B. hermsii* and *ospC* (see "Reciprocal Expression of OspA and OspC") from *B. burgdorferi* sensu lato differ in their patterns of expression. The expression of Vmp33 has been shown to be induced by cultivation either in artificial medium or within tick midguts at 23°C (Schwan and Hinnebusch, 1998). The OspC (see "Environmental Signals as Gene Regulators"), on the other hand, is poorly expressed at this lower temperature (either in vitro or within the unfed tick midgut) and instead is induced by the higher temperatures (33–37°C) experienced by spirochetes during infection of the mammalian host (Schwan et al., 1995). Based on these and other data, Schwan and Hinnebusch (1998) have proposed roles for the Vmp33-OspC lipoproteins in tick-transmission and/or early colonization of the mammalian host. According to the proposed model, Vmp33 is produced by spirochetes in the midguts of soft tick's (*O. hermsi*) following a short period required for the cooling of the bloodmeal contents. Vmp33 is then constitutively expressed by spirochetes as they persistently infect the tick's salivary glands, awaiting an opportunity to be transmitted to the next mammalian host. In addition, expression of *vmp33* has a "silencing" effect on the expression of the *vsp/vlp* present at the telomeric expression site, and vice versa; the mechanism for this inactivation is not known (Barbour et al., 2000). The OspC of *B. burgdorferi*, on the other hand, is not expressed in the midgut of unfed ticks. The Lyme disease spirochete remains within the midgut until the infected tick takes a next bloodmeal, during which the expression of OspC (see "Reciprocal Expression of OspA and OspC") is induced and the spirochetes migrate to the salivary glands to "prepare" for transmission to the mammalian host (Ribeiro et al., 1987; Zung et al., 1989; Lane et al., 1991; Coleman et al., 1997; Ohnishi et al., 2001). In contrast to the constitutive expression of Vmp33 and the rapid transmission (15–90 minutes) of the tick-borne relapsing fever spirochetes, expression of OspC (see "Reciprocal Expression of OspA and OspC") by the Lyme disease spirochete and subsequent transmission to the mammalian host can take a minimum of 2–3 days (Schwan et al., 1995; Schwan and Piesman, 2000; Ohnishi et al., 2001). This period, however, is well within the 3–5 days required for a hard tick to feed to repletion. The expression patterns of Vmp33 and OspC following transmission to the mammalian host are also different. Although readily visualized on spirochetes within the salivary glands of infected soft ticks by immunofluroescence, expression of the Vmp33 lipoprotein is undetectable once the density of spirochetes is high enough for visualization of the organism in the blood (Schwan and Hinnebusch, 1998). The loss of Vsp33 expression is accompanied by the appearance of one of the other VMP lipoproteins (Vsp or Vlp; Schwan and Hinnebusch, 1998). On the other hand, OspC is constitutively expressed by (most) spirochetes as they enter the salivary glands of the tick and as they are transmitted to the mammalian host, and expression continues during infection. These data could suggest that although Vmp33 and OspC may both facilitate the transmission of the relapsing fever and Lyme disease spirochetes, respectively, from their arthropod vectors to the mammalian host, the continued expression of Vmp33 (for the sake of not expressing a new VMP serotype, Barbour et al., 2000) is disadvantageous for the relapsing fever spirochete. In contrast, the continued expression of OspC may not offer any disadvantage or, alternatively, OspC (see "Reciprocal Expression of OspA and OspC") may be required for some *B. burgdorferi*-specific function.

Borrelia burgdorferi Vls System It has been long recognized that the Lyme disease spirochete, *B. burgdorferi*, can alter its antigenic composition during growth through differential gene expression (see "Differential Gene Expression"). The identification of a VMP-like system (*vls*), however, suggests that this spirochete may also employ antigenic variation as a mechanism for immune evasion and/or host-adaptation. The genetic organization of the *vls* (Fig. 25) system in *B. burgdorferi* is similar to that of the VMP system from relapsing fever spirochetes in the utilization of 15 variable silent loci (*vls* cassette) and a single "expression" locus (*vlsE*). In contrast to *B. hermsii*, both the silent and expression loci are located adjacent to each other on a telomeric end of a single 28-kb linear plasmid (lp28-1) in *B. burgdorferi* strain B31. Each *vls* cassette silent locus is flanked by a conserved 17-bp direct repeat that may be involved either in the alignment and recombination or in binding of a proposed site-specific recombinase(s) within the *vlsE* site. The VlsE from *B. burgdorferi* stain B31 contains two highly conserved domains, one at the amino terminus (96 amino acids) and one at the carboxyl terminus (51 amino acids; Zhang et al., 1997; Fig. 25). The amino acid sequence between these two invariable domains is composed of a central variable domain that contains six variable regions (VRs) and six invariable regions (IRs). These two types of regions are interspersed with each other, and each consti-

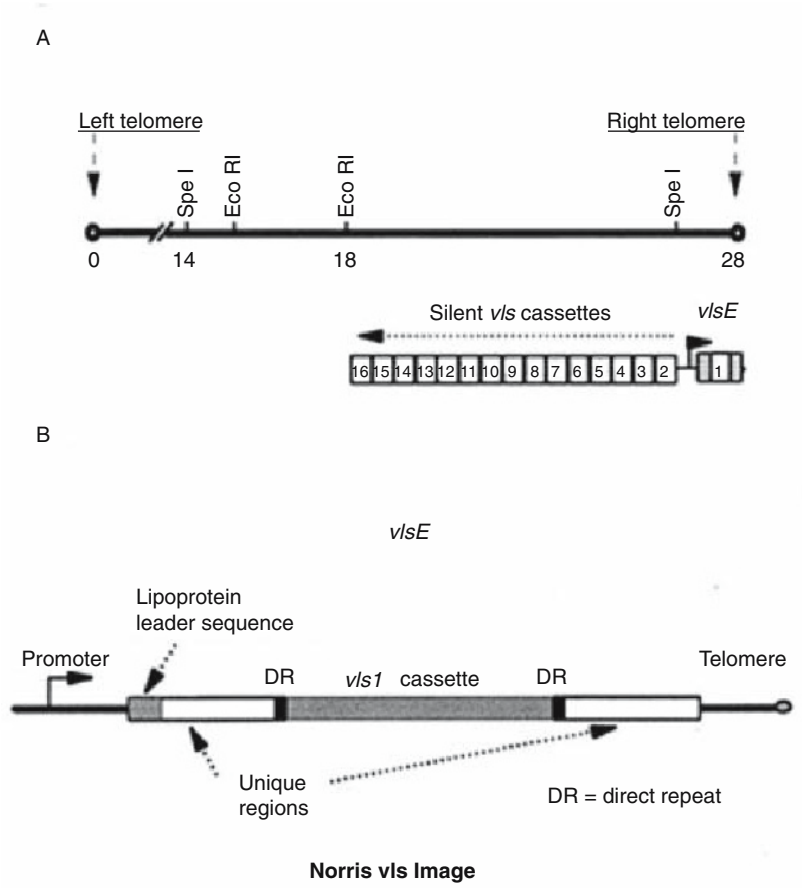

Fig. 25. *Borrelia burgdorferi* clone B31-5A3 *vls* locus. (A) Diagrammatic illustration of the overall arrangement of the *vls* locus in *B. burgdorferi* strain B31 plasmid lp28–1. (B) Structure of *B. burgdorferi* strain B31 *vlsE*. Taken from Zhang et al. (1997), © 1997, Cell Press, with permission.

tutes approximately one-half of the variable domain's length (Zhang et al., 1997; Liang et al., 1999). Additional variability within the *vls* system is achieved via combinatorial antigenic variation and promiscuous recombination resulting from replacement of portions of the expression sites by segments from several silent loci within the other *vls* cassette genes (Zhang et al., 1997; Liang et al., 1999). These recombinatorial events are dramatically induced during mammalian infection (Zhang and Norris, 1998). Also in contrast to the VMP system in the relapsing fever spirochetes in which each phase (relapse) of infection is predominated by one serotype (Barbour, 1993), multiple VlsE serotypes may be expressed within a given population of *B. burgdorferi* during infection of a single mammalian host (Zhang et al., 1997). Zhang and Norris (1998) examined the kinetics of *vlsE* sequence variation in C3H/HeN and severe combined immunodeficiency (SCID) mice. Results from these studies demonstrated that *vlsE* variation occurred in both mouse strains in as few as four days postinfection. The rate of accumulation of amino acid changes was significantly higher in the C3H/HeN mice, suggesting that immune selection may play a role in the persistence of *vlsE* variants. The finding that the rate of accumulation of amino acid changes in the *vlsE* loci within *B. burgdorferi*-infected SCID mice was higher than that in spirochetes cultured in vitro cannot be explained by adaptive immune selection and suggests that *vls* recombination is induced by a mammalian host factor(s). Subsequent immune selection, however, may explain the higher rate of changes in the surviving variant clones (over the parental clone) in the C3H/HeN mice compared to SCID mice (Zhang and Norris, 1998). Recent studies by Ohnishi et al. (2001) suggest that tick feeding may increase recombination at the *vlsE* locus.

To date, the *vls* (Fig. 25) system of only one *B. burgdorferi* strain (B31) has been characterized, but the *vls* cassette region (Kawabata et al., 1998) and *vlsE* expression (M. J. Caimano and J. D. Radolf, unpublished observation) loci have been identified for *B. burgdorferi* sensu stricto strain 297. Southern blot analysis of 22 blood

and erythema migrans biopsy (low-passage) isolates from human Lyme disease patients in Westchester County, New York, determined that all 22 isolates contained a *vlsE*-like sequence (Iyer et al., 2000). Although the size of the plasmid bands varied (from 21 to 38 kb) within the group of isolates, the *vlsE*-hybridizing bands were restricted to one plasmid species within an individual isolate. The consistent presence of *vls* sequences in Lyme disease isolates provides evidence supporting the view that the *vls* locus or associated sequences may be required for infection of mammalian hosts (Iyer et al., 2000). The *vls* system in *B. burgdorferi* is also implicated in virulence; isolates of *B. burgdorferi* strain B31 lacking the linear plasmid (lp28-1) encoding the *vls* locus exhibited reduced infectivity in a mouse model of Lyme disease (Purser and Norris, 2000). Additional infection data suggest that isolates lacking other linear plasmids may be similarly attenuated in virulence (Labandeira-Rey and Skare, 2001).

Studies have shown that five of the six invariable regions (IRs; Fig. 25) present within all VlsE polypeptides were not exposed on the surface of spirochetes cultivated in vitro (Liang et al., 1999; Liang et al., 2000). In addition, a recent study by Liang et al. (2001) examined the surface localization of the conserved C-terminal invariable domain of VlsE and found that it also was not exposed on the spirochetal surface. Consistent with these localization data, antibodies against the conserved C-terminal domain, although immunodominant during mammalian infection, failed to protect against challenge with *B. burgdorferi* (Liang et al., 2001). These data, along with the accumulation of substantial genetic heterogeneity within the variable regions during mammalian infection, suggest that although this molecule may play a role in infectivity, VlsE may not be useful as a vaccinogen (Liang et al., 2001).

Lipoproteins and the Innate Immune Response

Although many aspects of Lyme disease pathogenesis remain ill defined, it is generally accepted that clinical manifestations result primarily, perhaps entirely, from the host's local immune response to spirochetes in infected tissues (Duray and Steere, 1988; Szczepanski and Benach, 1991). For a more comprehensive review of the immunology of Lyme disease, see Sigal (1997). There is now a substantial body of evidence that borrelial lipoproteins are the major proinflammatory agonists in Lyme disease and the relapsing fevers and that lipid modification is a prerequisite for this biological property (Radolf et al., 1991; Radolf et al., 1995a; Ma and Weis, 1993; Boggemeyer et al., 1994; Norgard et al., 1996; Sellati et al., 1996; Morrison et al., 1997; Vidal et al., 1998). Although both borrelial lipoproteins and LPS initiate cell signaling by binding to CD14 (Sellati et al., 1998; Wooten et al., 1998) and both activate cells via nuclear factor-kappa B (NF-β; Norgard et al., 1996; Wooten et al., 1996), key differences in the signaling pathways utilized by these two agonists have come to light. Activation by lipoproteins is serum-independent and does not require LPS-binding protein (Sellati et al., 1998; Wooten et al., 1998). More importantly, the lipoprotein-CD14 complex signals through toll-like receptor (TLR)2 (Aliprantis et al., 1999; Brightbill et al., 1999; Hirschfeld et al., 1999; Lien et al., 1999), whereas LPS signals through TLR4 (Poltorak et al., 1998; Takeuchi et al., 1999). The importance of innate immunity in the establishment of Lyme disease is highlighted by the observation that *B. burgdorferi*-infected severe combined immunodeficiency (SCID) mice exhibit persistent spirochetemia and chronic progressive inflammation of the joints, heart and liver (Schaible et al., 1990; Barthold et al., 1992).

Role of Plasminogen/Plasmin in *Borrelia* Pathogenesis

Plasmin, a broad spectrum serine protease, is responsible for fibrin degradation during thrombolysis, but also has been proposed to be involved in other physiological and pathological processes such as skin, corneal, and arterial wound repair, tumor progression, and ischemic and excitotoxic brain damage. The discovery that pathogenic microorganisms (Gram-positive and -negative) can convert plasminogen into enzymatically active plasmin to increase their invasiveness and enhance their ability to cross tissue barriers has received much attention (reviewed in Broder et al., 1991). The observation that *Borrelia* species (*B. burgdorferi* and *B. hermsii*) can incorporate plasminogen onto their surfaces where it can be activated to plasmin by the host's plasminogen activation system (PAS) has lent itself to a study of the PAS and spirochetal virulence (Fuchs et al., 1994; Fuchs et al., 1996; Coleman et al., 1995; Coleman et al., 1997; Hu et al., 1995; Hu et al., 1997; Klempner et al., 1995; Perides et al., 1996; Gebbia et al., 1999; Coleman and Benach, 2000). Once incorporated onto the surface of the bacterium, the enzymatically active plasmin has the potential to degrade components of the extracellular matrix, such as fibronectin and laminin. The incorporated plasmin proteolytic activity on the surface of the pathogenic bacteria, such as *Borrelia* spp., must disseminate from their site of entry in the skin to the blood and other tissues (Gebbia et al., 1999). Evidence supporting this role for plasmin has

been reported by Benach and coworkers. Using an in vitro assay, a *B. burgdorferi* human isolate, once complexed with plasmin and supplied an exogenous plasminogen activator (uPA), had the ability to degrade purified extracellular matrix (ECM) components and an interstitial ECM. In two separate animal models of borrelial infection, relapsing fever and Lyme disease, the in vivo role for plasminogen/plasmin has been examined by using plasminogen-deficient knockout mice ($plg^{-/-}$). In the Lyme disease model, plasminogen was shown to be required for efficient spirochete dissemination in ticks and establishment of spirochetemia in mice (Coleman et al., 1997). Plasminogen was also shown to be an important host factor in the relapsing fever model. Plasminogen-deficient mice ($plg^{-/-}$) showed significantly decreased spirochetal burdens in both heart and brain tissues (as measured by PCR amplification). Furthermore, the decreased spirochetal load in the brains of $plg^{-/-}$ mice was associated with a significant decrease in the degree of inflammation of the leptomeninges in these mice, as compared to the control ($plg^{+/+}$ and $plg^{+/-}$) mice (Gebbia et al., 1999). Together these data strongly support a role for the PAS in *Borrelia* spp. infection.

Chemotherapy

Relapsing Fevers

For a review of antibiotic therapies for the relapsing fevers, see Cadavid and Barbour (1998). Relapsing fever has been successfully treated with tetracycline, chloramphenicol, penicillin and erythromycin (Sanford, 1976; Perine and Tekle, 1983; Butler, 1985; Horton and Blaser, 1985), although chloramphenicol treatment was not highly successful in the treatment of relapsing fever in animal models of infection (Cadavid and Barbour, 1998). For louse-borne relapsing fever, tetracycline, in a single oral dose (0.5 g), is the preferred therapy, except in pregnant women and children younger than 8 years (Perine and Tekle, 1983). Erythromycin in a single oral dose (0.5 g) is an equally effective alternative therapy (Perine and Tekle, 1983). For tick-borne relapsing fever, tetracycline (0.5 g), given in four divided doses at 6-h intervals for 5–10 days, is considered the drug regime of choice, owing to the higher rate of treatment failure and relapses in these patients (Sanford, 1976; Foster, 1977; Horton and Blaser, 1985). Although effective in cases of LBRF, erythromycin did not prevent relapse or neurological complications in patients with TBRF (Horton and Blaser, 1985; Colebunders et al., 1993). Parenteral antibiotics (i.e., penicillin G, cefotaxime or ceftriaxone) should be given for 14 or more days in patients with meningitis or encephalitis (Cadavid and Barbour, 1998).

Lyme Borreliosis

Early Lyme (Borreliosis) disease usually responds well to antimicrobial therapy. However, cases with persistent joint or central nervous system complications tend to be more resistant to treatment. Adults with the early manifestations generally respond to doxycycline (100 mg orally, 2 × daily, 10B30 days) or amoxicillin (500 mg orally, 4 × daily, 10B30 days). Children younger than 8 years of age are generally treated with amoxicillin (250 mg orally, 3 × daily, 10B30 days). Neurologic manifestations (Table 5) and other abnormalities are treated with ceftriaxone (Rocephin; 2 g, intravenously, 1 × daily, 14 days). Treatment failures have occurred with all of these regimens, and retreatment may be necessary. Since patients who have already developed a mature anti-borrelia IgG response often remain seropositive after apparently successful antibiotic therapy, the presence or absence of circulating antibodies to *Borrelia* following treatment is not a reliable indicator of cure (Dattwyler et al., 1989). Descriptions of clinical presentations and the medical progress of Lyme disease have been reviewed by Steere (1989) and Edlow (1999).

Jarisch-Herxheimer Reaction

Shortly (10–30 minutes) following the initiation of antibiotic therapy in a large number of relapsing fever patients, a Jarisch-Herxheimer reaction may occur, manifested by rigors, sudden fever, headache, and persistent hypertension, followed over the next few hours by profuse sweating and a slow decline in temperature and fall in blood pressure. The discovery of this distressing and potentially life-threatening (case fatality rate of approximately 5%) phenomenon is usually credited to Jarisch and Herxheimer, who first described the components of this syndrome in patients with secondary syphilis (see The Genus *Treponema* in this Volume) who received mercury treatment. This reaction has been described in a variety of bacterial infections, including five spirochetal infections (louse-borne and tick-borne relapsing fevers, Lyme disease, leptospirosis (see The Genus *Leptospira* in this Volume), and syphilis (see The Genus *Treponema* in this Volume) and closely resembles a classic endotoxin reaction (or systemic inflammatory response syndrome), which typically occurs when endotoxin (LPS) from cell walls of Gram-negative bacteria or other viral, protozoal, fungal

pyrogen, or bacterial toxin is released. More recently, bacterial lipoproteins (see "Lipoproteins and the Innate Immune Response") have been added to the list of molecules capable of inducing an acute inflammatory response (Radolf et al., 1991; Radolf et al., 1995a; Ma and Weis, 1993; Tai et al., 1994; Weis et al., 1994; Norgard et al., 1995; Norgard et al., 1996; Sellati et al., 1996; Sellati et al., 1998; Wooten et al., 1996; Morrison et al., 1997; Theus et al., 1998; Vincent et al., 1998). One general characteristic of all Jarisch-Herxheimer reactions is a substantial increase in circulating levels of tumor necrosis factor α (TNF-α), interleukin-6 (IL-6), and interleukin-8 (IL-8) just before symptoms develop. In a recent study by Fekade et al. (1996), treatment with Fab fragments of anti-TNF-α antibodies significantly reduced the incidence and severity of the Jarisch-Herxheimer reaction in patients with louse-borne (endemic) relapsing fever caused by *B. recurrentis*. This report was one of the first to establish that passive immunization against TNF-α can block the development of a shock-like illness in humans and has received support within the medical community as an attractive and viable therapy for the prevention of the Jarisch-Herxheimer reaction in spirochetal and potentially other bacterial infections (Beutler and Munford, 1996).

Lyme Disease Vaccine

In two large clinical trials, more than 10,000 adult volunteers received three doses (intramuscularly) of one of two Lyme disease vaccines directed against the *B. burgdorferi* outer surface lipoprotein, OspA (see "Reciprocal Expression of OspA and OspC"). Individuals were vaccinated at time 0, 1 and 12 months. After three doses, the OspA-based vaccine was shown to be 76–92% effective (Sigal et al., 1998; Steere et al., 1998b). The Food and Drug Administration (FDA) gave final approval, in 1998, to a Lyme disease vaccine, LymeRix, based on a recombinant form of OspA and manufactured by SmithKline Beecham Pharmaceuticals. There are several caveats to the use of the LymeRix vaccine (http://www.cdc.gov/epo/mmwr/preview/mmwrhtml/rr4807a1.htm). Although long studied using *Borrelia* cultivated in BSK II (Table 3) medium, the target of the vaccine, OspA (see "Reciprocal Expression of OspA and OspC"), was recently shown to be expressed only on the surface of spirochetes in the flat (unfed) tick and not on the surface of spirochetes in the tick salivary glands or on spirochetes transmitted to the human host. Once a tick begins to take a bloodmeal on a vaccinated individual, any spirochetes within the midgut of that tick are susceptible to the host's bactericidal anti-OspA antibodies. The end result is a lowering of the density of organisms within the tick salivary gland to below a critical threshold required for initiating events linked to transmission (de Silva et al., 1999). Those spirochetes that are not killed in the midgut prior to the downregulation and disappearance of OspA from the bacterial cell surface, however, are no longer susceptible to killing by antibodies directed against OspA (see "Reciprocal Expression of OspA and OspC"), thereby reducing the vaccine's efficacy. In addition, individuals who receive the vaccine will become ELISA positive (but Western-blot negative), making future diagnosis of those patients who subsequently become infected more difficult. Uncertainties about who should receive the vaccine (http://www.cdc.gov/epo/mmwr/preview/mmwrhtml/rr4807a1.htm), concerns about the limited duration of protective immunity (Onrust and Goa, 2000; Taege, 2000), and the unfortunate misperception that it has a high incidence of serious side effects, including autoimmune reactions (Sigal, 2000; OspA and Autoimmunity), have produced a less than enthusiastic reception among practitioners and the lay public. To date, these concerns have failed to materialize as there have been no significant side effects among the vaccinated public.

One attractive alternative to a vaccine based solely on OspA is the development of a multivalent vaccine based on a number of borrelial antigens that are expressed preferentially in either the arthropod (i.e., OspA Reciprocal Expression of OspA and OspC) or the mammalian host (i.e., Osp A/Osp C Reciprocal Expression of OspA and OspC, and OspE/OspF/Elp, Mlp, and DbpA. The increased expression of OspC in the mammalian host, the identification of OspC subtypes of *B. burgdorferi*, which are primarily responsible for invasive disease in humans (see *Borrelia* Genotype and Pathogenesis in the second edition), and the ability of OspC antibodies to prevent, as well as resolve, infection with *B. burgdorferi* (Zhong et al., 1999) make this molecule particularly attractive.

The vaccine, however, does not offer any protection against other tick-borne diseases, *Babesia microti* and the agent of human granulocytic ehrlichiosis (HGE), common to and transmitted by the same ixodid vectors. An area of active interest is the development of anti-arthropod vaccines. Such vaccines could be designed to interfere with one or more of the steps involved in pathogen transmission, including 1) preventing tick attachment and feeding, and 2) preventing pathogen attachment to and migration within the arthropod vector tissues. Such vaccines could have the potential to simultaneously protect

against multiple pathogens transmitted by the same vector.

For recent vaccine reviews, see Thanassi and Schoen (2000) and Poland and Jacobson (2001).

OspA and Autoimmunity

A study by Steere and coworkers (Gross et al., 1998), looking at patients with treatment-resistant and -responsive Lyme arthritis, suggested that infection with *B. burgdorferi* may lead to the development of an immune response to the OspA (see "Reciprocal Expression of OspA and OspC") lipoprotein that cross-reacts with a human antigen, human leukocyte function-associated antigen-1 (hLFA-1). In a small number of patients who possess a particular Major Histocompatability Class (MHC) II allele, HLA-DRB1*0401, the response against hLFA-1 may lead to the subsequent development of an autoimmune-mediated arthritis (Gross et al., 1998). The identification of OspA-reactive type-1 T helper (T_H1) cells that cross-reacted with a related-region within hLFA-1 in the synovial fluid of individuals with treatment-resistant Lyme arthritis supports this hypothesis (Gross et al., 1998). The association between an anti-OspA immune response and hLFA-1 cross-reactivity and the development of treatment-resistant Lyme arthritis is not fully understood. Some patients who develop hLFA-1 autoreactive T-cells do not possess the HLA-DRB1*0401 allele; conversely, some patients who possess that HLA-DRB1*0401 allele do not respond to either OspA or hLFA-1 (Gross et al., 1998). The implication(s) of these data for vaccine (see "Lyme Disease Vaccine") recipients remains to be seen.

Veterinary Diseases

Borrelia anserina is the etiological agent of avian borreliosis (Table 1), a highly fatal disease of geese, ducks, turkeys and chickens. Mammals are resistant to this infection. The disease is widespread, occurring in many countries including those in Europe, Asia, Australia, and South, Central, and North America. The vectors of *B. anserina* are species of *Argas* ticks. The disease begins with a high fever; then the birds become cyanotic and develop diarrhea. Spirochetes are present in the blood early during the disease, and relapses do not occur.

Borrelia coriaceae is the putative etiological agent of epizootic bovine abortion (Table 1), a disease of major economic importance in California (Lane et al., 1985; Johnson et al., 1987). This species of *Borrelia* (Johnson et al., 1987) is carried by the human-biting soft tick *Ornithodoros coriaceus* (Lane et al., 1985). Until recently, only one isolate of *B. coriaceae* Co53 had been characterized genetically and phenotypically (Johnson et al., 1987; LeFebvre and Perng, 1989). The publication of two additional strains of *B. coriaceae*, isolated from adult *O. coriaceus* ticks collected from northwestern California, has significantly increased our understanding of this little-known borrelial genospecies (Hendson and Lane, 2000). Hybridization studies of these two new isolates, along with the initial Co53 isolate, demonstrated low homology between these strains and the relapsing fever spirochete *B. parkeri* among the linear plasmids of these isolates. Pulsed field gel electrophoresis demonstrated that *B. coriaceae* exhibits genetic diversity within the linear plasmid profiles of these three isolates, a characteristic common among the borreliae (Hendson and Lane, 2000). Unlike most *Borrelia* spp., *B. coriaceae* can be passed transstadially and occasionally transovarially (Lane et al., 1985; Lane and Manweiler, 1988a). The Columbian black-tailed deer (*Odocoileus hemionus columbianus*) has been implicated as a probable natural host (Lane and Manweiler, 1988b).

Borrelia theileri is responsible for a mild disease of cattle, horses and sheep (Table 1). The illness is characterized by one to two episodes of fever, weight loss, weakness and anemia. The vectors of this spirochete are species of the hard ticks *Rhipicephalus* and *Boophilus*. *Borrelia theileri* also has been found to be transmitted transovarially in *Boophilus microplus* eggs (Smith et al., 1985). The disease has been reported in South Africa and Australia.

CHAPTER 4.4

The Genus *Leptospira*

BEN ADLER AND SOLLY FAINE

Introduction

Members of the genus *Leptospira* are helicoidal bacteria that may exist as free-living saprophytes or in association with a diverse range of animal hosts. They either are the cause of acute leptospirosis or are associated with particular host tissues (especially the renal proximal tubules) on a long-term basis (possibly for the life of the animal). Two additional species, *L. parva* and *L. illini*, which were previously included in the genus, have been reclassified as the separate genera *Turneria* and *Leptonema*, respectively (Hovind-Hougen, 1979; Hookey et al., 1993; Ellis, 1995), although the former has not been officially published. These three genera comprise the family Leptospiraceae within the order Spirochaetales, which also contains the families Spirochaetaceae and Serpulinaceae.

Human leptospirosis has clearly existed since the earliest times, but it is impossible to ascribe with any certainty various records of febrile jaundice to leptospirosis or to other causes. Many of the early descriptions are reviewed in Faine et al. (1999). It was in 1860 that Adolph Weil, professor of medicine at the University of Heidelberg, published his description of an "... infectious disease accompanied by splenomegaly, jaundice and nephritis" (Weil, 1886), the most severe form of which now bears his name as Weils disease. Leptospires were first isolated in pure culture by Japanese workers in 1914 (Inada et al., 1916) only a short time before a similar isolation in Europe (Uhlenhuth and Fromme, 1915), although it is clear that the first visual observations of *Leptospira* were made by Stimson a few years earlier in silver stained sections of human kidney from a patient thought to be suffering from yellow fever (Stimson, 1907; Stimson, 1909).

Taxonomy

The taxonomy of *Leptospira* has been both complicated and controversial; at various times over the past 60 years, the genus has contained only two species or almost 200 species. It is only with the relatively recent application of accepted molecular methods that the taxonomic status of members of the genus has been unequivocally determined.

The genus is defined as *Leptospira* Noguchi (1917), type species *Leptospira interrogans* (Stimson, 1907), type strain serovar Icterohaemorrhagiae, Ictero No. I (ATCC 43782).

Following the first isolation of *Leptospira*, the next three decades saw the isolation of scores of strains that were clearly different with respect to epidemiology, disease pattern and a very limited range of phenotypic characteristics. Because of the limited phenotypic differences available, antigenic differences in agglutinating (lipopolysaccharide; LPS) antigens were used as the basis for identification and classification. The serovar became the basic taxon, with each serovar accorded species status, e.g., *L. pomona*, *L. icterohaemorrhagiae*, *L. hardjo*, etc. Antigenically related serovars were placed together in serogroups, which per se have no taxonomic status. From a taxonomic viewpoint, this scheme was clearly erroneous. Accordingly, in 1982 the Subcommittee on the Taxonomy of *Leptospira* adopted a scheme by which all pathogenic leptospires were designated the single species *L. interrogans* (also known as the "*L. interrogans* complex") followed by the serovar name. All saprophytic serovars were placed in the species *L. biflexa* (the *L. biflexa* complex).

The application of DNA hybridization allowed the speciation of members of *Leptospira* based on the accepted definition of >70% hybridization under defined high stringency conditions, with less than 5% divergence. Following the original designation of several species of *Leptospira* (Yasuda et al., 1987), other workers have defined or isolated new species; currently 12 species of *Leptospira* are recognized (Brenner et al., 1999; Table 1), with at least four additional species that have not yet been named. Some confusion arises owing to the retention of the species names *L. interrogans* and *L. biflexa* for one of the genetically defined pathogenic and saprophytic species, respectively. This may be avoided by the use of

Table 1. Species classification of the genus *Leptospira*.

Species	Pathogenesis	G+C content (%)
L. alexanderi	Pathogenic	38.0
L. borgpetersenii		39.8
L. interrogans		34.9
L. kirschneri		ND[b]
L. noguchii		36.5
L. santarosai		40.5
L. weilii		40.5
Unnamed species 1[a]		39.8
Unnamed species 3[a]		43.4
Unnamed species 4[a]		38.9
Unnamed species 5[a]		37.9
L. fainei	Indeterminate	ND[b]
L. inadai		42.6
L. biflexa	Saprophytic	33.5
L. meyeri		35.2
L. wolbachii		37.2

[a]Brenner, 1999.
[b]Not determined.

the terms "sensu stricto" and "sensu lato" to refer to the species or the overall complex, respectively. See Faine et al. (1999) for a complete listing of the more than 230 serovars currently recognized.

A significant outcome of the genetic classification scheme was the finding that many antigenically related serovars, or even subtypes of the same serovar, may belong to different species. For example, the antigenically indistinguishable subtypes of serovar Harjdo (Hardjobovis and Hardjoprajitno) are placed in *L. borgpetersenii* and *L. interrogans*, respectively. Although the two subtypes are by definition identical serovars, they are often referred to as serovars Hardjobovis and Hardjoprajitno. Interestingly, genetic analysis of the LPS biosynthetic loci of the two subtypes has indicated a mosaic arrangement with evidence for lateral acquisition of blocks of functionally identical genes (De la Peña-Moctezuma et al., 1999; De la Peña-Moctezuma et al., 2001).

Cell Structure

By light microscopy, leptospires are best viewed with dark field illumination in which they appear as thin, helical, motile organisms, ranging from 10 to more than 20 μm in length. They are usually hooked at one or both ends (Fig. 1) and exhibit rapid, darting, to-and-fro motility in liquid media, as well as both flexing motion and constant rotational movement about their long axes. In viscous media and on cell surface mucus, leptospires exhibit a snake-like crawling motility. Straight, unhooked variants occur, which are less translationally motile and form dense colonies in solid media, in contrast to the spreading growth of the hooked forms. The straight forms are sometimes avirulent, but the molecular basis for this is unknown.

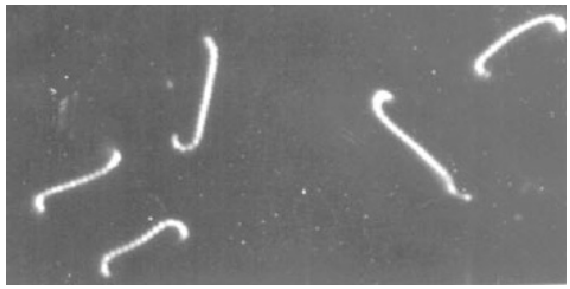

Fig. 1. Darkfield photomicrograph (magnification ca. × 1300) of *Leptospira* sp., showing helical morphology and hooked ends. From Faine et al. (1999).

Fig. 2. Shadowed electron micrograph of *Leptospira* sp. (magnification ca. × 30,000). The characteristic helical shape, periplasmic flagella (red arrow) and outer membrane (green arrow) can be seen. Micrograph by A Chang.

Leptospires notionally stain as Gram negative, but they are very thin and thus stained preparations are difficult to visualize microscopically. They may be seen more readily after staining by silver deposition methods or by immunostaining with fluorescent or immunohistochemical conjugates.

Electron microscopy is necessary to observe the detailed structural components of the leptospiral cell (Fig. 2), which resemble closely the architecture of a typical Gram-negative bacterial cell. There is an outer membrane, external to an inner membrane and peptidoglycan, wound in a helical shape. The direction of coiling is right-handed. Leptospires range in length from about 10–20 μm, with a coil amplitude of approximately 0.1–0.15 μm and a wavelength of about 0.5 μm.

Leptospiral Endoflagella

Each leptospire has two flagella, one arising at each end from an insertion through the inner membrane/peptidoglycan complex and lying in the periplasmic space between the peptidoglycan and the outer membrane. The two polar, peri-

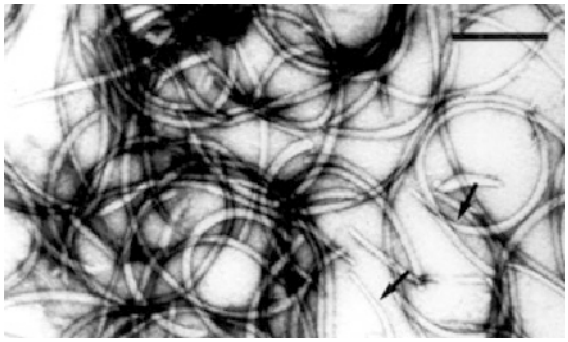

Fig. 3. Negatively stained electron micrograph of purified leptospiral flagella. Arrows indicate flagellar core without sheath. Bar = ca. 200 nm. Micrograph by B. Adler.

plasmic, single flagella are characteristic and distinguishing features of *Leptospira*. When a cell divides, it develops a new flagellum at the newly formed end, immediately after division. Flagella have been isolated from leptospires for morphological, chemical or immunochemical studies. The flagella, freed from the leptospiral body, were concentrated by differential centrifugation or by density gradient centrifugation (Chang and Faine, 1970; Kelson et al., 1988). In negatively stained electron micrographs, purified flagella appear to be approximately 15–18 nm wide, with an inner 12-nm core surrounded by a sheath (Fig. 3).

The flagella are similar in general structure to the flagella of other Gram-negative bacteria, comprising a hooked proximal end and disk rotor insertion structures, intercalated with the layers of the cell wall (Birch-Andersen et al., 1973; Holt, 1978). A hooked region penetrates the wall, outside of which the flagellum is seen to comprise a central core, made up of the flagella subunit protein, FlaB. Because of the periplasmic nature of leptospiral flagella, their role in motility and in the retention of the helical cell morphology has been controversial (Li et al., 2000). The recent inactivation by allelic exchange of the *flaB* gene in *L. biflexa* (Picardeau et al., 2001) demonstrated unequivocally the essential role of the flagella in motility, but not in helical cell morphology. The *flaB* mutants were shown to be nonmotile and devoid of flagella and hooked ends. However, they retained the characteristic helical shape of the wildtype parent.

The Leptospiral Surface

The outer membrane can be seen in shadowed, scanned or sectioned preparations and contains proteins, lipids, lipoproteins and LPS. Crude preparations of outer membrane (so-called "outer envelope") have been made by plasmolysing leptospires or otherwise disrupting them (Auran et al., 1972; Zeigler and VanEseltine, 1975). These preparations have been used as vaccines (Auran et al., 1972), the active component of which is almost certainly LPS. Freeze-fracture studies of *L. kirschneri* serovar Grippotyphosa revealed a low outer-membrane protein content compared with typical Gram-negative bacteria. Virulent strains had 443, and avirulent strains 990, molecules/μm^2, a highly statistically significant difference (Haake et al., 1991) and at least 10- to 100-fold less than the numbers seen in *Escherichia coli*.

The exposed leptospiral surface carries a net negative charge (Brown and Broom, 1929). In laboratory cultures, leptospires are always coated with adherent protein from the culture medium, the last traces of which cannot be removed, even with repeated centrifugal washing.

The leptospiral peptidoglycan layer is likewise similar to that of typical Gram-negative bacteria, lying external to, and associated with, the inner membrane. A role has been suggested for peptidoglycan in stimulating phagocytosis and production of the cytokine TNF-α by human monocytes (Cinco et al., 1993; Cinco et al., 1996). Penicillin-binding proteins have been shown to be associated with the inner membrane/peptidoglycan complex (Brenot et al., 2001a).

Leptospiral Lipids

Leptospires are characterized by a relatively high total lipid content and by unusual fatty acids (Johnson, 1976; Cacciapuoti et al., 1991); however, studies of lipids are complicated by the essential presence in the culture medium of long-chain fatty acids, required for growth, which also influence leptospiral lipid content and composition. Total lipids comprise about 14–26% of dry weight, of which 50–70% are phospholipids, mainly phosphatidyl ethanolamine (80–90%), although smaller amounts of phosphatidyl glycerol (5–10%), diphosphatidyl glycerol (1–5%), and lysophosphatidyl ethanolamine (0–3%) are also present.

Among the long chain fatty acids in lipid fractions, varying amounts of C 10:0, *cis*-12:9^9, 2OH 11:0, 3OH 12:0, 14:2, *cis*-14:1^9, *cis*-14:1^{11}; 14:0, a-15:0, 16:0, 16:2, *cis*-16:1^9, *cis*-16:1^{11}, 16:0, 3OH 15:0, *cis*-18:1^9, and *cis*-18:1^{11} have been found (Johnson et al., 1970; Cacciapuoti et al., 1991). Saprophytes contained more 14:0 than parasites contained, and in Canicola grown on 18:0 (octadecanoic acid), 87% of the C16 acid was the Δ 11 isomer. The *cis*-16:1^{11} isomer is unusual, characteristic and almost unique to *Leptospira* and related bacteria. Characteristic fatty acid methyl ester profiles obtained by gas-liquid chromatog-

raphy are useful in chemotaxonomy (Cacciapuoti et al., 1991).

The structure and composition of some leptospiral membrane components are represented schematically in Fig. 4.

Physiology and Metabolism

Cell Division

As leptospiral cells grow, they elongate to maximum length, at which time a constriction appears in the protoplasmic cylinder, extending to close off the fresh ends of each leptospire. Under conditions of nutritional stress, very long (50 µm or more) leptospires may develop that fail to separate so that long chains of elongated leptospires may be observed.

Growth Rates and Conditions

Saprophytic leptospires can be distinguished by their ability to grow at 11–13°C, whereas pathogens will not (Johnson and Harris, 1967), although the optimum temperature in laboratory media for both is 28–30°C. The optimum pH range for growth is 7.2–7.6; alkaline conditions are tolerated better than acidic conditions. Aerobic conditions are essential and growth rates are improved by shaking, sparging or increased surface areas. The typical doubling time for pathogenic leptospires adapted to laboratory cultivation under optimum conditions for growth is about 6–8 h, whereas doubling times of 3–4 h have been reported for *L. biflexa*. Cultures of pathogens therefore usually need to be incubated for 3–10 days, sometimes longer. Growth of primary isolates is much poorer, with doubling times in excess of 24 h.

Starting inocula from stationary phase cultures of as much as 1% (sometimes up to 10%) of the volume of fresh medium are used, so that maximum growth is reached in 4–7 days. Final densities of about 5×10^8–10^9 cells/ml can be achieved in Tween-albumin media for well-adapted laboratory strains of most leptospires.

Technical details of methods of observation, preparation of culture media, manipulation and subculture may be found in Faine et al. (1999). In liquid media, the first appearance of growth is a barely perceptible, but quite characteristic, birefringence, whereas fully grown cultures are obviously turbid to the naked eye at cell concentrations of approximately 5×10^7–10^8 leptospires/ml. However, some strains, especially fresh isolates, may grow to only 1/100 of this cell concentration. Growth must therefore be checked by removing a loopful of culture aseptically for dark-field microscopy.

Most strains of leptospires grow as subsurface colonies on solid media, but colonies may take days or weeks to appear; some serovars or strains may be impossible to grow as colonies on solid media. Plates should be incubated for 3–4 weeks, avoiding dehydration and contamination. Addition of pyruvate or rabbit serum (5–10%) enhances the growth of some strains.

Ordinary bacteriological membrane filters with average pore diameters of 0.2 µm or greater will allow leptospires to pass. Culture media or constituents made with tap water that has not been heat sterilized, or which have been held in vessels containing traces of tap water, have resulted in contamination of leptospiral or tissue cultures by *L. biflexa* and *L. inadai* strains able to pass through bacteriological filters.

Leptospires in cultures may remain viable for a very long time (at least 10 years in Korthof's medium has been recorded in the authors' laboratory) in glass tubes in the dark at room temperatures up to 35°C. Addition of hemoglobin to media in an amount sufficient to produce a pink color and use of 0.1–0.3% sloppy agar

media have been recommended to enhance survival.

Energy Metabolism

Leptospires are chemoorganotrophs that use O_2 as the final electron receptor. Cytochromes *a*, *c* and c_1, catalase and oxidase are present. Differences in the relative distribution of catalase and oxidase between serovars were reported, and no *L. biflexa* strains were catalase-positive (Corin et al., 1978). The only major carbon and energy sources are long-chain (more than C_{14}) fatty acids, from which energy is derived by β-oxidation (Henneberry and Cox, 1970). Sugars are not fermented and cannot be utilized as carbon sources, but carbohydrates may be synthesized by means of the tricarboxylic acid cycle and a nonoxidative pentose phosphate pathway or phosphogluconate and glyoxalate pathways, for which the key enzymes glucosephosphate isomerase, isocitrate lyase and malate synthase were detected in *L. biflexa* grown in synthetic medium (Yanagihara et al., 1984a; Yanagihara et al., 1984b).

Lipid Metabolism

Leptospires can shorten or desaturate essential long-chain fatty acids and incorporate them, but cannot synthesize them de novo (Stern et al., 1969; Johnson et al., 1970). Not surprisingly, the fatty acid composition of the leptospires reflects that of the growth medium.

Short-chain fatty acids can be utilized if longer chain fatty acids are also present (Johnson et al., 1969). Short-chain fatty acids, for example acetate, are metabolized, but their carbon is not selectively used in forming long-chain lipids (Stern et al., 1969). The essential fatty acids required for nutrition and energy metabolism are also toxic, so that they must be presented to the leptospires in the presence of a detoxifier that will adsorb them and release them slowly by equilibrium in low concentrations. Common detoxicants are serum albumin of bovine origin (in oleate-albumin media or in the albumin component of serum in media containing whole serum) and the usually concomitant use of sorbitol-complexed fatty acids (Tweens). In nature, leptospires probably obtain their essential long-chain fatty acids by attaching themselves to, and possibly by integrating their outer membrane with, surfaces on which the essential fatty acids are adsorbed (Kefford and Marshall, 1984).

All *L. biflexa* strains produce lipases (trioleinases), as do *L. inadai* and some *L. interrogans* strains (Kasarov and Addamiano, 1969). The other *interrogans* leptospires and *L. borgpetersenii*, *L. noguchii*, *L. santarosai* and *L. weilii* were reported not to produce lipases (Johnson and Harris, 1968; Yasuda et al., 1987), but more recent molecular analyses have contradicted these early reports (see Virulence Factors).

Amino Acid Metabolism

Alanine, arginine, aspartate, glutamate, glycine, leucine, phenylalanine and valine were incorporated into protein by serovar Pomona. Arginine, leucine, phenylalanine and valine were incorporated directly, almost exclusively in protein, but labeled carbon from glutamate and aspartate was also found in other cellular protein amino acids, whereas labeled carbon from alanine, aspartate, glutamate and glycine was in the lipid-soluble and trichloracetic acid precipitated fractions (Johnson and Rogers, 1964b). Different groups of leptospires may synthesize isoleucine by the classical threonine pathway, by an unusual pyruvate pathway, or by both, with the pyruvate pathway dominant (Charon et al., 1974; Westfall et al., 1983). Genes of the methionine biosynthetic pathway in *L. meyeri* serovar Semaranga have been cloned by complementation of *E. coli* mutants in the *metA* and *metB* genes (Bourhy et al., 1997; Belfaiza et al., 1998). However, despite functional similarity of the *E. coli* and *L. meyeri* enzymes, it is clear that the leptospiral pathway involves direct sulfhydrylation of *O*-acetyl homoserine and thus resembles the pathway in yeast rather than the more common bacterial pathway found in *E. coli*.

Purines and Pyrimidines

There are clear differences in the metabolism of purines and pyrimidines by different groups of leptospires. All species of *L. biflexa* can synthesize their purine and pyrimidine requirements and grow in the presence of 2,6-diaminopurine (10 mg/ml) or 8-azaguanine (225 mg/ml) added to the growth medium. In contrast, among the pathogenic species, *L. borgpetersenii*, *L. santarosai* and some of the *L. interrogans* grow in the presence of 2,6-diaminopurine. Except for *L. inadai*, whose pathogenic status is uncertain, 8-azaguanine inhibits all the pathogenic species.

Carbon Sources

Long-chain fatty acids and CO_2 are essential. Chain lengths of 12–18 carbon atoms are satisfactory, but only *L. biflexa* will grow on saturated fatty acids alone; indeed, they will also grow on long- or short-chain, saturated or unsaturated fatty acids. Unsaturated fatty acids alone will support the growth of pathogenic species, which require unsaturated fatty acids to be present in order to utilize saturated fatty acids. They also require longer chain length fatty acids than *L.*

biflexa does for the utilization of C15-16 fatty acids (Johnson et al., 1969).

The fatty acids may be provided in any nontoxic form or in the presence of a detoxicant. The most elementary detoxicants are surfaces on which the fatty acids are adsorbed, such as glass, charcoal, silica gel, or starch. Serum contains albumin, which is capable of absorbing large amounts of fatty acids, among other compounds, and releasing them into the medium at low, nontoxic concentrations. Alternatively, in place of serum, the serum albumin can be extracted and used in defined serum-free media. Additionally, the fatty acids can be presented in a nontoxic form by combination in a complex such as a polyoxyethylene sorbitan ester (Tween), designated by a number according to its chemical composition. Tween 80 is polyoxyethylene sorbitan monooleate, Tween 60 contains monostearate, and Tween 40 contains palmitate. Tweens are industrial chemicals that also contain unesterified fatty acids, polyethylene glycols and other byproducts, which may inhibit growth or saturate the capacity of the absorbent. Impurities in Tweens may be removed before their use in culture media by absorption with activated charcoal, followed by filtration to remove charcoal particles (Bey and Johnson, 1978b), polyvinylpyrolidone treatment (Schönberg, 1983), partition in lipid solvents or zeolite-silicic acid column chromatography (Kojima et al., 1984).

Glycerol (200 mg/liter) enhances the growth of some leptospires. Pyruvate assists the growth of some strains from small inocula, notably Hardjo and Ballum. Pyruvate and CO_2 enhance colonial growth in solid media (Johnson et al., 1973). No other sources of carbon are recognized.

Other Growth Requirements

Ammonium ions, whether provided as ammonium salts or by the deamination of amino acids, are the only recognized nitrogen source. Cyanocobalamin (vitamin B_{12}), thiamin (vitamin B_1) and for some strains biotin are required. Phosphate is essential, as are calcium, magnesium and iron, optimally as Fe^{+++} or heme compounds such as hemoglobin or hematin. In practice, other compounds containing copper, manganese, and sulfate are added, particularly for isolation and maintenance of pathogens (Faine et al., 1999).

Leptospiral Antigens

Lipopolysaccharide

Leptospiral LPS contributes to the pathology associated with disease and comprises the major surface component of leptospires (Fig. 4). Studies with monoclonal antibodies have shown that LPS is the target for agglutinating and opsonizing antibodies (Farrelly et al., 1987). Thus, LPS plays a key role in immunity to infection. Indeed, anti-LPS monoclonal antibodies provide passive protection against infection, and purified LPS can stimulate active immunity (Jost et al., 1986; Midwinter et al., 1990). As an agglutinating antigen, LPS is also important for serological classification of leptospires.

Early reports of antigenic carbohydrate preparations extracted from leptospires used phenol, alkali, acetone or other solvents. Terms such as TM (for type-specific main) antigen, ESS (for erythrocyte-sensitizing substance), LLS (for LPS-like substance), or PAg (for protective antigen) have been used for these extracts, but all of them clearly contained LPS or LPS components as major constituents. The structure of LPS remains unknown. However, chemical analysis of leptospiral LPS showed the presence of common hexoses, amino hexoses and pentoses, and some sugars found more rarely as LPS components, such as xylose and arabinose (Vinh et al., 1986; Vinh et al., 1989). Methylated and *O*-acetylated sugars have also been reported (Yanagihara et al., 1983). The detection of 2-keto-3-deoxyoctonate (KDO) in the LPS of *L. interrogans* serovar Copenhageni and *L. borgpetersenii* serovar Hardjo is consistent with a composition similar to that of typical Gram-negative LPS.

Despite the structural, biochemical and immunological similarity of leptospiral LPS to Gram-negative bacterial LPS, it is at least 10-fold less toxic for animals or cells. Nevertheless, leptospiral LPS can activate macrophages and act as a B-cell mitogen (Isogai et al., 1990a; Isogai et al., 1990b). It has been proposed that the reduced toxic activity is a result of the absence of β-hydroxy-myristic acid. The activation of macrophages occurs via the CD_{14} and toll-like receptors TLR2, rather than via TLR4 as seen for the LPS of Gram-negative bacteria (Werts et al., 2001). Notably, TLR2 is commonly used as a receptor for Gram-positive bacteria and for other non-LPS components.

Genetic analysis has identified the *rfb* loci involved in the biosynthesis of the LPS O-antigen in several leptospiral serovars. Rhamnose is a component sugar of all serovars analyzed to date. The four genes encoding enzymes required for the biosynthesis of dTDP-rhamnose from glucose were first cloned from serovar Copenhageni and shown to be functional by complementation of a defined *S. flexneri* mutant (Mitchison et al., 1997). Genes encoding rhamnosyl transferases were found downstream of the rhamnose biosynthetic cluster. Subsequent work delineated the *rfb* locus in *L. borgpetersenii* serovar Hardjo

(Kalambaheti et al., 1999). This locus contains at least 31 open reading frames (ORFs) that encode enzymes involved in the biosynthesis of activated sugars, glycosyl transferases, and sugar processing and transport proteins. Three sugar biosynthetic clusters are involved in the synthesis of rhamnose (*orfs24–27*), galactose, mannose and fucosamine (*orfs6–11*) and a dideoxy-aminohexose (*orfs18–20*). By complementation of defined mutations in different Gram-negative species, orf13 was shown to encode an enzyme with galactosyl transferase activity, whereas *orf8* and *orf10* were shown to encode the galactose epimerase, GalE, and an *N*-acetyl glucosamine epimerase, respectively (Bulach et al., 2000). A putative flippase and O-antigen polymerase were also identified, as well as other glycosyl transferases of unknown specificity. Leptospiral LPS thus appears to be assembled via the classical Wzy (Rfc)-dependent pathway. Interestingly, the *L. borgpetersenii* serovar Hardjo locus is bounded by insertion (IS*1533*) elements, raising the possibility of horizontal acquisition. In addition, an IS*5*-like element is found between *orf14* and *orf15*. The *rfb* loci of serologically indistinguishable representatives of serovar Hardjo from *L. interrogans* and *L. borgpetersenii* are similar, but the former lacks IS elements (De la Peña-Moctezuma et al., 1999). However, detailed comparison of the sequences revealed that the *L. interrogans* locus consists of four segments. Two of these (*orf1–14* and *orf21–22*) resemble the *L. borgpetersenii* serovar Hardjo locus, whereas the *orf15–20* and *orf23–31* clusters show greater sequence identity to loci of other *L. interrogans* serovars (De la Peña-Moctezuma et al., 1999). A comparison of the *rfb* loci of 14 other *L. interrogans* serovars revealed conservation in the region from *orf11* to *orf31*. Genes upstream of *orf11* vary among serovars or show more genetic drift (De la Peña-Moctezuma et al., 2001). This region thus appears to encode biosynthetic enzymes and glycosyl transferases responsible for serovar specificity and some genes of unknown function.

Protein and Lipoprotein Antigens

A large number of protein antigens have been described in terms of recognition by convalescent sera or following sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) analysis of whole cell lysates, but in most cases the proteins have not been identified or allocated to a particular cell component. Among the proteins described are a 62-kDa nonagglutinating subsurface genus-specific antigenic protein in serovar Kremastos (Sakamoto et al., 1985) and a variety of others in serovar Copenhageni (Niikura et al., 1987). A 35-kDa *L. interrogans* species-specific nonagglutinating, nonopsonic protein antigen (Jost et al., 1988) was related to outer envelope (OE) material in electron-microscopic immunogold staining, but probably originated from periplasmic material or the inner surface of the OE.

The use of immunoprecipitation studies aimed at identifying surface exposed proteins led to the identification of OmpL1, a transmembrane protein with porin activity that exists in a typical trimeric form in the leptospiral outer membrane (Haake et al., 1993; Shang et al., 1995). Subsequent studies identified two outer-membrane lipoproteins, LipL36 and LipL41, produced in *L. kirschneri*. LipL36, containing palmitate, is exported with LipL41 and LPS to the outer membrane. Production of LipL36 occurs more in the early log phase of growth in laboratory cultures than in the later stages and does not appear to occur when bacteria grow in vivo, that is, during infection, at least in the hamster kidney (Haake et al., 1998); however, these results do not preclude a role for LipL36 at other stages of the infectious process. In contrast, the major OMP, LipL32, as well as OmpL1, LipL41 and LPS, is expressed during growth in the hamster kidney (Haake et al., 2000b; Zuerner et al., 2000). Although LipL32 is known to be located in the outer membrane, its precise membrane topology is not yet known (Fig. 4). LipL41 and OmpL1 are highly conserved outer membrane proteins among pathogenic leptospires (Shang et al., 1996) and were the first, and to date only, protein antigens capable of eliciting a protective immune response (Haake et al., 1999). The two proteins in combination, but neither of them alone, could protect hamsters against lethal infection. Interestingly, the usual L-X-Y-C consensus cleavage sequence for transport and processing of Gram-negative lipoproteins varies substantially amongst spirochete lipoproteins, and the spirochete lipobox sequence of L(A/S)-L(V/F/I)-I(V/G)-A(S/G)-C has been proposed (Haake, 2000a; Zuerner et al., 2000).

Flagellar Antigens

In polyacrylamide gels, a doublet of 33–34 kDa, presumed to represent flagellar core proteins, reacts similarly in immunoblots with anti-leptospiral or anti-flagellar antisera (Kelson et al., 1988). Later work confirmed these observations and recognized 7 different proteins; a 34-kDa protein was associated with the core (measured as 11.3 nm) and a 36-kDa protein associated with a 21.5-nm diameter sheath filament (Trueba et al., 1992). The *flaB* gene has been cloned from *L. borgpetersenii* serovar Hardjo and expressed in *E. coli*. The 32-kDa

FlaB protein showed significant sequence similarity with FlaB homologues from *Treponema pallidum*, as well as from other Gram-negative and -positive bacteria (Mitchison et al., 1991). Sequences of *flaB* in Hardjobovis, Hardjoprajitno and Grippotyphosa were highly conserved and recombinant FlaB crossreacted antigenically between Grippotyphosa and Hardjobovis (Woodward and Redstone, 1994). Notably, the *flaB* gene was the first leptospiral gene to be inactivated by recombination-mediated allelic exchange (Picardeau et al., 2001).

Heat Shock Proteins

The operons encoding the major heat shock proteins, GroEL/GroES and DnaK, of *Leptospira* have been identified, cloned and sequenced (Ballard et al., 1993; Ballard et al., 1998). GroEL is a major immunogen recognized during infection in humans and animals, but was shown to play no role in immunity to infection. Interestingly, the regulation of the heat shock response in *Leptospira* shows features of both Gram-positive and Gram-negative regulatory mechanisms. In particular, the genetic organization and regulation of the *dnaK* locus more closely resemble those of Gram-positive bacteria.

Genetics

The Leptospiral Genome

The chromosome of *Leptospira* is characterized by a G+C content of 35–41 mol%, depending on species, with a genome size estimated to be ca. 5000 kb, measured in pulsed-field gel electrophoresis (PFGE) after digestion with *Not*I, *Nhe*I or *Apa*I (Baril and Girons, 1990). Using mainly the restriction enzymes *Not*I and *Sfi*I, a physical and genetic map of *L. interrogans* serovar Pomona was constructed (Zuerner, 1991), indicating a genome size of ca. 4750 kb, similar to that of Icterohaemorrhagiae. The genome consists of two circular replicons, of approximately 4750 kb and 350 kb (Boursaux-Eude et al., 1998). The large and the small replicons were regarded as chromosomes because the essential *asd* gene (for β-semialdehyde dehydrogenase) was located on the smaller unit. The small replicon is present in pathogenic serovars examined and shows very little variation in size. A comparison of genetic maps for strains of *L. interrogans* serovars Icterohaemorrhagiae and Pomona indicated considerable heterogeneity and variability within the species *L. interrogans*, which involves rearrangements of large segments of chromosome (Zuerner et al., 1993; Boursaux-Eude et al., 1998).

Ribosomal RNA Genes

Both *L. biflexa* (*sensu lato*) and *L. interrogans* (*sensu lato*) strains were shown to contain two ribosomal 23S rRNA genes, which not surprisingly cross-hybridized extensively with one another (Fukunaga and Mifuchi, 1989a). Two genes for 23S rRNA and for 16S rRNA, but only one for 5S rRNA, were found in *L. interrogans* serovar Canicola, each located far from other RNA genes. There were two 5S rRNA genes in *L. biflexa* (Fukunaga and Mifuchi, 1989b), one of which was sequenced (Fukunaga et al., 1992). Pathogenic strains of leptospires contained only one highly conserved 5S rRNA gene (Fukunaga et al., 1992). The 23S rRNA was further processed to 14S and 17S rRNA, in a pattern seldom found in prokaryotes, in *L. borgpetersenii* serovars Hardjo (type Hardjoprajitno) and Balcanica (Hsu et al., 1990). The primary, and especially the secondary, structures of the 5S rRNA gene in pathogenic strains of leptospires were found to be well conserved, similar to one another, and essentially similar to eubacterial 5S rRNA. It is uniquely organized, existing as a single copy within the genome, encoding a 117-nucleotide-long RNA molecule. The gene is flanked at both the 5′ and 3′ ends by A+T rich sequences, with a promoter sequence in the 5′ flanking region (Fukunaga et al., 1990; Fukunaga et al., 1991). The two genes for 5S rRNA in *L. biflexa* strains were located several kb apart on the chromosome, with divergent flanking sequences (Fukunaga et al., 1992). Thus, in contrast to the situation in many other bacteria where the 16S (*rrs*), 23S (*rrl*) and 5S (*rrf*) rRNA genes are clustered and co-transcribed, those in *Leptospira* are widely scattered on the large chromosome (Baril et al., 1992; Saint Girons et al., 1992).

IS Elements

Although no compound transposons have been found in the genus *Leptospira*, Zuerner (1994) identified and characterized IS1*533* from *L. borgpetersenii*. Multiple copies of IS1*533* were present on the genome. Two proteins encoded by IS1*533*, expressed and functional in *E. coli*, were related to a family of IS-encoded transposases and recombinases. Subsequently, a PCR assay based on IS1*533* sequences was adapted for identification of *L. interrogans* (*sensu lato*) strains. A similar IS element was reported in serovar Tarassovi (GenBank X77623). An IS*3*-like element, designated "IS1*500*," was present only in pathogenic leptospires (Boursaux-Eude et al., 1995). The IS1*500* insertions were present only on the large chromosome and appeared to coincide with genomic regions that had undergone rearrangement. This element was also used as

the basis for fingerprinting and epidemiological analysis of leptospiral isolates (Zuerner and Bolin, 1997).

Interestingly, the serovar Hardjo (type Hardjobovis, but not Hardjoprajitno) LPS biosynthetic locus is bounded by two IS*1533* elements (De la Peña-Moctezuma et al., 1999; Kalambaheti et al., 1999). A second IS element was also found in an intergenic region of the Hardjobovis locus; it appeared to be intact and is related to the IS*5* family, but no functional studies were performed (Kalambaheti et al., 1999). Similarly, an apparently intact IS*1500* element was found to disrupt the *orf35* gene in Ictero No. I, but not RGA, strains of serovar Icterohaemorrhagiae; this gene encodes a putative membrane protein within the LPS biosynthetic locus (De la Peña-Moctezuma et al., 2001). It has been speculated that the presence of these IS elements may regulate gene expression, leading to differences in LPS structure, but there is no evidence yet for such a role.

Heat Shock Genes

The early branching of spirochetes (before Gram-positive and -negative bacteria; Woese, 1987) is also reflected in the regulation of their heat shock response, which shows characteristics of both Gram-positive and -negative regulatory mechanisms.

The *groE* and *dnaK* operons of *Leptospira* have been identified, cloned and sequenced (Stamm et al., 1991; Ballard et al., 1993; Ballard et al., 1998). The *groE* operon encoding the GroEL and GroES proteins exhibits features found in heat shock operons regulated by either $Sigma^{32}$ or CIRCE (controlling inverted repeat of chaperone expression; Zeilstra-Ryalls et al., 1991; Zuber and Schumann, 1994). These are generally found in Gram-negative and Gram-positive bacteria, respectively. The CIRCE element was also found upstream of the dnaK locus, which contained the genes *hrcA*, *grpE*, *dnaK* and *dnaJ* (Ballard et al., 1998). The genetic organization and regulation of this locus are thus more like those in Gram-positive than in Gram-negative bacteria (Zeilstra-Ryalls et al., 1991; Zuber and Schumann, 1994).

Genetic Exchange Systems

Genetic analysis of *Leptospira* has been impeded by the lack of methods for the introduction of DNA into leptospiral cells. Standard methods such as transformation and gene inactivation have therefore not been available, and in this regard, work on *Leptospira* has lagged somewhat compared with advances in genetic exchange systems for other spirochetes. Early reports from the 1960s of bacteriophage-like particles in leptospires were not confirmed, but Saint Girons and her colleagues (Saint Girons et al., 1990) isolated and characterized three bacteriophages, whose replication was limited to the saprophyte *L. biflexa*. One of these phages, LE1, was shown to replicate as a plasmid in *L. biflexa* and was used as the basis for the first *L. biflexa-E. coli* plasmid shuttle vector, pGKLep4 (Saint Girons et al., 2000). An interesting feature is the necessity for a selectable marker of Gram-positive origin, the kanamycin-resistance gene from *Enterococcus faecalis*. No shuttle vectors or other plasmids have yet been reported for the pathogenic leptospires. A restriction-modification system has been demonstrated, at least in *L. biflexa* (Brenot et al., 2001b).

There is only one published report of successful gene inactivation by recombination-mediated allelic replacement in *Leptospira*. The kanamycin-resistance gene from pGKLep4 was used to inactivate the *flaB* gene encoding the flagellar subunit protein in *L. biflexa* (Picardeau et al., 2001). Mutants were nonmotile and lacked flagella and hooked ends, but retained their helical shape. The commonly used *sacB* gene was found to be an unsuitable counterselectable marker in *L. biflexa*, but the *rpsL* gene, which encodes the S12 ribosomal protein, was used to increase dramatically the number of double crossover transformants obtained. There are no published reports of allelic replacement in pathogenic leptospires.

Identification Methods

Serological Methods

The conventional method for identifying the serovar of a leptospiral isolate (the cross-agglutinin absorption test) by definition relied on a comparison of the agglutinating antigens of the unknown isolate with those of known reference strains. Two strains were considered to belong to different serovars if more than 10% residual homologous agglutinating titer remained after exhaustive absorption of hyperimmune rabbit sera with the heterologous strain (Dikken and Kmety, 1978). Despite both the inherent variability and rather arbitrary nature of this test, the concept of serovar has stood the test of time, probably because in most cases discrimination at this level was meaningful in terms of epidemiology, host association and severity of disease. Nevertheless, this method of identification is expensive and time consuming and is now performed infrequently, and then only by specialized reference laboratories; it is not recom-

mended. However, most of the more modern molecular identification and typing tests are judged by their ability to discriminate strains at about the level of the serovar.

The use of panels of agglutinating monoclonal antibodies has allowed strains to be identified by comparison of their reactivity pattern with those of reference strains, thereby generating a fingerprint for each serovar (Kolk et al., 1984; Terpstra et al., 1985; Terpstra et al., 1987; Korver et al., 1988). Any laboratory that can perform the microscopic agglutination test can therefore serotype isolates with relative ease.

Molecular Methods

The reference method for delineation of bacterial species remains the degree of homology at DNA level, as determined by DNA hybridization (Wayne et al., 1987). However, the procedure is cumbersome and unsuitable as a tool for identification. Restriction fragment length polymorphism (RFLP) based on polymerase chain reaction (PCR) amplification of either 16S rRNA or 23S rRNA genes has been shown to group strains in general agreement with their correct species designation (Ralph et al., 1993; Perolat et al., 1994). Probes derived from random primed PCR fingerprints were also able to discriminate at species level (Letocart et al., 1997).

At subspecies level, the first widely used method was restriction endonuclease analysis (REA) of whole genomic DNA (Marshall et al., 1981). Despite the difficulty (due to the large number of fragments generated) in reading complex restriction profiles, the technique has provided useful epidemiological information. For example, REA first identified the Hardjobovis and Hardjoprajitno subtypes now known to belong to different species, as well as allowed discrimination of three subtypes of Hardjobovis (Thiermann et al., 1986). Similar subtypes have been identified within other serovars. All leptospiral genomes appear to have multiple copies of a range of insertion sequences; some of these have been used as targets for identification and molecular typing schemes (Zuerner et al., 1995; Zuerner and Bolin, 1997).

Interestingly, and perhaps unexpectedly, the analysis by PFGE of restriction fragments generated by digestion with rare cutting enzymes such as *Not*I or *Sgr*AI yielded unique patterns for most serovars (Herrmann et al., 1992; Herrmann and Saint-Girons, 1993; Herrmann, 1994). In reality, PFGE has become accepted as the most appropriate and accurate molecular typing method. A disadvantage is the need for specialized equipment and expertise. For this reason, a range of methods based on random amplification of chromosomal DNA has been reported (Faine et al., 1999; Levett, 2001); in general, they show good correlation with PFGE and can be performed readily by any laboratory with PCR capacity.

Isolation, Cultivation and Preservation

Growth in Liquid Media

Leptospires are grown routinely in liquid media, sometimes supplemented with 0.1% agar for primary isolation or for maintaining stock cultures. Recipes and details of culture media can be found in Faine et al. (1999). Incubation periods may be as long as 3–4 weeks for some pathogens. Obviously, much more care about sterility and avoidance of airborne contamination is required than when working with conventional bacteria grown overnight on solid medium in culture plates. Media are sterilized by filtration because of the presence of heat-labile essential constituents, notably albumin. All containers, including holding vessels used prior to filtration, should be dry and all solutions should be heat sterilized or made with water that is heat sterilized because leptospires exist in tap water and can pass through the 0.2 μm filters used for filter-sterilizing media. An alternative precaution is to heat media at 56°C for 30 min after final dispensing into working containers.

Cultures are usually inoculated using relatively large inocula (1–10% of the volume of the new medium) using a pipette; the use of bacteriological loops for subculturing leptospires is not recommended. Shaking in air enhances the rate and amount of growth. Cotton plugs should be avoided in vessels used in the preparation of media or for cultivation because cotton contains toxic lipids, which melt or vaporize during autoclaving or incubation and contaminate the media. Screw-cap containers are best for cultures that require more than a day or two of incubation to avoid dehydration.

Media Containing Serum

Numerous media containing dilute animal serum, usually rabbit serum, have been described, all buffered to about pH 7.2–7.6 with phosphate and containing peptone and other common medium constituents (Faine et al., 1999). Best results are obtained when the serum is slightly hemolyzed; hemolysis releases essential iron and cyanocobalamin from the erythrocytes. Probably the most commonly used medium containing serum is Korthof's medium (Korthof, 1932), in which a dilute phosphate-

buffered saline containing a small amount of peptone is supplemented with about 8–10% pooled, heated, slightly hemolyzed rabbit serum and finally sterilized by filtration. Most serum media precipitate phosphates during preparation and sometimes afterwards, chelating metals in the process. Precipitates are a disadvantage when dark-field microscopy has to be used to check growth or end-points in a microscopic agglutination test for leptospiral antibodies.

Serum-free Media

Studies of the minimal nutritional requirements for growth of pathogenic leptospires led to the development of a serum-free, oleic-acid albumin medium and derivatives containing Tweens as the sources of fatty acids, with serum albumin as a detoxifier, such as the widely used, commercially available Ellinghausen-McCullough-Johnson-Harris medium (EMJH). Bovine serum albumin (BSA) for use in culture media is expensive. Each batch, even from the same supplier, must be checked for its ability to support the growth of a range of serovars and strains. BSA quality can be improved by extracting it with fat solvents (methanol, chloroform, and ether) before drying and weighing.

Protein-free Media

Protein-free media (Shenberg, 1967; Bey and Johnson, 1978b; Christopher et al., 1982) are those in which conditions are balanced and ingredients are selected or purified to avoid toxicity. Their main application is in use for vaccines (Marshall et al., 1979) where BSA is unacceptable because of the risks of hypersensitivity or autoimmune reactions in vaccinated animals or people. Success in their use depends on scrupulous care and attention to detail in water purification. Use fresh double-glass distilled water in preference to deionized water and take exceptional care in cleaning glassware to avoid all traces of lipids. Tweens must be cleaned freshly before use because they autoxidize to form traces of toxic fatty acids and peroxides on storage; likewise, the media have a limited shelf life. Strains usually need to be adapted to grow in protein-free media and subcultured every few days. Otherwise they die quite suddenly, probably as a result of endogenous lipases produced by the developing leptospires acting on the Tweens in the medium, releasing toxic, lytic lipids that cannot be absorbed in the absence of a detoxicant. Low-protein media (Bey and Johnson, 1978b; Christopher et al., 1982) containing 0.1% or 0.01% BSA are sometimes used as a compromise to cultivate strains that cannot be adapted to protein-free media or for maintenance of strains in protein-free medium.

Growth on Solid Media

Any liquid medium can be solidified by the addition of agar. The liquid medium may be made up double-strength, sterilized by filtration, and warmed to 45°C. Double the required concentration of agar in water is autoclaved, cooled to 45°C, and combined in equal volumes with the medium, mixed thoroughly and dispensed. Media solidified with 0.8–1% agar will support the growth of subsurface colonies, even after surface inoculation. Surface colonies can be seen on media with concentrations of 1.2–2% agar. Colonies can be visualized before they can be seen by eye if the redox dye and indicator (2-6-dichlorophenol-indophenol) is added (1 : 100,000) to the medium. A zone of colorless or pink decoloration of the blue dye precedes the appearance of leptospiral growth by 1–2 days at the position where the colony will appear.

Selective and Differential Media

Difficulties in the use of solid media and the risk of contamination on prolonged incubation or when attempting to isolate leptospires from natural sources, such as soil, mud, animal tissues or carcasses or body fluids, have led to the development of several selective media that contain various inhibitors of other bacteria. These include 5-fluorouracil (50–1000 μg/ml; Johnson and Rogers, 1964a); a combination of nalidixic acid (50 μg/ml), vancomycin (10 μg/ml), and polymyxin-B-sulfate (5 units/ml; Schöberg et al., 1980); or a combination of actidione (100 μg/ml), bacitracin (40 μg/ml), 5-fluorouracil (250 μg/ml), neomycin sulfate (2 μg/ml), polymyxin B (0.2 μg/ml) and rifampicin (10 μg/ml; Adler et al., 1986). Prompt subculturing, after not more than 2 days, into media free of inhibitors is recommended. Saprophytic leptospires can be cultured selectively in medium containing 8-azaguanine (225 μg/ml); the same medium will differentiate saprophytes, which will grow in it, from pathogens, which will not.

Purification of Contaminated Cultures

Leptospires pass through filters of average pore diameter 0.2 μm, which hold back most other bacteria. The contaminated culture is filtered, and the filtrate inoculated into fresh medium. An older method of decontamination is to inoculate a mouse intraperitoneally with approximately 0.5 ml of the culture and then bleed the mouse by heart puncture under anesthesia after about 15 min. Leptospires invade the bloodstream

faster than other bacteria, so they can be selectively recovered from the blood. Hamsters or guinea pigs are also suitable.

Preservation

A variety of methods have been reported over the years for long-term preservation of *Leptospira* strains. The authors' experience is that storage in liquid nitrogen is the most suitable method for preserving viability, antigenicity and virulence for many years. A simple protocol involves the addition of 5–10% dimethyl sulfoxide (DMSO) to late log phase cultures in EMJH medium, followed by slow cooling to –70°C; this is readily achieved by wrapping vials in a thick layer of cotton wool in a –70°C freezer. The vials are then transferred to liquid nitrogen the next day.

Clinical and Epidemiological Aspects of Infection and Disease

It is beyond the scope of this brief section to provide the details of the varied clinical aspects of infection with *Leptospira* in humans and animals. The reader is referred to the following books, chapters or reviews for detailed information on specific findings and clinical presentations in leptospirosis: Bolin (1996), Faine (1998), Faine et al. (1999), and Levett (2001).

General Features

Leptospirosis is in most instances an acute, febrile illness occurring in humans or animals all over the world. In humans, the disease is always contracted from an animal source; human-to-human transmission is for practical purposes nonexistent and the disease is regarded globally as a zoonosis. Pathogenic leptospires live in the proximal renal tubules of the kidneys of carriers, although other tissues and organs may also serve as a source of infection. From the kidneys, leptospires are excreted in urine and may then contaminate soil, surface water, streams and rivers. Infections of animals or humans occur from direct contact with urine or indirectly from contaminated water. The carriers may be wild or domestic animals, especially rodents and small marsupials, cattle, pigs and dogs. Almost every mammal (including aquatic mammals) and marsupial has been shown to be a carrier of leptospires. Humans almost never become chronic carriers, but suffer acute infections, sometimes with longer-term sequelae.

Leptospirosis in humans varies in severity according to the infecting serovar of *Leptospira* and the age, health and nutrition of the patient. It ranges from a mild influenza-like illness to a severe infection with renal and hepatic failure, pulmonary distress, myocarditis, hemorrhages and death (Weil's disease). Congenital infection occurs in humans and in animals, where it causes loss of productivity in livestock through abortion, still-birth or loss of milk production or failure to thrive. There is a worldwide strong occupational association with animal production (dairy farming, pig production, and abattoirs) and a universal risk from rodent-carrier-mediated infection, especially prevalent in tropical countries, where many serovars may be present in a locality. It is important to recognize and identify the infecting leptospires for clinical and epidemiological reasons. There are characteristic associations of particular serovars with certain species of animals as carriers, but the association is not absolute and the molecular basis for any such host "specificity" is unknown. The main associations recognized throughout the world are serovars Hardjo with cattle, Pomona with pigs, cattle, and rodents, and Icterohaemorrhagiae, Copenhageni, Bataviae, *Autumnalis*, *Australis*, and *Zanoni* with rats and a wide range of small rodents, which may become lifelong carriers.

The renal carrier state is thus a key component that is central to the persistence and epidemiology of leptospirosis. Leptospires colonize the surfaces of renal proximal tubular epithelial cells. They may persist there for periods of weeks to years, often for the lifetime of the animal in some leptospiral serovar-host associations, especially rodents. The molecular basis for this bacterial-cell association is unknown and specific adhesion factors have not been described. The ability of leptospires to bind fibronectin via specific fibronectin-binding proteins may be of significance in their ability to colonize epithelial surfaces (Merien et al., 2000). Excretion in urine may be intermittent or continuous and the urinary concentration of bacteria may be as high as 10^8/ml. Antileptospiral immunoglobulin is present in the tubular and bladder urine but does not kill the leptospires, probably because of the absence of complement. Leptospires do not survive well in acid urine, but remain viable in alkaline urine. Consequently herbivores and animals whose diet produces an alkaline urine are relatively more important as shedders than are producers of acid urine.

Leptospirosis in Humans

Leptospirosis commences suddenly with headache, fever (typically to 102°F, 39°C), malaise, myalgia, conjunctival suffusion (red eyes) and sometimes a transient rash on the palate and

skin. Thereafter the illness may be mild and self-limiting or severe and possibly fatal. The mild type may be serious and incapacitating, but seldom leads to kidney or liver failure, hemorrhages or death.

Mild Leptospirosis

This description is applicable worldwide to illness characteristically seen in infection with serovars Hardjo, Grippotyphosa or Pomona, but also with others. On the other hand, infection with some of these usually milder serovars can occasionally lead to severe leptospirosis, which may be life threatening. Human infection with Pomona may lead to renal failure, while severe cholecystitis has been reported for Hardjo infections. The initial symptoms may be followed by a transient remission, in 3–5 days, which may then proceed to an exacerbation and include aseptic meningitis, renal failure and abdominal or chest pains, reflecting the generalized pathology. Clinical differential diagnosis is required between leptospirosis and severe influenza, viral meningitis, acute abdominal conditions or glomerulonephritis. Recovery is usually complete but weakness, tiredness, depression, and even psychosis may prevent a return to normal living for weeks or months. Reports of chronic or recurrent leptospirosis have usually not been adequately proven or investigated, but there is sufficient anecdotal evidence for at least some of these claims to be taken seriously. A clear association was described between uveitis following leptospiral infection and the presence of leptospires (detected by PCR) in the anterior chamber of the eye (Chu et al., 1998).

Severe Leptospirosis

Characteristically this is seen in severe infections with serovars Icterohaemorrhagiae, Copenhageni, Lai and others. The illness worsens, usually rapidly after onset, so that renal failure appears within 7–10 days, sometimes accompanied or followed by skin and mucosal hemorrhages, jaundice, hemoptysis, myocarditis, or liver failure, leading to death if untreated. Case fatality rates approaching 20% have been reported (Everard et al., 1995). A more recently recognized respiratory manifestation involves severe pulmonary edema and hemorrhages, which have been the main cause of death in some epidemics (Shim et al., 1980; Zaki and Shieh, 1996). As with mild leptospirosis, chronic, long-term sequelae have been reported, but frequently not investigated fully. The host and microbial factors, which may lead to long-term persistence, are unknown.

Leptospirosis of either type in pregnancy carries the risks of intrauterine infection and fetal death.

Acute Leptospirosis in Animals

Acute leptospirosis is similar in all animals. In its most flagrant form, it is manifested by listlessness, loss of appetite, irritability, fever, ruffled fur, red eyes, and sometimes diarrhea, occurring 3–7 days after infection. There may be signs of hemorrhages and jaundice. Movement is accompanied by a characteristic arching of the back. Recovery may occur from here, or death may supervene. Recovery may be accompanied, or followed, by weight loss, runting in young animals, chronic renal failure and its signs, and delayed death. In milk-producing cattle, there may be disturbance of milk flow and quality. Congenital infection of fetuses in utero follows a similar course, leading to abortion if the fetus dies. The abortion products may be hemorrhagic or jaundiced or both; they may be heavily loaded with leptospires and a danger to animal handlers. Stillborn fetuses may likewise be hemorrhagic, jaundiced and infectious. Less severe infections, ranging down to the clinically unapparent, occur frequently.

Chronic Leptospirosis in Animals

The chronic persistence of leptospirosis in animals is the central feature that maintains the cycle leading to fresh infection of new animal hosts. In this sense, humans are an accidental host and are irrelevant in the maintenance of leptospires in the environment. Animals that have recovered from acute leptospirosis may develop a carrier condition in which leptospires grow and may remain in the renal tubules for periods of days to years. From here they are passed out in the urine. Leptospires may also persist in other organs, notably the genital tract, the brain and the eye. In horses especially, recurrent, autoimmune uveitis is well documented and involves crossreactivity of anti-leptospiral antibodies with host ocular tissue (Lucchesi and Parma, 1999).

Pathogenesis

Leptospires enter through small cuts or abrasions, via mucous membranes such as the conjunctiva or possibly through wet skin. They spread immediately and circulate in the bloodstream. This bacteremic phase lasts for about 1–7 days. After the numbers of leptospires in the blood and tissues reach a critical level, lesions (due to the action of undefined leptospiral toxin(s) or toxic cellular components) and con-

sequent symptoms appear. The primary lesion is damage to the endothelium of small blood vessels leading to localized ischemia in organs, resulting in renal tubular necrosis, hepatocellular damage, meningitis, myositis and placentitis. Hemorrhages occur in severe cases as do jaundice and frequently, platelet deficiency. There is usually a mild granulocytosis and splenomegaly. Once circulating antibodies appear, leptospires are removed from the circulation and tissues by phagocytosis, following opsonization. Tissue damage, even though it is severe, may be reversible and followed by complete repair (e.g., of the kidney and liver) although long lasting damage (e.g., myocarditis) may be a complication and may lead to scarring, well recognized in the kidneys of pigs and dogs, where it may be observed macroscopically as "white spots."

Epidemiology

Leptospirosis occurs worldwide wherever there is a risk of direct or indirect contact with the urine or kidneys of infected animals or their infected conception products. The organisms die when dry or in acid conditions (pH <7.0), so that transmission is confined to wet environments or circumstances. The most frequent sources of infection are urine, kidneys, and surface of stream waters contaminated with infected urine. Infection is not transmitted by ingestion of food or by inhalation of airborne particles.

Sources of nonoccupational leptospirosis in temperate climates are mainly rodents, dogs, leisure activities and travel (e.g., hobby farming, rafting, camping, boating and swimming), affecting city and rural dwellers. City dwellers may also be occupationally exposed (e.g., sewer workers, drainers, slaughter men, cattle-yarders, butchers, meat inspectors, and veterinarians). Rural dwellers are always at risk, especially in tropical countries where they are in close contact with potentially infected field or domestic rodents and with domestic animals in a warm, wet climate, usually without considerations of protective clothing or footwear. Their habitation is often subjected to flooding. In temperate climates, carriers (pigs, cattle and dogs) are the most important sources of leptospirosis in humans.

Treatment

Antibiotic treatment is effective within the first 7–10 days of infection. It should be given immediately on diagnosis or suspicion. Rapid effective antibiotic treatment can reduce the progression of symptoms and the likelihood of sequelae, thereby preventing the more severe manifestations of infection.

Antibiotics will eliminate leptospires from accessible tissues but will not reverse already established pathological changes, which must run their course and be treated symptomatically or by appropriate supportive therapy. The antibiotic of choice is benzyl penicillin by injection in doses of 5 mega units per day for 5 days. A variation is to give half the dose in procaine penicillin for the first 2 days of the regime. Patients genuinely allergic to penicillin may be given erythromycin, 250 mg four times daily for 5 days. Doxycycline (100 mg twice daily orally for 10 days) is also recommended for patients who can tolerate oral therapy. Tetracyclines were used previously but are contraindicated in patients with renal insufficiency (which occurs in almost all), in children or in pregnant women. They have no place nowadays where alternatives are available. Doxycycline has also been used as a prophylactic for short-term exposure, but it is not recommended for routine continuous use or for long-term occupational exposure.

Virulence Factors

The mechanisms by which leptospires cause host tissue damage and disease are not well defined. In particular, the molecular basis for virulence remains unknown, owing mainly to the absence of genetic tools for the manipulation of *Leptospira*. There have been reports dating back many years of pathogenic mechanisms, but in almost all cases the specific leptospiral components responsible for the activity investigated have not been identified.

For example, virulent leptospires were shown to adhere to cultured renal tubular epithelial cells (Ballard et al., 1986), while the adhesion to cultured fibroblasts was enhanced by antibody (Vinh et al., 1984); in neither case were the leptospiral adhesins identified. Virulent leptospires are resistant to complement and to killing by neutrophils in nonimmune hosts (Cinco and Banfi, 1983a; Wang et al., 1984), but are rapidly killed by either mechanism in the presence of specific antibody (Anderson and Johnson, 1968; Vinh et al., 1982; Farrelly et al., 1987). There is no unequivocal evidence for a classical secreted toxin in *Leptospira*; indeed, in the kidneys of experimentally infected guinea pigs, endothelial damage was closely associated with the presence of remnants of leptospiral cells (de Brito et al., 1992). The ability of leptospires to invade Vero cells and to induce apoptosis in macrophages was correlated with virulence (Merien et al., 1997). Significantly, both properties were lost very rapidly upon in vitro subculture. A cytotoxic, glycolipoprotein fraction was shown to inhibit host ATPase (Younes-Ibrahim et al., 1995), but the

activity was probably due to the presence of long-chain fatty acids (Burth et al., 1997). Likewise, the molecular basis for chemotaxis towards hemoglobin (Yuri et al., 1993) has not been defined. A 36-kDa fibronectin-binding protein was identified in a virulent strain of Icterohaemorrhagiae but was absent in an avirulent variant and in a saprophytic strain (Merien et al., 2000); the variant was not genetically defined.

Hemolysins sphgenes have been reported in a number of leptospiral serovars. Not surprisingly, therefore, a range of genes encoding sphingomyelinases, which are either cell-associated and/or extracellular, has been identified in different *Leptospira* species. Segers et al. (1990) cloned a gene, *sphA*, encoding a cell-associated sphingomyelinase C enzyme in *L. borgpetersenii* serovar Hardjobovis. Similar sequences were identified in all pathogenic strains tested, but were not present in nonpathogenic serovars (Segers et al., 1992). The enzyme activity appeared to be extracellular in Canicola and Pomona. On the basis of hybridization and cloning experiments, at least seven other *sphA*-like genes were detected among the pathogenic species of *Leptospira*. A gene designated "*sphB*" was cloned from *L. borgpetersenii*, *L. weilii* and *L. santarosai*, whereas hybridization studies suggested the presence of a third, related gene, *sphC*. Within the species *L. interrogans*. *L. noguchi* and *L. kirschneri*, an additional five *sph* genes were identified. A further sphingomyelinase, SphH, identified in serovar Lai, was postulated to be a pore-forming hemolysin (Lee et al., 2000). Preliminary studies indicated that SphA and SphB do not elicit a protective immune response. The significance in pathogenesis and/or immunity of the other *sph* genes remains undetermined.

The biological activity of leptospiral LPS and its potential role in pathogenesis is described under Leptospiral Antigens.

Immunity and Vaccines

Immunity to Infection

Immunity in leptospirosis is predominantly, and probably exclusively, humorally mediated. There is no convincing published evidence for a role for cellular immunity in protection from infection. Immunity can be readily transferred by convalescent human or animal serum, by experimentally produced antiserum, or by appropriate monoclonal antibodies (Mabs) such as those against polysaccharide epitopes of leptospiral LPS, which protected guinea-pigs, hamsters, dogs and monkeys against lethal infection (Jost et al., 1986; Schoone et al., 1989). MAbs against LPS determinants are agglutinating and opsonic (Adler and Faine, 1983; Farrelly et al., 1987), and in the presence of specific antibodies, leptospires are rapidly phagocytosed by macrophages and neutrophils, both in vitro and in vivo (Faine, 1964; Cinco et al., 1981; Vinh et al., 1982; Cinco and Banfi, 1983b; Farrelly et al., 1987). In addition, lysis of leptospires occurs in the presence of antibodies and complement within minutes of exposure in the laboratory (Anderson and Johnson, 1968). LPS is highly antigenic whether in its native form in whole or disintegrated leptospires or in chemically purified form, and immunization with purified LPS or LPS components elicits protective immunity (Jost et al., 1989; Midwinter et al., 1990; Midwinter et al., 1994; Masuzawa et al., 1996). Significantly, LPS is a major antigen recognized by human and animal convalescent sera (Chapman et al., 1988; Chapman et al., 1991; Guerreiro et al., 2001), and immunity following naturally acquired infection is restricted to serovars with serologically related LPS. Early work on immunity amongst antigenically unrelated serovars (Kemenes, 1964; Plesko and Lataste-Dorolle, 1970; Plesko and Hlavata, 1971) has not been confirmed; the responsible antigens were not identified.

There is only one published report of unequivocal protective immunity elicited by non-LPS antigens (Haake et al., 1999). Immunization of hamsters with *E. coli* membrane fractions containing a combination of OmpL1 and LipL41 induced significant protection against homologous challenge with *L. kirschneri* serovar Grippotyphosa. No protection was observed with either antigen administered alone. Interestingly, nonmembrane-associated forms of the antigens were not protective, even when used in combination, leading the authors to suggest that the manner in which these proteins associate with the membrane is important in the induction of a protective immune response.

Leptospiral Vaccines

Prevention against leptospirosis without vaccination is difficult. Measures for occupational hygiene such as protective clothing and avoidance of splash from urine or water are often useful but hard to implement because they impede work or are unacceptable to both workers and employers. For example, it is not practicable to advise dwellers in tropical villages to avoid hazardous activities like contact with pigs and other livestock or dogs and walking or working in wet conditions, including in soil or water, such as rice paddies, contaminated by the animals' urine.

Vaccines for humans and animals have been used since the 1920s; almost all of them were prepared from whole leptospiral cells killed by a variety of methods, including heat, formalin,

phenol, irradiation, etc. (Faine et al., 1999). The use of undefined, live avirulent, attenuated, or saprophytic leptospires (Stalheim, 1968; Rottini et al., 1972) has not gained acceptance. Many of these early preparations were too reactogenic for widespread human use. Attempts to reduce reactogenicity have included the use of protein-free media for growth of leptospires (Shenberg and Torten, 1973; Marshall et al., 1979; Christopher et al., 1982; Bey and Johnson, 1983) and the use of subcellular fractions (Bey et al., 1974; Bey and Johnson, 1978a; Bey and Johnson, 1982), the active component of which was almost certainly LPS.

Nevertheless, human vaccines containing whole killed leptospires have been used successfully in China following floods resulting in exposure of large populations to risk of leptospirosis (Chen, 1985) and in Japan and Vietnam. Generally, vaccines contain two or more locally prevalent serovars. For example, a trivalent killed vaccine was recently developed in Cuba following the unavailability of an imported vaccine (Martinez Sanchez et al., 2000). In all cases, repeated annual revaccination is recommended to retain immunity. As with natural infection, immunity is restricted to antigenically related serovars.

Vaccination of livestock can reduce urinary shedding and risk to human handlers especially, and perhaps only, when associated with a high level of education, awareness, and hygiene in the community and with support from the agencies responsible for administration of human and veterinary public health. Prenatal vaccination of sows protects young piglets from acute leptospirosis, but not from being carriers as adults because the acquisition of infection after maternal immunity wanes (Millar et al., 1987), thus failing to reduce the risks to handlers, slaughter men and other meat-workers. Traditionally, the ability of vaccines to elicit the production of agglutinating antibodies has been considered a reasonable measure of their efficacy. However, this association has been refuted at least for Hardjobovis infection in cattle, in which high levels of circulating antibody did not protect cattle against ocular challenge, thought to mimic more closely the natural challenge route (Bolin et al., 1989). Vaccines that are efficacious in this immunization-challenge model may stimulate either cellular immunity or antibodies against unknown nonagglutinating antigens.

Diagnosis

Clinical diagnosis of leptospirosis in humans requires the confidence of current experience supported by laboratory confirmation. The symptoms, while characteristic, are not pathognomonic. The epidemiological environment, clinical history, symptoms and findings on physical examination may allow a clinical diagnosis, but usually laboratory diagnosis is required. The main clinically useful features are the sudden onset of severe headache and fever, almost invariable proteinuria and initially mild or transient nitrogen retention, palatal and skin rash, conjunctival suffusion, and extreme muscle tenderness, especially in the calf and back muscles. Presenting symptoms may mimic or indeed result from an abdominal emergency (e.g., acute cholecystitis), hemorrhages (hemoptysis), renal failure or liver failure (jaundice).

In addition to general laboratory tests for meningitis, liver function, renal function and hematological parameters (Faine et al., 1999; Levett, 2001), specific microbiological tests are necessary. Diagnosis of leptospirosis is essentially similar in humans and animals. The same laboratory tests are available and useful. Checklists for the diagnosis of leptospirosis in humans and animals may be found in Faine et al. (1999).

Culture of Leptospires

As with other bacterial infections, culture and identification of the causative organism provides unequivocal proof of infection. Much mythology surrounds the perceived difficulty of culture of leptospires from clinical material. However, the success rate with blood culture can be very high if appropriate procedures are followed. Leptospiremia commences before the onset of symptoms and usually declines by the end of the first week. Blood cultures must therefore be taken as early as possible and before the initiation of antibiotic therapy. Best results are achieved when medium is inoculated at the bedside with freshly drawn blood. A recommended protocol involves the inoculation of 3 bottles of 5–10 ml EMJH medium with 1, 5 and 20 drops of blood; too much blood can be inhibitory. Provided that proper aseptic procedures are followed, the use of selective media for blood cultures is not recommended. Although leptospires may survive for a few days in conventional blood culture media (Palmer et al., 1984), reliance on this is not recommended. Cultures should be incubated at 28–30°C and examined by dark field microscopy at least weekly for the presence of leptospires; positive cultures should be subcultured immediately. Cultures may need to be kept and observed for several weeks before being discarded as negative. The use of semisolid media is said to increase the isolation rate, but this has not been the authors' experience.

If cerebrospinal fluid (CSF) is taken for other investigations, it should be cultured similarly to

blood. Urine culture in humans is rarely productive because the survival of leptospires in voided urine is poor. Urine must therefore be cultured immediately into selective medium.

The use of animal inoculation for primary isolation of leptospires is in most cases not practical and is not recommended.

Clearly, the slow growth rate of leptospires means that in many cases, a positive culture provides a confirmatory diagnosis. However, in addition to individual diagnosis, it is critical that isolations of locally prevalent serovars are made for epidemiological purposes and also for possible use as antigens for serodiagnosis.

Direct Observation

Direct observation of leptospires in blood and CSF is of very limited diagnostic value; it is not sufficiently sensitive and extremely time consuming. Theoretically 10^4 bacteria/ml would yield one organism per microscope field, but in reality the sensitivity is at least 10- to 100-fold lower. An additional problem is the presence in blood of fibrin strands, which appear to the inexperienced eye as leptospires, so-called "pseudospirochetes." However, unequivocal observation of leptospires by experienced personnel will provide a rapid presumptive diagnosis and facilitate patient management.

In situ staining by immunofluorescence, immunohistochemistry or silver deposition is routinely used for the detection of leptospires in veterinary histopathology, where it serves an important role (Ellis, 1986; Chappel et al., 1992). However, these methods have been largely supplanted by PCR-based detection methods.

Antigen Detection

There have been several reports in the literature of the use of various immunoassays for the detection of leptospiral antigens, including enzyme immunoassay (EIA), radioimmunoassay (RIA), and chemiluminescence. However, they have suffered from sensitivity problems and have not gained widespread acceptance.

Molecular Diagnostic Procedures

The availability of PCR technology has made possible the rapid and sensitive detection of leptospiral DNA in a variety of clinical samples from humans and animals, including serum, urine, CSF, aqueous humor and various organ tissues (see Levett, 2001, for a more extensive review). The most frequent target sequences for amplification have been 16S and 23S rRNA genes (Hookey, 1992; Merien et al., 1992), IS elements (Zuerner et al., 1995; Zuerner and Bolin, 1997) or sequences of unknown function derived from random genomic libraries (Gravekamp et al., 1993). None of the published PCR primers can identify target sequences to serovar level, and a rational PCR-based detection and identification method must await the unequivocal identification of leptospiral genes encoding serovar specificity, most probably within the *rfb* LPS biosynthetic locus. In an analogous situation, a rational PCR-based system was reported recently for *Pasteurella multocida*, based on defined genes encoding specificity of capsular polysaccharide antigens (Townsend et al., 2001).

Serological Diagnosis—Microscopic Agglutination Test

The great majority of cases of leptospirosis in humans and animals are diagnosed serologically. The "gold standard" for serodiagnosis remains the microscopic agglutination test (MAT) in which agglutination of live or killed leptospires by patient serum is assessed by dark field microscopy. Detailed methods and protocols for the performance of the MAT may be found elsewhere (Faine, 1982; Faine et al., 1999). As with blood culture, an undeserved negative mythology surrounds the MAT. It is in fact one of the most sensitive and specific serological tests available, and when performed correctly by trained experienced personnel, it is reliable and reproducible. In the authors' opinion, the oftenquoted drawbacks of occupational danger to laboratory staff and the need to maintain live cultures of *Leptospira* are overstated. However, it does remain a test that is in general performed by specialized laboratories because both the test and the culture of leptospires require particular expertise. As with other serological tests, a fourfold rise in titer in paired sera is the accepted criterion for definitive diagnosis. A single high titer (400 or higher) in a nonendemic area, together with appropriate clinical and epidemiological history, is highly suggestive of current or very recent infection, whereas similar findings in endemic areas may require further confirmation. Titers of greater than 100,000 may be observed with infections by some serovars, especially those of the Icterohaemorrhagiae serogroup (Alston and Broom, 1958). Conversely, very low maximal titers (less than 100) have been reported with Hardjo infections in both humans (Christmas et al., 1974) and animals and with Bratislava infections in animals (Ellis, 1991). Typical titers against Hardjo are in the order of 400 to 1600. Antibiotic therapy may reduce,

delay, or, rarely, abrogate completely the antibody response.

A battery of serovars representing those prevalent in each geographical area must be included in the panel used for MAT, and it is recommended that fresh, authenticated strains be obtained yearly from a certified reference laboratory (listed in Faine et al., 1999). The use of formalin-killed cultures results in lower titers (Palmer et al., 1987). Lyophilized leptospiral suspensions also have been produced and are reported to give similar results.

It must be emphasized that the precise infecting serovar cannot be determined from the patient's serological response, which is at best serogroup specific. However, the MAT response, together with an up-to-date knowledge of locally prevalent serovars, can usually give a reasonable indication of the likely identity of the infecting serovar. This emphasizes the continuing importance of culture as a diagnostic and epidemiological procedure.

Serological Diagnosis—Other Tests

A variety of alternative serological tests have been used over the years, but none of them matches the MAT in terms of specificity and sensitivity. Complement fixation, passive hemagglutination, latex agglutination and slide agglutination tests have all been described (Faine, 1982; Faine et al., 1999; Levett, 2001), but none of them warrants recommendation for routine use.

Enzyme-based antibody assays (ELISA or EIA) were first described over 20 years ago (Adler et al., 1980; Terpstra et al., 1980), and a number of commercial EIA kits are now available for both humans and animals, including a rapid dipstick IgM EIA (Gussenhoven et al., 1997). Most EIAs use disrupted whole leptospires as antigen and the EIA therefore detects antibodies against both agglutinating LPS antigens and subsurface nonagglutinating antigens, such as the heat shock proteins GroEL and DnaK. EIAs are accordingly more broadly reactive than the MAT, although claims of genus-wide reactivity have not been unequivocally demonstrated. A common misconception arises about the significance of a positive IgM EIA test in humans, which is often erroneously taken to indicate a current infection. Because LPS is a dominant antigen in leptospires, it elicits a typical T-independent antibody response in which IgM predominates, even many months or years after infection. The presence of human anti-leptospiral IgM does not therefore necessarily indicate a current or even a recent infection. Certainly, a positive IgM EIA result provides evidence of previous infection, but in all cases the diagnosis must be confirmed by MAT. Because of the occurrence of both false positive and false negative reactions, reliance on IgM EIA as a sole serological test for leptospirosis is not recommended.

Acknowledgments. The National Health and Medical Research Council, Canberra, Australia supported original research in the authors' laboratory. The contributions over many years of staff and students in the authors' laboratory are gratefully acknowledged. In more recent years, the assistance of Dieter Bulach has been especially appreciated.

CHAPTER 4.5

Termite Gut Spirochetes

JOHN A. BREZNAK AND JARED R. LEADBETTER

Introduction

There are few habitats on earth in which spirochetes are such prominent members of the microbial community as in the hindgut of termites. This was first documented over a century ago by Joseph Leidy (Leidy, 1874–1881; Leidy, 1877), who was struck by their abundance in hindgut contents of the eastern subterranean termite, *Termes* (now *Reticulitermes*) *flavipes*. In some termites, spirochetes account for up to 50% of all prokaryotes in the hindgut (Paster et al., 1996), and even casual phase contrast microscopic observation of hindgut contents usually reveals about a dozen different morphological types, distinguishable on the bases of cell size, wavelength and amplitude, or pitch (Fig. 1).

Their size range is striking: from cells measuring only 0.1 μm in diameter × 2.5 μm in length (i.e., at or near the limit of resolution of light microscopy) to many as large as 1.5 μm × 100 μm (Hollande and Gharagozlou, 1967; Bermudes et al., 1988; Paster et al., 1996). Thus, it is not surprising that termites were long ago recommended as an excellent source of spirochetes (and other diverse pro- and eukaryotic microbes) for classroom demonstrations (Beckwith and Light, 1927). Electron microscopy has revealed additional intriguing morphological features of some of the spirochetes, including the presence of crenulations (folds) and a sillon (deep groove) in the outer membrane, bundles of periplasmic flagella, cytoplasmic tubules, and tube-like polar appendages (Bermudes et al., 1988; Radek et al., 1992). Spirochetes are also fairly abundant in hindguts of *Cryptocercus punctulatus* (Grimstone, 1963; Wier et al., 2000), a wood-eating cockroach that, by most analyses, is closely related to termites phylogenetically (Nalepa and Bandi, 2000). However, not much work has been done on spirochetes of *C. punctulatus*, perhaps owing to the somewhat limited distribution of this insect (Cleveland et al., 1934).

In hindgut contents, spirochetes occur as individual, free-swimming cells within the gut fluid. In so-called "lower termites" (families Kalotermitidae, Mastotermitidae, Rhinotermitidae, Serritermitidae and Termopsidae), they also occur as epibionts attached end-on to the plasma membrane of flagellate protozoa, which are also abundant in such termites. Depending on the particular protozoan, the attached spirochetes may be uniformly distributed over the surface or localized in specific regions (Kirby, 1941; Ball, 1969; Radek et al., 1992; Radek et al., 1996; Rösel et al., 1996). Attachment appears to be facilitated by a structural modification of the protozoan plasma membrane and/or the end of the spirochetal cell (Cleveland and Grimstone, 1964; Bloodgood et al., 1974; Smith and Arnott, 1974; Smith et al., 1975a; Smith et al., 1975b; Bloodgood and Fitzharris, 1976; Radek et al., 1992; Radek et al., 1996). A spectacular consequence of such attachment is seen for *Mixotricha paradoxa*, a protozoan whose locomotion is conferred by a vestment of about 100,000 spirochetes, each inserted into the posterior face of bracket-like structures formed by evaginations of the plasma membrane (Cleveland and Grimstone, 1964). Although located primarily in the hindgut proper, spirochetes have also been observed among microvilli of the "mixed segment" of higher termites (family Termitidae; Bignell et al., 1983). The mixed segment is a relatively short region of the gut lying at the juncture of the midgut and hindgut: it is lined partially by microvilli of the midgut and partially by the cuticular lining of the hindgut.

The abundance of spirochetes in guts of healthy, vigorous termites showing no outward signs of disease implied that they were probably not pathogenic and might even benefit the termites. Evidence consistent with the latter possibility was obtained by Eutick and coworkers, who observed that elimination of spirochetes from the gut of the higher termite, *Nasutitermes exitiosus*, by treatment with metronidazole or by exposure to pure oxygen was accompanied by a rapid decrease in termite survival (Eutick et al., 1978). Although from such experiments it is not possible to conclude that spirochetes were the

Fig. 1. A wood-eating termite, *Reticulitermes flavipes* (top), is positioned next to a gut extracted from a separate individual (middle). Vertical white arrowhead indicates the juncture between the hindgut (left) and tubular midgut (right). Bottom is a phase contrast micrograph of diluted gut contents obtained by needle puncture of the bulbous "paunch" region of the hindgut at the point shown (circle). Numerous spirochetes of various size and shape (white arrows) are seen among protozoa (P), a few nonspirochete prokaryotes (black arrows), and a not-yet-digested wood particle (W). Note also spirochetes attached end-on to the surface of the protozoan (red arrow).

only members of the gut microbiota that were eliminated, most of the microscopically observable nonspirochetal microbes appeared to remain after such treatments, suggesting that spirochetes contributed in some way to termite vitality. Unfortunately, the nature of their putative contribution(s) remained obscure, as none had yet been isolated and studied in pure culture.

Ghidini and Archetti (1939) obtained an enrichment of what appeared to be spirochetes and other motile microbes from guts of *Reticulitermes lucifugus* by allowing the organisms to migrate as a band into the lateral arm of a culture tube filled with a medium containing Ringer's solution (composition not stated), 5% heat-inactivated rabbit serum, and 0.2–0.8% agar. However, although the spirochetes retained motility for several days, it is not clear that they actually grew in the medium or in subcultures made from the migrating band of microbes. No electron microscopy was done, but light micrographs included in their paper suggest that the spiral and undulate forms were indeed spirochetes. Most of the other published work on termite gut spirochetes over the past hundred years dealt with their occurrence in various termite species, their morphological diversity and ultrastructure, and their associations with hindgut protozoa, and over the years an assortment of new genus and species names were proposed for various types, largely on the basis of morphological properties. Early work on termite gut spirochetes has been reviewed elsewhere (Breznak, 1973; Breznak, 1984; Margulis and Hinkle, 1992).

In recent years, our understanding of termite gut spirochetes has taken a giant step forward. The nucleotide sequences of several hundred 16S rRNAs have been determined for spirochetes from a variety of termites by using cultivation-independent, molecular biological approaches. This has helped to clarify their phylogenetic diversity and their natural relationships to each other and to other spirochetes. Three years ago, the first pure cultures were obtained (Leadbetter et al., 1999). Yet even in the short time that such strains have been available, research on them has already revealed metabolic properties heretofore unrecognized in spirochetes (e.g., H_2/CO_2-acetogenesis and N_2 fixation) and, from that, some of the ways in which they contribute to termite nutrition. This chapter will describe a simple procedure (suitable for classroom use) for observing termite gut spirochetes, as well as methods and media that were used to isolate the first pure cultures. It will also summarize our knowledge of their phylogeny and our recently enlightened, but still limited, understanding of their physiology and biochemistry.

Microscopic Observation

Termite gut spirochetes are easily observed by light microscopy in diluted hindgut contents, liberated by puncturing the hindgut region of an extracted gut and allowing the contents to ooze into a drop or two of buffered salts solution on a microscope slide, which is then covered with a coverslip (Fig. 1). Termites can be obtained from a biological supply house (e.g., Carolina Science and Math, http://www.carolina.com) or collected from nature.

Extraction of termite guts is done by holding the insect by the thorax with one pair of forceps, and with another pair of fine-tipped forceps, grasping the extreme posterior portion (anus) perpendicular to the long body axis and pulling smoothly outward. The gut will often tear at or

near the foregut-midgut juncture so that only the hindgut, with a variable length of tubular midgut, is obtained. By chilling termites beforehand in a Petri dish held on crushed ice, they become almost completely immobile and easier to grasp with the forceps. Use of a dissecting microscope facilitates the degutting procedure, but is not absolutely necessary. The extracted hindgut is then placed on a glass slide and immediately covered with a small amount of anoxic buffered salts solution prior to being punctured with a needle or with the sharp tip of the same forceps used to remove the gut. One satisfactory buffered salts solution, BSS (below), is based on the major inorganic salts determined to be present in hindgut fluid of *Zootermopsis angusticollis* (Yamin, 1978).

"Worker" termites (i.e., externally undifferentiated larvae), which are typically the most abundant members of a colony, have the most robust, microbe-packed guts and are the best specimens to use for this procedure. For relatively small guts 1–2 µl in volume (e.g., those from subterranean termites such as *Reticulitermes* or *Coptotermes* species), it is not absolutely necessary to remove the guts or gut fragments prior to application of the coverslip. In fact, as most of the spirochetes appear to be sensitive to oxygen, the respiratory activity of the remaining gut tissue will help create and maintain anoxia. For relatively large termites (e.g., the western United States dampwood termite, *Zootermopsis angusticollis*), it is usually necessary to remove the gut from the slide after liberation of hindgut contents to allow the coverslip to lie flat. For extended observation, the edges of the coverslip can be sealed with petroleum jelly or nail polish to retard evaporation. Spirochetes in such preparations often retain their motility for several hours. They are best viewed by using phase contrast or darkfield microscopy at 400–1000X final magnification. However, many can be seen with brightfield illumination at 100–200X by using inexpensive student microscopes. If preparations are made from lower termites, the coverslip should be applied gently and without forceful compression so as to retain the morphological integrity and motility of the flagellate protozoa, which are also interesting to observe.

Phylogeny

The first insights into the phylogeny of termite gut spirochetes came from analysis of spirochetal 16S rRNA-encoding genes (16S rDNAs) cloned after polymerase chain reaction (PCR) amplification from termite gut DNA. The nucleotide sequence of the first clone so obtained, clone MDS1 from the Australian termite *Mastotermes darwiniensis* (family Mastotermitidae), grouped within the genus *Treponema*, but it was not closely related to any known treponeme (Berchtold et al., 1994). This report was soon followed by reports of numerous additional spirochete 16S rDNA clones from *M. darwiniensis* (Berchtold and Köig, 1996), as well as from *Nasutitermes lujae* (family Termitidae) (Paster et al., 1996), *Reticulitermes speratus* (family Rhinotermitidae; Ohkuma and Kudo, 1996a) and *Cryptotermes domesticus* (family Kalotermitidae; Ohkuma and Kudo, 1998), and all of those clones grouped within the genus *Treponema* as well. As part of some of these investigations, fluorescent, 16S rRNA-targeted oligonucleotide probes were designed on the basis of the nucleotide sequences of the rDNA clones, and the probes were shown to react with hindgut spirochetes (Berchtold and Köig, 1996; Paster et al., 1996), thereby confirming the spirochetal origin of the cloned rDNAs.

In 1999, Lilburn and coworkers analyzed nearly 300 spirochetal 16S rDNA clones obtained from termites representing five of the seven termite families (Lilburn et al., 1999). The emergent picture was that although all clones could be grouped in the genus *Treponema*, none were closely related (i.e., all bore ≤91% sequence similarity) to any known treponeme or to any 16S rDNA clone derived from not-yet-cultured treponemes. Moreover, the clones were remarkably diverse at what could be considered the "species-level," a result consistent with the morphological diversity of spirochetes seen in termite guts. Conservative estimates implied that individual termite species such as *Reticulitermes flavipes* contain as many as 21 different species of *Treponema*. However, phylotype rank-abundance plots analyzed by methods used for macroecological systems (Tokeshi, 1993) implied that the distribution of clone types in *R. flavipes* was quite equitable. This may suggest either that the termite gut ecosystem is not in equilibrium or that there exists in the gut an assortment of niches capable of being filled by different species of treponemes. The data also revealed the existence of at least two major phylogenetic groups of treponemes: one (the traditional treponemes) consisting of all currently known isolates of *Treponema* from animals other than termites, as well as a large number of spirochetal 16S rDNA clones from the human gingival crevice and from digital dermatitis lesions of cattle, but containing a minority of termite gut clones; and another, termed the "termite cluster," containing the vast majority of termite gut clones (Fig. 2), as well as the free-living spirochetes *Spirochaeta stenostrepta* and the thermophile *S. caldaria*.

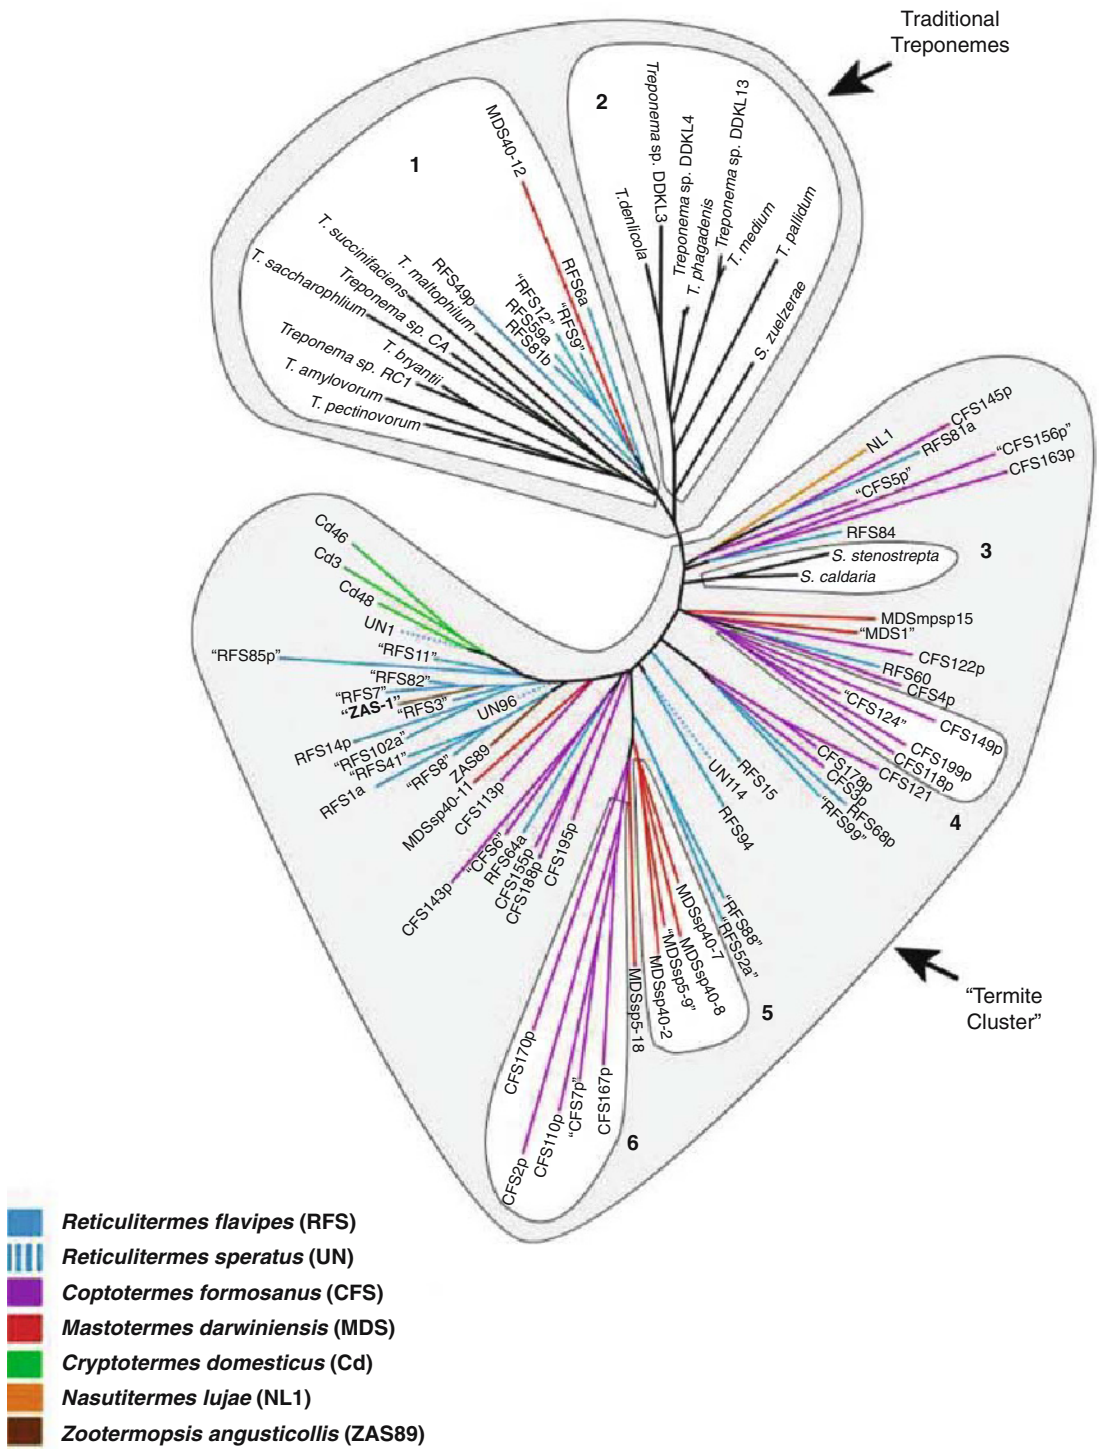

Fig. 2. A radial phylogenetic tree based on 16S rRNA sequence analysis of individual termite gut spirochete phylotypes or (in quotation marks) groups of closely related phylotypes color-coded to the termite species (bottom left) from which they were obtained. The latter are representatives from five of the seven known termite families. Branches in black were used for known species of *Treponema* and *Spirochaeta* and for treponemal phylotypes inferred from cloned 16S rDNAs. Within the two major groupings (the Traditional Treponemes and the "Termite Cluster" of treponemes), subgroups 1 and 2 represent treponemal subgroups defined by Paster et al. (1991); subgroup 3 represents the *Spirochaeta* subgroup; and subgroups 4, 5 and 6 represent closely related phylotypes from *C. formosanus* and *M. darwiniensis*. *Leptospira noguchii* (not shown) was used as the outgroup. A scale bar is not included, because some of the branch lengths were distorted during construction. Modified from Lilburn et al. (1999), which should be consulted for further details.

(The latter two, as well as *S. zuelzerae*, were named before their 16S rRNA sequences were known. Inasmuch as they were free-living anaerobes, they were assigned to the genus *Spirochaeta*. However, they group within the genus *Treponema* on the basis of their 16S rRNA sequences; Paster et al., 1991.)

Four nucleotide signatures were identified that almost perfectly distinguished members of the "termite cluster" from other treponemes. These were (*Escherichia coli* numbering): 289-GC-311; A at 812; and an inserted nucleotide at 1273. The first hints of possible coevolution between termites and their hindgut spirochetes were also seen, i.e., some subgroups of clones derived from a particular termite species were more closely related to each other than to clones derived from other termite species (subgroups 4, 5 and 6; Lilburn et al., 1999; see Fig. 2). However, there were also numerous exceptions (Lilburn et al., 1999). This was observed by Ohkuma and coworkers as well, who concluded that patterns of evolution between spirochetes and termites were far from simple (Ohkuma et al., 1999a). Nevertheless, it was becoming apparent that the roughly 2000 species of termites on earth constituted an enormous reservoir of novel treponemal diversity.

Isolation

Background and General Procedures

In 1999, the first stable and transferable enrichment cultures of termite gut spirochetes were established from hindgut contents of *Zootermopsis angusticollis* (family Termopsidae), and from them the first pure cultures of termite gut spirochetes were obtained: *Treponema* sp. strains ZAS-1 (Fig. 3a, b and c) and ZAS-2 (Leadbetter et al., 1999).

A third strain, ZAS-9 (Fig. 3d and e) was subsequently isolated by direct inoculation of hindgut contents into an agar dilution series (Lilburn et al., 2001).

The composition of the original enrichment and isolation media and improved growth media for routine cultivation of ZAS strains is given below. However, it is worth relating some characteristics of the initial enrichment cultures, as well as the methods used to monitor their progress and to isolate spirochetes from them, as this may aid future efforts. One factor that probably contributed to the success of initial enrichments was the inclusion of rifamycin and fosfomycin in media (two drugs to which spirochetes are intrinsically resistant; Stanton and Canale-Parola, 1979; Wyss et al., 1996). Another was supplementation of media with nutrient broth and pre-fermented, pH neutralized, clarified rumen fluid as a source of growth factors. Pre-fermentation of rumen fluid was done in an effort to minimize the amount of readily fer-

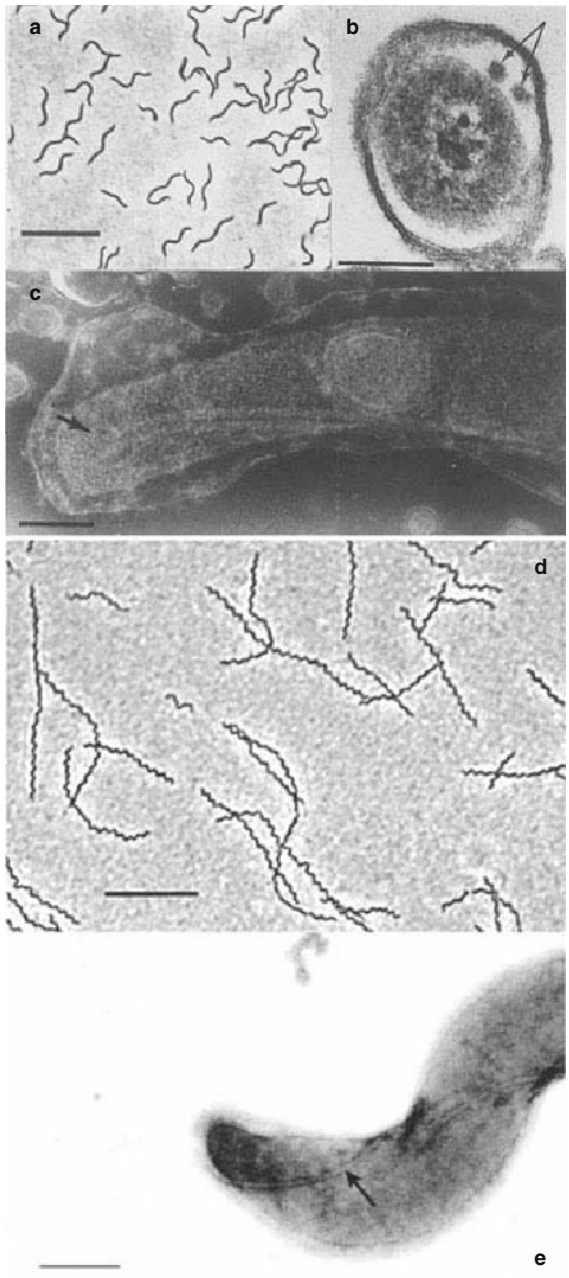

Fig. 3. Morphology of termite gut *Treponema* strain ZAS-1 (a, b and c), which is similar to strain ZAS-2 (not shown) and strain ZAS-9 (d and e). Arrows point to periplasmic flagella. Marker bars correspond to 10 μm (a and d; phase contrast micrographs) and 0.1 μm (c, d and e; electron micrographs). Panels a, b and c are from Leadbetter et al. (1999); panels d and e were provided by J. R. Graber. All were used by permission. Reprinted with permission from Leadbetter et al., *Science* 283, 686, Fig. 1. Copyright 1999 American Association for the Advancement of Science.

mentable carbohydrate present and hence discourage overgrowth of spirochetes by undesired fermentative forms (a problem that plagued many previous isolation attempts in our laboratory even when rifamycin was used to suppress nonspirochetal bacteria). A third factor was the use of an anoxic headspace composed of 80% H_2/20% CO_2 (a mixture that later proved to be an energy source for some of the isolates), along with the inclusion of bromoethanesulfonate in the medium to inhibit H_2-utilizing methanogens (Oremland, 1988). A fourth factor was patience. Successful enrichments took a long time to develop (10–12 weeks at room temperature) and even then did not result in much turbidity (maximum $OD_{600nm} \approx 0.1$; 18 mm light path). Enrichments were periodically checked for growth by viewing the rubber-stoppered, anoxic culture tubes or bottles when held near a diffusely sunlit window in an otherwise unlit room. The elongated, slender nature of spirochetal cells tended to impart a convective or silky appearance to the liquid medium when swirled, and so cultures were qualitatively examined for this property. Samples of culture fluid were also monitored microscopically, by using darkfield or phase contrast optics at 100X or 400X magnification. Periodic microscopy of incipient enrichment cultures exhibiting little or no visible turbidity was useful in evaluating which of a variety of test media formulations supported the longest retention of spirochete motility and morphological integrity and an increase in spirochete biomass. The latter was seen as an increase in the length of cells and the appearance of division stages. Microscopic examination also enabled an estimation of the number of spirochetes relative to nonspirochetal microbes and revealed when spirochete growth and motility were slowing, thereby prompting subculture into fresh medium.

It was noticed that growth of spirochetes in successful enrichments was accompanied by consumption of H_2 and CO_2 from the headspace and production of near stoichiometric amounts of acetate, suggesting that some of the spirochetes might be capable of performing H_2/CO_2-acetogenesis (i.e., $4\ H_2 + 2\ CO_2 \rightarrow CH_3COOH + 2\ H_2O$ [$\Delta G^{o\prime} = -105$ kJ per mol acetate]), an assumption that later proved to be correct (see below). Consumption (or production) of headspace gas in rubber-stoppered culture vessels is easily measured by using graduated glass syringes, whose matched barrel and plunger surfaces are lubricated with a thin application of Sigmacote (Sigma-Aldrich, St. Louis, MO) so as to be gas tight but slide easily. These are fitted with a sterile, disposable filter unit (0.22 μm pore diameter) and a 25-gauge needle. The syringe is flushed several times with the sterile anoxic gas of choice and left half-filled on first insertion through the rubber stopper, whereupon the pressure is allowed to return to 1 atmosphere by allowing the plunger to glide to rest. If the cells use the headspace gas as a substrate, a syringe filled with that gas will simultaneously replenish the amount consumed. The size of syringe used depends on the volume of the headspace in the vessel and the extent of gas production or consumption. In general, the syringes used have a capacity of 10–20% of the headspace being measured. Syringe methods for the isolation and manipulation of anaerobes are described by Hungate (1969).

In such enrichments, spirochetes eventually grew to outnumber other bacteria by about 50 : 1, and from these the first pure cultures (*Treponema* strains ZAS-1 and ZAS-2) were isolated by performing dilution series in rubber stoppered tubes of the same medium solidified with agar. It was later found that spirochetes could be isolated directly from hindgut contents in agar dilution series without prior enrichment (*Treponema* strain ZAS-9). Agar tubes should be incubated upside down (mouth side down) to allow the water exuded from the agar to accumulate on the rubber stopper, from which it can be periodically removed by using a sterile syringe and needle. This will keep the surface of the agar relatively dry, facilitating subsequent picking of subsurface colonies for isolation of pure cultures. Sterile syringes can also be used to monitor gas consumption and production within the tubes, as described above. The general procedure for performing agar dilution series (which can be done by using rubber stoppered tubes and sterile, O_2-free gas-flushed syringes and needles) and for picking subsurface colonies with a drawn out Pasteur pipette is described by Hungate (1969) and by Widdel and Bak (see Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the second edition).

In agar dilution series incubated at room temperature, colonies of spirochetes took 2–3 months to develop. Isolated colonies were spherical, and their diameter (1–3 mm) increased with time. They were semi-transparent and difficult to see and were best observed in diffuse light (as described above). Colonies of strains ZAS-1 and ZAS-2 growing under an atmosphere of 80% H_2/20% CO_2 were larger near the meniscus owing to their use of inwardly diffusing H_2 as an energy source. By contrast, colonies of strain ZAS-9 (which produces H_2) were accompanied by gas bubbles or cracks in the agar gel.

In pure culture, the growth rate and yield of isolated strains were greatly improved by replacing the rumen fluid and nutrient broth components of the isolation medium with yeast autolysate and by supplementation of the medium with additional cofactors (2YACo

medium and 4YACo medium, below) and, for strain ZAS-9 (which is not an H_2/CO_2-acetogen), by provision of a mixture of disaccharides.

Nine additional "ZAS" strains have since been isolated in our laboratory from *Z. angusticollis*, and six "RFS" strains have been isolated from *R. flavipes* (J. A. Breznak, unpublished data). However, these 15 strains still grow very poorly and hence have not yet been studied in detail. By contrast, we have been unsuccessful in establishing enrichment cultures or performing direct isolation of spirochetes from hindgut contents of the Formosan subterranean termite, *Coptotermes formosanus*, which is in the same family (Rhinotermitidae) as *R. flavipes*. Clearly, much remains to be learned about the nutritional and physiological idiosyncrasies of termite gut spirochetes.

Media for Observation, Enrichment, Isolation and Cultivation

For routine microscopic examination of termite hindgut contents, the following medium is recommended.

Buffered Salts Solution (BSS; Breznak and Switzer, 1986)

K_2HPO_4	2.5 g
KH_2PO_4	1.0 g
KCl	1.6 g
NaCl	1.4 g
Distilled water	999 ml

Adjust to pH 7.2; deoxygenate by boiling and cooling under 100% N_2; add deoxygenated 1 M dithiothreitol to a final concentration of 1 mM. Store in a butyl rubber-stoppered tube or serum bottle under 100% N_2.

Use the following for enrichment and isolation of termite gut *Treponema* strains ZAS-1 and ZAS-2.

Modified JM-4 Medium (Leadbetter et al., 1999)

NaCl	1.0 g
KCl	0.5 g
$MgCl_26H_2O$	0.4 g
$CaCl_22H_2O$	0.1 g
NH_4Cl	10.3 g
KH_2PO_4	0.2 g
Na_2SO_4	0.15 g
Nutrient broth (Difco)	2.0 g
Bromoethane sulfonate (BES), Na salt	10.0 g
Bovine rumen fluid (below)	170 ml
0.1 M 3-*N*-[morpholino]propanesulfonate (MOPS), pH 7.2	100 ml
Distilled water	686 ml
1.0 M $NaHCO_3$ (below)	69 ml
Trace element mixture with EDTA (below)	1 ml
Selenite-tungstate solution (below)	1 ml
Six-vitamin solution (below)	1 ml
Vitamin B_{12} Solution (below)	1 ml
Rifamycin-fosfomycin solution (below)	10 ml

The medium is prepared by using procedures similar to those described for cultivation of other anaerobic microbes (see Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the second edition). All components except for the last six solutions are combined, autoclaved, and cooled under a gas phase of 80% N_2/20% CO_2, after which the other ingredients are added, and the pH is adjusted to 7.2–7.3. The headspace is then changed to 80% H_2/20% CO_2 for dispensing into culture tubes or larger vessels, which are subsequently sealed with butyl rubber stoppers. Prior to inoculation, the medium is reduced by adding 100 mM dithiothreitol (separately sterilized under 100% N_2) to a final concentration of 1 mM. Resazurin (0.1 mg per liter, final concentration) may be incorporated into the medium (if desired) as a redox indicator. Solid media are prepared by incorporating agarose (Gibco/Invitrogen, Carlsbad, CA) at a final concentration of 8.0–10.0 grams per liter.

Bovine Rumen Fluid

This is obtained from a fistulated, forage-fed dairy cow. Large particles are removed by wringing the fluid through two layers of cheesecloth immediately after collection and the expressed liquid is pooled in an Erlenmeyer flask, whereupon it is left to ferment overnight at 37°C in a water bath in a vented fume hood. The fermented liquid is adjusted to pH 7.0 with NaOH, clarified by centrifugation, and autoclaved under 100% N_2.

1.0 M $NaHCO_3$, Trace Element Mixture with EDTA, Selenite-Tungstate Solution and Vitamin B_{12} Solution

For composition, see Widdel and Bak, Gram-Negative Mesophilic Sulfate-Reducing Bacteria, in the second edition.

Six-Vitamin Solution (Widdel and Pfennig, 1981)

4-Aminobenzoic acid	4 mg
Nicotinic acid	10 mg
Calcium-D(+)-pantothenate	5 mg
Pyridoxine HCl	15 mg
Thiamine HCl	10 mg
Biotin	1 mg
Distilled water	80 ml

While being stirred, the mixture is neutralized by dropwise addition of 0.1 M NaOH, which facilitates solubilization of all constituents. The solution is then brought up to 100 ml with distilled water, filter-sterilized, and stored at 4°C.

Rifamycin-Fosfomycin Solution

Rifamycin SV (Na salt)	1.0 g
Fosfomycin	1.0 g
Distilled water	100 ml

This solution is filter-sterilized and stored at 4°C.

The following media are also for cultivation of *Treponema* strains ZAS-1 and ZAS-2.

2YACo and 4YACo Media (Leadbetter et al., 1999)

These are similar to modified JM-4 medium (above), except rifamycin-fosfomycin solution is omitted, and rumen fluid and nutrient broth are replaced in

2YACo medium by 140 ml of distilled water, 20 ml of yeast autolysate (below) and 20 ml of cofactor solution (below), and in

4YACo medium by 120 ml of distilled water, 40 ml of yeast autolysate and 20 ml of cofactor solution.

Yeast Autolysate Solution

> Preparation is similar to that described for inclusion in the OTI medium of Smibert (Miller et al., 1992). Fifty-six grams of dry baker's yeast (Red Star Yeast and Products, Milwaukee, WI) are suspended in 200 ml of distilled water in an Erlenmeyer flask and allowed to autolyse for 24 h at 56°C with occasional swirling of the contents. Cell debris is then removed by centrifugation, and the supernatant liquid is neutralized with 5 N NaOH, filter-sterilized, and stored under 100% N_2 at 4°C.

Cofactor Solution

> This includes a mixture of cofactors used in a defined medium for cultivating oral anaerobes (Wyss, 1992) and contains (mg per 100 ml of stock solution): thiamine pyrophosphate, 250; pyridoxal HCl and pyridoxal phosphate, 25 each; calcium folinic acid, β-NAD, coenzyme A and FAD, 5 each; nicotinamide, 2.5; folic acid, 0.25; riboflavin, 0.05; and 10 ml of hemin (650 μg/ml in 10 mM NaOH). It is filter-sterilized and stored under 100% N_2 at 4°C.

The following is recommended for the cultivation of *Treponema* strain ZAS-9.

SYACo Medium

> The composition is identical to that of 2YACo medium, except that it includes a mixture of disaccharides (cellobiose, maltose, sucrose and trehalose, 5 mM each; added from a 50X, filter-sterilized stock solution under 100% N_2) and is incubated under a headspace of 80% N_2/20% CO_2.

For studies of nitrogen fixation, cells were grown in homologous media (above), except that tungstate was omitted from the selenite-tungstate solution; $Na_2MoO_42H_2O$ present in the trace element mixture with EDTA was increased from 36 mg (equiv. to 0.15 μM in the complete medium) to 1200 mg (5 μM); and exogenous NH_4Cl was omitted for derepression of nitrogenase (Lilburn et al., 2001).

Properties of Isolated Strains

Treponema strains ZAS-1 and ZAS-2 are similar in morphology and size (0.2 μm × 3–7 μm), and both have two periplasmic flagella, each inserted at opposite ends and overlapping for most of the length of the cell (Fig. 3a, b and c). Both are homoacetogens capable of H_2/CO_2-acetogenesis, and cell extracts of both possess CO dehydrogenase, formate dehydrogenase and hydrogenase activities (Leadbetter et al., 1999), implying that H_2/CO_2-acetogenesis probably occurs via the Wood/Ljungdahl (acetyl CoA) pathway (Drake, 1994).

In 4YACo medium under a headspace of 80% H_2/20% CO_2 at 30°C, ZAS-1 grows with a doubling time of 23–24 h and achieves cell densities of 1.4×10^9 cells/ml, whereas ZAS-2 grows with a doubling time of about 48 h and achieves cell densities of about 3×10^8 cells/ml. However, although both strains consume H_2 during growth in 4YACo medium, the growth of ZAS-2 is strictly dependent on the presence of H_2 in the headspace, whereas ZAS-1 grows equally well in the absence of H_2 by using as yet unknown constituents of yeast autolysate as fermentable substrates. Little or no growth of either strain occurs if the cofactor solution or yeast autolysate is omitted from the medium, and for as yet unknown reasons, yeast autolysate prepared in the laboratory could not be replaced by a variety of commercial yeast extracts and autolysates (Leadbetter et al., 1999).

Treponema strain ZAS-9 is easily distinguished from strains ZAS-1 and ZAS-2 morphologically (Fig. 3d). Cells of ZAS-9 are longer (0.2 μm × 10–15 μm) and appear more tightly coiled, i.e., their wavelength or cell body pitch (1.2 μm) is substantially shorter than that of ZAS-1 and ZAS-2 (3.8 μm). Nevertheless, like ZAS-1 and ZAS-2, ZAS-9 also possesses two periplasmic flagella (Fig. 3e). ZAS-9 also differs from ZAS-1 and ZAS-2 physiologically. It is not a homoacetogen, but produces a mixture of acetate, ethanol and hydrogen (and presumably also CO_2) during sugar fermentation, and it is incapable of growth on $H_2 + CO_2$. During growth in SYACo medium at 30°C, strain ZAS-9 exhibits a doubling time of 46 h and attains a density of about 7×10^8 cell/ml (Graber and Breznak, 2000). When grown under nitrogen-fixing conditions (above), ZAS-9 exhibits N_2-dependent growth, and the levels of nitrogenase activity (1.2 μg N_2 fixed per h per mg protein; estimated by acetylene reduction) are much greater than those exhibited by strains ZAS-1 and ZAS-2 (<0.1 μg N_2 fixed per h per mg protein). Fixation of $^{15}N_2$ by ZAS-9 was demonstrated (Lilburn et al., 2001). Conditions have not yet been established to demonstrate N_2-dependent growth by strains ZAS-1 and ZAS-2.

Treponema strains ZAS-1, ZAS-2 and ZAS-9 all group within the "termite cluster" of treponemes (Fig. 4).

Ecology

Acetogenesis

The production of acetate by termite gut spirochetes, either by homoacetogenesis or heteroacetogenesis, implies an important role for them in the nutrition of termites, which use microbially produced acetate as a major carbon and energy source. However, the performance of H_2/CO_2-acetogenesis by termite gut spirochetes, although offered as a speculation nearly 25 years earlier (Breznak, 1973), was still surprising because this mode of metabolism had never been described in spirochetes. Nevertheless, this met-

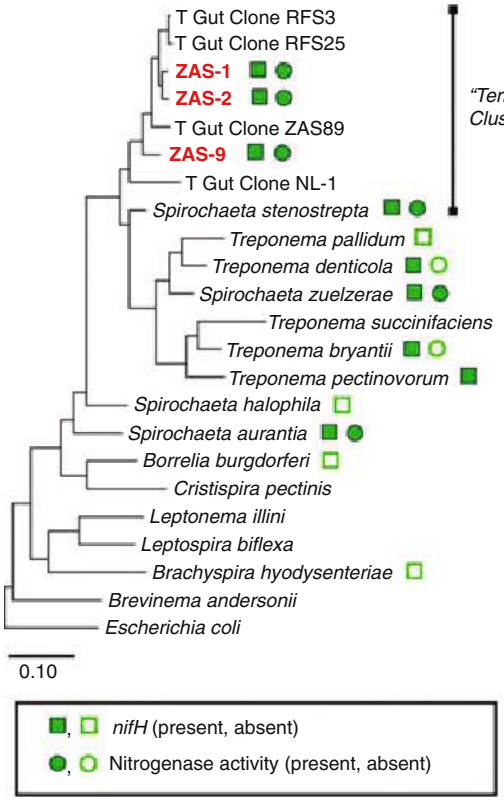

Fig. 4. Phylogeny of selected spirochetes and termite gut spirochete 16S rDNA clones (T Gut Clone) showing the distribution of *nifH* and nitrogenase activity within this phylum. The tree was inferred by maximum likelihood analysis of 16S rDNAs from isolated termite gut *Treponema* strains ZAS-1, ZAS-2 and ZAS-9 (red), from other representative host-associated and free-living spirochetes, and from cloned 16S rDNA genes obtained by PCR amplification from gut contents of the termites *Zootermopsis angusticollis* (prefix ZAS), *Reticulitermes flavipes* (RFS) and *Nasutitermes lujae* (NL). The homologous sequence from *E. coli* was used as the outgroup. Scale bar represents units of evolutionary distance and is based on sequence divergence. Absence of a symbol next to the species name indicates that the spirochete was not examined for the property. Modified from Lilburn et al. (2001).

abolic property helps explain the enigmatic dominance of H_2/CO_2-acetogenesis over H_2/CO_2-methanogenesis in the hindgut of many wood-feeding termites (Breznak, 1994). Microelectrode-determined, radial profiles of H_2 gradients in hindguts of wood-feeding termites such as *R. flavipes* had revealed that the highest concentrations of H_2 (up to 50,000 parts per million by volume [ppmv]) occurred in the luminal region (Ebert and Brune, 1997), being produced there largely by the protozoa in "lower" termites (such as *R. flavipes*) and by prokaryotes in "higher" termites. This is also the region of the hindgut in which spirochetes were most abundant. By contrast, H_2-consuming methanogens (and most other non-spirochetal prokaryotes) in *R. flavipes* were situated on or near the hindgut epithelium (Leadbetter and Breznak, 1996), where H_2 concentrations were lowest (ca. 3,000 ppmv). Thus, it appears that the dominance of H_2/CO_2-acetogenesis reflects, in large part, the spatial separation of the H_2-consuming populations, with H_2/CO_2-acetogenic spirochetes consuming most of the H_2 at its source of production and wall-associated methanogens using what H_2 is left over. That wall-associated methanogens are indeed limited for H_2 was shown by the fact that externally supplied H_2 stimulated methane emission (Ebert and Brune, 1997; Messer and Lee, 1989), but it had virtually no effect on in situ rates of acetogenesis from CO_2 (Tholen and Brune, 2000). The importance of microbial spatial relationships on the functioning of the termite gut microbiota has recently been discussed in detail (Brune and Friedrich, 2000).

The ability of spirochetes to conserve the energy of H_2 oxidation suggests that attachment of spirochetes to the surface of hindgut protozoa probably reflects a strategy used by some of them to remain close to major sites of H_2 production. Recent elegant experiments with fluorescent, rRNA-targeted oligonucleotide probes suggest that attachment to protozoa is limited to distinct phylogenetic types of spirochetes (Iida et al., 2000). However, the fact that strain ZAS-9 produces, but does not consume, H_2 implies that interspecies transfer of H_2 between spirochetes is probably also occurring in the luminal region of termite hindguts.

Nitrogen Fixation

N_2 fixation by termite gut microbes has been known for many years (Breznak, 2000), and in light of the typically carbon-rich but nitrogen-poor diet of termites, it is not surprising that N_2 fixation contributes as much as 60% of the N in some termite colonies (Tayasu et al., 1994). However, N_2-fixing microbes from termites were not well-represented in culture, and those that had been obtained *M Citrobacter freundii* (French et al., 1976), *Enterobacter* (now *Pantoea*) *agglomerans* (Potrikus and Breznak, 1977) and *Desulfovibrio* sp. (Kuhnigk et al., 1996)—were of uncertain quantitative significance to the process occurring in vivo. Indeed, surveys of *nifH* (nitrogenase Fe-protein-encoding gene) homologues present in termite guts indicated that the diversity of N_2-fixing organisms was far greater than that inferred by using cultivation-based methods, with most of such *nifH* homologues not readily attributable to known microbial taxa (Ohkuma et al., 1996b; Ohkuma et al., 1999b).

Recent examination of ZAS-strains revealed that each possessed two homologues of *nifH* and each exhibited nitrogenase activity, with ZAS-9 exhibiting the greatest specific activity, ca. 100-fold greater than that of ZAS-1 and ZAS-2 (Lilburn et al., 2001). Of particular interest was the fact that the deduced NifH amino acid sequences of several spirochetes, including ZAS-strains, were identical or nearly identical to various NifHs previously observed in termite guts, including NifHs known to be expressed in vivo (Noda et al., 1999), suggesting that the latter were likely to be of spirochete origin. Estimates of the potential contribution of spirochetes to the N_2-fixing activity exhibited by live termites indicated that it could be significant and account for all or a substantial fraction of N_2 fixed by various termite species (Lilburn et al., 2001).

Inasmuch as N_2 fixation was another property hitherto unknown in spirochetes, a survey was made for the presence of *nifH* and nitrogenase activity in other members of this phylum. So far, these traits are found to be restricted to certain species of *Treponema* and *Spirochaeta*; however, not all spirochetes that possessed *nifH* could be shown to fix N_2 (Lilburn et al., 2001; Fig. 4).

Conclusion

Our understanding of termite gut spirochetes, and in particular their role in termite nutrition, has come a long way in a relatively short time. It is now clear that spirochetes contribute to the carbon, nitrogen and energy requirements of termites via acetogenesis and N_2 fixation, and this is probably why their elimination from guts reduces the life span of termites. However, in light of the phylogenetic diversity of spirochetes in termites, it seems almost certain that the few strains now in culture offer but an introductory glimpse of the physiological diversity of the group as a whole, to be fully appreciated only when more representatives are coaxed into culture and better culture conditions are developed for those strains whose growth is still poor. In the meantime, metabolic properties elucidated with the already studied strains in vitro must now be evaluated in vivo. For example, what is the spirochete-specific contribution to H_2/CO_2-acetogenesis and N_2 fixation occurring in vivo? Which phylogenetic groups of spirochetes are most important in these processes? What properties of spirochetes (or of the termite gut itself) enable them to become such a prominent component of the microbiota? Hopefully, creative and converging experimentation will soon provide answers to these intriguing questions.

CHAPTER 4.6

The Genus *Brachyspira*

THADDEUS B. STANTON

Phylogeny and Taxonomy

Brachyspira is the sole genus assigned to the proposed Family "Brachyspiraceae" in the Order Spirochaetales (Paster and Dewhirst, 2000). The Order Spirochaetales contains all spirochetes. The spirochetes represent a monophyletic lineage and a major early branch in eubacterial evolution (Paster et al., 1984; Paster and Dewhirst, 2000). *Brachyspira* cells share with other spirochetes several properties that distinguish them from other bacteria. These include a helical cell shape (Fig. 1) and a cell ultrastructure that features internal periplasmic flagella, 16S rDNA sequences with spirochete signature nucleotide bases, and a natural resistance to the antibiotic rifampin (Paster and Dewhirst, 1997; Paster and Dewhirst, 2000). *Brachyspira* species are readily differentiated from other spirochete genera based on comparisons of their 16S rDNA sequences (Paster et al., 1991; Paster and Dewhirst, 1997).

General Characteristics

Brachyspira species have been isolated from animal or human intestinal contents, feces-contaminated habitats (e.g., duck ponds), and human blood. They are anaerobic bacteria but are aerotolerant due, at least in part, to high NADH oxidase activity. They use soluble sugars as carbon and energy sources. Growing cells of *Brachyspira* species (*B. aalborgi* has not been investigated) consume low concentrations of oxygen via NADH oxidase and produce acetate, butyrate, H_2 and CO_2 from glucose. Some species also produce ethanol. *Brachyspira* DNAs have a low G+C content (24.5–26.7 mol%; undetermined for *B. aalborgi*). *Brachyspira* species have high 16S rDNA sequence similarities with each other. *Brachyspira* strains have been assigned to eight electrophoretic type (ET) groups based on multilocus enzyme electrophoresis (MEE) analysis. The MEE groups correspond to seven species as defined from DNA homology studies and one currently uncharacterized provisional species ("*B. canis*"). Uncharacterized intestinal spirochetes of chickens are likely to represent a new *Brachyspira* species, "*B. pulli*" (Gabe et al., 1998; Stephens and Hampson, 2001). It has been recommended that uncharacterized/uncultured spirochetes from the human intestine be named "B. christiani" (Jensen et al., 2001).[1]

Brachyspira Species

There are seven recognized species of the genus *Brachyspira* (Table 1). The species *B. hyodysenteriae*, *B. pilosicoli*, *B. alvinipulli* and *B. intermedia* have been shown to cause disease when inoculated as pure cultures into their healthy, natural hosts. The type strain of each species is available from the American Type Culture Collection (ATCC; Table 1) and these strains should be included in studies of *Brachyspira* species.

History of *Brachyspira* Taxonomy

In the past 25 years, there have been several taxonomic changes for spirochetes now assigned to the genus *Brachyspira*. Initially, the designation "*Treponema hyodysenteriae*" was applied to both pathogenic (strongly hemolytic) and nonpathogenic (weakly hemolytic) strains of intestinal spirochetes from swine. By analysis of DNA-DNA relative reassociation, Miao and colleagues found that these pathogenic and nonpathogenic strains share only 28% sequence homology (Miao et al., 1978). This low sequence homology led to the reclassification of the nonpathogenic strains as a new species, *Treponema innocens* (Kinyon and Harris, 1979). In 1991, Stanton and colleagues proposed a reclassification of *T. hyodysenteriae* and *T. innocens* to a new genus "*Serpula*" based on 16S rRNA sequence analysis, DNA-DNA relative reassoci-

[1]The naming of uncharacterized/uncultured brachyspires is scientifically imprudent, even as a temporary precedent to proper taxonomic studies. It can become detrimental to future scientific communication. The practice is not a substitute for phenotypic and genotypic analyses of these marvelous spirochetes and should be avoided.

ation (S1 nuclease method), protein electrophoretic profiles, and genomic DNA restriction endonuclease analysis (Stanton et al., 1991). The genus name *Serpula* was then changed to "*Serpulina*" after it was determined that *Serpula* had prior use as a name for a genus of fungi (Stanton, 1992). Most recently, Ochiai et al. (1997) proposed the unification of the genera *Serpulina* and *Brachyspira*. The genus name *Brachyspira* was first given to a human intestinal isolate, *Brachypsira aalborgi*, in 1982 (Hovind-Hougen et al., 1982). Owing to the use of the genus name *Brachyspira* prior to the genus designation *Serpulina*, this proposed change is consistent with international taxonomic rules governing bacterial nomenclature and should be followed. Unfortunately, at the same time, the action has raised *Brachyspira aalborgi* to the status of type species of the genus *Brachyspira*. Unlike strains of the other *Brachyspira* species (especially *hyodysenteriae* and *pilosicoli*), only strain 513A^T of *B. aalborgi* has undergone a very limited characterization (Hovind-Hougen et al., 1982; Ochiai et al., 1997). More extensive biochemical, physiological and genetic investigations of this species are clearly needed. *Brachyspira aalborgi* is currently considered a commensal species of the human intestinal microbiota. Finally, in older literature references, the species *B. pilosicoli* was given the provisional designation "*Anguillina coli*" (Lee et al., 1993b; Park et al., 1995).

Multilocus Enzyme Electrophoresis (MEE) Analysis

MEE analysis is a useful molecular typing technique for differentiating, identifying and determining phylogenetic relationships of taxonomically related bacteria and for determining their phylogenetic relationships (Selander et al., 1986). Based on MEE analysis of 15 constitutive enzymes, Hampson and colleagues (Lee et al., 1993a; Lee et al., 1993b; Lee et al., 1993c; Lee and Hampson, 1994; Swayne et al., 1995; Trott et al., 1996a) have assembled hundreds of intestinal *Brachyspira* strains into MEE groups (Stanton et al., 1996; Duhamel et al., 1998). The DNA homologies between strains in different MEE groups range from 21 to 64% and the homologies between strains within the same MEE group are 78% or greater (Stanton et al., 1991; Stanton et al., 1997b; Stanton et al., 1998; Trott et al., 1996c). The recommended phylogenetic definition of a species includes strains with 70% or greater DNA-DNA relatedness and with 5°C or less ΔT_m (Wayne et al., 1987). Thus, the MEE technique can be used for the presumptive identification of *Brachyspira* species and for predicting new species. The single best "stand alone" technique for confirmed identification of a new

Table 1. *Brachyspira* species, pathogenicity, and animal hosts.

Species	Type strain	ATCC number	Intestinal origin	Demonstrated pathogenicity (animal)[a]
B. hyodysenteriae	B78^T	27164	Swine and rheas	Yes (swine)
B. innocens	B256^T	29796	Swine	No
B. intermedia	PWS/A^T	51140	Swine and chickens	Yes (chickens)
B. pilosicoli	P43/6/78^T	51139	Swine, birds, dogs, humans, and nonhuman primates	Yes (swine) Yes (chickens)
B. murdochii	56-150^T	51254	Swine and rats	No
B. aalborgi	513A^T	43994	Humans	No
B. alvinipulli	C1^T	51933	Chickens	Yes (chickens)

[a]Pure cultures of either the type strain or other strains cause disease when inoculated into normal, healthy host animals.

Brachyspira species is DNA-DNA relative reassociation using the S1 nuclease method (Crosa et al., 1973; Grimont et al., 1980).

16S rDNA Sequence Analyses

Comparative analysis of 16S rDNA (rrs gene) sequences has played an essential role in establishing a phylogeny-based classification of the spirochetes (Paster and Dewhirst, 2000). Based on 16S rDNA sequence comparisons, the *Brachyspira* represent a distinct line in spirochete evolution (Paster et al., 1991; Stanton et al., 1991; Paster and Dewhirst, 1997). Consequently, 16S rDNA sequence determinations are important for classifying these enteric bacteria as spirochetes and for identifying them as members of the genus *Brachyspira* (Olsen et al., 2000).

Partial *rrs* sequences have been obtained for intestinal spirochetes from various animal hosts and humans (Hookey et al., 1994; Fellstrom et al., 1995; Pettersson et al., 1996; Stanton et al., 1996; De Smet et al., 1998; Kraaz et al., 2000). Intestinal spirochete dendrograms based on 16S rDNA sequence comparisons correlate with the genetic groupings based on MEE analysis (Stanton et al., 1996).

In view of the substantial *rrs* gene similarity among *Brachyspira* species (Table 2), it is recommended that new species be designated only after their phylogenetic relationships with known *Brachyspira* species are confirmed by additional techniques (Stanton et al., 1996). One additional method is MEE analysis (MEE analysis). Another method, the conventional "gold standard" technique for identification of bacterial species, is DNA sequence homology estimation (Wayne et al., 1987). For estimating DNA sequence homology, DNA-DNA relative reassociation using the S1 nuclease method with ΔT_m evaluation is recommended (Crosa et al., 1973; Grimont et al., 1980).

16S rDNA of Uncultured *B. aalborgi*-like Species

Recent studies suggest there are uncharacterized *Brachyspira* species phylogenetically more closely related to *B. aalborgi* than to *B. hyodysenteriae* (Pettersson et al., 2000). *Rrs* genes were amplified from unknown bacteria within colonic biopsy samples of two human patients. Seventeen spirochetal-like sequences resembled those of *B. aalborgi*. Three clusters of sequences could be differentiated. One contained the two cultivated strains of *B. aalborgi*. Although only 0.5–1.3% of the 16S rDNA sequence is different between clusters, this same level of sequence difference exists between different *Brachyspira* species (Table 2). Thus, the strains more than likely represent one or two new *Brachyspira* species (Pettersson et al., 2000).

By contrast to these studies analyzing almost complete 16S rRNA sequences of intestinal spirochetes, other investigators have relied on sequences of short sections (i.e. 433 bp and 241bp) of 16S rRNA genes for the identification of *Brachyspira aalborgi* strains (Koteish et al., 2003; Munshi et al., 2003). The highly conserved nature of the16S rRNA sequences of known *Brachyspira* species and the potential diversity of human intestinal spirochetes make these identifications, at best, presumptive. Important in determining the significance of intestinal spirochetes to human health will be the characterization of the HIS-specific spirochetes in pure culture.

23S rDNA Sequence Analysis

Approximately 2,470-bp of the 23S rDNA genes of *B. hyodysenteriae*, *B. innocens*, *B. intermedia*, *B. murdochii* and *B. pilosicoli* strains have been sequenced (Leser et al., 1997). The 23S rDNA sequences are highly (96.8–99.8%) similar. A phylogenetic tree based on sequence comparisons is consistent with 16S rDNA-based and MEE-based comparisons of these species. Various *Brachyspira* species can be differentiated by 23S rDNA-targeted polymerase chain reaction (PCR) assays (Leser et al., 1997) or by PCR-restriction fragment length polymorphism (RFLP) analysis of 23S rRNA genes (Barcellos et al., 2000).

Habitat

Brachyspira species colonize the lower intestinal tracts (ceca and colons) of animals and humans. *Brachyspira pilosicoli*, *B. aalborgi*, *B. hyodysenteriae* and *B. alvinipulli* have been observed in close physical proximity to epithelial tissues lining the intestinal tract. Intestinal mucus secreted by goblet cells is likely to be important both as a physical matrix and as chemical substrate for these spirochetes in their microhabitats. Various cell traits are considered or have been demonstrated to be important for *Brachyspira* to colonize the intestinal tract (see Ecology; Disease).

Cells of *B. pilosicoli*, a species isolated from various animal hosts, and *B. aalborgi*, a species so far isolated only from humans, can colonize intestinal mucosal surfaces by attaching to enterocytes (Barrett, 1997; Swayne and McLaren, 1997; Taylor and Trott, 1997; Mikosza et al., 1999; Jensen et al., 2000). One end of the spirochete cell attaches to an epithelial cell and the other end extends away from the surface of the epithelial cell (Fig. 2). Densely packed,

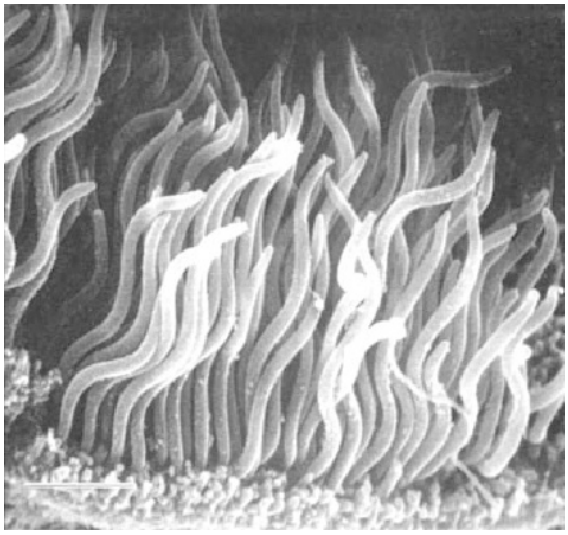

Fig. 2. Scanning electron micrograph of the colonic mucosa of a pig with colitis showing the typical appearance of intestinal spirochetosis. Epithelial cells are extensively colonized by spirochetes attached by one end to the luminal surface of the cells. Marker bar = 2 μm. From Sellwood and Bland (1997), with permission.

parallel arrays of spirochetes in close proximity form on the epithelial surface in this way. The density of spirochetes in these assemblages is estimated to be 20–80 spirochete cells per enterocyte (Stanton, 1997a). Although end-on attachment is a characteristic feature of *B. aalborgi* and *B. pilosicoli* colonization, it may not be a sine qua non for colonization and disease (Thomson et al., 1997; Jensen et al., 2000).

End-on attachment to intestinal tissues by densely packed, parallel arrays of *B. pilosicoli* or *B. aalborgi* cells creates the appearance of a "false brush border" on mucosal epithelial cells. This appearance of colonizing spirochetes has been commonly referred to as "intestinal spirochetosis" by histologists (Duhamel, 1997a; Swayne and McLaren, 1997). Intestinal spirochetosis has been observed in tissue sections both of healthy animals and humans and of individuals with intestinal disorders. Takeuchi and Zeller (1972) estimated that unidentified spirochetes attached to rhesus monkey colonic mucosa were present at a density of 1,800 bacteria·mm^{-2}. So far, *B. pilosicoli* and *B. aalborgi* are the only characterized spirochetes associated with intestinal spirochetosis.

Attachment to intestinal tissues is not a colonization feature of *B. hyodysenteriae*, the agent of swine dysentery, or of *B. alvinipulli*, a chicken pathogen. In the early stages of swine dysentery, *B. hyodysenteriae* cells first colonize along the intestinal epithelium of the swine cecum and colon and then among epithelial cells and within goblet cells (Glock et al., 1974; Kubo et al., 1979; Kennedy et al., 1988). As the disease progresses, lesions appear in the mucosa at sites of spirochete colonization, and host blood passes into the intestinal lumen through the lesions (Glock et al., 1974; Kennedy and Strafuss, 1977; Kubo et al., 1979). *Brachyspira alvinipulli* strain C1^T cells colonize chicken ceca and colons by irregular cell aggregates adjacent to intestinal epithelial cells and within villus crypts (Swayne et al., 1995; Swayne and McLaren, 1997; Stanton et al., 1998).

Microhabitats have yet to be extensively studied for *B. innocens*, *B. intermedia*, and *B. murdochii*.

Isolation

Physical Isolation Methods

In the first studies to identify *B. hyodysenteriae* as the etiologic agent of swine dysentery, the spirochete was isolated from dysenteric pigs after filtering colon contents through a 0.65 μm filter (Taylor and Alexander, 1971) and colonic epithelial tissue extracts through a series of filters of decreasing pore size (Harris et al., 1972b). The filtrates were inoculated onto agar media and incubated anaerobically to obtain isolated colonies.

Another physical isolation method takes advantage of bacterial motility to separate *Brachyspira* strains from nonmotile intestinal bacteria (Olson, 1996). Sterile scalpels are used to cut parallel lines in a selective agar medium containing spectinomycin (400 μg/ml). Intestinal samples are inoculated as streaks in the center of the Petri plates and perpendicular to the cut lines. The motile *B. hyodysenteriae* cells (strongly hemolytic) and cells of other intestinal spirochetes (weakly or nonhemolytic) migrate along the lines. The spirochetes can be isolated from agar medium samples taken at the ends of the cut lines and away from the original inoculation site.

Selective Culture Media

Brachyspira hyodysenteriae and other *Brachyspira* species can be isolated by inoculating intestinal contents or tissues onto solid agar culture media containing antibiotics selective for the growth of those spirochetes (Table 3). Achacha and Messier (1992) compared various selective media and found BJ medium (Table 3) with five antibiotics provided the highest rate of isolation of *B. hyodysenteriae* from feces of experimentally infected swine (130 of 145 samples tested). They also reported the encouraging observation that pig feces extract could be eliminated from

Table 3. *Brachyspira* culture media.

Values in table are final concentration (v/v or w/v). Antibiotic concentrations expressed as μg/ml of medium.

the medium with essentially no effect on isolation success (128 of 145 samples tested).

Brachyspira species other than *B. hyodysenteriae* can be isolated from swine, other animals, and humans by using selective culture media similar, if not identical, to those used for *B. hyodysenteriae* (Barrett, 1997; Jensen, 1997; Table 3). A note of caution is that antibiotics used to select for *B. hyodysenteriae* growth may select against growth of strains of certain *Brachyspira* species, such as *B. aalborgi* (Kraaz et al., 2000) and *B. pilosicoli* (Trott et al., 1996b). Selective culture media to directly isolate *B. aalborgi* from human feces have been described (Brooke et al., 2003; Calderaro et al., 2003). The media appear promising but so far have been used successfully for samples from only two patients.

Sample Handling, Inoculation, and Incubation Conditions

Brachyspira cells are aerotolerant anaerobes. *Brachyspira hyodysenteriae* strain B204 cells can withstand exposure to air for two or more hours (Stanton et al., 1999b). Nevertheless, whenever possible, intestinal contents or tissue samples should be protected from air exposure (for example, placed in anaerobic culture broth) and maintained on wet ice for transport to the laboratory. Swab samples of feces should be kept moist in a transport medium.

Brachyspira colonies can be isolated from intestinal samples by standard streaking methods using sterile inoculating loops to dilute bacterial cells across agar plate surfaces. Alter-

natively, serial tenfold dilutions of the samples can be made in tubes containing prereduced (oxygen-free) sterile basal culture broth (e.g., trypticase soy or brain heart infusion) and by spreading samples across the surface of agar plates. The latter technique, of course, enables viable colony forming units (CFU) in the original sample to be estimated.

Owing to their aerotolerant nature, preliminary steps in the isolation of known *Brachyspira* species (streaking agar plates and diluting samples) can be carried out on the lab bench (in an air atmosphere). Inoculated agar plates are incubated under anaerobic conditions by placing them within an anaerobic glove box or within anaerobic Gas-Pak jars. To further reduce exposure of *Brachyspira* cells to oxygen, intestinal samples can be transferred into an anaerobic glove box and all subsequent processing of samples carried out within the anaerobic atmosphere.

Brachyspira pilosicoli from Blood

Brachyspira pilosicoli strains have been isolated from the blood of critically ill human patients without the use of selective agar medium (Trott et al., 1997b). Cells of the spirochete were cultured from blood samples inoculated into Hemoline blood culture medium (bioMerieux, Lyon, France), BioArgos Sanofi diagnostic anaerobic medium (Pasteur Institute, Paris, France) and ESP automated blood culture media (Becton Dickinson Difco, Detroit, Michigan, United States). A study comparing various commercial blood culture systems indicated that prolonged culture incubation (5–14 days) is necessary to detect *B. pilosicoli* cells (Brooke et al., 2000).

Alternative Isolation Techniques

With few exceptions, isolation techniques for *Brachyspira* have revolved around selective culture media containing antibiotics and developed to clinically detect *B. hyodysenteriae*. These methods have led to the successful isolation of seven different *Brachyspira* species. It seems likely that the use of alternative sources of inocula, the modification of medium components and incubation conditions, and the incorporation of physical separation techniques will yield additional *Brachyspira* species.

Identification of Species

Various phenotypic characteristics and PCR based tests are useful for identifying known *Brachyspira* species (Table 2). "Strong" hemolysis of *B. hyodysenteriae* colonies and a unique signature sequence in the 16S rDNA of *B. pilosicoli* are often used in clinical and epidemiological studies to identify those pathogens.

Colony Hemolysis

Brachyspira hyodysenteriae is the only recognized *Brachyspira* species that is "strongly hemolytic" (Table 2). Colonies of *B. hyosysenteriae* form zones of β-hemolysis on trypticase soy-blood agar plates. Diagnosis of the disease swine dysentery is based on culturing of spirochete-like bacteria forming strongly hemolytic colonies and on histological evidence of spirochete-induced lesions in the ceca and colons of dysenteric swine. Well-isolated colonies on freshly prepared blood agar plates should be examined to assess hemolysis type of an intestinal spirochete. Control cultures of *Brachyspira*-specific type strains should be included for hemolysis comparisons.

Cell Ultrastructure

The number of flagella per cell has been commonly used in spirochete taxonomy and identification. *Brachyspira* species can be divided into two groups based on flagellar numbers and cell size (Table 2). Larger size species, such as *B. hyodysenteriae*, *B. innocens*, *B. intermedia*, *B. murdochii* and *B. alvinipulli*, have 20–30 flagella per cell. *Brachyspira pilosicoli* and *B. aalborgi* cells are shorter in length and have 8–12 flagella per cell. As with other spirochetes, the flagella attach in roughly equal numbers at each end of the cell (Fig. 3) and wind around the spirochete cell between the protoplasmic cylinder and outer sheath, and their free ends overlap in the cell center. Accurate estimates of flagellar numbers can be obtained by transmission electron microscopy of bacteria suspended in distilled water and negatively stained (e.g., 2% phosphotungstic acid, pH 7.0). Both flagella and flagellar attachment sites at the ends of the cells can be counted (Fig. 3).

Biochemical Tests

Biochemical tests for indole production (Finegold and Martin, 1982), hippurate hydrolysis (Smibert and Krieg, 1981), and commercial assay kits, such as API-ZYM (Hunter and Wood, 1979; Fellstrom et al., 1999; Stanton et al., 1998), have been used to characterize *Brachyspira* species (Table 2). For *B. aalborgi* and *B. alvinipulli*, only a limited number of strains have been examined.

Attempts have been made to classify porcine *Brachyspira* isolates based on hemolysis pattern, indole production, hippurate hydrolysis, colorimetric tests for sugar hydrolyzing enzymes, and pathogenicity for swine (Fellstrom et al., 1995;

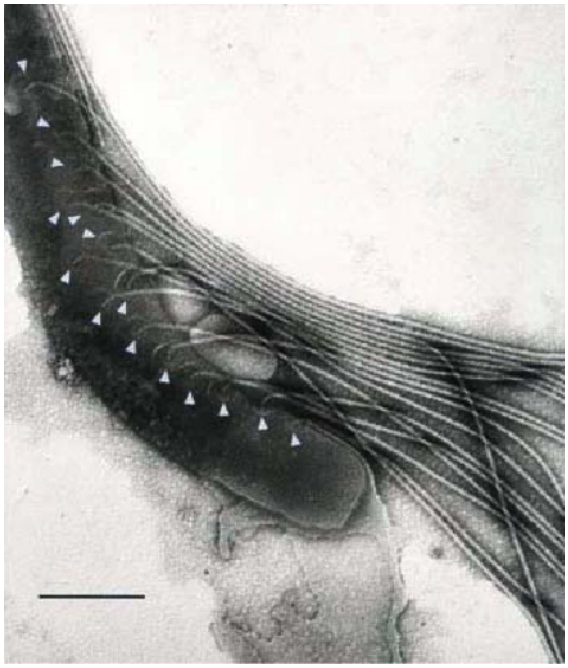

Fig. 3. Electron micrograph of one end of *B. alvinipulli* $C1^T$ cell negatively stained with 2% phosphotungstic acid (pH 7.0). Disrupted outer sheath enables insertion sites of 15 periplasmic flagella to be seen (white arrowheads). Marker bar = 0.25 μm. From Stanton et al. (1998), with permission.

Fellstrom et al., 1997). Unfortunately, porcine strains with properties different from the expected test results have been identified (Fellstrom et al., 1997; Fellstrom et al., 1999). Additionally, the biochemical classification of *Brachyspira* species does not work when non-porcine strains are included (De Smet et al., 1998; Stanton et al., 1998). Many biochemical tests, such as the hydrolysis of a certain color-yielding substrate, rely on one or a few encoding genes and therefore do not provide an extensive phylogenetic basis for taxonomy.

Species-specific PCR-based Assays

PCR assays have been described for the specific detection of porcine strains of *B. hyodysenteriae* (Elder et al., 1994; Harel and Forget, 1995; Leser et al., 1997; Atyeo et al., 1998; Atyeo et al., 1999), *B. pilosicoli* (Park et al., 1995; Fellstrom et al., 1997; Leser et al., 1997; Muniappa et al., 1997; Atyeo et al., 1998), and *B. intermedia* (Leser et al., 1997). A restriction fragment length polymorphism (RFLP)-PCR assay targeting 16S rDNA was developed to differentiate the type strains of seven *Brachyspira* species (Stanton et al., 1998). Unfortunately, clinical isolates of weakly hemolytic spirochetes, *Brachyspira* stains, have restriction patterns that do not match those of the type strains (T. B. Stanton, unpublished observation). In addition, PCR assays targetting NADH oxidase and 16S rRNA genes have been developed to differentiate *Brachyspira* species and used to detect *B. aalborgi* and *B. pilosicoli* in human biopsy specimens (Atyeo et al., 1999; Mikosza et al., 1999; Mikosza et al., 2001). Also, PCR assays targeting 23S rDNA were developed to distinguish porcine strains of *B. hyodysenteriae*, *B. intermedia* (group II) and *B. pilosicoli* (group IV) (Leser et al., 1997). RFLP-PCR assays targeting genes encoding NADH oxidase or 23S rRNA have been developed to differentitate *Brachyspira* species (Barcellos et al., 2000; Rohde et al., 2002).

Investigations with additional strains of known *Brachyspira* species and partially characterized intestinal spirochete isolates ("*B. canis*") are needed to determine whether these assays or any PCR-based assays will suffice as an individual test for identifying *Brachyspira* species. At this time, a likely to be reliable approach for species detection and identification would incorporate a combination of PCR-based tests for more than one gene (Mikosza et al., 1999; La et al., 2003).

Establishing New *Brachyspira* Species

Based on investigations of known *Brachyspira* species (see Phylogeny and Taxonomy), a new *Brachyspira* species should be characterized by 16S rDNA sequence analysis or/and MEE analysis (preferably both) of multiple isolates. Isolates (one or more strains) forming a unique 16S rDNA branch or MEE electrophoretic type should be compared by DNA sequence homology (S1 nuclease method with ΔT_m estimates) with closely related *Brachyspira* species. Finally, the ultrastructural, cultural, and biochemical characteristics of a species help define its lifestyle and facilitate additional research. These should be determined.

Preservation and Transport of *Brachyspira* Cultures

Short-term Stock Cultures

Broth cultures of most *Brachyspira* species remain viable when stored at 5°C for short time periods of 1–2 weeks. These cultures can be used as "working" stock cultures to inoculate fresh cultures for experiments. Refrigerated cultures should be in the exponential phase of growth (for many strains, 2–4 × 10^8 cells/ml, direct microscope counts). Importantly, avoid exposing cultures to air. The junction between the culture

tube mouth and the rubber stopper corking the tube should be firmly sealed with stretchable yellow plastic tape (3M Scotch Brand #471) before storage. These working stock cultures should be transferred every two weeks. Long-term in vitro passage of strains (with possible loss of virulence) should be avoided by starting fresh working stock cultures from long-term stock cultures every several months.

Agar plate cultures of *B. hyodysenteriae* can be stored at room temperature in an anaerobic atmosphere for at least a week. The plates should be sealed (Parafilm, American National Can Inc.) to prevent desiccation. A slowly growing spirochete identified as *B. aalborgi* remained viable when kept at room temperature in an anaerobic jar for over 3 months (Kraaz et al., 2000).

Long-term Stock Cultures

For long-term storage of *Brachyspira* strains, the following method is recommended. *Brachyspira* cultures in the exponential phase of growth in broth media ($2–4 \times 10^8$ cells/ml) are harvested by centrifugation (15 min, 5,000*g*). The pelleted bacteria are resuspended at 50–100 times their original concentration in fresh sterile broth medium containing dimethyl sulfoxide (DMSO), 10% (v/v, final concentration). The concentrated cell suspension is dispensed into Nunc cryovials (0.5–1.0 ml/vial). The sealed vials are placed upright in a beaker containing enough 95% ethanol to equal the fluid level of the suspensions (and well below the tops of the cryovials). The ethanol bath is intended to provide a more uniform rate of freezing of the cells and, with the DMSO as a cryoprotectant, prevent ice crystals from damaging the bacteria. The beaker is placed in an ultracold freezer (–75°C). After 24 h, the frozen stock cultures are transferred to storage boxes in the freezer. After 7–10 d, one of the cryovials should be examined to insure recovery of contaminant-free *Brachyspira* cells. *Brachyspira* cells have remained viable in frozen stocks prepared in this way for over 15 years (T. B. Stanton, unpublished observations). Completely thawed stocks should not be re-frozen. However, it is often possible to subculture without thawing the frozen stocks, by scraping the surface of a frozen cell suspension with a sterile inoculation loop and inoculating fresh media with the ice scrapings. *Brachyspira hyodysenteriae* cultures also have been preserved by lyophilization (Stanton and Lebo, 1988).

Shipping Stock Cultures

Brachyspira strains can be successfully transported through the mail as frozen cell stocks on dry ice. Alternatively, agar plate cultures will survive shipment by express mail delivery, without the need for wet or dry ice. Within an anaerobic chamber, agar plates with visible colony growth are sealed shut with flexible film (Parafilm). Within the chamber, the plates are then double-sealed in two plastic bags (smaller bag within larger bag) using a heat seal device (Seal-a-Meal, Dazey Corp., Industrial Airport, KS), such as used for DNA-DNA membrane blot hybridizations, and placed in appropriate shipping containers. For overnight delivery, stoppered broth cultures can be sealed with plastic tape and mailed in special shipping containers. Appropriate government and private carrier regulations governing the packaging and shipping of bacterial cultures must be followed.

Physiology

Culture Broth Media

Various anaerobic, nutritionally complex broth media have been described for *Brachyspira* species (Stanton, 1997a). Brain heart infusion with serum (BHIS) broth and Kunkle's broth are commonly used for routine growth of *Brachyspira hyodysenteriae* (Table 3) (Kunkle et al., 1986; Stanton and Lebo, 1988). Both media support high growth yields of this species (10^9 to 4×10^9 cells/ml, direct microscope counts). In BHIS broth, the population doubling times for type strains of *B. hyodysenteriae*, *B. innocens*, *B. intermedia*, *B. murdochii* and *B. alvinipulli* are 2–4 hours (Table 3). *Brachyspira pilosicoli* P43/6/78^T has a doubling time of 1–2 hours. Incubation temperatures of 38–40°C (the swine body temperature is 39°C) are used for *Brachyspira*, and stirring of broth cultures (with magnetic stir bars) is important for optimum growth.

Heart infusion with serum (HS) broth for *Brachyspira* species (Table 3) requires added carbohydrates to support optimum growth yields of *Brachyspira* species. Consequently, HS broth is useful for identifying growth substrates (Table 4) and metabolic end products. Since animal serum contains glucose, a minimal serum concentration, i.e., one not limiting for growth, should be used in studies to identify growth substrates and products.

NT broth, a serum-free medium ultrafiltered (10,000 MW cutoff filter) to remove high MW proteins, supports *B. hyodysenteriae* growth (Humphrey et al., 1997). Cholesterol, an essential growth requirement for the spirochete, is added to the medium in place of serum. NT broth cultures of *B. hyodysenteriae* are used to purify the generalized transducing bacteriophage VSH-1 (Humphrey et al., 1997). (See Genet-

Abbreviations: NG, no detectable growth above background (medium without added substrate); and NT, substrate not tested.

[a]Based on growth studies with *B. hyodysenteriae* cultures in HS broth by Stanton and Lebo (1988); Trott et al. (1996); and Stanton et al. (Stanton et al., 1997b; Stanton et al., 1998). In those studies, additional substrates were found not to support growth of any species. Values in table refer to relative cell yields.

ics.) NT broth also may be useful for identifying and purifying extracellular (protein) products of *Brachyspira* spp.

The oxidation-reduction potential of broth cultures may be a controlling factor for *B. hyodysenteriae* growth (Stanton, 1997a). The spirochete can be difficult to culture in stringently prepared anaerobic broth media unless a small amount of air is introduced into the culture oxygen-free atmosphere (Stanton and Lebo, 1988). A simple method is to inject a volume of sterile air through the rubber stopper sealing a culture vessel so that the culture atmosphere contains 1% oxygen (e.g., 1% O_2:99% N_2). *Brachyspira hyodysenteriae* cells have been successfully cultured beneath an air atmosphere in large (i.e., 12 liter) volumes in a fermentor (Stanton and Jensen, 1993a; Mikosza et al., 1999). Alternatively, chemical reducing agents such as L-cysteine can be left out of the medium. *Brachyspira* species will not grow in tubes of media that have become oxidized (i.e., in which the resazurin indicator dye has become colored due to air exposure).

Fermentation and Growth Substrates

Potential fermentation substrates of *Brachyspira* spp. and unidentified intestinal spirochetes added to broth or solid agar media are identified as bona fide substrates when lower medium pH values (compared to medium without added substrate) result from spirochete growth (Kinyon and Harris, 1979; Jones et al., 1986; Tompkins et al., 1986; Ochiai et al., 1997). Fructose, galactose, glucose, lactose, maltose, mannose and trehalose are fermentation substrates for *B. aalborgi* 513A^T (Ochiai et al., 1997).

The sensitivity of medium pH changes for detecting *Brachyspira* growth substrates is questionable. Furthermore, fermentation substrates may not always correspond to carbon and energy sources used by bacteria for growth. A more definitive method for identifying growth substrates uses a culture medium, such as HS broth, in which *Brachyspira* growth is limited unless a carbon/energy source is added (Table 4).

In HS broth, *B. hyodysenteriae* B78^T, *B. innocens* B256^T, *B. intermedia* PWS/A^T, *B. murdochii* 56/150^T, *B. pilosicoli* P43/6/78^T and *B. alvinipulli* C1^T use for growth various monosaccharides, disaccharides, the trisaccharide trehalose, and amino sugars (Table 4). Other strains of these species use similar growth substrates (Stanton and Lebo, 1988; Trott et al., 1996b). None of the tested *Brachyspira* strains use polysaccharides such as cellulose, hog gastric mucin, pectin, glycogen and various other tested compounds. Growth substrates for *B. aalborgi* have not been identified in similar experiments.

Brachyspira hyodysenteriae and *B. innocens* strains contain a sucrase activity that increases 3- to 10-fold when sucrose is added to cultures (Jensen and Stanton, 1994). The sucrase is the

first inducible enzymatic activity to be identified for *Brachyspira* species.

Cholesterol and Phospholipids

Brachyspira hyodysenteriae requires cholesterol and phospholipid for growth (Lemcke and Burrows, 1980; Stanton and Cornell, 1987b; Stanton, 1997a). These requirements can be met by supplementing media with either cholesterol-phosphatidylcholine or erythrocyte membranes (Stanton and Cornell, 1987b). Cholesterol is likely required for outer membrane biosynthesis based on the following observations. Nutrient amounts of cholesterol (8–26 nmoles/ml culture broth) are sufficient for growth (Lemcke and Burrows, 1980; Stanton and Cornell, 1987b). *Brachyspira hyodysenteriae* cells incorporate radiolabel from [4-^{14}C] cholesterol into cell membrane fractions (Stanton, 1987a). Cholesterol preferentially locates within *B. hyodysenteriae* outer membranes (Plaza et al., 1997). The sterol requirement is unusual for a nonmycoplasma subgroup of bacterial species.

Brachyspira hyodysenteriae cellular fatty acids are distinct from those of *Borrelia* and *Leptospira* spirochetes (Livesley et al., 1993). *Brachyspira hyodysenteriae* and *B. innocens* cellular phospholipids and glycolipids were found to contain acyl (fatty acids with ester linkage) and alkenyl (unsaturated alcohol with ether linkage) side chains (Matthews et al., 1980a; Matthews et al., 1980b; Matthews and Kinyon, 1984). The culture medium for these spirochetes did not contain these same lipids, an indication that the bacteria have some capacity for fatty acid and lipid biosynthesis.

Intermediary Metabolism

Glucose and Pyruvate Metabolism Pathways of glucose and pyruvate metabolism have been analyzed extensively only for *B. hyodysenteriae* (Stanton, 1989; Stanton, 1997a). The endproducts of glucose metabolism by growing cells of numerous *Brachyspira* species are the same as those of *B. hyodysenteriae*—acetate, butyrate, H_2 and CO_2—suggesting these species have similar catabolic routes (Stanton and Lebo, 1988; Stanton, 1989; Trott et al., 1996d; Stanton et al., 1997b; Stanton et al., 1998).

Brachyspira hyodysenteriae uses the Embden-Meyerhof-Parnas (EMP) pathway for converting glucose to pyruvate (Fig. 4). Pyruvate is catabolized by a clostridial-type clastic reaction to acetyl-CoA, H_2 and CO_2. Acetyl-CoA is converted to either acetate or butyrate via a branched fermentation pathway. The ATP-yielding mechanisms are substrate-level phosphorylation reactions mediated by phosphoglycerate kinase and pyruvate kinase in the EMP pathway and by acetate kinase converting acetyl phosphate to acetate (Fig. 4).

NADH-H$^+$ Oxidation Reactions *Brachyspira hyodysenteriae* cells are versatile when it comes to NADH-H$^+$ oxidation reactions (Fig. 4). This versatility could enhance the metabolic fitness of the spirochete in its animal host (Thauer et al., 1977; Stanton, 1997a). The NADH-H$^+$ produced during glycolysis can be recycled or oxidized to NAD$^+$ by 3-hydroxybutyryl-CoA dehydrogenase and butyryl-CoA dehydrogenase (butyrate pathway), by NADH-ferredoxin oxidoreductase plus hydrogenase, and by NADH oxidase (Fig. 4).

Various *Brachyspira* species produce more H_2 than CO_2, indicative of the NADH-ferredoxin oxidoreductase reaction. Ethanol is produced in cultures of *B. pilosicoli*, *B. alvinipulli*, *B. murdochii*, *B. intermedia* and *B. innocens* (Stanton and Lebo, 1988; Stanton, 1989; Trott et al., 1996c; Stanton et al., 1997b; Stanton et al., 1998) and is likely formed from acetyl-CoA by the enzymes acetaldehyde dehydrogenase and alcohol dehydrogenase (Fig. 4).

NADH oxidase is widely distributed among *Brachyspira* species (Atyeo et al., 1999; Stanton et al., 1995). The *B. hyodysenteriae* NADH oxidase is a water-forming, FAD-linked enzyme (Stanton and Jensen, 1993b) and its gene (*nox*) has been cloned (Stanton and Sellwood, 1999a). *Nox*-defective mutant strains of *B. hyodysenteriae* are sensitive to oxygen (Ecology) and lose virulence (Stanton et al., 1999b; see Virulence).

Iron Metabolism

Several observations suggest that specific iron uptake mechanisms are present and are important for *Brachyspira* growth in animal hosts. *Brachyspira hyodysenteriae* cells grow in broth containing an iron chelator, 2,2′-dipyridyl, and increase the expression of three unidentified high molecular mass proteins, >200, 134, and 109 kDa (Li et al., 1995). Catechol and hydroxamate do not enhance *B. hyodysenteriae* growth in iron-depleted medium, suggesting the spirochete does not use these common bacterial siderophores to bind and take up iron. Dugourd and coworkers have identified a *B. hyodysenteriae* genome locus, designated *bit* ("*Brachyspira* iron transport"), encoding six proteins that are likely to form an iron ATP-binding transport system (Dugourd et al., 1999). BitD has ATP-binding motifs. BitA, BitB and BitC are lipoproteins with iron binding properties. BitE and BitF resemble membrane permeases. All of the Bit proteins are smaller in molecular mass (28–42 kDa) than are previously described iron-regulated proteins (Li et al., 1995).

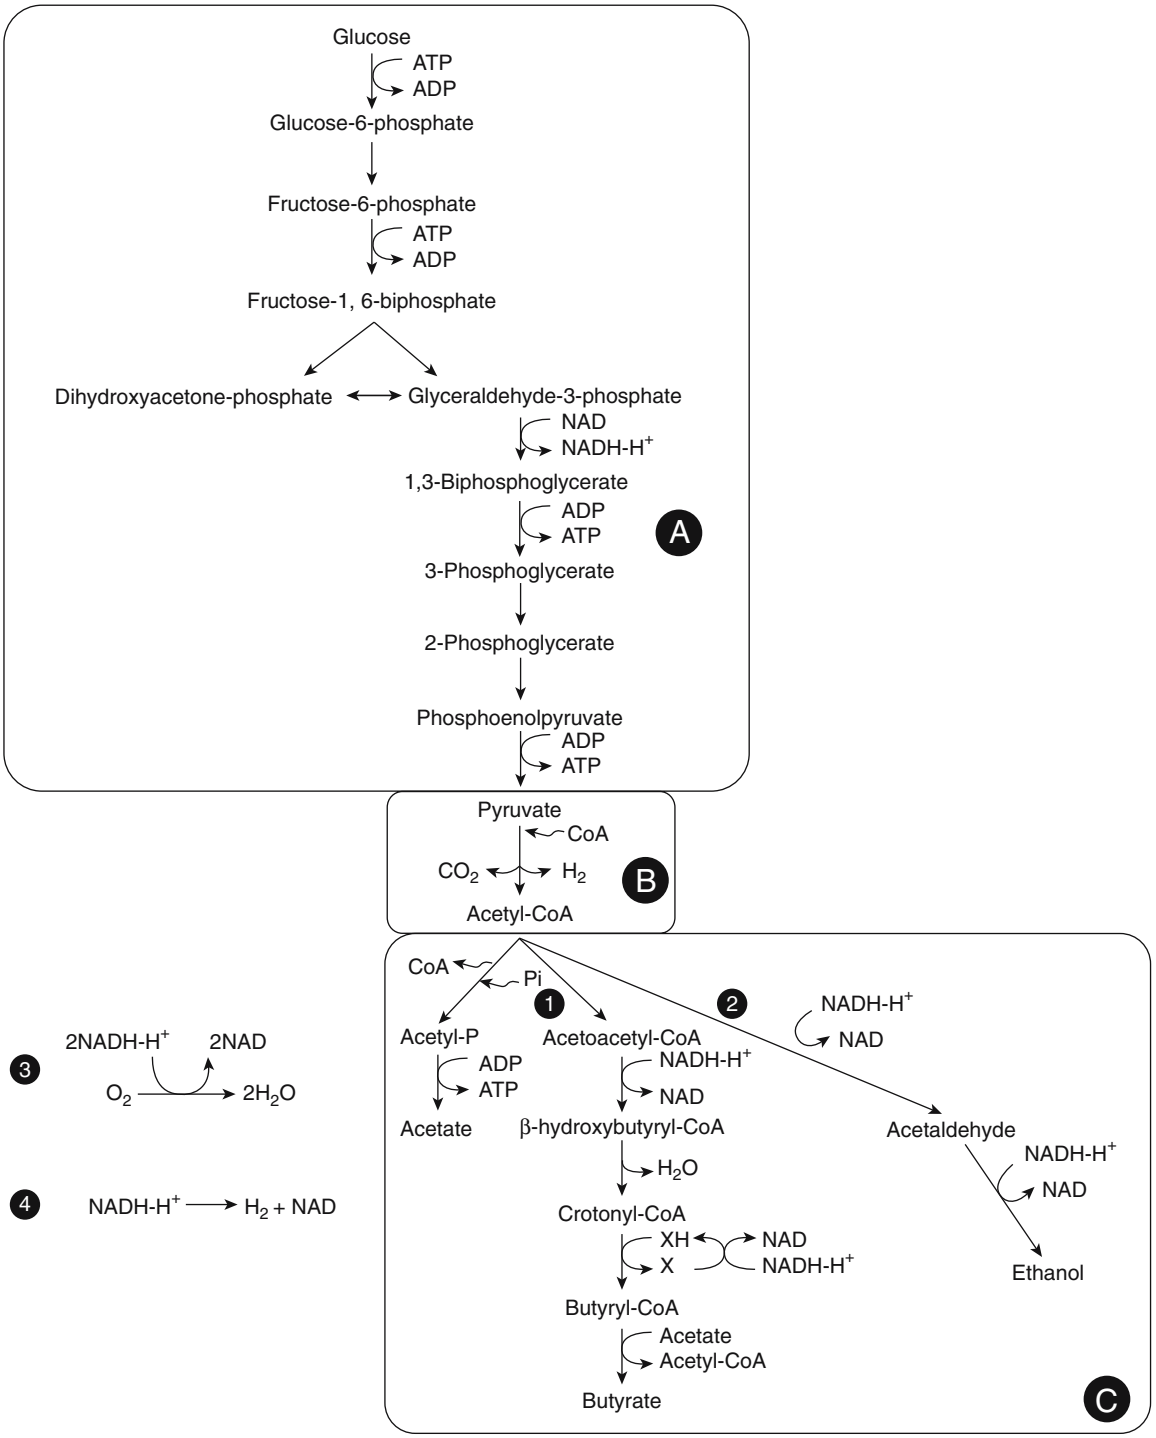

Fig. 4. Glucose metabolism by *Brachyspira* species. A) Glucose is converted to pyruvate by the Embden-Meyerhof-Parnas pathway. B) Pyruvate is metabolized by a clostridial-type clastic reaction. C) Acetyl-CoA is a branch point for pathways leading to acetate, butyrate, or ethanol. (Note: the pathway to ethanol has not been demonstrated.) NADH-H$^+$ is oxidized in the pathways to butyrate (1) and ethanol (2) and by two alternative mechanisms: NADH oxidase (3) and NADH-ferredoxin oxidoreductase coupled to hydrogenase (4) (Stanton, 1997a).

Genetics

Brachyspira Genes

Brachyspira genetics is at an early, promising stage of development (van der Zeijst and ter Huurne, 1997; Zuerner, 1997; Hardham and Rosey, 2000). Only a limited number of *Brachyspira* genes have been cloned and expressed as recombinant proteins (Table 5). *Brachyspira* genome libraries can be created by using *E. coli*-based vectors, primarily lambda phages and plasmids. An expression vector has been created that enables posttranslational processing of *B. hyodysenteriae* lipoprotein BlpA in *E. coli* and the incorporation of the protein into the *E. coli* outer membrane (Cullen et al., 2003). Cosmid cloning of *B. hyodysenteriae* DNA has generally been inefficient for unknown reasons (van der Zeijst and ter Huurne, 1997). Nearly complete 16S rRNA and 23S rRNA gene sequences are known for all *Brachyspira* species (Table 2) and are used for both taxonomic and clinical detection applications (See Phylogeny and Taxonomy and Identification).

Genome Properties

Unfortunately, no Brachyspira genome has yet been sequenced. A physical map of the *B. hyodysenteriae* B78^T chromosome is based on restriction enzyme fragments of the chromosome separated by pulsed field gel electrophoresis (PFGE) (Zuerner and Stanton, 1994). The *B. hyodysenteriae* chromosome is circular and has 3.2 Megabase pairs (Mbp), and the map (restriction fragment) locations are known for many *B. hyodysenteriae* genes (Zuerner and Stanton, 1994; Hsu et al., 2001; Zuerner et al., 2004). *Brachyspira pilosicoli* P43/6/78^T has a circular chromosome approximately 2.4 Mbp (Zuerner et al., 2004) and thus carrying substantially fewer genes than the *B. hyodysenteriae* chromosome. Rothkamp et al. (2002) recently cloned a putative *B. hyodysenteriae* phosphotransferase operon that was absent from *B. pilosicoli* and other *Brachyspira* species. Differences in gene content, organization, and regulation are likely to reflect differences in host range and disease capacities among the brachyspires. The physical and genetic maps of the genomes of *B. hyodysenteriae*, *Leptospira interrogans*, *Borrelia species*, *Treponema pallidum* and *T. denticola* reveal broad diversity among these spirochetes in terms of chromosomal conformation (linear and circular), chromosomal numbers (1–2), size (0.95–4.9 Mbp), and number and arrangement of rRNA genes on the chromosome (Zuerner, 1997).

Plasmids and Extrachromosomal DNA

Plasmids and extrachromosomal DNAs have been reported for various *Brachyspira* species (Combs et al., 1989; Turner and Sellwood, 1997; Cattani et al., 1998). Unfortunately, there is little information about these nucleic acids beyond their properties in electrophoretic gels. Plasmid DNA was not detected during the construction of a genomic map for *B. hyodysenteriae* B78^T (Zuerner and Stanton, 1994). In some reports (Combs et al., 1992; Turner and Sellwood, 1997), the characteristics of the plasmid/extrachromosomal DNAs resemble those of bacteriophage VSH-1 (virus of *Serpulina hyodysenteriae*; see Genetics). Some of the extrachromosomal DNAs could be DNA from VSH-1-like bacteriophage particles spontaneously produced in *Brachyspira* cultures.

Genetic Techniques

MUTAGENESIS The first isolation of a *B. hyodysenteriae* strain (mutated at a specific locus, *tlyA*) was reported in 1992 (ter Huurne et al., 1992b). The cloned *tlyA* gene, conferring a hemolytic phenotype in *E. coli* cells, was inactivated in vitro by inserting a gene encoding kanamycin resistance at a *BglII* site in the *tlyA* gene. This construct was then introduced as a plasmid into *B. hyodysenteriae* cells by electroporation. Mutant cells in which the kanamycin-resistant *tlyA* "knockout mutation" had undergone allelic exchange with the wild-type *tlyA* gene were selected by plating the bacteria on media containing kanamycin (ter Huurne et al., 1992b). With some further modifications, including the incorporation of another antibiotic selection marker (chloramphenicol), this technique has been used by other investigators to create *B. hyodysenteriae* strains with specific mutations in genes for flagellar proteins (Rosey et al., 1995; Li et al., 2000) and NADH oxidase (Stanton et al., 1999b).

The allelic exchange technique enables investigators to "custom design" *B. hyodysenteriae* strains, that is, to derive mutant strains that are isogenic to their progenitor strains, except for single genetic loci. Such strains are essential in determining bacterial virulence traits (See Disease).

Brachyspira hyodysenteriae mutant strains can be produced by exposure to UV light. Using UV mutagenesis, coumermycin A1-resistant *B. hyodysenteriae* strains with identifiable mutations in their *gyrB* (DNA gyrase subunit B) genes have been generated (Stanton et al., 2001). In addition to the kanamycin resistance and chloramphenicol resistance markers used for allelic exchange

mutagenesis, coumermycin resistance is a third antibiotic selection marker for genetic manipulations of *Brachsypira*. Some *B. hyodysenteriae* strains are resistant to the macrolide antibiotic tylosin, owing to a nucleotide base change in the 23S rDNA gene (Karlsson et al., 1999). Tylosin resistance can also be used as a selection marker for gene transfers in this species (T. B. Stanton, unpublished observations).

Bacteriophages and Generalized Transduction (VSH-1) When cultures are treated with mitomycin C, both *B. hyodysenteriae* and *B. innocens* cells lyse and release bacteriophage-like particles whose morphology is similar to, but smaller than, λ phage virions of *E. coli* (Humphrey et al., 1995). These virions resemble spontaneously appearing phages first detected by electron microscopy of *B. hyodysenteriae* cultures (Ritchie et al., 1978). A bacteriophage was purified from mitomycin C-treated *B. hyodysenteriae* cultures and named "VSH-1." The VSH-1 particles package random, 7.5-kB linear fragments of host DNA (Humphrey et al., 1997). The sequences of genes encoding several VSH-1 capsid head proteins have been deposited in GenBank (Table 5).

The significance of VSH-1 to *B. hyodysenteriae* genetics lies in its role as a gene vector. Purified from cultures of a chloramphenicol-resistant *B. hyodysenteriae* strain A203 (Δ*flaA1* 593:762::*cat*), VSH-1 virions will transfer chloramphenicol resistance to *B. hyodysenteriae* strain A216 (Δ*nox* 438-760::*kan*) (Humphrey et al., 1997). This is the first example of natural gene transfer for a spirochete and indicates that VSH-1 behaves like a generalized transducing bacteriophage. More significantly, it is not necessary to use purified VSH-1 particles for gene exchange. Coumermycin-resistant *gyrB* genes are transferred by spontaneously produced VSH-1 between two *B. hyodysenteriae* strains when the strains are cocultured (Stanton et al., 2001).

VSH-1 may also have ecological significance. Based on MEE analysis of 231 *B. hyodysenteriae* strains, Trott et al. (1997c) concluded that substantial genetic recombination had shaped the overall population structure of this spirochete. Virions of VSH-1 are logical vehicles for cell-to-cell gene transfer among *B. hyodysenteriae* strains.

Bacteriophages have also been detected in both mitomycin C-treated and untreated cultures of weakly hemolytic intestinal brachyspires from humans and animals (Calderaro et al., 1998a; Calderaro et al., 1998b; Stanton et al., 2003). These bacteriophages should be examined for gene transduction capabilities similar to those of VSH-1.

Ecology

General Concepts

Brachyspira natural habitats are animal intestinal tracts. The species *B. hyodysenteriae*, *B. pilosicoli*, *B. aalborgi* and *B. alvinipulli* colonize the mucosal epithelial surfaces of the cecum and colon (See Habitat). *Brachyspira pilosicoli* and *B. aalborgi* have been observed attached to intestinal enterocytes (Fig. 2) whereas *B. hyodysenteriae* and *B. alvinipulli* colonize over, among, and perhaps within intestinal epithelial cells.

To be successful intestinal colonizers, all *Brachyspira* species must survive passage between hosts, reach suitable intestinal sites, establish dividing cell populations at those sites, and persist at least long enough to allow exiting cells to colonize other hosts. Additionally, the pathogenic *Brachyspira* species inflict damage on host tissues. *Brachyspira* ecology, knowledge of the interactions of these spirochetes with the living and nonliving components of their environment, has arisen from investigations of virulence-associated traits of the pathogenic species (Disease). Nevertheless, some of these virulence-associated traits are undoubtedly also colonization factors shared by nonpathogenic *Brachyspira* species. These colonization traits are discussed below.

Chemotaxis and Motility

The intestinal mucosal epithelium is covered with a layer of mucus, a barrier to bacterial colonization (Savage, 1980; Forstner et al., 1984). *Brachyspira* species, whether or not they attach to the underlying epithelial cells, transit and populate this mucus blanket. The ability to swim in environments of high viscosity, such as mucous gels, and the ability to be attracted to mucus components or compounds diffusing from the underlying tissues are likely to be important adaptations for *Brachyspira* spirochetes (Canale-Parola, 1978; Holt, 1978; Kennedy et al., 1988; Milner and Sellwood, 1994; Kennedy and Yancey, 1996). *Brachyspira hyodysenteriae* cells are highly motile within mucus samples taken from dysenteric pigs and do not attach to intestinal epithelial cells (Kennedy et al., 1988). Cells of the pathogen are commonly observed in mucus-filled crypts of Lieberkuhn and within mucigen droplets of mucus-secreting goblet cells (Glock et al., 1974; Kennedy et al., 1988). In chemotaxis assays, *B. hyodysenteriae* cells are attracted to gastric mucin, the structural glycoprotein of mucus (Kennedy et al., 1988; Milner and Sellwood, 1994). Fucose and L-serine, chemical components of mucin, are strong chemoattractants (Kennedy and Yancey, 1996).

Oxygen Metabolism, Oxidative Stress, NADH Oxidase

Those *Brachyspira* species that have been studied are aerotolerant anaerobes. *Brachyspira hyodysenteriae* cells will grow in sealed culture vessels containing an initial atmosphere of 1% O_2 : 99% N_2 and will consume oxygen (Stanton and Lebo, 1988). Strains of *Brachyspira hyodysenteriae* and of other *Brachyspira* species contain the enzyme NADH oxidase at high levels of specific activity (Stanton et al., 1995). The *B. hyodysenteriae* NADH oxidase is a soluble, FAD-dependent, monomeric protein with a molecular mass of 47–48 kDa (Stanton and Jensen, 1993b).

NADH oxidase is considered to be a mechanism by which *B. hyodysenteriae* cells cope with oxygen in their native microhabitats, i.e., among the oxygen-respiring mucosal tissues of the swine intestinal tract (Stanton, 1997a; Stanton et al., 1999b). *Brachyspira hyodysenteriae nox*-deficient mutant strains are 100- to 10,000-fold more sensitive to oxygen exposure than are cells of an isogenic, wild-type strain (Stanton et al., 1999b). The mutant stains also are attenuated in virulence (See Disease). Protection from oxidative stress is an important factor in colonization of intestinal mucosal surfaces by *B. hyodysenteriae* cells. NADH oxidases are involved in protecting pathogenic *Streptococcus* species from oxidative stress and in achieving virulence (Gibson et al., 2000; Yu et al., 2001). *Brachyspira hyodysenteriae* has additional enzymes for protection against oxidative stress, namely, NADH peroxidase, superoxide dismutase, and catalase (Jensen and Stanton, 1993b; Stanton et al., 1999b).

Intestinal spirochete strains representing all seven *Brachyspira* species (Table 1) have NADH oxidase genes and the tested strains also contain significant NADH oxidase activity (Stanton et al., 1995; Atyeo et al., 1999). Neither swine intestinal spirochete *Treponema succinifaciens* 6091 nor bovine rumen spirochete *T. bryantii* RUS-1 has detectable NADH oxidase (Stanton et al., 1995).

Attachment to Tissues and Intestinal Colonization

Brachyspira pilosicoli and *B. aalborgi* spirochetes attach by one end to mature intestinal cells. Colonization in this manner leads to dense parallel assemblages of spirochetes (Fig. 2). In histological examinations of sectioned intestinal tissues, these assemblages give the appearance of a false brush border. This histological phenomenon, commonly referred to as "intestinal spirochetosis," is observed for both healthy and diseased humans and non-avian animal species (Taylor and Trott, 1997). It should be noted that the term "avian intestinal spirochetosis" (AIS) has been given to intestinal disorders of poultry associated with spirochetes regardless of whether the spirochetes are attached or not attached to intestinal tissues (Swayne and McLaren, 1997; Swayne, 2002).

For so elegant an example of prokaryotic-eukaryotic cell interactions, the mechanisms and significance of *Brachyspira* end-on attachments are disappointingly understudied. The polar attachment of *B. pilosicoli* cells to cecal enterocytes in one-day-old chicks currently provides the most practical experimental model for these investigations (Trott et al., 1995; Muniappa et al., 1998). Lattice-like structure (Sellwood and Bland, 1997) and surface, ring-like structures (Muniappa et al., 1998) observed at the tips of *B. pilosicoli* cells may be involved in attachment to the enterocytes.

Intestinal spirochetosis occurs in tissues from both healthy animals and animals with intestinal disorders (Takeuchi and Zeller, 1972; Neutra, 1980; Ruane et al., 1989; Barrett, 1997; Duhamel et al., 1997b). In swine this appearance is associated with *B. pilosicoli*-induced colitis (Taylor and Trott, 1997; Hampson and Trott, 1999b). In humans both *B. pilosicoli* and *B. aalborgi* can be detected in rectal biopsy samples where intestinal spirochetosis is identified (Hovind-Hougen, 1982; Trivett-Moore, 1998; Mikosza, 1999; Kraaz, 2000; Mikosza, 2001). Fluorescent oligonucleotide probes can be used to identify *Brachyspira* species among swine intestinal tissues (Jensen et al., 2000). This fluorescent in situ hybridization (FISH) technology will undoubtedly be important for the confirmed identification of spirochetes attached to cecal and colonic tissues.

Brachyspira aalborgi and *B. pilosicoli* may not be the only spirochete species capable of end-on attachment to enterocytes. Intestinal spirochetes attached to the rectal mucosa of humans (Neutra, 1980) and rhesus monkeys (Takeuchi and Zeller, 1972) are larger in cell diameter (0.5 μm) than cells of *B. aalborgi* (0.2 μm) and *B. pilosicoli* (0.3 μm) (Sellwood and Bland, 1997). *Brachyspira*-like spirochetes also colonize by end-on attachment to the cecal mucosal tissues of guinea pigs with typhlitis (Vanrobaeys et al., 1998). Other than *B. aalborgi* and *B. pilosicoli*, none of these attached spirochetes has been isolated.

Survival Outside the Host

An important aspect of the transmission of any host-associated bacterium is the ability to survive outside the host species. *Brachyspira hyodysenteriae* cells at concentrations sufficient to induce swine dysentery will survive up to a week in

lagoon water used to clean swine buildings (Olson, 1995). *Brachyspira* pilosicoli cells survive in lake water for 66 days at 4°C (Oxberry et al., 1998). In laboratory studies, *B. hyodysenteriae* cells remain viable in diluted feces stored at 5°C for up to 60 days (Chia and Taylor, 1978). Pure cultures of *B. hyodysenteriae* and *B. pilosicoli* added at high concentrations (>10^9 cfu/gm) to swine feces or a 10:90 mix of feces and soil and stored at 10°C remain viable for 78–210 days (Boye et al., 2001). Environmental factors such as humidity and temperature undoubtedly affect survival. *Brachyspira* bacterial traits involved in survival have not been identified.

Epidemiology

Subspecies Identification

Serotype Analysis *Brachyspira hyodysenteriae* strains can be subdivided into serotypes based on the immunological reactivities of lipo-oligosaccharides (LOS) in hot water-phenol extracts of whole cells (Baum and Joens, 1979; Li et al., 1991). A more elaborate system of immunological identification assigns *B. hyodysenteriae* strains to serogroups and subdivides the groups into serovars (Hampson et al., 1989; Hampson et al., 1997; Lau and Hampson, 1992). This system has not been widely adopted because serogroups are not entirely consistent with genetic groupings based on MEE analysis (Lee et al., 1993a; Trott et al., 1997c). Enzyme-linked immunosorbent assay (ELISA) methods based on antibodies to LOS have been used to detect animal herd exposure to *B. hyodysenteriae* strains (Joens et al., 1982; Wright et al., 1989).

Differentiation Based on Gene and Genome Differences Several methods for differentiating strains of uncharacterized intestinal spirochetes and strains within the species *B. hyodysenteriae* or *B. pilosicoli* take advantage of DNA sequence differences. Sequence differences have been directly detected through restriction endonuclease analyses of genomic DNAs either with or without hybridization with specific gene probes (Combs et al., 1992; ter Huurne et al., 1992a; Koopman et al., 1993a; Harel et al., 1994; Atyeo et al., 1996; Rayment et al., 1997; Fellstrom et al., 1999).

Multilocus enzyme electrophoresis (MEE) analysis is useful for determining genetic relationships among intestinal spirochetes at the species level for taxonomy. The technique can also be used to differentiate *B. hyodysenteriae* or *B. pilosicoli* at the subspecies level for epidemiological purposes (Lymbery et al., 1990; Oxberry et al., 1998; Trott et al., 1998).

Brachyspira Population Structure

Trott and colleagues investigated the genetic diversity of 231 *B. hyodysenteriae* isolates by MEE (Trott et al., 1997c). The electrophoretic profiles of 12 out of 15 tested enzymes were used to identify 50 different electrophoretic types among the isolates. Based on the findings, *B. hyodysenteriae* appears as a genetically diverse species with an epidemic population structure. Substantial genetic recombination likely has shaped the population structure of the species. Generalized gene transduction by VSH-1 (see Genetics) could play a role in this natural genetic recombination (Trott et al., 1997c; Stanton et al., 2001). *Brachyspira hyodysenteriae* population structure and epidemic clones may result from disease control measures and animal management practices, including antibiotic use (Trott et al., 1997c; Fellstrom et al., 1999).

Based on both MEE and PFGE methods, population analyses of *B. pilosicoli* from indigenous peoples of villages in Papua, New Guinea, suggest a recombinant structure also for that spirochete (Trott et al., 1998). Thus far, assays to differentiate *B. pilosicoli* strains originating from different host species indicate a high diversity of genotypes for this spirochete, making it difficult to conclude that zoonotic transmission of the pathogen to humans occurs (Rayment et al., 1997; Trott et al., 1997c), although this remains a possibility.

Disease

Brachyspira hyodysenteriae, *B. pilosicoli*, *B. intermedia* and *B. alvinipulli* cause intestinal disease when inoculated into their normal, healthy host animals (Table 1). *Brachyspira hyodysenteriae*, the etiologic agent of swine dysentery, has been investigated for several decades, whereas the other two species were identified and have been studied only over the last few years. Thus, most disease-related research on *Brachyspira* has focused on *B. hyodysenteriae*.

Several recent publications extensively describe *Brachyspira* diseases from the viewpoint of host manifestations, clinical detection methods, therapies, and experimental models (Barrett, 1997; Galvin et al., 1997; Hampson et al., 1997; Swayne and McLaren, 1997; Taylor and Trott, 1997; Hampson and Trott, 1999b; Harris et al., 1999; Swayne, 2002; Stephens and Hampson, 2001). Published research papers from the recurrent International Conference on Colonic Spirochaetes also provide topical information on these subjects.

Swine Dysentery (*B. hyodysenteriae*)

Swine dysentery (bloody scours or black scours) is a severe intestinal disease that affects piglets, primarily in the postweaning stage of growth (8–14 weeks after birth). The disease has been reported worldwide in every major pig producing country. A typical sign of the disease is profuse bleeding into the large bowel lumen through lesions induced by *B. hyodysenteriae* cells. Afflicted animals pass loose stools containing blood and mucus and microscopically visible spirochetes. These are presumptive signs of the disease. Culturing and identifying *B. hyodysenteriae* cells, along with histopathological observations, provide conclusive evidence of swine dysentery. Up to 90–100% of a herd can become infected, and without effective treatment, 20–30% of infected animals may die. Economic losses result from death, poor weight gain/feed efficiency, and medication expenses. Swine management strategies, including segregation by age and prophylactic administration of antibiotics, are believed responsible for a reduction in swine dysentery in the United States in recent years.

Swine dysentery is easily produced by feeding or intragastrically inoculating normal swine with *B. hyodysenteriae* cultures (Kinyon et al., 1977; Kennedy et al., 1988; Stanton and Jensen, 1993a). However, the type strain B78^T of *B. hyodysenteriae* is weakly virulent and should not be used in experimental infections (Jensen and Stanton, 1993a).

Various approaches have been used to develop whole cell or cell subunit-based vaccines for swine dysentery (summarized in Lee et al., 2000). One commercial vaccine for swine dysentery is based on pepsin-digested *B. hyodysenteriae* cells (Intervet, Akzo Nobel, DeSoto, KS). The immunological properties of the vaccine are now being examined (Waters et al., 2000).

Brachyspira hyodysenteriae has a limited host range. Swine are the common, but not the exclusive, hosts. Strains of the spirochete also have been isolated from juvenile rheas with a severe necrotizing typhlitis (Sagartz et al., 1992; Jensen et al., 1996; Buckles et al., 1997). Mice (Joens and Glock, 1979; Nibbelink and Wannemuehler, 1992; ter Huurne et al., 1992b; Rosey et al., 1996) and one-day-old chicks (Sueyoshi and Adachi, 1990) have been used in experimental infections. Nevertheless, nuances or inconsistencies are associated with the use of these surrogate animal models (Jensen and Stanton, 1993a; Achacha et al., 1996). For this reason, conclusions regarding *B. hyodysenteriae* pathogenesis based on mouse or one-day-old chick models should be confirmed through the use of swine infections.

Brachyspira hyodysenteriae Virulence Determinants

Several cell properties are putative or demonstrated virulence-associated traits of *B. hyodysenteriae*. They include the following: LOS in a mouse model (Nuessen et al., 1982; Nuessen et al., 1983; Greer and Wannemuehler, 1989; Nibbelink and Wannemuehler, 1991); hemolysin/hemolytic activity (Saheb et al., 1980; Saheb et al., 1981; Kent et al., 1988; Lysons et al., 1991; ter Huurne et al., 1992b; ter Huurne et al., 1994; Hutto and Wannemuehler, 1999; Hsu et al., 2001); chemotaxis/motility (Glock et al., 1974; Kennedy et al., 1988; Milner and Sellwood, 1994; Kennedy and Yancey, 1996); oxygen metabolism/NADH oxidase (Jensen and Stanton, 1993b; Stanton and Jensen, 1993b; Stanton, 1997a; Stanton et al., 1999b); and immunoreactive membrane proteins VspH and BlpA with a potential for antigenic variation (Cullen et al., 2003; Gabe et al., 1998; McCaman et al., 2003). The ability to create strains with specific gene mutations provides direct evidence of a link between virulence and NADH oxidase activity, motility/flagella (see Ecology), and hemolytic activity. Mutant strains with specific deletions of *nox* (Stanton et al., 1999b), *flaA* or *flaB* (Kennedy et al., 1997), or *tlyA* (Hyatt et al., 1994; Joens, 1997) are avirulent for swine compared to their isogenic wild-type counterparts.

Though *tlyA*, *tlyB*, and *tlyC* were considered to be hemolysin genes of *B. hyodysenteriae* (Muir et al., 1992; ter Huurne et al., 1992b; ter Huurne et al., 1994), a recent study raises questions about whether the proteins encoded by these genes are true hemolysins (Hsu et al., 2001). In that study, a protein with hemolytic activity was purified from *B. hyodysenteriae* cells and its gene (*hlyA*) was cloned in *E. coli*. The recombinant protein has hemolytic and biochemical activities similar to those of the native purified hemolysin. These properties are different from those of the previously described TlyA-C proteins. The latter proteins, obtained by random "shotgun" cloning of *B. hyodysenteriae* DNA into *E. coli* with selection for hemolytic colonies, are possibly *B. hyodysenteriae* regulatory proteins that induce synthesis of known or cryptic hemolysins in *E. coli* cells. Alternatively they could be "pseudo"-hemolytic proteins, the result of being overexpressed from high copy plasmids in *E. coli*. Interestingly, although its identity as a true hemolysin has been questioned, the *tlyA* gene product is essential for virulence (ter Huurne et al., 1992b; Hyatt et al., 1994). Its role in virulence should be examined further.

Spirochetal Colitis and Spirochetal Diarrhea (*B. pilosicoli*)

Spirochetal colitis caused by *Brachyspira pilosicoli* is a mild to moderate diarrheal disease of swine, birds, and possibly humans (Swayne and McLaren, 1997; Taylor and Trott, 1997; Hampson and Trott, 1999b). Watery, mucoid diarrhea and a reduction of growth rate of affected animals are common clinical signs. Spirochetal colitis of swine resembles a mild case or a very early stage of swine dysentery. The disease can be experimentally produced by inoculating pure cultures of *B. pilosicoli* into normal swine (Taylor et al., 1980; Trott et al., 1996c; Thomson et al., 1997).

Evidence that *B. pilosicoli* is a pathogen of humans is circumstantial but multifarious. *Brachyspira pilosicoli* strains have been isolated from humans, including some (homosexual males or those living in developing countries) with intestinal disorders and who are immunocompromised (Barrett, 1997; Trott et al., 1997a; Trott et al., 1997b). Human strains are virulent for healthy piglets (Trott et al., 1996b). A human volunteer became colonized after drinking cultures of *B. pilosicoli* strain Wes B (Oxberry et al., 1998). Finally, *B. pilosicoli* has been isolated from the blood of human patients (Trott et al., 1997b). The significance and the capacity of *B. pilosicoli* cells to leave the intestinal tract and circulate throughout the host's body have not been sufficiently investigated.

Virulence factors of *B. pilosicoli* are unknown. By virtue of their location, outer membrane proteins undoubtedly mediate interactions between spirochete cells and their environment and are likely involved in host colonization and virulence (Trott et al., 2001; Trott et al., 2004). Cell motility, chemotaxis and spirochete end-on attachment to host tissues (see Ecology) are likely to be associated with colonization of the intestinal tract and therefore important for pathogenesis. In the absence of gross lesions, extensive colonization of intestinal tissues by *B. pilosicoli* cells with associated damage to microvilli could interfere with intestinal absorptive processes and lead to diarrhea (Gad et al., 1977; Taylor and Trott, 1997).

Human Intestinal Spirochetosis (*B. pilosicoli*, *B. aalborgi*, *Brachyspira* spp.)

There is no doubt that human colonic and rectal mucosae can be colonized by dense arrays of spirochetes (Barrett, 1997; Harland and Lee, 1967; Korner and Gebbers, 2003). The colonization is visible upon histological examination of intestinal biopsies and is known as human intestinal spirochetosis (HIS). There are unanswered questions, however, about the clinical significance of HIS and about the identities of the colonizing spirochetes. The prevalence of HIS appears greater among humans with poor living standards and among immunocompromised patients, for example HIV patients, than among healthy humans. HIS has been associated with intestinal disorders but also has been observed in healthy humans (reviewed in Barrett, 1997; Korner and Gebbers, 2003). Spirochetes in human feces and/or in association with HIS biopsies have been reported to be strains of *B. pilosicoli*, *B. aalborgi*, and unknown *Brachyspira* species (Brooke et al., 2003; Hovind-Hougen et al., 1982; Jensen et al., 2001; Mikosza et al., 2001). This species diversity could explain differences in clinical symptoms in humans. An alternative explanation is that HIS strains belonging to the same *Brachyspira* species may differ in pathogenic properties. The patient's physiologic, immune response, and non-spirochete microbiota could also be factors in determining whether the colonizing spirochetes are commensals or pathogens. Progress in understanding HIS would undoubtedly benefit from advances in understanding the diversity and unique properties of human spirochete species.

Avian Spirochete Intestinal Diseases

Avian diarrheal diseases can have various *Brachyspira* species as etiological agents (Swayne and McLaren, 1997; Swayne, 2002; Stephens and Hampson, 2001, 2004). In addition to *B. pilosicoli* and *B. hyodysenteriae* (see Disease), *B. alvinipulli* $C1^T$, isolated from a diarrheic chicken, is a chicken enteropathogen. The $C1^T$ cells colonize the ceca of 1-day-old chicks and 14-month-old hens and produce mild typhlitis with discolored and watery cecal contents (Swayne et al., 1995). *Brachyspira alvinipulli* has been isolated only from poultry and resembles an enteropathogenic spirochete earlier described by Davelaar et al. (1986).

Many studies of avian intestinal infections associated with spirochetes were made before *Brachyspira* species had been characterized and taxonomically established (Davelaar et al., 1986; Griffiths et al., 1987; Dwars et al., 1989). *Brachyspira intermedia* appears to be another common avian enteropathgen, inasmuch as spirochetes of that species have been isolated from birds with moderate intestinal colitis (Swayne and McLaren, 1997; Stephens and Hampson, 2001; Swayne, 2002). One-day-old chicks inoculated with pure cultures of an intestinal spirochete strain 1380, later identified by MEE analysis as a strain of *B. intermedia* (Swayne and McLaren, 1997), shed watery feces containing spirochetes and had detectable reductions in body weight compared to control birds (Dwars

et al., 1992). Avian *B. intermedia* strain HB60 isolated from a hen with diarrhea causes reduced egg production and watery feces when inoculated into healthy hens (Hampson and McLaren, 1999a). A *B. intermedia* strain, freshly isolated from a swine herd with diarrhea, was not pathogenic for swine (Jensen et al., 2000).

Virulence traits of *B. alvinipulli* and other avian enteropathogenic *Brachyspira* species have yet to be determined.

Brachyspira spp. Antimicrobial Resistance

International and national guidelines for evaluating and monitoring *Brachyspira* antimicrobial susceptibilities under standard culture conditions are not yet available. *B. hyodysenteriae* strains have been divided into sensitive and resistant groups based on their susceptibilities to tylosin, erythromycin, and clindamycin (Karlsson et al., 2003). Resistance to these antibiotics is associated with a 23S rRNA gene mutation (Karlsson et al., 1999). *B. pilosicoli* isolates from humans or swine were found to be resistant to tetracycline, clindamycin, and amoxicillin. All strains were susceptible to an amoxicillin-clavulanic acid combination, indirect evidence that a b-lactamase is involved in resistance to amoxicillin.

Applications

Among the spirochetes, *Brachyspira hyodysenteriae* stands out as a good, practical choice for studying spirochete genetics and for investigating basic biological mechanisms of spirochetes, including host-pathogen interactions. The cultural, nutritional, and metabolic properties of *B. hyodysenteriae* have been substantially characterized and a serum-free, low-protein culture medium has been described (See Physiology). *Brachyspira hyodysenteriae* is an anaerobic spirochete but is aerotolerant. An experimental disease model featuring swine, the natural animal host of *B. hyodysenteriae*, has been available for many years (See Disease). Most importantly, recent research has provided a basis for understanding and manipulating this spirochete at the gene level (See Genetics).

Brachyspira hyodysenteriae is currently being used as a model in studies of spirochete motility. Strains with single or double mutations in specific flagellar genes are being created and used to evaluate the role of specific flagellar proteins in flagellar ultrastructure and cell motility (Li et al., 2000; C. Li and N. W. Charon, personal communication).

CHAPTER 5.1

The Family Chlorobiaceae

JÖRG OVERMANN

Introduction

Green sulfur bacteria (*Chlorobiaceae*) represent a phylogenetically coherent and isolated group within the domain Bacteria (see "Phylogeny"). As a distinct cytological feature, *Chlorobiaceae*-contain special light-harvesting complexes, so-called chlorosomes which harbor bacteriochlorophylls and carotenoids. Furthermore, green sulfur bacteria differ from most other phototrophic organisms with respect to the chemical structure of the antenna bacteriochlorophylls. Similar antenna complexes have only been found in the phylogenetically distant bacterial family *Chloroflexaceae*.

Green sulfur bacteria are obligate photolithotrophs and are similar to the *Chloroflexaceae*, *Chromatiaceae*, and phototrophic species of the α- and β-proteobacteria, such that water cannot serve as electron donating substrate of the photosynthetic reaction center and molecular oxygen is not generated during anoxygenic photosynthesis. Instead, the electrons which are ultimately required for the assimilatory reduction of CO_2 originate from sulfur compounds with low redox potential or from molecular hydrogen (see The Phototrophic Way of Life in Volume 2).

Because of their limited physiological flexibility, the ecological niche of green sulfur bacteria is rather narrow. All known species of the green sulfur bacteria are typical aquatic microorganisms and occur where light reaches anoxic water layers of lakes or littoral sediments. In some of these ecosystems green sulfur bacteria play a key role in the transformations of carbon and sulfur compounds. Another phenotypic trait of ecological significance is the adaptation to low light intensities. Compared to any other phototrophic microorganism, green sulfur bacteria are able to colonize the lowermost water or sediment layers in oxic/anoxic ecosystems (see "Ecology").

The cells of most species of green sulfur bacteria are morphologically rather inconspicuous members of natural bacterial communities (see "Identification"). Exceptions are the phototrophic consortia, stable associations of green sulfur bacteria with chemotrophic bacteria which are found in many freshwater habitats. At the present state of knowledge, these phototrophic consortia represent the most highly evolved symbiosis in the prokaryotic world.

Phylogeny

Relatedness to Other Bacterial Phyla

Based on a recent phylogenetic analysis (Overmann and Tuschak, 1997b), green sulfur bacteria as a group are phylogenetically isolated within the eubacterial radiation. The comparison of 16S rRNA gene sequences thus fully confirmed earlier results of ribosomal oligonucleotid cataloguing (Gibson et al., 1985; Woese et al., 1985). The closest relative presently in pure culture is *Cytophaga* sp. strain BD1-15 (77.9% similarity, Knuc = 0.26). Green sulfur bacteria appear to be the sister taxon of the *Bacteroides*/*Flavobacterium* phylum (Stackebrandt et al., 1996), which is also indicated by sequence homology of the *recA* gene of both groups (Gruber et al., 1998b).

Green sulfur bacteria harbor chlorosomes which contain bacteriochlorophylls *c*, *d*, or *e* as accessory pigments. Chlorosomes and the bacteriochlorophylls *c* or *d* are also present in the multicellular filamentous gliding bacteria of the family *Chloroflexaceae*. Furthermore, the CsmA proteins of the chlorosome envelope are homologous in *Chlorobiaceae* and *Chloroflexaceae*. The occurrence of chlorosomes in such distantly related bacterial groups could indicate a lateral transfer of the genetic information coding for this unique photosynthetic light-harvesting structure (Stackebrandt et al., 1996).

On a more detailed level, however, differences exist between the molecular architecture of the photosynthetic apparatus in green sulfur bacteria and *Chloroflexaceae*. The photosynthetic unit of green sulfur bacteria contains ten times more antenna pigments as the one in *Chloroflexus* contains (Olson, 1998) and the amino sequences of the chlorosome proteins of both groups exhibit a rather low degree of homology (Blankenship et al., 1995). The antenna bacteriochlorophylls in

green sulfur bacteria are esterified with the alcohol farnesol, those of *Chloroflexus* with stearol instead. Furthermore, the water-soluble trimeric FMO-protein which in green sulfur bacteria links the chlorosome to the reaction center is absent from the photosynthetic apparatus of *Chloroflexus*. Even more significantly, the structure of the reaction center is conspicuously different for both phylogenetic groups. Whereas the reaction center of green sulfur bacteria belongs to the iron-sulfur-type, the quinone-type is found in *Chloroflexus* (see The Phototrophic Way of Life in Volume 2). These considerable differences support the phylogenetic divergence between green sulfur bacteria and *Chloroflexaceae*.

Compared to the photosynthetic *Proteobacteria*, the *Heliobacteriaceae*, and the *Cyanobacteria*, all green sulfur bacteria sequenced to date branch shallow within the phylogenetic tree of eubacteria (Stackebrandt et al., 1996), suggesting a more recent radiation. This could indicate either a lateral transfer of genes for chlorosome formation to a single predecessor containing a Fe-S-type reaction center or that the more deeply branching green sulfur bacteria have not been isolated so far. Several 16S rRNA sequences cloned from environmental samples exhibit a significantly higher sequence similarity than that of members of the *Bacteroides*/*Flavobacterium* phylum (76.3–87% similarity; Overmann and Tuschak, 1997b). Because these sequences originate from uncultured bacteria in geothermal springs (Kopczynski et al., 1994; Ward et al., 1992) or soil samples (Maidak et al., 1994), closer relatives of the green sulfur bacteria must actually exist in a variety of habitats and still await isolation and characterization.

Diversity within the Family Chlorobiaceae

Green sulfur bacteria can be considered as a family of genetically related species. The similarity of the 16S rRNA gene of all species except one is >90.1% ($K_{nuc} < 0.11$). Only *Chloroherpeton thalassium* is more distantly related (85.5 to 87% similarity) and thus may represent an isolated branch within the radiation of green sulfur bacteria.

Presently, the genera and species of green sulfur bacteria are distinguished according to cell morphology, motility, ability to form gas vesicles, and pigment composition (Pfennig, 1989; see "Taxonomy"). The results of the 16S rRNA sequence analysis indicate that most of these phenotypic traits are of little phylogenetic significance. Some species belonging to different genera are phylogenetically closely related (e.g. *Prosthecochloris aestuarii* with *Chlorobium vibrioforme*). The three different species of the genus *Pelodictyon* do not form a coherent cluster within the green sulfur bacterial radiation. Furthermore, considerable genetic diversity has been discovered within the species *Chlorobium limicola* or the species *Chl. vibrioforme*; different strains of the same species can exhibit as much as 8% sequence divergence of the 16S rRNA gene (Figueras et al., 1997; Overmann and Tuschak, 1997b). The mol% G+C of *Chl. limicola* strains varies between 49 and 58.1 mol% and total genome size ranges from 1,435 to 3,342 kb (Méndez-Alvarez et al., 1996). Consequently, the genera and species of the green sulfur bacteria have to be redefined. However, because only a limited number of 16S rRNA gene sequences are presently available, additional strains need to be isolated and analyzed before a consistent new classification system can be established.

Taxonomy

Green sulfur bacteria are presently divided into 5 genera and 14 species. As all of the species share most of the physiological capacities, the six genera *Ancalochloris*, *Chlorobium*, *Chloroherpeton*, *Clathrochloris*, *Pelodictyon*, and *Prosthecochloris* are presently distinguished based on cell morphology, motility, and ability to form gas vesicles. Species are classified according to their morphology and pigment composition (Table 1).

A recent analysis of the phylogenetic relationships between the different species of green sulfur bacteria (Diversity) within the family *Chlorobiaceae* has revealed that most of the phenotypic traits used in the classification of this family have no taxonomic implications. Because the current taxonomy of green sulfur bacteria is based on these latter characteristics, it is not congruent with the phylogenetic tree. However, ternary fission has been observed only for the two closely related *Pelodictyon clathratiforme* and *Pld. phaeoclathratiforme*. Other traits of phylogenetic significance might be the filamentous morphology and gliding motility which are only found in the phylogenetically rather isolated *Chloroherpeton thalassium*. Interestingly, closely related strains seem to have similar salt requirements for growth (Overmann, 1999a). Although only few data are available, the fatty acid composition may similarly reflect the phylogenetic relations. For example, three phylogenetically closely related saltwater strains (*Chlorobium phaeovibrioides* DSM 269T, *Chl. vibrioforme* DSM 262, and *Pelodictyon luteolum* DSM 273T) contain relatively low amounts of the fatty acid myristate but high amounts of palmitate and palmitoleate (Kenyon and Gray, 1974; Knudsen et al., 1982; Imhoff, 1988).

Table 1. Phenotypic characteristics of the known species of green sulfur bacteria.

Species	Shape	Size (µm)	Cell aggregates	Gas vesicles	Color of cell suspension	Antenna BChl	Major carotenoid	GC content (mol%)	Salt requirement	Vitamin B_{12} requirement	Type or neotype strain
Ancalochloris perfihevii	Sphere	0.5–2.0	Microcolonies	+	Green	n.d.	n.d.	n.d.	–	+	—

Abreviations: +, present; –, absent; n.d., not determined; BChl, bacteriochlorophyll; chl, chlorobactene; irt, isorenieratene; car, carotene.
Adapted from Trüper and Pfennig, 1992.

Habitat

Green sulfur bacteria are found in various types of aquatic habitats like the pelagial of lakes or lagoons, bottom layers of bacterial mats in intertidal sediments or bacterial mats in hot springs. As a result of their limited physiological capacities, these bacteria can only grow in the narrow zone of overlap between the opposing gradients of light and sulfide. In lakes and lagoons this zone extends over 0.5 to 2 m and occurs at a depth of 2 to 20 m. Layers of *Prosthecochloris aestuarii* in marine sediments are only 1 mm thick and are found at about 5 mm depth (Pierson et al., 1987). In contrast to their purple counterparts, the *Chromatiaceae*, macrocopically visible accumulations of green sulfur bacteria are observed less frequently. Nonetheless, *Chlorobium* species can be enriched using anoxic mud and sediment samples from a wide variety of freshwater and marine environments (Trüper and Pfennig, 1992). This indicates that small populations of green sulfur bacteria are able to survive in a wide range of habitats.

Inland Lakes and Lagoons

Blooms of green sulfur bacteria occur at the chemocline of thermally stratified or meromictic lakes. For example, *Chlorobium limicola* dominates the green layer in the chemocline of Wadolek Lake (Poland) (Czeczuga, 1968). *Chlorobium phaeobacteroides* and *Chlorobium phaeovibrioides* thrive in the chemocline of fjords (Pfennig, 1968), meromictic lakes (Trüper and Genovese, 1968; Culver and Brunskill, 1969), or tropical lagoons (Caumette, 1984). Frequently, such planktonic habitats are predominantly colonized by those species which are capable of forming gas vesicles, like *Ancalochloris perfilievii* (Gorlenko and Lebedeva, 1971b), *Pelodictyon luteolum* (Gorlenko and Lebedeva, 1971b), *Pelodictyon phaeum* (Gorlenko et al., 1973), or *Pelodictyon phaeoclathratiforme* (Overmann and Tilzer, 1989b). A complete list and a description of the various habitats were recently compiled by van Gemerden and Mas, 1995.

Black Sea

Today, the Black Sea represents the largest anoxic water mass on Earth. The chemocline is positioned at a depth of 68–98 m and harbors the deepest extant assemblage of green sulfur bacteria known so far, albeit at a very low biomass density (0.94 ng bacteriochlorophyll $\cdot$ L^{-1}) (Repeta et al., 1989). A strain of *Chlorobium phaeobacteroides* isolated from chemocline samples exhibited outstanding low-light adapatation (see Physiology). This is an impressive example of the capacity of brown *Chlorobium* species to survive at incredibly low light intensities. The Black Sea may serve as a model ecosystem for past anoxic states of large ocean basins (Green Sulfur Bacteria during Geological Time Scales).

Marine Sediments

Only in a few marine sediments green sulfur bacteria have been found to develop profusely. In their fully developed state some multilayered microbial mats ("Farbstreifensandwatt") contain a bottom layer of green sulfur bacterial cells belonging to the species *Prosthecochloris aestuarii* and *Chloroherpeton thalassium* (Gibson et al., 1984; Nicholson et al., 1987).

Sulfur Springs

The first reports of natural accumulations of green sulfur bacteria are from Szafer, 1910, and Streszewski, 1913, who observed layers of green bacteria in the effluents of sulfur springs in Poland. Subsequently, dense accumulations of thermophilic green sulfur bacteria were described for sulfur springs in New Zealand, where green sulfur bacteria form 3 mm-thick, unlaminated mats on the bottom substrate and thrive at sulfide concentrations above 50 µM, pH values between 6.0 and 4.5, and temperatures between 55° and 45°C (Castenholz et al., 1990). From the latter habitat, the thermophilic *Chlorobium tepidum* has been isolated (Wahlund et al., 1991).

Isolation

Direct Isolation

During enrichment of green sulfur bacteria in defined liquid media, those species which dominate in natural samples may be entirely outcompeted by the rare species. Consequently, samples in which green sulfur bacterial cells of unknown morphology or phylotype have been detected by microscopy or molecular methods (see "Identification") must be inoculated directly in deep-agar dilution series. Medium GSB is used and supplemented with 3 mM sodium acetate, which serves as an additional carbon source and therefore yields much larger colonies. The tubes are incubated at 20–50 $\mu mol \cdot m^{-2} \cdot s^{-1}$ of fluorescent light in order to provide the least selective conditions. At least in one case (*Pld. phaeoclathratiforme* DSM 5477^T) colony formation in the agar tubes is critically dependent on the addition of sodium dithionite (final concentration, 200 µM) to the agar medium (Overmann and Pfennig, 1989a).

Pure cultures are obtained by repeated application of the deep-agar dilution method. A

3.3% (w/v) suspension of Difco Bacto agar is prepared and washed five times with distilled water. After boiling (or autoclaving for 10 min), 3-ml aliquots of the water agar are dispensed into test tubes which are stoppered with cotton plugs and autoclaved. The agar is kept molten in a water bath at 60°C, 6-ml aliquots of perwarmed (42°C) mineral medium GSB are added to each tube, and the complete molten agar medium kept at 42°C. After inoculation with 0.05 to 0.5 ml of the sample, serial dilutions of 8 tubes are made in 1 : 10 dilution steps. Afterwards, all tubes are transferred to a cold water bath in order to harden the agar plugs, and each tube is flushed with a mixture of N_2/CO_2 (90/10) and sealed with a butyl rubber stopper. The media have to be preincubated in the dark for at least 12 h before incubation in the light. After the growth of green sulfur bacteria, well-separated lens-shaped green or brown colonies are removed with sterile Pasteur pipettes and—if pure—transferred to liquid medium. Alternatively, a colony is resuspended in 0.5 ml of medium and used as inoculum for subsequent deep-agar dilution series until a pure cultures is obtained.

Selective Enrichment

Green sulfur bacteria can be obtained from a wide variety of anoxic aquatic habitats if water, mud, or sediment samples are used as inoculum for selective enrichment cultures. Medium GSB should be used at pH values between 6.6 and 6.9, but not above 7.0. High light intensities (50–200 $\mu mol \cdot m^{-2} \cdot s^{-1}$, daylight fluorescent tubes) and temperatures (30–35°C) select for green *Chlorobium* and *Prosthecochloris* species (Trüper, 1970a, Matheron and Baulaigue, 1972). Many typical gas vacuole-containing freshwater species, like *Pelodictyon clathratiforme*, *Pld. phaeoclathratiforme*, and *Ancalochloris perfilievii*, compete successfully only at low sulfide concentrations (≤2 mM) and low temperatures (≤20°C). For the enrichment of green sulfur bacteria from samples containing large numbers of purple sulfur bacteria, cool white fluorescent light should be used at low intensities (0.5–5 $\mu mol \cdot m^{-2} \cdot s^{-1}$). Using this technique, cultures of green sulfur bacteria can be obtained even from samples in which green sulfur bacteria represent only 0.001% of the total number of phototrophic cells (Overmann et al., 1991a). The phototrophic consortium "Chlorochromatium aggregatum" can be enriched from anoxic lake sediment samples using the mineral medium GSB supplemented with 2 mM 2-oxoglutarate. It is mandatory to lower the sulfide concentration to 300 µM sulfide in order to suppress growth of free-living green sulfur bacteria. The pH of the mineral medium should be set to 7.2 and for illumination, daylight fluorescent tubes and a light intensity of 2–5 $\mu mol \cdot m^{-2} \cdot s^{-1}$ should be employed. Under these conditions, highly enriched cultures of intact consortia can be maintained in the laboratory (Fröstl and Overmann, 1998).

Identification

Phenotypically, the genera and species of green sulfur bacteria are distinguished based on their morphology and pigment composition (see "Taxonomy"). It has to be kept in mind, however, that both morphological traits have no phylogenetic significance (see "Phylogeny"). Depending on the species, cells are spherical, ovoid, or curved-shaped. All species multiply by binary fission and are immotile (Table 1). Cells of *Chloroherpeton thalassium* are long unicellular filaments, highly flexible, and motile by gliding. During stationary phase, strains of rod-shaped *Chlorobium* spp. may form long chains of almost spherical cells, and strains with vibrioid morphology can form coils of C-shaped cells. Ternary fission occurs in *Pelodictyon clathratiforme* and *Pld. phaeoclathratiforme* and leads to the formation of large three-dimensional nets. Fig. 1 shows the different morphologies which occur among the known species of green sulfur bacteria. The cells stain Gram-negative.

Depending on their pigment composition, cultures of green sulfur bacteria are either green- or brown-colored and thus macroscopically can resemble those of purple sulfur bacteria. In contrast to the latter, however, the pigments dominating in green sulfur bacteria are bacteriochlorophylls *c*, *d* or *e*. In intact cells, the long wavelength absorption peaks of these bacteriochlorophylls (BChl) are positioned at 745–755 nm (BChl *c*), 715–745 nm (BChl *d*), and 710–725 nm (BChl *e*) (Fig. 2) (Gloe et al., 1975) and can be used to rapidly differentiate between green sulfur bacteria and other photosynthetic prokaryotes like *Chromatiaceae*, *Ectothiorhodospiraceae*, and *cyanobacteria*. When recording the absorption spectra of living cell suspensions, light scattering can be decreased by the addition of 5 g sucrose to 3.7 ml of culture fluid and by using a spectrophotometer equipped with an end-on photomultiplier (Pfennig and Trüper, 1992). The scattering can further be decreased by a disintegration of the cells, passing them once through a french press. Control experiments have demonstrated that no change in the position of the absorption peaks of bacterial pigments occurs if the lysates are scanned directly after french press treatment (Glaeser and Overmann, 1999).

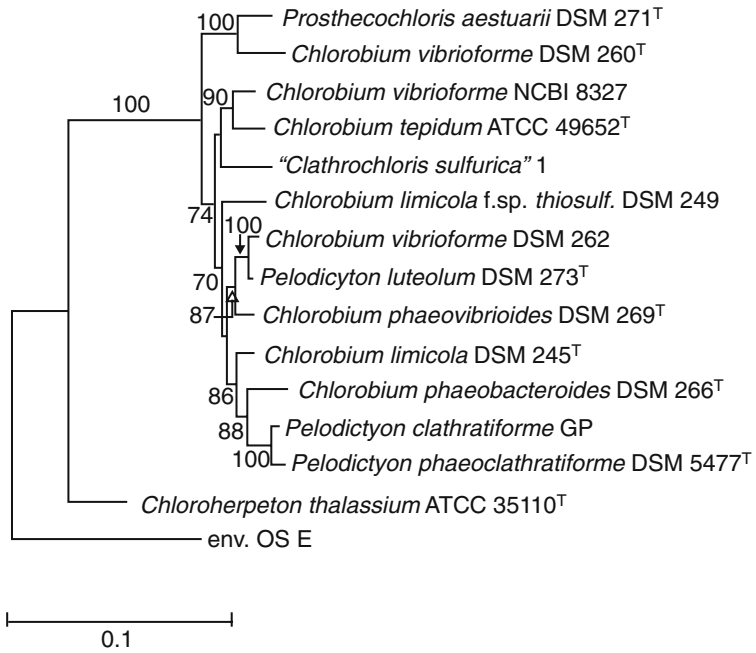

Fig. 1. Phylogenetic tree of the green sulfur bacteria. Construction was done as described by Overmann and Tuschak (1997b), using the most closely related 16S rRNA gene sequence available as the outgroup. Numbers at nodes indicate bootstrap values for each node out of 100 bootstrap resamplings, only values <50 are given. Bar, branch length for 0.1 substitutions per base.

Certain features of green sulfur bacteria can be observed by simple light microscopy. Due to the high intracellular concentrations of antenna pigments, bright field microscopy is often sufficient to discern even individual cells of green sulfur bacteria from accompanying chemotrophic cells in natural samples. During oxidation of sulfide, droplets consisting mainly of zero valence sulfur form outside of the cells and become microscopically visible as highly refractile sulfur globules. In phase contrast, these globules appear yellowish and are surrounded by a pronounced dark fringe (Fig. 1A). Strains which are capable of gas vesicle formation may be devoid of gas vesicles at the high light intensities routinely employed during laboratory incubations. At least in one strain (*Pelodictyon phaeoclathratiforme* DSM 5477^T), gas vesicle formation is induced exclusively by transfer of cultures to very low light intensities (<5 µmol·m^{-2}·s^{-1}, fluorescent light).

An important diagnostic feature of green sulfur bacteria is the presence of chlorosomes, although these structures are not exclusively found in this group but also are found in *Chloroflexaceae*. Chlorosomes can be detected by electron microscopy either in ultrathin sections (see The Phototrophic Way of Life in Volume 2) or by negative staining.

Meanwhile, a fluorescently labelled oligonucleotide probe with a high specificity for green sulfur bacteria has become available (Tuschak et al., 1999, Fig. 6) and permits a rapid and unambigous identification of members of this family in complex microbial communities. In order to obtain previously unkown 16S rRNA gene sequences of green sulfur bacteria in natural samples, an oligonucleotide primer pair has been developed for the selective amplification of these sequences by PCR. Different sequences can then be separated based on their different melting behaviour in denaturing gradient gel electrophoresis (DGGE) and the resulting DNA bands excised from the gel and sequenced (Overmann et al., 1999b). Using this technique, a number of new sequence types of green sulfur bacteria were detected in natural samples.

For a physiological characterization, a set of 40 different carbon substrates is routinely employed (Overmann and Pfennig, 1989a) with the standard medium GSB. Only pyruvate, acetate, and propionate are photoassimilated by the strains tested so far.

Future descriptions of new species or genera have to be based on pure cultures and not only should contain detailed information about cell morphology (color, size, shape, motility, mode of division, presence of gas vesicles, slime capsules, sheath), the occurrence of cell aggregates, the ultrastructure, and photosynthetic pigments, but also must contain the full 16S rRNA gene sequence and the GC content. The sulfide tolerance, salinity requirements, optimum growth temperature and pH, vitamin requirements, the sulfur compounds used as electron-donating substrates, and the carbon sources utilized should be indicated. A description of typical habitats is also necessary. At the present state of knowledge, the creation of a new species only appears to be justified if a new isolate shows a considerable

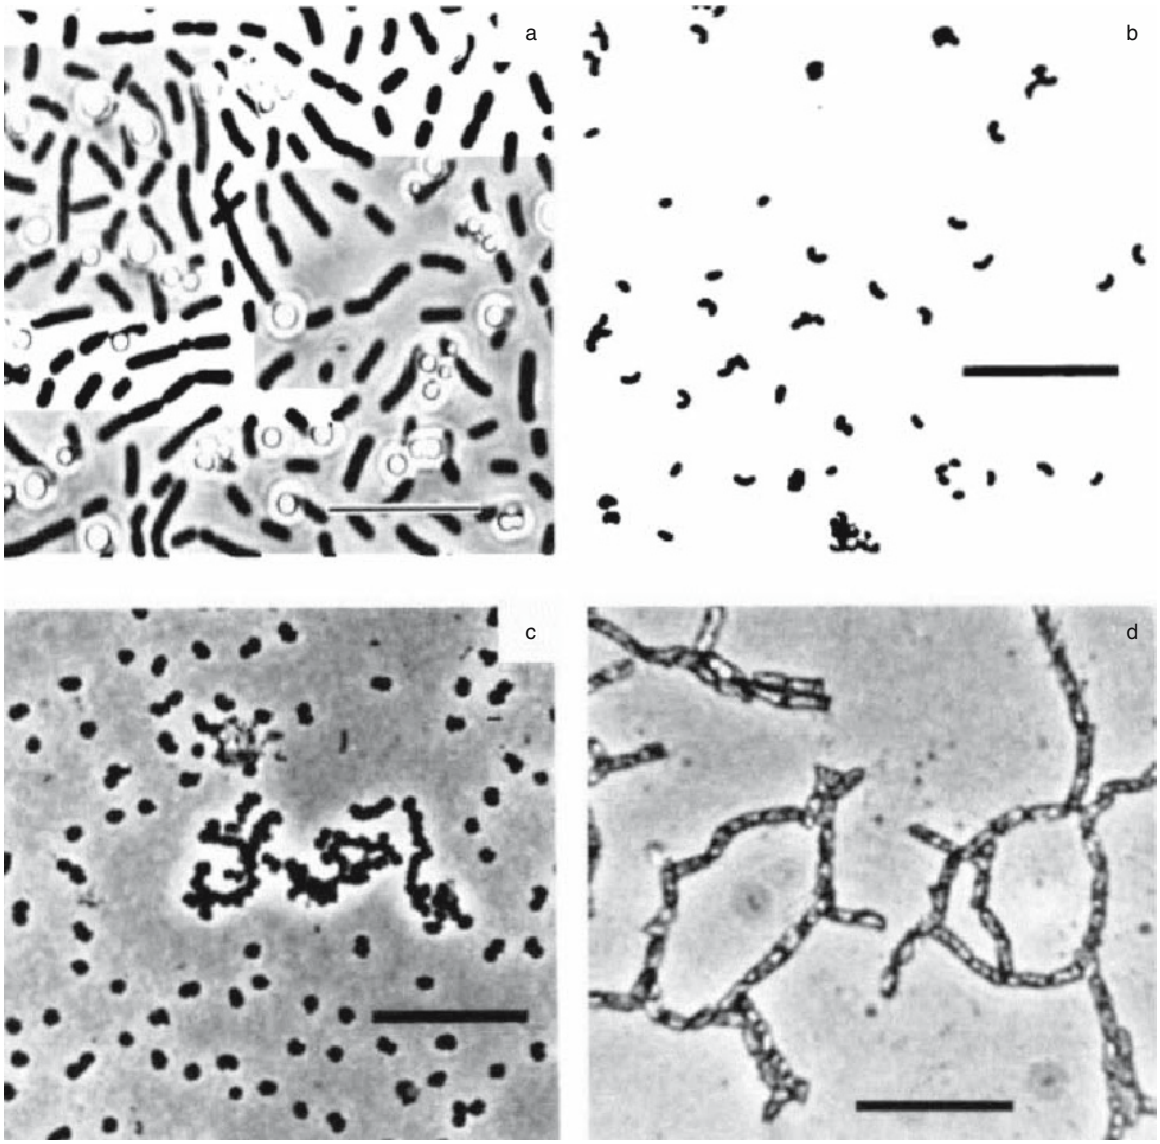

Fig. 2. Morphology of the Chlorobiaceae (phase contrast micrographs). Bars 10 µm. (a) *Chlorobium limicola*. (b) *Chlorobium phaeovibrioides*. (c) *Prosthecochloris aestuarii*. (d) *Pelodictyon clathratiforme*. (Courtesy of Trüper and Pfennig, 1992.)

sequence divergence to all known strains of green sulfur bacteria and if the strain exhibits distinctly different physiological or morphological properties.

Screening PCR-amplified dispersed repetitive DNA sequences (ERIC-fingerprinting) is a rapid method which is well suited to distinguish between strains with very similar or identical 16S rRNA gene sequences (Overmann and Tuschak, 1997b).

A type strain must be designated and deposited in one of the recognized national type culture collections, preferably ATCC, DSM, NCBI, or NHTC, as required by the International Code of Nomenclature of Bacteria (Lapage et al., 1975).

Cultivation

The defined medium for green sulfur bacteria, medium GSB, is prepared anoxically as described for the sulfate-reducing bacteria and contains per liter of distilled water:

	For freshwater strains For marine strains
KH_2PO_4	0.30 g 0.30 g
NH_4Cl	0.34 g 0.34 g
KCl	0.34 g 0.34 g
$CaCl_2 \cdot 2H_2O$	0.15 g 0.15 g

NaCl	—
	20.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g
	3.0 g

After the medium has been autoclaved and cooled under an atmosphere of 90% N_2/10% CO_2, aliquots of the following stock solution are added aseptically:

Stock solution	Added per l of medium GSB
10% (w/w) $NaHCO_3$, saturated with CO_2	15 ml
1 M $Na_2S \cdot 9H_2O$ (autoclaved under N_2)	2.5 ml
2 mg vitamin B_{12} in 100 ml H_2O	1 ml
Trace element solution SL 10*	1 ml

*SL 10 contains per liter of distilled water: 25% HCl, 10 ml; FeSO4 · 7H2O, 2.0g; CoCl2 · 6H2O, 190 mg; MnCl2 · 4H2O, 100 mg; ZnCl2, 70 mg; Na2MoO4 · 2H2O, 36 mg; NiCl2 · 6H2O, 24 mg; H3BO3, 6 mg; and CuCl2 · 2H2O, 2 mg. The FeSO4 is dissolved in HCl, and distilled water is then added, followed by the other components.

The final pH of the medium is adjusted to 6.7–6.8.

The concentration of sulfide initially present in medium GSB yields only a limited amount of cell biomass. After oxidation of sulfide and sulfur, cells stop growing and—depending on the strain—are rapidly damaged and eventually die. Therefore the cultures have to be replenished with sterile, neutralized sulfide solution which is prepared in a serum vial by neutralizing a stirred sodium sulfide solution (60 mM) under a N_2 atmosphere with 2M sulfuric acid to a pH of about 7.2. A convenient device for the preparation and long time storage of neutralized sulfide solution is described by Siefert and Pfennig, 1984.

In addition to the liquid medium, a new medium suitable for the growth of green sulfur bacteria on agar plates has been designed (Wahlund and Madigan, 1995).

Preservation

Just after depletion of sulfide and sulfur, most stock cultures can be stored for 3–4 months in the dark at 4°C. Long term preservation is done in nitrogen. Dense cell suspensions of liquid cultures are supplemented with DMSO (final concentration, 5% v/v) as a protective agent and filled into 2-ml plastic ampules, sealed, and freeze-stored. Some *Chlorobium* strains are successfully preserved by lyophilization.

Physiology

The photosynthetic apparatus of green sulfur bacteria has a particular molecular organization (Olson, 1998). Light is absorbed in unique structures, the chlorosomes. These ovoid organelles are 70 to 180 nm long and 30 to 60 nm wide and are attached to the reaction centers in the cytoplasmic membrane. Chlorosomes of the green sulfur bacteria contain bacteriochlorophylls *c*, *d*, or *e*, small amounts of bacteriochlorophyll a and three isoprenoid quinones (1′-oxomenaquinone-7, a derivative thereof, and menaquinone-7). The chlorosome envelope has a width of 2–3 nm and consists of monogalactosyl diglyceride and several polypeptides. Up to 10 different polypeptides can be present (Chung et al., 1994). Compared to the light-harvesting complexes in photosynthetic species of the α-Proteobacteria, β-Proteobacteria, *Heliobacteriaceae*, and *cyanobacteria*, the protein content of chlorosomes is tenfold lower such that the chlorosome proteins cannot serve as a scaffold for the attachment of the antenna bacteriochlorophylls. The functional role of the polypeptides CsmA, CsmB, and CsmC is not well understood. CsmA represents a major fraction of chlorosome proteins. Relatively abundant is also CsmB, which seems to be a component of the chlorosome envelope (Chung and Bryant, 1996) and may be a constituent of the chlorosome baseplate (Højrup et al., 1991). As indicated by insertional inactivation studies, CsmA is required for viability, whereas cells are capable of growing phototrophically (albeit slower than the wild type) in the absence of CsmC (Chung et al., 1998). The current molecular model assumes that antenna bacteriochlorophylls are tightly packed in a highly aggregated, crystalline state and form the (5–10 nm diameter) rod elements which can be visualized by electron microscopy inside the chlorosomes. Thus chlorosomes are unique in that their structure and function seem to be determined by pigment-pigment interactions (Blankenship et al., 1995) rather than by pigment-protein-interactions (*Chromatiaceae*).

Unique to the green sulfur bacteria, a small water-soluble protein is located between the chlorosome and the photosynthetic reaction center. This so-called Fenna-Matthews-Olson FMO-protein is trimeric, contains bacteriochlorophyll *a*, and is assumed to pass excitation energy from the chlorosome to the reaction center.

The antenna pigments of green sulfur bacteria are the bacteriochlorophylls *c*, *d*, or *e* and carotenoids. Green-colored strains contain bacteriochlorophyll c or d and the carotenoid chlorobactene, and brown-colored strains contain bacteriochlorophyll e and the carotenoids isorenieratene and b-isorenieratene. In the genus *Chloroherpeton*, γ-carotene is the main carotenoid. The absorption maxima of isorenieratene and β-isorenieratene are located at 505–520 nm. Intracellular concentration of carotenoids in

brown-colored strains of green sulfur bacteria are up to 4 times higher than those of their green-colored counterparts (Montesinos et al., 1983). This fact is of significance for the competition between the green and brown-colored species of *Chlorobiaceae* and between *Chlorobiaceae* and *Chromatiaceae* (see Interactions between Different Groups of Phototrophic Sulfur Bacteria). The majority of antenna bacteriochlorophyll molecules are farnesol esters. Up to 15 different bacteriochlorophyll homologues occur within the cells of a single strain of green sulfur bacteria (Borrego and Garcia-Gil, 1994) and differ with respect to the aliphatic side chains which are attached to the tetrapyrrole moity. A higher degree of alkylation (with mainly isobutyl or neopentyl side chains) occurs during growth at low as opposed to high light intensities (methyl, ethyl, n-propyl side chains) (Huster and Smith, 1990). Higher alkylation leads to a red-shift of the position of the absorption maximum (van Noort et al., 1997).

The transfer of excitation energy to the photosynthetic reaction center results in the formation of low redox potential electron carriers which in turn react readily with molecular oxygen to form harmful activated oxygen species. Under oxidizing conditions, energy transfer from chlorosomes to the reaction center decreases significantly due to the quenching by chlorobium quinone which decreases photooxidative damage (Frigaard et al., 1997). Similarly, the formation of oxidized bacteriochlorophyll *c* radicals under oxidizing conditions seems to decrease the energy transfer (van Noort et al., 1997).

Because each chlorosome contains about 10,000 molecules of bacteriochlorophyll and is energetically connected to only 5 to 10 reaction centers within the cytoplasmic membrane (Amesz, 1991), the size of the photosynthetic antennae of green sulfur bacteria exceeds that of *Chromatiaceae* by one order of magnitude. The large size of their antennae is one prerequisite for the extreme low light adaptation of the green sulfur bacteria (see Ecology; Black Sea). Biosynthesis of bacteriochlorophylls is regulated by light intensity. Upon a shift to growth-limiting light intensities, an increase in the size (Fuhrmann et al., 1993) and the cellular number of chlorosomes occurs (Broch-Due et al., 1978; Holt et al., 1966) and the cell-specific bacteriochlorophyll content rises by a factor of up to four (Overmann et al., 1992). This adaptation increasing the light-harvesting capacity of the cells of green sulfur bacteria. Experiments with axenic biofilms of *Prosthecochloris aestuarii* have provided indirect evidence of chromatic adapatation of this species. The ratio of bacteriochlorophyll *a*: bacteriochlorophyll *c* seems to increase at lower light intensities and higher fractions of infrared light (Pringault et al., 1998).

Green sulfur bacteria require about one-fourth of the light intensity of the purple sulfur bacteria in order to attain comparable growth rates (Biebl and Pfennig, 1978). Most strains of green sulfur bacteria reach light saturation of growth at 5–10 $\mu mol \cdot m^{-2} \cdot s^{-1}$ of fluorescent light (Bergstein et al., 1979; Overmann et al., 1991b; Overmann et al., 1992) and are inhibited at intensities above 200 $\mu mol \cdot m^{-2} \cdot s^{-1}$. The strain *Chlorobium phaeobacterioides* MN1 which was isolated from the chemocline of the Black Sea exhibited the most pronounced low light adaptation known for any phototrophic microorganism so far (Overmann et al., 1992).

Most strains of green sulfur bacteria require vitamin B_{12} for growth (Pfennig and Lippert, 1966). In the absence of this vitamin the specific bacteriochlorophyll content of the cells is drastically reduced and cells are incapable of forming chlorosomes (Fuhrmann et al., 1993).

Photosynthesis: Reaction Center

The photosynthetic reaction centers are located in the cytoplasmic membrane. They are of the iron-sulfur-type and thus resemble photosystem I of the oxygenic phototrophs and the reaction center of *Heliobacteriaceae* (Olson, 1998), but differ from the quinone-type of *Chromatiaceae*, *Ectothiorhodospiraceae*, and phototrophic members of the α-Proteobacteria and β-Proteobacteria. The reaction center contains a highly symmetric dimer of bacteriochlorophyll *a*, the primary donor P840, which receives excitation energy from the chlorosomes via the FMO-protein and additional bacteriochlorophyll *a* molecules in the reaction center.

Upon excitation, the reduced P840 becomes a powerful reductant [$E_0'(P840^+/P840^*) \approx -1200$ mV] and the electrons are transferred by several cofactors, a chlorophyll *a* isomer (A_0, $BChl_{663}$), a menaquinone-7 (A_1, Kjaer et al., 1998), and three iron-sulfur centers (F_x, F_A, F_B) towards the cytoplasmic side of the membrane. Because of the low redox potential of F_A and F_B ($E_0' \approx -540$ mV), the electrons can be directly transferred to soluble ferredoxin ($E_0' = -410$ mV). Ferredoxin is the electron donor in the reductive tricarboxylic acid cycle. Furthermore, NAD^+ can be directly reduced by ferredoxin. Therefore a reverse electron flow for NAD^+ reduction is not necessary, which partially explains the low energy requirements of green sulfur bacteria. Cyclic photophosphorylation in the green sulfur bacteria proceeds like in *Chromatiaceae* (Brune, 1989; Drews, 1989).

Because the standard redox potential of the photosynthetic reaction center in its oxidized

state is +240 mV, it cannot oxidize water to O_2. Instead, sulfide (S^0/HS^-, $E_0' = -270$ mV), sulfur/polysulfide-sulfur, in some cases thiosulfate (see sulfur metabolism) or—in most species (Lippert and Pfennig, 1969)—molecular hydrogen serves as electron donor of anoxygenic photosynthesis. Uptake hydrogenases appear to be membrane-bound and probably contain nickel and iron-sulfur clusters as do other uptake hydrogenases (Gogotov, 1986). Recently, a *Chlorobium* strain has been isolated which is capable of anoxygenic photosynthesis with ferrous iron ($Fe(OH)_3/Fe^{2+}$, $E_0' = -236$ mV) as electron donor for photosynthesis. In noncyclic electron flow, electrons removed by reduction of ferredoxin are replaced by external electrons transferred from sulfide via menaquinone or soluble cytochrome c_{555} and a membrane-bound monoheme cytochrome c_{551} on the periplasmic side of the membrane (Meyer and Donohue, 1995). As mobile intramembraneous hydrogen carriers, menaquinones replace the ubiquinones of purple bacteria.

Because of the considerably shorter span in redox potential, absorption of only about one photon is required per electron transferred to CO_2. Fixation of 1 mol C in green sulfur bacteria requires ~4 (3.3–4.5) mol photons (Brune, 1989); thus the quantum yield (mol C assimilated: mol quanta absorbed = 0.25) is twice as high as that of purple sulfur bacteria (0.12) or oxygenic phototrophic organisms (maximum, 0.125).

Sulfur Metabolism

Sulfide and elemental sulfur are utilized by all known isolates of green sulfur bacteria, whereas thiosulfate can serve as electron donor in only a few strains (*Chlorobium limicola* f.sp. thiosulfatophilum DSM 249, *Chl. vibrioforme* f.sp. thiosulfatophilum DSM 265, *Chl. tepidum* ATCC 49652^T, *Pelodictyon phaeoclathratiforme* DSM 5477^T). A soluble homodimeric cytochrome c_{551} is involved in thiosulfate oxidation of *Chlorobium limicola* f.sp. thiosulfatophilum DSM 249 (Klarskov et al., 1998). *Chlorobium limicola* f.sp. thiosulfatophilum and *Chl. vibrioforme* f.sp. thiosulfatophilum are also capable of sulfur disproportionation in the absence of CO_2 (Paschinger et al., 1974, Trüper et al., 1988). Only *Chl. vibrioforme* f.sp. thiosulfatophilum forms extracellular sulfur globules from thiosulfate (Steinmetz and Fischer, 1982). Tetrathionate ($S_4O_6^{2-}$) is utilized as electron donor by *Chlorobium limicola* f.sp. thiosulfatophilum and *Chl. vibrioforme* f.sp. thiosulfatophilum (Brune, 1989).

Oxidation of sulfide results in the formation of sulfur globules (zero valence sulfur). After depletion of sulfide, zero valence sulfur is further oxidized to sulfate. *Chlorobium limicola* f.sp. thiosulfatophilum and *Chl. vibrioforme* f.sp. thiosulfatophilum form thiosulfate simultaneously to elemental sulfur (Trüper, 1992), and the thiosulfate formation from sulfide is catalyzed by flavocytochrome *c* (Fischer, 1984). None of the green sulfur bacteria presently in pure culture are known to use sulfite as photosynthetic electron donor and sulfite can even inhibit the growth of *Prosthecochloris aestuarii* (Pringault et al., 1998). Sulfate formation in *Chlorobium* is mediated by adenylylsulfate reductase (Trüper and Peck, 1970b; Kirchhoff and Trüper, 1974), followed by cleavage of adenylylsulfate into sulfate and ADP or ATP by the enzyme ADP sulfurylase in *Chl. vibrioforme* (Trüper and Fischer, 1982; Khanna and Nicholas, 1983; Bias and Trüper, 1987) or ATP sulfurylase in *Chl. limicola* (Bias and Trüper, 1987), respectively.

The affinity for sulfide of the green sulfur bacteria is one order of magnitude higher than that of *Chromatiaceae* (van Gemerden and Mas, 1995). Growth is inhibited at concentrations of 5–8 mM (Bergstein et al., 1979, Overmann and Pfennig, 1989a, Overmann, 1999a). Green sulfur bacteria lack assimilatory sulfate reduction and require a reduced sulfur source during growth with molecular hydrogen as electron donating substrate (Lippert and Pfennig, 1969).

Carbon Metabolism

In contrast to *Chromatiaceae* with which they share the anoxygenic phototrophic type of metabolism, all known strains of green sulfur bacteria grow exclusively photolithoautotrophically. Carbon dioxide is fixed by the reductive tricarboxylic acid cycle (Fuchs et al., 1980). The key enzymes of the cycle are the ferredoxin-dependent a-oxoglutarate and pyruvate synthetases and an ATP-dependent citrate lyase. The latter is inhibited by oxaloacetate. All other enzymatic steps of the tricarboxylic acid cycle are reversible. Compared to the Calvin cycle, less ATP are required per molecule CO_2 fixed (5 ATP for one molecule glyceraldehyde-3-phosphate [Brune, 1989] as opposed to 9 ATP in the *Chromatiaceae*), which, together with the large size of their photosynthetic antennae, explains the low light adaptation of the family.

The reductive tricarboxylic acid cycle provides the cells with precursors for the biosynthesis of cell compounds. As the enzyme α-oxoglutarate dehydrogenase is not present and the tricarboxylic acid cycle can only function in the reductive direction, organic carbon compounds cannot be oxidized to yield CO_2 and reducing power for biosynthetic purposes. In the presence of inorganic reductants and CO_2, however, green sulfur bacteria are potentially mixotrophic and use simple organic carbon compounds (acetate, propionate, or pyruvate) for biomass formation.

Acetate is incorporated by reductive carboxylation, which requires the reducing equivalents from sulfide and involves a reduced ferredoxin. In the presence of acetate, the biomass yield per mol sulfide is increased about threefold, accordingly (Bergstein et al., 1979). In green sulfur bacteria, the affinity for acetate is one order of magnitude lower than that in the *Chromatiaceae* (van Gemerden and Mas, 1995).

The enzymes involved in the CO_2-fixation in the reverse tricarboxylic acid cycle discriminate only slightly against heavy carbon isotopes as compared to the enzymes of the Calvin cycle (Sirevåg et al., 1977b). This fact is of prime significance for paleoecological investigations of marine sediments and sedimentary rocks, where molecular fossils of green sulfur bacteria indicate past anoxia of certain ocean basins (Green Sulfur Bacteria during Geological Time Scales).

In the presence of excess carbon substrates and light energy, but limiting amounts of inorganic nutrients like ammonium and phosphate, green sulfur bacteria synthesize glycogen which is deposited intracellularly as non membrane-bound granules. During incubation in the dark, polyglucose is oxidized and excretion of its degradation products acetate, propionate, caproate, and succinate occurs (Sirevåg and Ormerod, 1977a).

Nitrogen Metabolism

Although the best nitrogen source for growth is the ammonium ion, the majority of strains of the green sulfur bacteria are capable of nitrogen fixation (Hallenbeck, 1987; Vignais et al., 1985).

Genetics

The size of the total genome in strains of the genus *Chlorobium* varies between 1,435 and 3,342 kilo base pairs (Méndez-Alvarez et al., 1996). Some 34 genes of green sulfur bacteria, mostly from *Chlorobium vibrioforme*, have been sequenced (Shiozawa, 1995). Aside from the 16S rRNA genes, most of these genes code for enzymes and polypeptides involved in photosynthesis.

Only one gene for the large reaction center polypetide PscA has been detected, which corresponds to the homodimeric structure of the reaction center of green sulfur bacteria. As expected, *pscA* shows sequence homology with the genes of Fe-S-type reaction centers in other photosynthetic bacteria. The polypeptide which contains the two FeS-cofactors FA and FB of the reaction center is coded by *pscB* which together with *pscA* forms a bicistronic unit. The gene of the cytochrome subunit of the reaction center, *pscC*, does not exhibit significant similarities with other genes coding for cytochrome subunits.

Of the genes coding the chlorosome polypeptides, *csmC* and *csmA* form the *csmCA* operon, whereas *csmB* is transcribed as a monocistron (Shiozawa, 1995).

Another operon contains three genes encoding enzymes of bacteriochlorophyll synthesis, *hemA* (glutamyl-tRNA reductase; Majumdar and Wyche, 1997), *hemC* (coding porphobilinogen deaminase; Majumdar and Wyche, 1997), and *hemD* (uroporphyrinogen III synthase). As a special feature, the 3′-region following the termination codon of each of the genes contains dA/dT-rich DNA stretches. In addition, *hem A* is followed by a potential adenylation signal and represents the first example for the occurrence of this typical eukaryotic feature in a bacterial genome (Shiozawa, 1995).

The limited data concerning the transcription start signals show that transcripts contain sequence motifs that are quite similar to the *Escherichia coli* σ^{70} consenus promotor sequence (TTGACA-17bp-TATAAT) (Chung and Bryant, 1996). *Chlorobium tepidum* contains only one group 1 sigma factor of the σ^{70} family (Gruber and Bryant, 1998a). In the same species, an AT-rich spacer region occurs between the –35 and –10 recognition sites in the promoter regions of several genes (Gruber and Bryant, 1998a) and may act as an additional promotor element. Transcription of the genes in green sulfur bacteria in most cases seems to be terminated by rho-independent stemloop structures. Characteristically, stemloops often begin with a stretch of 6 or 7 deoxyadenosines and with 4–7 deoxythymidines (Chung and Bryant, 1996; Gruber and Bryant, 1998a).

Chlorobium limicola strain 8327 exhibits a natural competence for intrastrain genetic transformation with chromosomal DNA (Ormerod, 1988). However, DNA extracts of this strain did not transform other *Chlorobium* strains. Similarly, transfer of an endogeneous plasmid which confers the ability to utilize thiosulfate has been demonstrated for *Chlorobium limicola* (Méndez-Alvarez et al., 1994). However, foreign DNA has been successfully introduced into *Chlorobium vibrioforme* by electroporation and was integrated into the genome by homologous recombination (Kjaerulff et al., 1994). A conjugation system for genetic studies of the thermophilic *Chlorobium tepidum* strains WT2321 and Nal-1 has been established which permits genetic analysis of gene expression and regulation directly within a green sulfur bacterium (Wahlund and Madigan, 1995). Two broad-host-range IncQ group plasmids can be transferred by conjugation from *E. coli* to *Chl. tepidum*. The latter species is especially well-suited for genetic

studies because of its short generation time of 2 h. As another prerequisite for molecular genetic studies, a new medium for the growth of green sulfur bacteria on agar plates has been designed (Wahlund and Madigan, 1995).

Ecology

Limiting Factors

Accumulations of green sulfur bacteria are positioned in the narrow zone of overlap between the opposing gradients of light and sulfide. In general, anoxygenic photosynthesis is limited by the availability of light (van Gemerden and Mas, 1995). In lakes, the light intensity available for anoxygenic photosynthesis is determined by the absorption of light in the water layers above the chemocline. Morphology and physicochemical factors like the density differences between water layers and wind-induced water currents determine the vertical position of the chemocline. Absorption of light in oxic water layers is high in eutrophic lakes and mediated by phytoplankton, whereas in dystrophic lakes light absorption is mainly due to the high concentrations of humic substances (Parkin and Brock, 1980). In general, the biomass density of green sulfur bacteria is inversely correlated with their depth in the environment and the thickness of the bacterial layer and reaches up to 120,000 μg bacteriochlorophyll·L^{-1} in benthic microbial mats (1 mm thin; Pierson et al., 1987), an average of 600 μg bacteriochlorophyll·L^{-1} in lakes, but only 0.94 μg bacteriochlorophyll·L^{-1} in the deepest anoxygenic phototrophic community which extends from 68 to 98 m depth in the Black Sea (Repeta et al., 1989). However, the physicochemical environment of green sulfur bacteria may be more dynamic not only in microbial mats but also in some lakes. For example, temporary exposure of the phototrophic bacteria to higher light intensities occurs during the daily lift up of the chemocline by internal seiches in Lake Kinneret and may explain the growth of *Chlorobium phaeobacteroides* in the chemocline despite of the prevailing very low light intensities (Bergstein et al., 1979).

The major factor determining the species composition of green sulfur bacteria in natural habitats is the spectral composition of underwater light. In lakes where the chemocline is located at greater depths (≥9 m) and in eutrophic lakes, the selective absorption of light by phytoplankton and water results in a progressive narrowing of the spectrum such that only light in the blue-green to green wavelength range is available for anoxygenic photosynthesis. The brown-colored forms of green sulfur bacteria which contain high intracellular concentrations of the light-harvesting carotenoids isorenieratene and β-isorenieratene have a selective advantage under these conditions (Montesinos et al., 1983). In contrast, green-colored species dominate underneath populations of purple sulfur bacteria (Interactions between Different Groups of Phototrophic Bacteria) or in dystrophic lakes (Parkin and Brock, 1980), where light of the blue (450 nm) or red (700 nm) wavelength range prevails, respectively.

Gas vesicle formation occurs in six of the fourteen described species. Green sulfur bacteria in pelagic microbial communities frequently contain gas vesicles (Caldwell and Tiedje, 1975; Clark and Walsby, 1978). In *Pelodictyon phaeoclathratiforme* DSM 5477^T, gas vesicle formation is induced exclusively at low light intensities (Overmann et al., 1991a). Given the low light intensities in most of their habitats, the growth rates of green sulfur bacteria are low. Gas vesicles are of selective advantage because they reduce the buoyant density of the cells and thereby minimize the loss of cells by sedimentation into dark bottom layers. However, unlike cyanobacteria, diurnal migrations by means of rapid changes in cellular gas vesicle content have not been observed so far for the green sulfur bacteria (Parkin and Brock, 1981).

Interactions between Different Groups of Phototrophic Sulfur Bacteria

Green sulfur bacteria and *Chromatiaceae* are both photolithoautotrophic and employ reduced sulfur compounds as electron donating substrates for anoxygenic photosynthesis. However, green sulfur bacteria are capable of using significantly lower light intensities for photosynthetic growth (see Physiology), and their maintenance energy requirements are significantly lower than those of the *Chromatiaceae* (Veldhuis and van Gemerden, 1986; Overmann et al., 1992). Unlike many *Chromatiaceae*, green sulfur bacteria cannot grow chemotrophically with molecular oxygen as the terminal electron acceptor and cannot use organic carbon compounds as photosynthetic electron donors. Because of these differences in their ecological niches, green sulfur bacteria often thrive below layers of *Chromatiaceae* (Caldwell and Tiedje, 1975; Gorlenko and Kuznetsov, 1971a; Overmann et al., 1998); however, both groups show some overlap. Light penetrating the layers of purple sulfur bacteria has its maximum intensity at 420–450 nm, coinciding with the short wavelength absorption maximum of bacteriochlorophylls *c* and *d* (see "Identification"). As a consequence, green-colored forms of the green sulfur bacteria accompany *Chromati-*

aceae in the natural environment (Montesinos et al., 1983). Although absorption of light by *Chromatiaceae* in upper water layers limits the light energy which can be harvested by green sulfur bacteria below, the photooxidation of sulfide by the low-light adapted green sulfur bacteria in turn may limit the diffusive flux of sulfid into the layers of purple sulfur bacteria.

However, syntrophic interactions also occur between the two groups of phototrophic sulfur bacteria, as exemplified by cocultures of *Chlorobium limicola* and *Chromatium vinosum*. These positive interactions are based on the oxidation of sulfide to zero valence sulfur by the green sulfur bacterium and the subsequent oxidation of sulfur to sulfate by the purple sulfur bacterial partner (van Gemerden and Mas, 1995). At limiting sulfide concentrations, *Chl. limicola* has a selective advantage due to its higher affinity (see Physiology), but the oxidation of the generated sulfur is inhibited in the presence of sulfide. The extracellular sulfur formed by the green sulfur bacterium abiotically reacts with sulfide to form polysulfides, which then can be used instanteneously by *Chr. vinosum*. Syntrophic interactions of this kind may be one major reason for the coexistence of purple and green sulfur bacteria, which is frequently observed in the natural habitat.

Interactions with Chemotrophic Bacteria

Stable associations between green sulfur bacteria and sulfur- or sulfate-reducing bacteria can be established in laboratory cocultures (Pfennig, 1980; Warthmann et al., 1992). As for the interactions between different groups of phototrophic sulfur bacteria such associations are based on the exchange of inorganic sulfur compounds. In this case, however, a closed sulfur cycle is established: sulfide is oxidized photosynthetically to sulfur or sulfate which in turn are utilized by the chemotrophic partner bacterium. Due to the extensive recycling of inorganic sulfur compounds, sulfur syntrophy can proceed even at trace concentrations of reduced sulfur compounds. Ultimately, the cycling of sulfur is fueled by the oxidation of organic carbon substrates and light.

One of the outstanding features of the green sulfur bacteria is their participation in highly specialized symbiotic associations with other bacteria, the phototrophic consortia. These morphologically conspicuous and yet still enigmatic structural associations of green sulfur bacteria and chemotrophic bacteria occur in the pelagial of many freshwater habitats. The regular structure of phototrophic consortia is unique in the microbial world such that they can be distinguished from other cell aggregates by light

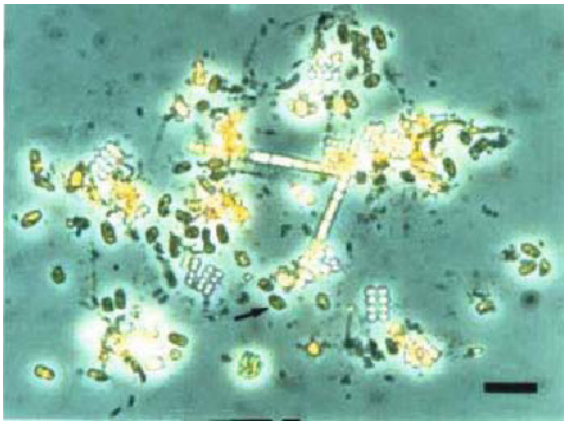

Fig. 3. Phase contrast photomicrograph of the bacterial community found in the chemocline of a little eutrophic hard-water lake (Lake Dagow; Overmann et al., 1998). A major fraction of phototrophic sulfur bacterial cells is found in the phototrophic consortium "*Pelochromatium roseum*" (arrow). In addition, *Thiopedia rosea* (flat sheaths of eight cells) and multicellular filaments of *Chloronema* spp. (center) are observed. Bar, 20 μm. (Courtesy of Jens Glaeser.)

microscopy (Fig. 3, 4). Presently, seven different types of phototrophic consortia are known (Fig. 5). In "*Chlorochromatium aggregatum*" (Lauterborn, 1915; *Chloronium mirabile*, Buder, 1914), "*C. glebulum*" (Skuja, 1957), "*C. lunatum*" (Abella et al., 1998), "*Pelochromatium roseum*" (Lauterborn, 1914), "*P. roseo-viride*" (Gorlenko and Kusnezow, 1972), and "*P. selenoides*" (Abella et al., 1998), the cells of green sulfur bacteria form a regular array around a central colorless bacterial cell (Fig. 6). "*C. aggregatum*" and "*P. roseum*" contain up to 24 epibionts, the other associations up to 69. Epibionts in "*Chlorochromatium*" are green, whereas those in "*Pelochromatium*" are brown-colored. "*Chloroplana vacuolata*" (Dubinina and Kusnezov, 1976) has a different structural arrangement and consists of parallel rows of alternating green and colorless bacteria. These platelets comprise up to 400 green cells and are immotile. "*Cylindrogloea bacterifera*" is an association of a colorless filamentous bacterium covered with a slime layer in which green sulfur bacteria are embedded (Perfiliev, 1914; Skuja, 1957). According to bacterial nomenclature, all of the above binominal names are without taxonomic significance and are therefore given in quotation marks only (Trüper and Pfennig, 1971).

The number of epibionts per central bacterium in "*C. aggregatum*" and "*P. roseum*" is rather constant and all epibionts have the same size. This indicates that all epibionts and the central bacterium must divide synchronously (Overmann et al., 1998). "*C. aggregatum*" accumulates at 740 nm in the light, corresponding to the wavelength of the absorption maximum of

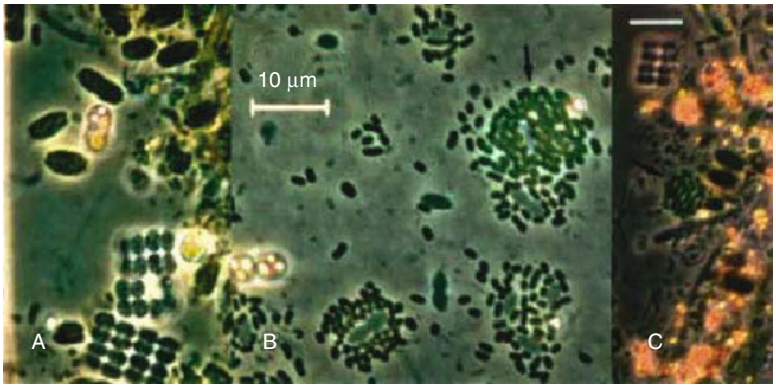

Fig. 4. Phase contrast photomicrographs of samples from the chemocline of a small eutrophic hardwater lake (Lake Dagow; Overmann et al., 1998). A) Untreated sample (bar is the same as for B). B) Same sample, but squash preparation of several "*Pelochromatium roseum*" consortia and one green consortium (arrow; note that gas vacuoles can be discerned in some of the epibiont cells). C) Sample containing globular green consortia (arrow) in which epibionts are arranged in loose unordered fashion as compared to "*P. roseum.*" Bars, 10 µm (taken from Overmann et al., 1998).

the bacteriochlorophyll present in the epibionts. As only the colorless central bacterium is flagellated, a rapid signal transduction must therefore occur between the light-sensitive epibionts and the central bacterium. Based on their 16S rRNA gene sequences, the epibionts in "*Chlorochromatium aggregatum*," "*C. glebulum*," and "*Pelochromatium roseum*" are phylogenetically different from all known phylotypes of green sulfur bacteria. Phototrophic consortia therefore seem to be highly specialized symbiotic associations. In symbiosis, green sulfur bacteria attain the ecologically significant capacity to respond to different light intensity, as do the motile *Chromatiaceae* (Pfennig, 1980).

Interestingly, "*C. aggregatum*" exhibits a chemotaxis toward 2-oxoglutarate, citrate, sulfide, and thiosulfate, while the typical carbon substrates of green sulfur bacteria (acetate, propionate, pyruvate) do not act as chemoattractants (Fröstl and Overmann, 1998). It has been suggested that the central bacterium of the phototrophic consortia is a sulfate- or sulfur-reducing bacterium (Kuznetsov, 1977; Pfennig, 1980). Based on the results of in situ-hybridization with group-specific oligonucleotides probes, the central bacterium does not belong to the δ-subgroup of the *Proteobacteria* and therefore does not represent a classical sulfate- or sulfur-reducing bacterium.

An antagonistic relationship of green sulfur bacteria has been described with the Gram-negative bacterium *Stenotrophomonas maltophilia*. This chemotrophic bacterium causes growth inhibition zones on cell lawns of several *Chlorobium* species (Nogales et al., 1997), in which green sulfur bacterial cells are lyzed and form ghosts. This anatagonism is non-obligatory and not limited to green sulfur bacteria as the hosts.

Ecological Significance

Green sulfur bacteria can reach high biomass densities (up to 4000 µg bacteriochlorophyll·L^{-1}, van Gemerden and Mas, 1995) in some lakes and contribute up to 83% of total primary production (Culver and Brunskill, 1969). Because anoxygenic photosynthesis is indirectly fueled by carbon that has previously been fixed by oxygenic phototrophs, the production of green sulfur bacteria represents a net biomass input only in those aquatic ecosystems where the anaerobic food chain and thus sulfide production are driven by the degradation of allochthonous organic carbon (Overmann, 1997a). Exceptions are geothermal springs, in which the sulfide is of geological origin and anoxygenic photosynthesis represents true primary production.

Green Sulfur Bacteria during Geological Time Scales

With the exception of the Black Sea, the habitats of green sulfur bacteria known today represent rather small bodies of water, mainly stratified lakes, coastal lagoons or fjords. However, isorenieratene and its degradation products have been discovered in Devonian sedimentary rocks (Hartgers et al., 1994), Miocene evaporites (Kohnen et al., 1992) and eastern Mediterranean sapropel sediments of the Pliocene (Passier et al., 1999) which originally were located at the bottom of much larger oceanic basins. Isorenieratene seems to occur solely in green sulfur bacteria. These bacteria fix CO_2 in the reverse

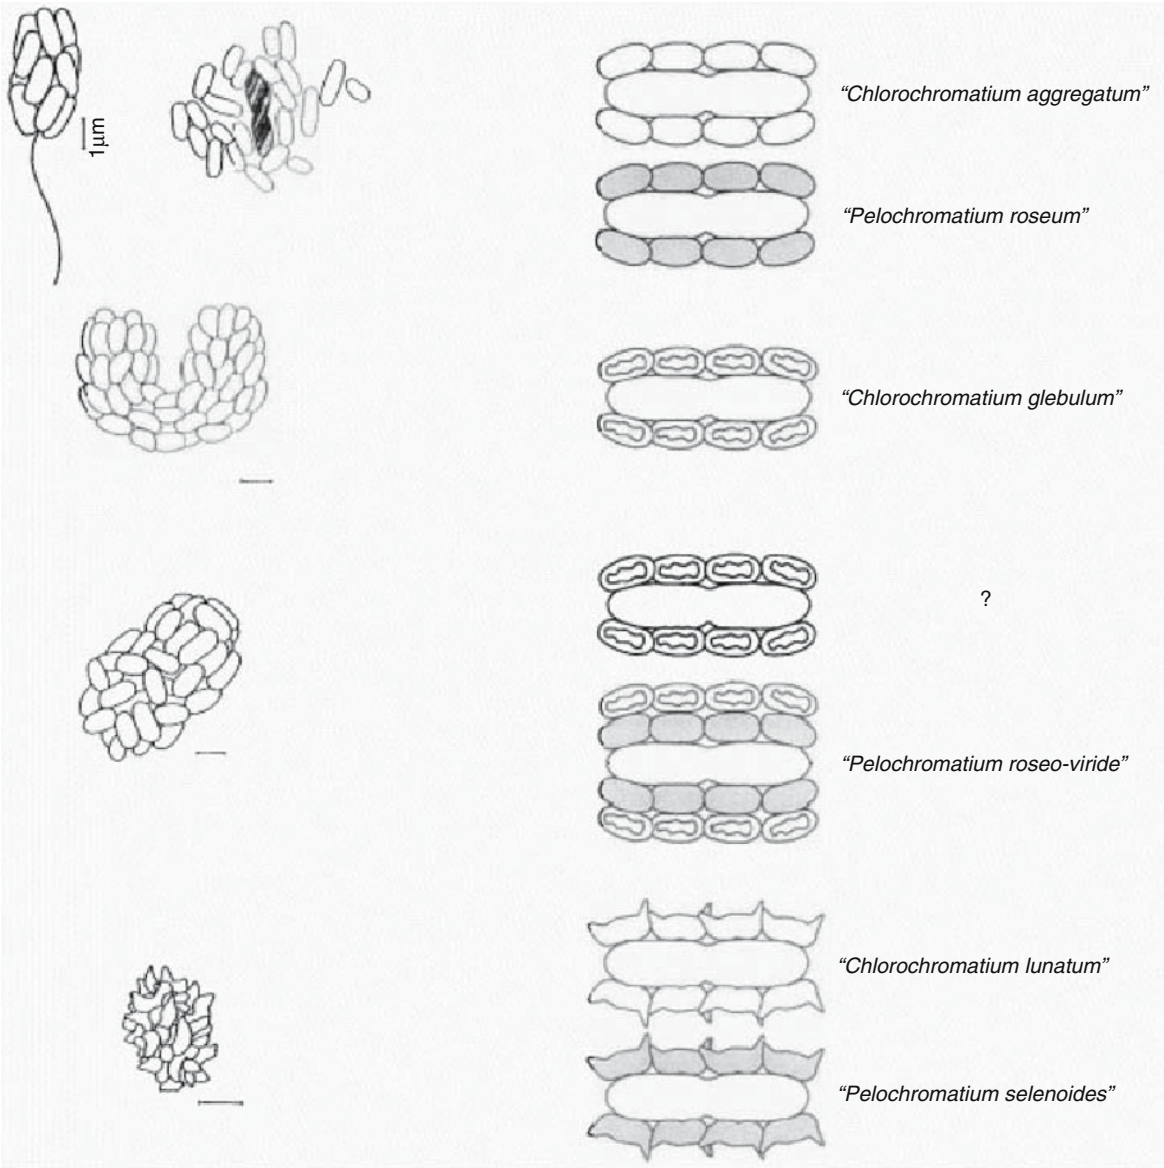

Fig. 5. Schematic representation of 7 different morphological types of motile phototrophic consortia. Left part depicts light microscopic appearance of the different types. Bar is 1 µm. In the right part of the figure, the central cell represents the unknown chemotrophic bacterium. White epibiont cells indicate green-colored, shaded epibiont cells the brown-colored forms of green sulfur bacteria. Irregular central area indicates the presence of gas vesicles in epibionts. One morphological type has yet to be described (question mark). (Modified after Pfennig, 1980, and Abella et al., 1998.)

tricarboxylic acid cycle which leads to organic carbon anomalously enriched in ^{13}C. Indeed isorenieratene and its degradation products are enriched by 12–24% in ^{13}C in the geological samples. Consequently, these molecular fossils have been taken as evidence that a large portion of the water column in major oceanic basins contained sulfide and extended into the photic zone. The Black Sea may represent a model ecosystem for such euxinic (restricted circulation leading to oxygen depletion) states of larger ocean basins during geological time scales. Anoxia of the bottom photic zone even seems to have occurred in the open North Atlantic Ocean during the Cenoman/Turon (i.e. up to 100 Mio years ago) (Sinninghe Damsté and Köster, 1998).

Applications

Green sulfur bacteria may be used for the removal of obnoxious smells of the toxic hydrogen sulfide during anaerobic waste treatment (Kobayashi et al., 1983). Cork and Cusanovich

A) DAPI fluorescence. B) Fluorescence of Cy 3-labeled probe GSB-532, showing the phylogenetic affiliation of the epibionts of "*Pelochromatium roseum*" with the Chlorobiaceae. Bar, 10 µm.

(1979) presented a process for the continuous disposal of sulfate by a mutual bacterial system consisting of *Desulfovibrio desulfuricans* and *Chlorobium limicola*. A system has been developed for the formation of elemental sulfur and organic carbon (biomass) from acid gas (containing H_2S and CO_2) which employs *Chl. limicola* as a biocatalyst (Cork, 1982a; Cork and Ma, 1982b; Cork et al., 1983; Cork et al., 1985). This represents an alternative to the Claus desulfuration process used in cleaning sour natural gases.

CHAPTER 6.1

The Medically Important *Bacteroides* spp. in Health and Disease

C. JEFFREY SMITH, EDSON R. ROCHA AND BRUCE J. PASTER

Introduction to the *Bacteroides*

The genus *Bacteroides* contains Gram-negative, nonsporeforming, nonmotile, anaerobic rods generally isolated from the gastrointestinal tract (GI-tract) of humans and animals. Up until about 12 years ago the genus was quite diverse and included nearly every organism that fit this generalized description. In 1989, however, the genus was formally restricted to include only those organisms that are closely related to the type species, *Bacteroides fragilis*, resulting in a group that is much more biochemically and genetically cohesive (Shah and Collins, 1989). This group is now comprised of what were previously *B. fragilis* subspecies plus a few additional newly recognized species. The genus includes *Bacteroides fragilis*, *B. thetaiotaomicron*, *B. ovatus*, *B. uniformis*, *B. vulgatus*, *B. distasonis*, *B. eggerthii*, *B. caccae*, *B. merdae* and *B. stercoris* (Shah and Collins, 1989).

This narrowed description of the *Bacteroides* has resulted in a genus in which all of the recognized species have some role in human or animal health. These organisms are generally isolated from human hosts as members of the normal microflora, and in fact *Bacteroides* spp. are the predominant organisms in the human colon. As members of the indigenous flora, they play a variety of roles that contribute to normal intestinal physiology and function. These include beneficial roles such as polysaccharide breakdown or nitrogen cycling, as well as other functions that may be disadvantageous such as the rapid deconjugation of bile acids or the production of mutagenic compounds (Macy, 1984; Salyers, 1984). Another important aspect of *Bacteroides* biology is their pathogenic potential. In this regard, several of the species including the type species, *B. fragilis*, are important opportunistic pathogens and the most frequently isolated organisms from anaerobic infections (Finegold and George, 1989). Thus it is clear that the *Bacteroides* spp. display a range of complex interrelationships with their animal hosts. It is the host-commensal or host-parasite interactions that define this group of organisms. In the following sections we will focus primarily on those characteristics that contribute to their successful colonization of mammals. Unfortunately, most serious research on the *Bacteroides* has focused on *B. fragilis* and *B. thetaiotaomicron* owing to their prominence in human infection and in the indigenous microflora. Much of the discussion in this chapter will necessarily describe the results of this work; however, these two organisms do in fact embody many of the features responsible for the success of the *Bacteroides* genus in its environment, and in this regard they have proven to be suitable model systems.

Phylogeny and Taxonomy

On the basis of the comparative analysis of 16S rRNA gene sequences, members of the genus *Bacteroides* form a coherent phylogenetic cluster within the *Cytophaga-Flexibacter-Bacteroides* (CFB) phylum (Paster et al., 1994; Fig. 1). According to the *Bergeys Manual of Systematic Bacteriology*, 2nd edition (Garrity, 2001) this bacterial phylum or group is referred to as the Bacteroidetes phylum (see the Bergeys website). The genus *Bacteroides* falls within the family Bacteroidaceae of the proposed Order "Bacteroidales" of the proposed Class "Bacteroidetes." Those species shown in the figure include cultivable and not-yet-cultivated species of *Bacteroides* in addition to representatives of closely related genera, such as *Porphyromonas*, *Prevotella* and misclassified species of *Bacteroides* (Olsen and Shah, 2001). It had been suggested previously that the two oral species, *B. heparinolyticus* and *B. zoogleoformans*, be members of the genus *Prevotella*; however, on the basis of 16S rRNA sequence analysis, it has been recommended these species be reinstated as true members of the *Bacteroides* (Olsen and Shah, 2001). Most of the known species and unclassified strains have been isolated from the human intestine or oral cavity; however, a few have been isolated from animal sources. For example, *B. acidifaciens* was isolated from the mouse cecum (Miyamoto

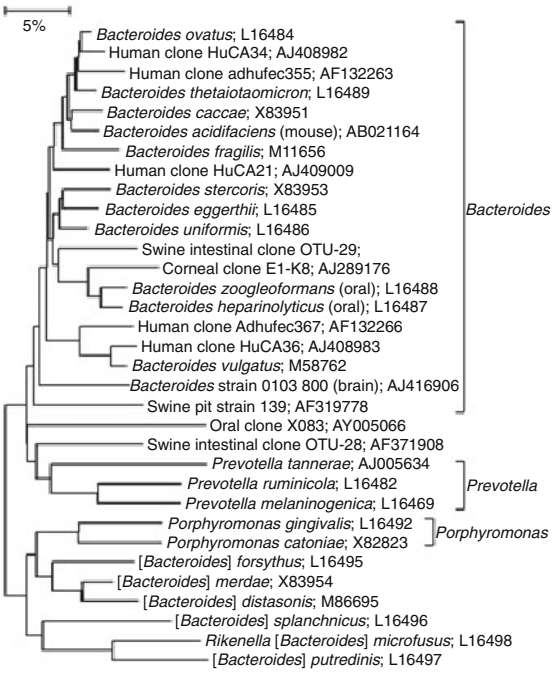

Fig. 1. Phylogeny of the genus *Bacteroides*. On the basis of 16S rRNA gene sequence comparisons, the phylogenetic position of known species, uncharacterized strains, and not-yet-cultivated phylotypes of *Bacteroides* is shown relative to other genera of family Bacteroidaceae. Misclassified species of *Bacteroides* are bracketed since they are clearly not true members of the genus. GenBank accession numbers for the 16S rRNA sequences of the species tested are shown. Similarity matrices were corrected for multiple base changes by the method of Jukes and Cantor (1969). The neighbor-joining method (Saitou and Nei, 1987) was used for phylogenetic tree construction. TREECON, a software package for the Microsoft Windows environment, was used for the construction and drawing of evolutionary trees (Van de Peer and De Wachter, 1994). The scale bar represents a 5% difference in nucleotide sequence determined by taking the sum of all of the horizontal lines connecting two species. Vertical distance has no meaning.

and Itoh, 2000), and *B. ovatus* and *B. thetaiotaomicron* were isolated from the bovine rumen (GenBank accession numbers AF139524 and AF139525, respectively).

In addition to cultivable species of *Bacteroides*, novel phylotypes, i.e., species that have not yet been cultivated in vitro, were detected by phylogenetic analysis of 16S rRNA genes amplified from DNA isolated from the human intestine (Suau et al., 1999; Hold et al., 2002), the human oral cavity (Paster et al., 2001), and the swine intestine (Lesser et al., 2002). Most of these phylotypes, designated as clones, cluster together with other members of the genus (Fig. 1). Some phylotypes, e.g., oral clone X083 and swine clone OTU-28, fall just outside the cluster. Another culture-independent study demonstrated the presence of a *Bacteroides ovatus*-like phylotype from the cecum of chickens (not included in Fig. 1 since it was not a complete sequence; Zhu et al., 2002). Although many members of the CFB group have been recovered from the hindgut of the termite, no true *Bacteroides* have been detected thus far from that environment (Ohkuma et al., 2002).

Although the *Bacteroides* clearly form a distinct cluster on the basis of 16S rRNA sequences, early DNA homology studies established that there was only minimal DNA identity between the major species (Johnson, 1978a). For example, *B. fragilis* shares 21–36% identity with *B. thetaiotaomicron*, 13–22% with *B. ovatus*, 21% with *B. uniformis*, 18% with *B. eggerthii*, 5–10% with *B. vulgatus*, and 5% with *B. distasonis*. Similar ranges have been observed between the other species as well. Even with this DNA sequence variability, the morphological and general metabolic properties of the genus are relatively uniform as can be seen in these brief descriptions of the major species (Holdeman et al., 1986). *Bacteroides fragilis* is the type species; it is the most frequently isolated anaerobe from clinical specimens, and it also is found in feces. A variety of sugars are fermented, but polysaccharide digestion is limited. Glucose grown cultures yield cells that are 0.8–1.3 by 1.6–8.0 μm, are rounded at the ends, often occur in pairs, and frequently contain large vacuoles. On the surface of horse blood agar plates, colonies are 1–3 mm, circular, entire, low convex, and semiopaque, and hemolysis is rare. *Bacteroides fragilis* cells are very aerotolerant, growth is enhanced by 20% bile, and hemin is required for normal, optimal growth. *Bacteroides thetaiotaomicron* is more frequently isolated from feces than from clinical samples. A wide range of sugars is fermented, and this is one of the more versatile organisms with regard to polysaccharide digestion. Glucose-grown cells are pleomorphic, 0.7–1.1 by 1.3–8.0 μm. Cells are aerotolerant and surface colonies on blood agar plates are punctiform, circular, entire, convex, semiopaque, and not hemolytic. Hemin and bile stimulation are similar to *B. fragilis*. *Bacteroides vulgatus* will ferment a range of sugars but is restricted in its polysaccharide use, similar to *B. fragilis*. It produces slightly smaller cells in glucose broth. Colonies on blood agar plates are 1–2 mm, circular, entire, convex, semiopaque, and not hemolytic. Hemin is required and bile stimulates growth. *Bacteroides vulgatus* is one of the most frequent isolates from feces but rarely is found in clinical samples. *Bacteroides uniformis* is a frequent stool isolate, but it sometimes is found in clinical specimens. The organism is a versatile

sugar fermenter and will degrade a range of polysaccharides. Glucose-grown cells are somewhat more slender than *B. fragilis*, and colonies on the surface of blood agar plates are only 0.5–2.0 mm, circular, entire, low convex, translucent, and generally not hemolytic. Bile is not stimulatory, hemin is required, and cells are somewhat less aerotolerant. *Bacteroides ovatus* uses a wide range of sugars and it is the most versatile polysaccharide fermenter. *Bacterides ovatus* is rarely isolated from clinical samples but is a common inhabitant of the colon. Cells taken from glucose broth are generally more rounded than *B. fragilis* and only range in size from 0.6–0.8 by 1.6–5.0 μm. *Bacteroides ovatus* is not hemolytic on sheep blood and colonies are 0.5–1.0 mm, circular, entire, convex, and semiopaque. This organism requires hemin for normal growth and bile is stimulatory. *Bacteroides eggerthii* is not a common clinical isolate but is often found in feces. Hemin stimulates growth but to a much lesser extent than seen in other *Bacteroides* spp. Cells from broth cultures are 0.4–1.0 by 1.0–1.6 μm, and surface colonies on blood agar plates are punctiform, circular, entire, convex, translucent, smooth and not hemolytic. Finally, *B. distasonis* is one of the most common fecal isolates and an infrequent isolate from clinical specimens. *Bacteroides distasonis* does not utilize many plant polysaccharides, although it does have the ability to ferment a wide range of sugars. Twenty percent bile is highly stimulatory and hemin is required for optimal growth. Glucose-grown cells are 0.6–1.0 by 1.6–11.0 μm with rounded ends and occasional vacuoles. Strains are occasionally α-hemolytic on sheep blood agar plates, and colonies are pinpointed to 0.5 mm, circular, entire, convex and semiopaque.

Physiology and Metabolism

Nutritional Features

The *Bacteroides* have simple nutritional requirements that reflect their environment. Most of the species can be grown on a defined medium containing a fermentable carbohydrate, hemin, vitamin B_{12}, ammonia, carbon dioxide, and sulfide, all of which are plentiful in the colon in some form. As discussed in the section on Polysaccharide Utilization, a wide variety of mono-, di-, and polysaccharides serve as carbon and energy sources, and together with carbon dioxide, they provide all of the carbon requirements for the cell. Nitrogen requirements are minimal, with ammonia serving as the preferred nitrogen source for all of the species (Varel and Bryant, 1974). Ammonia is plentiful in the colon since it is a product of urea cycling and a byproduct of protein/amino acid catabolism. Amino acids, on the other hand, are not present at high concentrations in the colon, and they are not utilized as the sole source of nitrogen. It may be that amino acid transport is not sufficient to supply the needs for cellular nitrogen, or the yield of ammonia from amino acid catabolism is below levels the organisms can optimally assimilate. An apparent paradox is that *B. fragilis* has the ability to utilize a mixture of peptides for nitrogen; however, the peptides are not utilized as efficiently as ammonia. Even when provided at fivefold higher molar concentrations, they only support about 35–70% of the growth yield observed with ammonia. Likewise, proteins such as gelatin or trypticase only allow about 20% of the growth yields seen when *B. fragilis* is grown with ammonia. It is not known whether the other *Bacteroides* spp. can utilize peptides. No other nitrogen sources such as nitrate or urea can be utilized by these organisms (Varel and Bryant, 1974).

Sulfur sources for the *Bacteroides* are typically reduced compounds such as sulfide, cysteine, and, to a lesser extent, thioglycolate. Sulfate, sulfite, thiosulfate, β-mercaptoethanol, or methionine is not used (Varel and Bryant, 1974). The requirements for other inorganic ions has been examined, and the needs proved to be fairly typical with Na^+, K^+, PO_4^{-3}, Ca^{+2}, and Mg^{+2} being required for optimal growth of *B. fragilis* and *B. vulgatus* (Caldwell and Arcand, 1974). It was interesting to note that both *B. fragilis* and *B. thetaiotaomicron* displayed a requirement for Fe^{+2} above what was provided by hemin. With the possible exception of *B. ovatus*, the only vitamin required by the *Bacteroides* spp. is B_{12}. The requirement for B_{12} was substituted by methionine, but other potential methyl donors such as betaine, choline, or dimethylacetothetin were not effective replacements, suggesting a specific need for B_{12} in methionine biosynthesis. *Bacteroides ovatus* also required B_{12}, but the requirement was not replaced by methionine, and a strain of *B. distasonis* had a methionine requirement that was not replaced by B_{12} (Varel and Bryant, 1974).

All of the *Bacteroides* spp. require hemin for optimal growth. This requirement has been the subject of a number of studies, some of which have indicated an essential growth requirement for hemin (or closely related compounds), but the majority have shown that hemin greatly stimulates both growth rate and yield (Varel and Bryant, 1974; Sperry et al., 1977; Chen and Wolin, 1981; Fuller and Caldwell, 1982; Al-Jalili and Shah, 1988). Although there may be some strain-to-strain variation, *B. fragilis* and *B. vulgatus* both can substitute protoporphyrin, hematoporphyrin, and hemoglobin for hemin with little effect on growth, and catalase can par-

tially substitute for hemin (Fuller and Caldwell, 1982). Tetrapyrrole precursors were of little benefit and did not effectively replace hemin (Sperry et al., 1977; Fuller and Caldwell, 1982). In the absence of hemin, growth yields of *B. fragilis* are greatly reduced, but the organisms can be maintained in chemostats for weeks without added hemin. Cells grown in this manner were similar morphologically to hemin-grown cells, but they did lack the *b*-type cytochrome and there was a shift in fermentation products (Al-Jalili and Shah, 1988). Other reports have also linked the synthesis of a *b*-type cytochrome to the hemin requirement (Fuller and Caldwell, 1982). These studies have documented the importance of heme for the synthesis of cytochrome *b* and for optimal growth. More information on the specific role of cytochrome *b* in energy generation will be presented in the section on Sugar Catabolism and Fermentation Pathways. Hemin utilization mechanisms have not been elucidated in any *Bacteroides* spp. yet, but in *B. fragilis* there is a 44-kDa outer-membrane protein involved in the uptake. This protein is iron repressible, and blocking studies using a polyclonal antibody raised against this protein inhibited hemin-dependent growth (Otto et al., 1990). Thus there is evidence for a specific hemin uptake system that is at least in part iron responsive. This will be addressed further during a discussion of pathogenic mechanisms as they relate to iron uptake systems (see section on Iron Acquisition from Host Tissues in this Chapter). The last specific growth requirement is for CO_2, which primes the synthesis of oxaloacetate (the precursor for the fumarate used as an electron acceptor during energy generation; see section on Sugar Catabolism and Fermentation Pathways in this Chapter). In the absence of CO_2, long lag periods are experienced until the requirement can be met through internal generation of CO_2 during fermentation of carbohydrates (Caspari and Macy, 1983).

Energy Metabolism

Polysaccharide Utilization The *Bacteroides* are saccharolytic, and this directly reflects their environment, which is rich in complex polysaccharides derived from dietary sources (cellulose, hemicellulose, starch and pectin) and host secretions (chondroitin sulfate). Degradation of these compounds is an important characteristic of most *Bacteroides* spp. In fact, as a group this genus is extremely versatile in the range of substrates that can be utilized as carbon and energy sources. Polysaccharides commonly used by *Bacteroides* spp. are listed in Table 1 together with the enzymes and genes associated with their use (if known). The efficiency of polysaccharide digestion also is significant. Chemostat studies and batch cultures with *B. thetaiotaomicron* and with *B. ovatus* have indicated utilization of starch, guar gum, xylan, arabinogalactan, and chondroitin sulfate was greatest at low dilution rates, which mimic the slow transit times in the gut (Salyers et al., 1982; Salyers, 1984; Macfarlane et al., 1990; Macfarlane and Gibson, 1991b; Degnan et al., 1997a; Degnan et al., 1997b). Further, growth rates and growth yields are as good or better for the organisms grown with various polysaccharides when compared to their component sugars. These results suggest that the mechanisms of polysaccharide digestion are highly effective, having adapted to the varied substrates available in the intestinal tract ecosystem. Although the range of substrates is wide, there are several common properties that characterize their utilization by *Bacteroides*. That is, these are complex, highly regulated systems relying on a network of outer membrane proteins to bind and degrade the substrates, rather than secreted extracellular enzymes. Generally these systems are induced by their substrates and repressed by glucose or other readily utilizable sugars.

Very early on, it was found that high activities of various polysaccharidases were only possible when *Bacteroides* spp. cultures were grown with their particular substrate (Salyers et al., 1977b). Interestingly it also was shown that in the case of *B. thetaiotaomicron*, the outer membrane protein profiles changed markedly during growth with different polysaccharides (Kotarski et al., 1985). Since most of the polysaccharidases are cell associated, it has been reasoned that these outer membrane proteins are important for binding of substrates to aid their passage to the periplasm and cytoplasm. Starch utilization by *B. thetaiotaomicron* exemplifies this scenario; there are seven structural genes of which four (*susC*, *susD*, *susE* and *susF*) encode outer membrane proteins with a role in starch binding (Reeves et al., 1996; Reeves et al., 1997; Shipman et al., 2000; Cho and Salyers, 2001a). Other genes in this regulon encode for a soluble neopullulanase (*susA*), an outer membrane neopullulanase (*susG*), and an α-glucosidase (*susB*), all of which are important for the digestion of the starch molecule into oligosaccharides and then glucose. All of these *sus* genes are transcriptionally controlled by a regulator SusR in response to the presence of starch or maltose in the medium (D'elia and Salyers, 1996a; Cho et al., 2001b).

Information on starch utilization is less complete for other *Bacteroides* spp. Studies with *B. ovatus* growing in a chemostat with mixtures of different polysaccharides indicated that starch and pectin were preferentially utilized, suggesting these were the most important carbon/energy

Table 1. Utilization of polysaccharide substrates among *Bacteroides* spp.

Polysaccharide	Organism	Enzymes	Genes
Starch	*B. fragilis*, *B. thetaiotaomicron*, *B. ovatus*, *B. uniformis*, *B. eggerthii*, and *B. vulgatus*	pullulanase	*pull* U67061
		neopullulanase	*susA* U66897
		amylase	*osuD*
		α-glycosidase	*susB* U66897
		gluycoamylase/-glycosidase	
		β-amylase	
Cellulose Xylan	*Bacteroides* spp. *B. ovatus*, *B. eggerthii*, and *B. vulgatus*	ND	ND
		xylanase	*xyl* U04957
		xylosidase/arabinosidase	*xa* U04957
		arabinosidase I	*asdl* U15178
		arabinosidase II	*asdll* U15179
Pectin	*B. thetaiotaomicron*, *B. ovatus*, and *B. vulgatus*	polygalacturonic acid lyase	ND
		polygalacturonic acid hydrolase	
		pectate lyase	
		pectin esterase	
Dextran	*B. thetaiotaomicron*, *B. ovatus*, and *B. uniformis*	dextranase	ND
Arabinogalactan	*B. thetaiotaomicron*, *B. ovatus*, *B. uniformis*, and *B. vulgatus*	arabinogalactanase	ND
		galactosidase	
Guar gum	*B. uniformis*	galactomannanase	ND
		mannosidase	
		galactosidase	
Laminarin	*B. thetaiotaomicron*, *B. uniformis*, and *B. distasonis*	β-glucanase	ND
		β-glucosidase	
Chondroitin sulfate	*B. thetaiotaomicron* and *B. ovatus*	chondroitin lyase I	*csuA*
		chondroitin lyase II	*csuB* L42367
		chondro-4-sulfatase	*csuC*
		chondro-6-sulfatase	*csuD*
		β-glucuronidase	*csuE*
Hyaluronic acid	*B. thetaiotaomicron* and *B. ovatus*	chondroitin lyase I	*csuA*
		chondroitin lyase II	*csuB* L42367
Heparin sulfate	*B. thetaiotaomicron*, *B. ovatus*, and *B. eggerthii*	ND	ND

Abbreviation: ND, not determined.
From Salyers et al. (1977a, b), Salyers and Leedle (1983), Macfarlane and Cummings (1991), Cheng et al. (1995), D'elia and Salyers (1996b), and Whitehead (1995).

sources in their environment (Degnan et al., 1997a). Digestion of starch was best at lower dilution rates where the activities of amylase and α-glucosidase were highest. The amylase and α-glucosidase activities were soluble and could be resolved into three components, one of which was a 70-kDa protein dimer with dual amylase and α-glucosidase activities. Glucosamylase and β-amylase activities also were found in *B. ovatus*, but there has been little in the way of genetic analysis of the starch utilization genes. An examination of starch digestion by *B. vulgatus* showed that amylase and α-glucosidase activities were induced 20–40-fold when cultures were grown with maltose, amylose, or amylopectin and that both enzymes had the same molecular weight and pH optimum, suggesting that they are the same enzyme, perhaps similar to the *B. ovatus* enzyme (McCarthy et al., 1988). Finally, starch utilization in *B. fragilis* also seems to require some of the same outer membrane proteins as *B. thetaiotaomicron* requires. A starch or maltose inducible operon with homologs to *susC*, *susD* and *susF* and an α-amylase were recently shown to be involved in starch and glycogen utilization in *B. fragilis* (Smith, 2002). In addition, periplasmic α-glucosidase activity has been demonstrated previously in this organism (Berg et al., 1980). Thus at least superficially, starch utilization among these four *Bacteroides* spp. has some significant similarities.

Chondroitin sulfate utilization in *B. thetaiotaomicron* is the model for digestion of host-derived polysaccharides. This highly sulfated polymer of *N*-acetylgalactosamine-glucuronic acid dimers is degraded by an inducible set of enzymes located in the periplasm and cytoplasm (Salyers and O'Brien, 1980; Guthrie et al., 1985; Hwa and Salyers, 1992a). The enzymatic activities documented are two periplasmic chondroitin lyases (CsuA and CsuB), two cytoplasmic sulfatases (CsuC and CsuD), and a β-glucuronidase

(CsuE) in the cytoplasm. As seen with starch, there were several outer membrane proteins induced by growth with chondroitin sulfate and one of these, CsuF, appears to be involved in substrate binding and was required for growth on the substrate (Kotarski et al., 1985; Cheng et al., 1995b). The regulatory mechanism of this inducible system has not yet been elucidated (Hwa and Salyers, 1992b; Cheng and Salyers, 1995a). Chondroitin sulfate utilization in *B. ovatus* and an unnamed *Bacteroides* spp. also has been examined and found to be similar to *B. thetaiotaomicron*. That is, all three organisms produced two inducible, cell-associated chondroitin lyases with similar biochemical properties, and there were similar chondroitin sulfate inducible outer membrane proteins synthesized (Lipeski et al., 1986). The digestion of these host polysaccharides in the environment most likely requires that the organism degrade protein complexes to which the polysaccharides are covalently linked. The chondroitin sulfate present in proteoglycan was degraded by *B. thetaiotaomicron*, albeit at a slower rate than purified substrate (Kuritza and Salyers, 1983). The rate of utilization was not improved when proteoglycan was treated with protease, suggesting that this is not an important rate-limiting step in degradation.

Another important dietary polysaccharide is xylan, a component of hemicellulose, which is utilized by *B. ovatus*. Some initial genetic and biochemical studies on *B. ovatus* xylan degradation have been performed showing that the major enzymatic activities, xylanase, arabinosidase, and xylosidase, were induced 6- to 100-fold by growth on oatspelt xylan (Whitehead and Hespell, 1990). Two genes involved in xylan utilization were cloned and found to encode the xylanase activity (*xylI*) and a dual function xylosidase-arabinosidase enzyme (*xsa*). These genes were part of an inducible operon that probably includes an additional arabinosidase (Weaver et al., 1992; Whitehead, 1995). Interestingly, mutations in these genes did not abolish xylan utilization, although the rate was considerably slower. This finding, together with some additional analysis of the xylan breakdown products produced by the mutants, suggested that another set of enzymes may be responsible for removal of glucose and hexuronic acid residues from the xylan molecule, thus allowing for growth of the *xsa* and *xylI* mutants (Weaver et al., 1992). The presence of xylan-specific outer membrane proteins was not examined.

The examination of other polysaccharide degrading systems has been minimal, with only cursory studies documenting the presence of specific enzymatic activities. Pectin degradation in *B. thetaiotaomicron* was shown to require several activities, a polygalacturonic acid hydrolase and lyase, pectate lyase, and pectin esterase, all of which were inducible by pectin or polygalacturonate (McCarthy et al., 1985; Tierny et al., 1994). The genes encoding the *B. thetaiotaomicron* pectate lyase and pectin esterase have been cloned, but little in the way of genetic or further biochemical data is available on these or any of the other polysaccharide degrading activities (Tierny et al., 1994; Table 1). Inducible, cell-associated laminarinase and galactomannanase also have been documented in a variety of *Bacteroides* spp. (Salyers et al., 1977b; Salyers and Leedle, 1983). Overall, it seems likely that these polysaccharide digestion systems will use a strategy similar to the starch and chondroitin sulfate models in which outer membrane proteins mediate binding of the polymers for digestion by cell-associated enzymes.

Consistent with the range of polysaccharide substrates utilized is the need for a variety of glycosidase activities. In one study with *B. fragilis*, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-N-acetyl glucosaminidase, and α-fucosidase activities were identified and partially purified (Berg et al., 1980). In addition, a β-glucosidase capable of esculin hydrolysis has been cloned from *B. fragilis* and expressed in *Escherichia coli*, and the gene, *bglA*, was sequenced (GenBank accession number AF006658). An insertional mutant in *bglA*, however, was still able to hydrolyze esculin, suggesting the presence of at least one additional β-glucosidase in this organism (Smith, 2002). In fact, examination of the *B. fragilis* genome sequence does reveal a second β-glucosidase gene.

Sugar Catabolism and Fermentation Pathways Most studies on the utilization of sugars have focused on *B. fragilis* and *B. thetaiotaomicron*. This work has shown that there are distinct patterns of carbohydrate preferences, and in the case of *B. thetaiotaomicron*, mannose appears to play a central role in controlling sugar uptake (Hylemon et al., 1977; Degnan and Macfarlane, 1995). Glucose, galactose, arabinose and xylose can all be co-utilized in batch or chemostat cultures; however, their catabolism is rapidly inhibited by the addition of mannose but not glucose (Degnan and Macfarlane, 1995). This result suggests the presence of an active catabolite inhibition mechanism, and it is consistent with earlier work, which showed that glucose transport was strongly inhibited by the addition of mannose (Hylemon et al., 1977). In addition, other transport studies showed that the rates of hexose uptake were greatest in cells grown with glucose and lowest in mannose grown cells (Degnan and Macfarlane, 1995). Taken together,

these studies indicate that some form of catabolite repression operates in the *Bacteroides* spp., and although the mechanism is not known, the classic Enterobacteriaceae pathway does not operate in these organisms since they do not form cAMP (Hylemon and Phibbs, 1974). Induction mechanisms also may be involved in control of sugar catabolism. In *B. fragilis*, sucrose uptake and sucrase activity were induced 8- and 3-fold, respectively, in cultures grown with sucrose, and in *B. thetaiotaomicron* xylose, uptake was clearly induced by its substrate (Scholle et al., 1990; Degnan and Macfarlane, 1995).

The mechanisms of sugar transport have not been elucidated. It has been shown that *B. thetaiotaomicron* does not use a phosphoenolpyruvate:phosphotransferase for transport of glucose, mannose, galactose or xylose (Hylemon et al., 1977; Degnan and Macfarlane, 1995). Sugar transport is inhibited by a variety of compounds that interfere with the generation of proton gradients, electron transport processes, and substrate phosphorylation. The fact that the transport of different sugars was inhibited by different combinations of inhibitors suggests that several types of energy dependent carrier-mediated transport systems are involved in *B. thetaiotaomicron* sugar uptake (Degnan and Macfarlane, 1995). In *B. fragilis* grown under conditions of excess carbon/energy, the glucose taken up by the cell was stored in cytoplasmic glycogen granules, which could be rapidly degraded when glucose became limiting (Lindner et al., 1979). A similar finding was seen in *B. thetaiotaomicron* cells given [^{14}C]-glucose, -mannose, -galactose or -xylose, and it was suggested that the ability to form these storage polymers may provide a competitive advantage in the colon (Hylemon et al., 1977; Degnan and Macfarlane, 1995).

The catabolism of glucose to pyruvate generally occurs via the Embden-Meyerhof pathway. Pathway enzymes such as fructose 1,6,-diphosphate aldolase, phosphofructokinase, hexokinase, and glucose-6-phosphate isomerase have been demonstrated in *B. thetaiotaomicron* and *B. fragilis* (Macy et al., 1978; Caspari and Macy, 1983). In *B. fragilis*, both ATP and PPi-linked phosphofructokinase activity were observed. Although the PPi-linked activity was much higher than the ATP-linked activity, which of these has a more important role in glycolysis has not been resolved (Roberton and Glucina, 1982). Other observations from [^{14}C]-glucose labeling studies indicated that the labeled fermentation products in *B. fragilis* were consistent with Embden-Meyerhof degradation (Macy et al., 1978). There also is enzymatic evidence for the presence of the pentose pathway as well. Strains of *B. fragilis*, *B. thetaiotaomicron*, *B. ovatus*, *B. vulgatus*, *B. distasonis* and *B. eggerthii* all have been shown to possess 6-phosphogluconate dehydrogenase and glucose 6-phosphate dehydrogenase, but the role of this pathway in *Bacteroides* catabolism has never been closely examined (Shah and Williams, 1982; Shah et al., 1987).

During growth with glucose, hemin and carbon dioxide, the major fermentation products produced by *Bacteroides* spp. include succinate, propionate and acetate, with lesser amounts of lactate, formate and malate (Macy et al., 1975; Macy et al., 1978; Holdeman et al., 1977; Caspari and Macy, 1983). The pathway leading to succinate and propionate in *B. fragilis* begins with formation of oxaloacetate by the carboxylation of phosphoenolpyruvate (PEP) in an ATP-generating reaction mediated by PEP carboxykinase (Macy et al., 1978; Caspari and Macy, 1983). *Bacteroides thetaiotaomicron* uses a similar pathway, but pyruvate carboxylase activity also has been demonstrated in these organisms (Pan and Imlay, 2001). Oxaloacetate is reduced to malate and then to fumarate by malate dehydrogenase and fumarate hydratase (Macy et al., 1978). The reduction of fumarate by fumarate reductase is one of the key reactions in *Bacteroides* energy metabolism. Fumarate is the terminal electron acceptor in a rudimentary electron transport system, which provides additional ATP as judged by studies on the molar growth yields of *B. fragilis* grown with and without hemin (Macy et al., 1975). On the basis of studies with different electron transport inhibitors, the flow of electrons likely involves reduction of a flavoprotein by reduced nicotinamide adenine dinucleotide (NADH) followed by quinone reduction and then reduction of cytochrome *b* (Macy et al., 1975; Harris and Reddy, 1977). The formation of succinate is then mediated by a membrane-bound fumarate reductase, which is specifically induced in the presence of hemin (Macy et al., 1975). In *B. fragilis*, hydrogen and formate also have been shown to be possible electron donors in this pathway; thus, potentially this is a branched electron transport system (Harris and Reddy, 1977). Fumarase- and NADH-linked fumarate reductase activities also have been demonstrated in *B. thetaiotaomicron* (Pan and Imlay, 2001).

Some succinate is metabolized further to propionate in a series of reactions that may or may not lead to further energy gains. One enzyme involved in propionate formation is methylmalonyl-CoA mutase, a B_{12}-dependent enzyme commonly found in succinate-propionate pathways (Macy et al., 1978). This enzyme activity has been demonstrated in *B. fragilis*, and B_{12}-dependent propionate formation has been shown in *B. fragilis* and *B. eggerthii* (Macy et al., 1978; Chen and

Wolin, 1981). Acetate formation in the *Bacteroides* has not been studied, but it is likely that reducing equivalents produced during the oxidation of pyruvate to acetyl-CoA will enter into the electron transport system.

Bacteroides spp. grown in the absence of hemin have a major shift in fermentation, with the major products being lactate, fumarate and acetate (Macy et al., 1975; Sperry et al., 1977; Al-Jalili and Shah, 1988). In *B. fragilis*, this shift reflects the lack of fumarate reductase and cytochrome *b*, which are required for succinate production. The result is fumarate accumulation, and pyruvate becomes a major electron sink from which lactate is formed by the action of an NAD-dependent lactate dehydrogenase (Macy et al., 1978).

Nitrogen Metabolism

Ammonia Assimilation The central features of *Bacteroides* nitrogen metabolism relate directly to their dependency on ammonia as the primary nitrogen source and their inability to utilize amino acids as a sole source of nitrogen. Rapid growth is dependent on the uptake and fixation of ammonia into glutamate. As found in other eubacterial species, the *Bacteroides* have two pathways for ammonia assimilation. First is the glutamine synthetase/glutamate synthase route that is often associated with growth under limiting ammonia conditions in organisms such as the Enterobacteriaceae. The activity of this pathway was established in *B. fragilis*, but the activity of glutamate synthase was very low (Yamamoto et al., 1984). In addition, on the basis of studies with the glutamine synthetase inhibitor, methionine sulfoximine, it was concluded that the pathway was not required for growth with low ammonia, since growth rates did not decrease in cells treated with the inhibitor, and glutamate dehydrogenase levels increased dramatically. The glutamine synthetase activity was highest under nitrogen limiting conditions, and another report using a reporter gene to assess glutamine synthetase transcription indicated that the enzyme was upregulated under nitrogen limiting conditions, thus indicating some role during nitrogen limitation (Yamamoto et al., 1984; Abratt et al., 1993). Clearly more defined genetic studies will be needed to elucidate the role of glutamine synthetase in ammonia assimilation.

The *B. fragilis* glutamine synthetase gene has been cloned and sequenced, but to date the glutamate synthase gene has not yet been identified (Southern et al., 1986; Hill et al., 1989). *Bacteroides thetaiotaomicron* also has glutamine synthetase activity; no pyridine nucleotide-linked glutamate synthase activity was detected in whole cell assays (Baggio and Morrision, 1996). The glutamine synthetase from *B. fragilis* is novel when compared to those of other eubacterial species. The subunit size is somewhat larger (82,827 Da), and the enzyme in its native form is a hexamer rather than the dodecamer (or octamer) structural arrangement seen in other organisms (Southern et al., 1986). Not surprisingly, phylogenetic analyses of glutamine synthetases have revealed that the *B. fragilis* enzyme was part of a novel group designated "GSIII" that also includes the enzymes of *Synechocystis*, *Butyrivibrio* and a few other non-Enterobacteriaceae species (Reyes and Florencio, 1994). The GSIII enzymes do not appear to be controlled by adenylylation, and they lack several other key structural features of the more common enzymes. Little information on glutamine synthetase is available for the other *Bacteroides* spp.

In their normal environment, the *Bacteroides* rarely encounter growth-limiting concentrations of ammonia. Thus these organisms may have evolved their primary strategy for ammonia assimilation on the basis of the second pathway, direct incorporation of ammonia into glutamate via glutamate dehydrogenase. Both *B. fragilis* and *B. thetaiotaomicron* possess two glutamate dehydrogenase enzymes. The enzyme encoded by *gdhA* has dual cofactor dependency, whereas the *gdhB* gene encodes for an NADH specific enzyme (Glass and Hylemon, 1980; Yamamoto et al., 1987a; Baggio and Morrison, 1996). The GdhA from *B. fragilis* and *B. thetaiotaomicron* has a subunit size of about 48,500 and the holoenzymes are about 300,000 Da, suggesting a hexameric structure (Gibson and Macfarlane, 1988a). The GdhA of both species also has greater activity with reduced nicotinamide adenine dinucleotide phosphate (NADPH) as opposed to NADH, but in *B. fragilis*, the K_m values for ammonia are 1.7 and 4.9 mM, which are much lower than the 5.0 and 15 mM values obtained for the *B. thetaiotaomicron* enzyme (Yamamoto et al., 1987a; Gibson and Macfarlane, 1988a). Thus in *B. fragilis*, GdhA is thought to be involved in ammonia incorporation during growth with low levels of ammonia. GdhA undergoes a rapid inactivation in response to exposure to high concentrations of ammonia during growth, indicating it can be rapidly shut down as the need for glutamate decreases (Yamamoto et al., 1987b; Saito et al., 1988). Cells shifted from media containing 50 mM ammonia to media with 1 mM ammonia had a fivefold increase in GdhA activity. Also, when cells are grown in the presence of high concentrations of peptide nitrogen, the activity of GdhA is low but increases if ammonia is added to the culture (Abrahams et al., 2001). There have been no transcriptional studies of *gdhA* in *B. fragilis*, but in *B. thetaiotaomicron*,

levels of message for different growth conditions did not change (Baggio and Morrision, 1996). This suggests that control of activity may be the primary mechanism used to regulate GdhA, and a candidate for this inactivation activity is encoded by the *gdhX* gene, which is co-transcribed with *gdhA* in *B. thetaiotaomicron*. Overall, however, the role for GdhA is not entirely clear because the growth of a *B. thetaiotaomicron* mutant lacking an intact *gdhA* gene was not affected on any medium tested (Baggio and Morrision, 1996). That is, there was no obvious phenotype for the *B. thetaiotaomicron gdhA* mutant, but similar studies have not yet been performed in *B. fragilis*.

The second glutamate dehydrogenase, GdhB, has been cloned from *B. fragilis* and was found to belong to the hexameric glutamate dehydrogenase Family I (Abrahams and Abratt, 1998). The structural gene would encode a peptide of 49,000 Da, and this peptide had greatest similarity to the NADH-specific Gdh from *P. gingivalis* and GdhA from *B. thetaiotaomicron*. In contrast to *gdhA*, there was significant induction of *gdhB* seen in Northern blots of cells grown in the presence of peptides (Abrahams and Abratt, 1998). There also may be some modification of GdhB activity in response to environmental conditions, since activity rapidly decreased when cells were removed from media containing high levels of peptides. Further, it was found that GdhB localized to the cell surface even though there was no obvious signal sequence (Abrahams et al., 2001). Taken together, it is thought that this enzyme may play a role during growth on proteins or peptides, perhaps during infection as well as in the intestinal tract.

In *B. fragilis* and *B. thetaiotaomicron*, there are two distinct glutamate dehydrogenases with different regulatory patterns, but little information is available for the other *Bacteroides* spp. However, one survey looking at electrophoretic mobility showed that an NADH-linked glutamate dehydrogenase activity migrated as a single protein species in *B. fragilis*, *B. thetaiotaomicron*, *B. ovatus*, *B. vulgatus*, *B. eggerthii* and *B. distasonis* (Shah and Williams, 1982). Additionally in another survey, the *B. fragilis*, *B. thetaiotaomicron*, *B. ovatus*, *B. vulgatus*, *B. uniformis* and *B. distasonis* Gdh enzymes were found to function with either NADPH or NADH (Glass and Hylemon, 1980). Taken together, the two results suggest that these are enzymes with dual cofactor specificity.

Protein Utilization The *Bacteroides* spp. have significant proteolytic capability, but they cannot use peptides as a sole carbon and energy source. They can however grow with peptides as the sole nitrogen source, and as mentioned above, GdhB may have a role in the assimilation of the nitrogen in glutamate-containing peptides. Proteolytic activity has been demonstrated in several *Bacteroides* spp. In one survey, protease activity (gelatinase) was found in *B. fragilis*, *B. distasonis* and *B. vulgatus* (Rudek and Haque, 1976). Approximately 50% of both *B. fragilis* and *B. thetaiotaomicron* were found to have elastase activity and a 100-kDa protein with fibrinogen-degrading activity was purified from *B. fragilis* (Chen et al., 1995; Mikamo et al., 1999). This protease appeared to be a serine-thiol protease that had activity against azocasein, casein, fibrinogen, gelatin and azocoll but not bovine serum albumin fibronectin, hemoglobin or collagen. Other species, *B. thetaiotaomicron*, *B. ovatus*, *B. uniformis*, *B. eggerthii* and *B. distasonis*, also had similar fibrinolytic activity, but the activities were reduced compared to those of *B. fragilis*. In another study on *Bacteroides* proteases, three separate activities with high levels of activity against trypsin and casein were found in *B. fragilis* (Gibson and Macfarlane, 1988b). The substrate profile was somewhat different in that gelatin and azocoll were not degraded and elastase activity was absent in this strain. The range observed on synthetic substrates was also very restricted (Gibson and Macfarlane, 1988a). Two of the *B. fragilis* proteases were endopeptidases (P2 and P3) with characteristics of serine-thiol proteases, and the third (P1) was an exopeptidase in the cysteine protease group. The P2 and P3 proteases were cell bound and associated with the outer membrane, while P1 was predominately associated with the periplasm (Gibson and Macfarlane, 1988a). The overall protease activity was higher in organisms grown in media with casein than in those from media with ammonia as the nitrogen source. In general, it appears that the substrate range of the GI-tract *Bacteroides* proteases is limited when compared to the proteolytic activities of related organisms such as *Prevotella ruminicola* or *P. gingivalis*. The *Bacteroides* proteases probably have a role in the utilization of nitrogen and turnover of protein in the gut, and a potential role in pathogenesis cannot be overlooked. More of the proteolytic capabilities important for growth in the intestinal tract or for pathogenesis are discussed in their relevant sections on Protease Activity in the Colon and on Proteases and Hydrolytic Enzymes in Pathogenesis.

Amino Acid Biosynthesis There are few studies of *Bacteroides* amino acid biosynthesis, but it is clear from the nutritional studies that with the possible exception of *B. ovatus*, all *Bacteroides* spp. can synthesize their amino acids de novo (Varel and Bryant, 1974). Glutamate is likely the primary source for α-amino groups of amino

acids, which are formed via transamination of the corresponding 2-oxoacid. As described above, glutamate dehydrogenase catalyzes the reductive amination of α-ketoglutarate in a typical reaction, but the synthesis of the precursor α-ketoglutarate does not occur by typical pathways. The major route of α-ketoglutarate synthesis occurs via a reductive carboxylation of succinate as shown by studies following the incorporation of [^{14}C]-succinate into glutamate. This α-ketoglutarate synthase activity has been demonstrated in *B. fragilis*, *B. vulgatus*, *B. uniformis* and *B. distasonis* (Allison et al., 1979; Allison et al., 1984). Reductive carboxylation also appears to be important in *B. fragilis* for the synthesis of leucine, isoleucine and phenylalanine, which can be derived from isovalerate, 2-methylbutyrate and phenylacetate, respectively (Allison et al., 1984). Thus the presence of these acid precursors in the external environment may be a competitive advantage by providing the carbon skeletons for biosynthesis. Recent studies also have documented the synthesis of α-ketoglutarate by a pathway that involves the oxidative branch of the Krebs cycle (Baughn and Malamy, 2002). In an important observation, it was shown that aconitase (GenBank accession number AF434843) and isocitrate dehydrogenase were present in *B. fragilis* and that this route of α-ketoglutarate synthesis was used during growth in the absence of hemin, inasmuch as succinate cannot be produced via the fumarate reductase reaction under these conditions (see section on Sugar Catabolism and Fermentation Pathways in this Chapter). This work and further inspection of the *B. fragilis* genome database indicate that most of the forward Krebs cycle enzymes are present, although it is not likely to function in the synthesis of fumarate from succinate (http://www.sanger.ac.uk/Projects/B_fragilis/).

During growth under conditions that do not provide the acids for reductive carboxylation, *B. fragilis* has the ability to synthesize the amino acids from glucose by typical pathways. In the case of leucine biosynthesis, two of the requisite enzymes have been demonstrated in *B. fragilis*, α-isopropylmalate synthase (*leuA*) and β-isopropylmalate dehydrogenase (*leuB*; Wiegel, 1981; Sarker et al., 1995a; Sarker et al., 1995b). The *B. fragilis leuB* gene was in fact cloned by complementation of the *leuB* mutation in *E. coli*, thus indicating functional, as well as sequence homology in this pathway. Interestingly, isopropylmalate synthase appears to be regulated such that its activity is lower in cells grown with isovalerate or leucine in the medium, thus supporting the notion that it may be advantageous to obtain this precursor from the environment when it is available. Nutritional studies provide insight into methionine biosynthesis. The vitamin B_{12} requirement for *B. fragilis*, *B. vulgatus*, *B. thetaiotaomicron* and *B. distasonis* could be replaced by methionine, suggesting that biosynthesis occurs via a B_{12}-dependent homocysteine-N5-methyltetrahydrofolate transmethylase (MetH, methionine synthase). A gene encoding a protein with 45% identity to MetH from *E. coli* was present in the B. fragilis unfinished genome database.

The completed genome sequence will be a powerful tool for better understanding the peculiarities of amino acid biosynthetic pathways in *Bacteroides* spp.

Aerotolerance and the Response to Oxidative Stress

Many studies have shown that anaerobic bacteria are not uniformly sensitive to oxygen, and their range of oxygen tolerance is broad (Morris, 1991). Among anaerobic bacteria, the *Bacteroides* spp. are some of the most aerotolerant species known. In addition, aerotolerance may prove to be an important virulence factor. This is supported by the fact that clinical isolates of *B. fragilis* are more resistant to oxygen exposure than fecal strains are. The former strains were able to survive in the presence of oxygen for 48–72 h, while the latter lost viability after 4 h of oxygen exposure (Tally et al., 1975; Rolfe et al., 1977). This suggests that there is an adaptive mechanism that may protect cells during an oxidative stress. In fact, *B. fragilis* is able to adapt and survive in tissues with oxygen tensions up to 6% during the initial steps of infection until adequate anaerobic conditions for growth are established (Rotstein et al., 1985; Park et al., 1992).

To survive in the more oxygenated environment outside the colon, *B. fragilis* must defend itself from the damage caused by reactive oxygen species (ROS). The formation of these ROS is an unavoidable consequence of aerobic exposure and can lead to macromolecule damage such as peroxidation of membrane lipids, oxidation of amino acids in proteins, the destruction of iron-sulfur clusters in enzymes, and DNA base modifications and strand breaks (Storz and Imlay, 1999). A few studies describe the mechanisms leading to oxidative damage in anaerobes. Studies comparing the oxidative DNA damage between the strictly anaerobic *Prevotella melaninogenica* and *B. fragilis* after exposure to O_2 or H_2O_2 have demonstrated that formation of 8-hydroxydeoxyguanosine (8OHdG, a DNA damage marker) was induced in *P. melaninogenica* but not in *B. fragilis* (Takeuchi et al., 1999). Furthermore, in vivo and in vitro studies have shown

that aeration caused a drastic reduction in the fumarase and pyruvate:ferredoxin oxidoreductase as well as oxidation of other iron-sulfur center-containing proteins in *B. thetaiotaomicron* (Pan and Imlay, 2001).

More information is available for enzymes that protect from ROS. Among *Bacteroides* spp., catalase activity is not universally present, although *B. fragilis* and *B. distasonis* are generally catalase positive while *B. thetaiotaomicron*, *B. ovatus* and *B. eggerthii* possess variable catalase activity (Wilkens et al., 1978). *Bacteroides vulgatus* and *B. uniformis* are catalase negative. A single catalase gene (*katB*) was found in *B. fragilis*, and hybridization analysis showed that *katB* had strong homology with all *B. fragilis* strains tested but not with other *Bacteroides* spp. except for *B. thetaiotaomicron*. Also, some rearrangements in the catalase gene region were observed between *B. fragilis* ATCC 2393 (homology group II) and the two homology group I strains ATCC 25285 and 638R (Rocha and Smith, 1995). Superoxide dismutase (Sod) activity was found in cell extracts of *Bacteroides* species. Isoelectric focusing has demonstrated that Sod occurs in different forms in the different species (Carlsson et al., 1977). Moreover, the frequency of Sod occurrence varies within the genera and among the species (Gregory et al., 1978). For example, Sod activity in some *B. fragilis* strains varies over a 15-fold range, while some strains of *B. vulgatus* have no detectable Sod activity. *Bacteroides fragilis* and *B. thetaiotaomicron* synthesize a single superoxide dismutase that exists as dimers of 42,000 and 46,000 Da, respectively (Gregory and Dapper, 1983; Pennington and Gregory, 1986). *Bacteroides fragilis* and *B. thetaiotaomicron* Sod enzymes are cambialistic metalloenzymes that contain Fe (FeSod) in anaerobic cells, and under aerobic conditions, Fe is replaced by Mn (MnSod; Gregory and Dapper, 1983; Pennington and Gregory, 1986). The variation in oxygen sensitivity among *Bacteroides* species might be attributed to the heterogeneous expression of catalases and superoxide dismutase among the different species.

Bacteroides cannot change to aerobic metabolism, and when shifted from an optimal anaerobic growth condition to an adverse aerobic environment, it will most likely "redirect" its energy resources and metabolism for protection and survival. Consistent with this, *B. fragilis* synthesizes two very similar and overlapping sets of approximately 28 new proteins following stress induction by either oxygen exposure or addition of hydrogen peroxide. Thus far, superoxide dismutase, alkyl hydroperoxide reductase (AhpCF), the nonspecific DNA-binding protein, Dps, catalase (KatB) and *nrdA* have been identified as important components of the oxidative stress response (Gregory and Dapper, 1983; Rocha et al., 2000; Smalley et al., 2002). Pretreatment with sublethal concentrations of hydrogen peroxide has been shown to induce catalase (*katB*) expression and protection against further exposure to high concentrations of hydrogen peroxide (Rocha et al., 1996). In addition, catalase was important (but it was not the only factor needed) to protect *B. fragilis* DNA against oxidative damage as determined by the levels of 8OHdG following treatment with H_2O_2 or O_2 (Takeuchi et al., 1999). *Bacteroides fragilis* mutants in *ahpCF* or *katB* have an increased sensitivity to the toxic and mutagenic effects of peroxides, which confirms the role of this inducible response in protection from oxidative stress (Rocha et al., 1996; Rocha and Smith, 1999).

The *B. fragilis* peroxide response is regulated by OxyR, which is a LysR-family transcriptional activator similar to that found in facultative organisms (Rocha et al., 2000). The OxyR protein regulates the transcription of *katB*, *ahpCF* and *dps* in response to H_2O_2 or O_2. A mutated OxyR with a glycine substitution for the aspartate at position 202 resulted in a permanently activated form of OxyR, which was responsible for the constitutive expression of *katB*, *ahpCF* and *dps* in the *B. fragilis* mutant strain. There also appears to be an oxygen responsive regulatory network that is independent of OxyR. This was suggested by transcriptional analysis of *dps*, where induction by H_2O_2 was lost in an *oxyR* mutant, but some induction still occurred during exposure to air (Rocha et al., 2000). In addition, recent results showed several other genes (*nrdA*, *sod* and *asdA*) that were induced only by O_2 and not by H_2O_2 (Rocha et al., 2000; Smalley et al., 2002).

Mechanisms other than classic "detoxification" also seem to help *B. fragilis* withstand long periods of oxygen exposure. One novel mechanism was the discovery of the *Bacteroides* aerotolerance operon (*batABCDE*). The *bat* genes were shown to be important for survival in the presence of oxygen and growth in vivo in model systems (Tang et al., 1999). The less aerotolerant *bat* mutants were unable to compete with the wildtype strain in an experimental mixed infection. This clearly demonstrated an association between the ability of *B. fragilis* to survive in the presence of oxygen and survival in host tissues. Bat proteins seem to form a complex involved in the generation or export of reducing power equivalents into the periplasm of *B. fragilis* (Tang et al., 1999), but no data are available yet to determine whether the *bat* operon are induced as part of the oxidative stress response.

Genetics

Genome Structure

During the past 15 years, understanding of *Bacteroides* genetics and the development of molecular tools have progressed sufficiently so that genetic manipulation of these organisms is now routine. Thus, there is a wealth of new information available and the promise of even more rapid advances as the genome sequencing projects for two *B. fragilis* strains (see http://www.sanger.ac.uk/Projects/B_fragilis/) near completion.

The G+C content of *Bacteroides* ranges from 39–48 mol%, averaging 44% for all species (Johnson, 1978a; Table 2). Genome sizes for the predominant species have been estimated by pulsed-field gel electrophoresis analysis of chromosomes digested with the rare-cutting restriction enzymes *Cru*I, *Not*I, and *Asc*I (Shaheduzzaman et al., 1997). As shown in Table 2, genome size varies from the smallest for *B. eggerthii* at 4.4 Mb to the largest, *B. ovatus* at 6.7 Mb. Overall the average size range of the *Bacteroides* genomes is similar to the median size of the known eubacterial genomes that are already or in the process of being sequenced (see TIGR in progress and TIGR complete websites). A chromosome map of one *B. fragilis* strain (homology group II strain YCH46) has been constructed for the enzymes *Not*I (16 sites), *Asc*I (7 sites), and *Ceu*I (6 sites; Kuwahara et al., 2002). The chromosome was circular and approximately 5.3 Mb. Several genetic markers, including *cfiA*, *glnA*, *recA*, *nanH* and six rRNA operons, were mapped and found to be scattered around the chromosome. In the case of *B. fragilis*, genome size (5.225 Mb) has been independently verified by the near completion (99.9%) of the genome sequence for the type strain, ATCC 25285. *Bacteroides* genomes are composed of a diverse array of plasmids, transposons and insertion sequence (IS) elements, as will be discussed in the section Genetic Elements, but evidence for a pathogenicity island(s) in strains containing the zinc metalloprotease toxin, fragilysin, is also present (Moncrief et al., 1998; Franco et al., 1999). The first of these is BfPAI, which is about 6 kb and 35 mol% G+C. BfPAI encodes two metalloprotease toxin genes, *bft1* and *mpII*, which share about 28% identity at the amino acid level. This pathogenicity island is located within a larger genetic element (≥12 kb; 49 mol% G+C), which shared some features associated with mobilizable *Bacteroides* plasmids. On the basis of their dissimilar mol% G+C composition (compared to the chromosomal values), it was suggested that these two genetic elements were obtained by horizontal transfer (Franco et al., 1999).

Table 2. Structural features of *Bacteroides* genomes.

Species	G+C (mol%)	Genome size (Mb)
B. fragilis	41–44	5.2
B. thetaiotaomicron	40–43	4.7
B. vulgatus	40–42	5.2
B. uniformis	45–48	4.8
B. ovatus	39–43	6.7
B. distasonis	43–45	4.8
B. eggerthii	44–46	4.4

From Johnson (1978), Holdeman et al. (1986), and Shaheduzzaman et al. (1997).

Genetic Elements

Additional genetic elements that make up the genomes of *Bacteroides* spp. are plasmids, IS elements, and transposons. Plasmids are found frequently in all of the *Bacteroides* spp., with surveys reporting 20–50% of clinical or fecal isolates containing plasmid DNA (Stiffler et al., 1974; Wallace et al., 1981; Callihan et al., 1983; Odelson et al., 1987; Soki et al., 1999). Multiple plasmids (each 2.7–80 kb) are not uncommonly found in a single strain. The majority of plasmids isolated from these organisms are small (<8 kb), cryptic plasmids that can be classified into one of just several homology groups, and most appear to contain mobilization genes that allow them to be transferred by conjugation (see Conjugation; Callihan et al., 1983; Smith et al., 1998). Although relatively rare, antibiotic-resistance plasmids also have been described in *Bacteroides* spp. These plasmids have been associated with transmissible resistance to macrolide-lincosamide-streptogramin drugs (MLS) and to 5-nitroimidazole drugs (reviewed in Smith et al., 1998). The MLS-resistance determinant, *ermF*, has been found on several unrelated plasmids, but in each case, it was located in closely related compound transposons (reviewed in Odelson et al., 1987, and Smith et al., 1998). The MLS-resistance plasmids were either self-transmissible (pBF4 and pBI136) or mobilizable (pBFTM10). The 5-nitroimidazole-resistance determinants (*nim*) have been observed on a wide variety of mobilizable plasmids. In contrast to the MLS-resistance plasmids, the *nim* genes were not part of compound transposons. Other than the MLS and *nim*-resistance plasmids, there are no other verified antibiotic-resistance plasmids in the *Bacteroides*.

Similar to other genera, the *Bacteroides* harbor a variety of IS elements that have been

found in the chromosome and on plasmids of several different species. Thus far about nine different IS elements have been documented, and these generally fall in the 1.1–1.6-kb range. The elements belong to several different IS families (e.g., IS*5*, IS*30*, IS*4* and IS*21*) that represent a range of genetic organizations and transposition mechanisms (reviewed in Smith et al., 1998). All of the *Bacteroides* IS elements identified to date were first found to be associated with antibiotic-resistance genes. In these cases, the IS elements were located directly adjacent to the resistance determinants and had outward firing promoters that controlled transcription of the resistance genes. IS elements have been shown to activate expression of *nim*, *ermF*, *cfiA* (metallo-β-lactamase) and *cepA* (β-lactamase) by acting as transcription promoters (Podglajen et al., 1992; Podglajen et al., 1994; Podglajen et al., 2001; Haggoud, et al., 1994; Rogers et al., 1994). Even though the IS elements are required for expression of many antibiotic-resistance genes, they are not frequently found associated with compound transposons. Thus far, only IS*4351* has been linked to compound transposons, and it is part of Tn*4351*, Tn*4400* and Tn*4551*, which are three plasmid-borne compound transposons encoding MLS-resistance. The structure of these transposons is similar to the IS elements in direct orientation, flanking the *erm* gene and one other antibiotic-resistance gene (Odelson et al., 1987; Smith et al., 1998). The compound transposons have been used as genetic tools for random mutagenesis of *B. fragilis* and *B. thetaiotaomicron* and other related genera from the oral cavity (Salyers et al., 2000). Recently, a modified version of Tn*4400* was constructed to increase transposition frequency and identification of mutants (Tang and Malamy, 2000).

The most common transposons found in *Bacteroides* spp. are conjugative transposons (CTn) and mobilizable transposons (MTn), both of which share common features and are highly transmissible by a conjugation-like mechanism (Salyers et al., 1995a; Salyers et al., 1995b). The CTns are generally large elements ranging in size from 50 kb to more that 150 kb. The common features of the CTns are that they encode tetracycline-resistance, mediated by the *tetQ* gene, and they are self-transmissible, encoding all of the genes for the conjugation apparatus. A recent survey that included all of the *Bacteroides* species showed that these elements are widespread, being found in 60–80% of recent isolates as compared to about 30% of isolates obtained prior to 1970 (Shoemaker et al., 2001). This dissemination can be accounted for by the broad host range of the CTns, which are able to transfer to all *Bacteroides* spp., to related genera (*Porphyromonas* and *Prevotella*), and to *E. coli*. The majority of CTns appear to be closely related, sharing significant DNA sequence homology to each other and to CTnDOT, which is the prototypic element (Shoemaker et al., 2001; Whittle et al., 2001). However, the structure of the CTns is somewhat variable, and the elements can be classified into several groups on the basis of restriction fragment length polymorphisms (RFLPs; Shoemaker et al., 2001). Also, a few CTns contain the *tetQ* gene but otherwise do not hybridize with CTnDOT, suggesting that other conjugative transposon classes are present in these organisms. The mechanism of CTn transposition appears similar to that of the well-studied Tn*916* except that transposition is not random and there are only a limited (5–10) number of CTn insertion sites in the *Bacteroides* chromosomes (Bedzyk et al., 1992; Cheng et al., 2000). Transposition is a several step process that requires the element to excise from the chromosome and then form a covalently closed circular intermediate. Next the transposon can either insert at a new location or be transferred to a new host where it will integrate upon entry. Both the integration and excision steps require a lambda-family integrase that makes staggered cuts 5 bp from the ends of the transposon to excise the element and then presumably produces similar cuts in the target site for integration (Cheng et al., 2000). Further characterization of the transposition mechanism is underway. Perhaps the most notable feature of the *Bacteroides* CTns is that their transfer and transposition are induced (100–1000-fold) by exposure to tetracycline (Privitera et al., 1979b; Salyers et al., 1995a). This induction is mediated by a signal transduction mechanism involving three regulatory genes (*rteA*, *rteB* and *rteC*) plus the resistance gene *tetQ* (Stevens et al., 1993). This regulatory system appears to control expression of the conjugation apparatus, but no specific targets of this control have yet been identified (Stevens et al., 1993). The RteA and RteB gene products have homology to classic two-component regulatory system sensors and regulators, and their roles in signal transduction are currently being worked out.

The last class of transposon frequently encountered in *Bacteroides* spp. is the novel mobilizable transposons (MTn). These elements can be transferred to a wide variety of bacterial genera, but they differ from the CTns in that they cannot self-transfer. Rather, they require a co-resident CTn or conjugative plasmid to provide the conjugation apparatus for transfer and thus are mobilized in *trans* by these conjugative elements. There have been five MTns studied in detail: NBU1 and NBU2 (from *B. uniformis*), Tn*4555* (from *B. vulgatus*), and Tn*4399* and

Tn*5520* (from *B. fragilis*; reviewed in Smith et al., 1998). Surveys using NBU1 or NBU2 as a probe in Southern hybridization assays have shown that MTns are found in virtually all *Bacteroides* spp. (Wang et al., 2000). These elements range in size from 4.7 to 12.1 kb, and all have the same basic genetic organization, containing at a minimum a lambda-family integrase, a mobilization gene(s) and an *oriT*. Among the MTns, there is considerable homology, but this appears to be due to their modular construction. That is, some elements share related integrase genes and others share similar mobilization genes but have unrelated integrases (Smith et al., 1998). It is thought that these elements may be important for antibiotic-resistance dissemination in *Bacteroides*, since two MTns have been shown to encode resistance determinants (Parker and Smith, 1993; Smith and Parker, 1993; Wang et al., 2000).

Mechanisms of Genetic Exchange

Conjugation First described in 1979 for the MLS-resistance plasmids and the CTns, conjugation is the most important genetic exchange mechanism in *Bacteroides* spp. and is responsible for the widespread dispersal of all genetic elements in this genus (Privitera et al., 1979a; Privitera et al., 1979b; Welch et al., 1979). Conjugation requires direct cell-to-cell contact of donor and recipient cells on a solid substrate, and there have been no reports of successful matings in liquid cultures. In contrast to many other organisms, self-transmissible plasmids such as pBF4 and pBI136 seem to be relatively rare; thus nearly all conjugation among the *Bacteroides* is driven by the CTns. The CTns are remarkable, self-transmissible elements that also have the ability to mobilize a diverse set of unlinked plasmids and MTns. In fact, mobilization does not appear to be specific, and essentially any element that has a *Bacteroides* spp. mobilization gene and *oriT* can be transferred by a CTn. As mentioned above, transfer and mobilization are highly inducible by pre-exposure to tetracycline, which increases conjugation frequencies by as much as 1000-fold (Salyers et al., 1995a; Salyers et al., 1995b). Control appears to be at the transcriptional level and depends on the same regulatory genes as found for transposition (Stevens et al., 1992; Stevens et al., 1993). This signal transduction pathway is very complex and there are likely other factors involved, but their identity remains to be determined. Recently the 19-kb conjugation region from CTnDOT was cloned and sequenced (GenBank accession number AF289050). There were 17 genes in the transfer region with a mol% G+C content of 48–60% (Li et al., 1995; Bonheyo et al., 2001a). All but one of the genes encoded apparently novel proteins that have never been seen in conjugation systems from other Gram-negative or Gram-positive bacteria. One gene, *traG*, encoded a protein that had homology to VirB4 or TrsE, which are proteins thought to be involved in the translocation of DNA across the mating pore. The TraG protein also had homology to BctA, which is required for conjugation of pBF4 (Morgan and Macrina, 1997; Bonheyo et al., 2001a; Bonheyo et al., 2001b).

Conjugation also has been the most successful technique used for the genetic manipulation of *Bacteroides* spp. Plasmids can be readily transferred into any *Bacteroides* spp. from *E. coli* using the IncP plasmid-based conjugation systems such as RK2, RP4, R751 or S17-1 (which contains RP4 in the chromosome) as first described by Guiney et al. (1984a). The main requirements are that the vectors contain an *oriT* recognized by RK2 and a selectable marker such as *ermF*, which can be expressed in a *Bacteroides* spp. host. A wide variety of vectors are currently available including suicide vectors for allelic exchange or insertional mutagenesis as well as replication-competent vectors for complementation or gene expression studies. All of these plasmids can be transferred at a relatively high frequency (10^{-3}–10^{-5} transconjugants per input donor cell) to recipient cells using standard mating protocols (Shoemaker et al., 1986; Smith et al., 1998; Salyers et al., 2000). The most common technique for conjugation experiments is to mix donor and recipient cells together and deposit them on a 0.45-μm filter that has been placed on an agar plate of suitable growth medium. An overnight incubation then is done under anaerobic conditions if the donor cells are *Bacteroides* spp., but in cases where *E. coli* donor cells are being used (for recombinant plasmids), aerobic incubatation of the mating plate is recommended for optimal transfer frequency (Shoemaker et al., 1986; Salyers et al., 2000). Following overnight incubation, the cells are washed off the filter and plated on selective media.

Transformation Although there are no known natural genetic transformation systems in the *Bacteroides*, both chemically induced competence and electroporation have been successfully used for the introduction of plasmid DNA into these organisms (Smith, 1985; Smith et al., 1990). Electroporation has proven more effective than chemical methods of induction, but for both methods, transformation has been documented only for strains of *B. fragilis*. Further, the utility of transformation as a genetic tool has been limited by low transformation frequencies when us-

ing plasmid DNA isolated from *E. coli*. Typical transformation frequencies are 10^4–10^6 transformants per μg of plasmid DNA for *B. fragilis* strains transformed with plasmid DNA isolated from *B. fragilis*. Frequencies are usually about 1/10 these values when plasmid DNA was from *B. uniformis*, *B. thetaiotaomicron* or *B. ovatus* and 1/1000 when the DNA was of *E. coli* origin (Smith et al., 1990). The strong inhibition of transformation most likely is due to the effective restriction/modification systems present in *Bacteroides* spp. There have been reports of restriction enzymes from *B. fragilis*, *B. distasonis*, *B. caccae* and *B. vulgatus*, and the recognition sequences for these can be viewed at the rebase website (rebase.neb.com/rebase/rebase.html). Enzymes with 4- , 5- or 6-bp cleavage sites have been identified and the enzymes have been shown to produce flush ends or ends with 5′ overhangs (Murakami et al., 1990; Murakami et al., 1991; Reinecke and Morgan, 1991; Azeddoug et al., 1992). Thus far the only methylase activity demonstrated has been for *Bfr*BI (ATG^CAT) from *B. fragilis* (Azeddoug et al., 1992). The significance of these restriction systems is apparent from inspection of the DNA sequence from two MTns, Tn*4555* and NBU1. These elements (12.1 and 10.3 kb, respectively) harbor only one *Bfa*I (C^TAG) site, two *Bfr*BI sites, and no *Bfr*I (C^TTAAG) sites. Selection against the *Bacteroides* endonuclease recognition sites is obvious since (for example, in the case of Tn*4555*) one would predict on the basis of the nucleotide composition of the element that there would be 46 *Bfa*I sites (Tribble et al., 1999).

Bacteriophage The last potential mechanism of genetic exchange is transduction mediated by bacteriophage. There have been numerous reports on the isolation of bacteriophage capable of growth on all of the *Bacteroides* spp. except *B. vulgatus* (Keller and Traub, 1974; Booth et al., 1979; Cooper et al., 1984; Kory and Booth, 1986). These phage are easily isolated, usually from sewage effluent, and in one extensive survey, 68 bacteriophage representing four morphological types were isolated (Booth et al., 1979). Each of the phage had a narrow host range, infecting only *Bacteroides* species from which it was originally isolated. This specificity has been used to devise a phage typing scheme to differentiate *B. thetaiotaomicron* and *B. ovatus* (Cooper et al., 1984). There is one report of successful transfection of a *Bacteroides* spp. in which cells of *B. thetaiotaomicron* were transfected with DNA isolated from phage β_1, a hexagonal headed DNA bacteriophage (Burt and Woods, 1977). Transfection required Ca^{+2} treatment of cells obtained from any stage of growth, and efficiency was 5.5×10^8 PFU per μg of DNA. In these studies and in an earlier work with a *B. fragilis* phage, an unusual pseudolysogeny or phage-carrier state was demonstrated in which phage and bacteria existed in equilibrium, but a true lysogen was not produced. Despite the widespread presence of phage, numerous attempts have failed to demonstrate any form of transduction in *Bacteroides* spp. (Booth et al., 1979).

Ecology and Habitat

Features of the Gastrointestinal Tract Environment

The *Bacteroides* spp. are obligate host-associated organisms most commonly found in the gastrointestinal tract of humans and other mammals. All of the *Bacteroides* spp. also have the potential to be opportunistic pathogens when translocated to a normally sterile body site; thus they can survive outside of their normal habitat in a mammalian host. Of the two major alimentary tract architectures of mammals, those with a hindgut fermentation generally seem to be preferred, although *Bacteroides* spp. have occasionally been isolated from the rumen of sheep or cattle (Holdeman et al., 1977; Holdeman et al., 1986; Macy, 1984; Wood et al., 1998). In hindgut habitats, *Bacteroides* spp. are found most frequently distal to the stomach where the gastric secretions have been diluted and transit times begin to decrease. The primary areas of colonization begin in the distal small intestine towards the terminal ileum and are maximal in the colon (Finegold et al., 1983). The intestinal tract should be considered as an open ecosystem in which nutrients enter at one end and bacterial cells and waste exit from the other end. This ecosystem, especially the large intestine, is a highly competitive environment in which some 500 species of bacteria compete for the limiting nutrient supply. A variety of other environmental factors also limit or influence the growth of microorganisms in this habitat, but these are for the most part stable. Temperature is maintained at a relatively high level in mammals, and this leads to high metabolic activity and rapid fermentation rates of the flora. The pH of the colon varies along its tract from slightly acid along the ascending colon to neutrality or slightly above in the descending colon (Fallingborg, 1999). These values are thought to reflect the relative carbohydrate fermentation activity, which is highest as fresh material enters the cecum, slows in the transverse colon as substrates become limiting, and then finally switches to a protein fermentation as carbohydrate is exhausted (Macfarlane and Cummings,

1991a). Gas composition and redox potential of the colon also are the result of the high level of microbial activity. This is an anaerobic environment with oxygen at less than 12 mmHg (1.5%) and carbon dioxide levels of up to 84 mmHg (5–10%; Bornside et al., 1976). Other gases present in the environment include hydrogen and methane, both of which are products of metabolism in a complex anaerobic ecosystem. In such highly reducing conditions, the redox potential for the intestinal tract usually runs in the range of –150 to –350 mV.

Distribution of *Bacteroides* spp. in the Colon as a Function of Space and Time

Flora of the Adult Intestinal Tract In rodents, *Bacteroides* spp. colonize the upper gastrointestinal tract including the stomach and small intestine, reaching numbers of 10^9 and 10^6 per g wet wt., respectively, but in humans, *Bacteroides* spp. are not routinely isolated from either of these locations (Tannock, 1977; Finegold et al., 1983; Bernhardt and Knoke, 1989). Progressing down the tract toward the distal small intestine, there is an increase in the numbers of *Bacteroides* spp. until the ileum, where the composition of the flora begins to take on characteristics typical of the colonic flora with numbers of *Bacteroides* spp. reaching 10^6 per g wet wt. However, this flora and that of the cecum generally have fewer numbers and a lesser percentage of *Bacteroides* than are encountered further down the tract (Marteau et al., 2001). The large intestine is the primary site of *Bacteroides* colonization, in which these organisms can account for ca. 30% of the total microbial population in humans as determined by direct culture methods (Finegold et al., 1974; Moore and Holdeman, 1974; Holdeman et al., 1976; Duerden, 1980). Similarly, using an oligonucleotide hybridization approach to detect 16S rRNA, *Bacteroides*-specific probes were found to account for 37% of the total bacterial rRNA in fecal samples, thus upholding the findings from direct culture methods (Sghir et al., 2000).

Each of the *Bacteroides* spp. is isolated from the colon in high numbers (10^9–10^{11} per g dry wt), but there is considerable variation from person to person and there seems to be an important contribution of diet and culture on the distribution of *Bacteroides* spp. (Table 3). *Bacteroides thetaiotaomicron* and *B. vulgatus* are generally considered to be the most numerous species in the colon, sometimes accounting for more than 20% of the total flora; however, variable isolation, even of these numerous species, is observed from individuals on certain diets (e.g., Japanese diet with no beef) (Finegold et al., 1974; Moore and Holdeman, 1974; Holdeman et al., 1976; Duerden, 1980). Next *B. distasonis* and *B. eggerthii* appear to be important residents of most flora, consistently isolated from up to 64% of subjects. In some cases though, the data are limited since earlier studies on fecal flora often did not recognize *B. eggerthii*, and *B. thetaiotaomicron* was a compilation of several species. The last two species for which there are sufficient data, *B. ovatus* and *B. fragilis*, are the least common of the *Bacteroides* intestinal isolates from subjects on most diets, but in one study, *B. fragilis* was the most common *Bacteroides* spp. (8.7% of flora) isolated from fecal samples of rural native Africans (Moore and Moore, 1995). It is interesting to note here that even though *B. fragilis* generally is a small percentage of the total microbial population in the colon, it is by far the most frequently isolated species from clinical specimens (Finegold and George, 1989). Finally, there has been considerable discussion and study on the effect of diet on the composition of the colonic microflora and in general the results tend

Table 3. Presence of *Bacteroides* spp. in the fecal flora of humans and animals.

	Count/g dry wt (mean)	Human flora Percent of total flora (range)	Percent of positive samples (range)	House pets	Swine	Cattle	Sheep	Poultry	Horse	Rodent
B. thetaiotaomicron	4.5×10^{10}	1.0–8.9	67–100	X	X	X	X	X	X	X
B. vulgatus	4.2×10^{10}	7.5–13.1	47–100	X	X	X	X	X	0	0
B. distasonis	2.9×10^{10}	1.3–6.0	36–64	X	X	X	X	X	0	0
B. eggerthii	2.8×10^{10}	nd	2.1–5.0	nd	nd	nd	nd	nd	nd	nd
B. fragilis	2.3×10^{10}	0.3–8.7	17–68	0	X	0	X	0	0	0
B. ovatus	0.8×10^{10}	0.1–2.6	17–44	0	0	0	0	X	0	0

Abbreviations: X, organism is present; 0, organism not present; and nd, analysis not done.
From Finegold et al. (1974, 1983), Moore and Holdeman (1974), Holdeman et al. (1976), Robinson et al. (1981), Macy (1984), Moore et al. (1987), and Moore and Moore (1995).

to show that while some differences do exist, there is a remarkable similarity in the makeup of the flora, with each of the *Bacteroides* spp. comprising 0.1–12% of the flora and *B. vulgatus* being ranked as the first or second most common fecal isolate (Finegold et al., 1974; Moore and Holdeman, 1974; Holdeman et al., 1976; Duerden, 1980; Finegold et al., 1983; Moore and Moore, 1995). Only through continued study of the flora will it be possible to determine the significance of these variations.

Colonization of the Infant Intestinal Tract At birth the human colon is sterile, but within hours colonization begins and proceeds as a predictable succession of bacterial populations. Colonization occurs in several phases and can be influenced by diet, i.e., whether the infant is breast-fed or bottle-fed. Initially, colonization is by the facultative anaerobes, *Enterobacteriaceae* and enterococci, which apparently provide the anoxic environment suitable for the next phase of colonization by *Bifidobacterium* spp., followed closely by the appearance of the *Clostridium* and *Bacteroides* by the end of the first week (Long and Swenson, 1977; Cooperstock and Zeed, 1983). In bottle-fed infants, the anaerobic populations continue to develop and the levels of facultative species are maintained. *Bacteroides fragilis*, *B. vulgatus* and *B. ovatus* are among the most common of the *Bacteroides* spp. being isolated from 20–75% of samples (Cooperstock and Zeed, 1983; Mevissen-Verhage et al., 1987). In contrast, in breast-fed infants, the *Bacteroides*, *Clostridium* and the facultative species all decline or disappear after about the first week and the *Bifidobacterium* spp. predominate. Once dietary supplements are introduced to the infants, the clostridia, bacteroides, and other facultative and obligate anaerobes appear in higher numbers. After weaning, the flora begins to take on characteristics of the adult as the facultative species decline, and by two years of age, the normal flora is well established (Cooperstock and Zeed, 1983).

Bacteroides spp. in Animals The intestinal tracts of many animals also are a source of *Bacteroides* spp. (summarized in Table 3), but their concentration is generally much lower. Commonly, *B. vulgatus* and *B. distasonis* are associated with house pets, and *B. thetaiotaomicron* is a common inhabitant of the rodent gastrointestinal tract (Tannock, 1977; Macy, 1984; Kreader, 1995; Wang et al., 1996). A notable member of the swine intestinal microflora is *B. uniformis*, which has been consistently isolated at a level of 1–3% of the flora (Robinson et al., 1981; Moore et al., 1987). *Bacteroides fragilis* also has been a common isolate from sick and healthy lambs, calves, and other livestock where it is often associated with a diarrheal disease of young animals (Border et al., 1985; Myers et al., 1985; Myers and Shoop, 1987).

Indicators of Fecal Pollution Even though *Bacteroides* spp. are associated with animals, the numbers are low, and it has been suggested that the *Bacteroides* might be useful indicators of human fecal pollution, since they do not replicate in the environment and they are highly correlated with their human hosts. Direct culture methods were originally used to show that *Bacteroides* spp. rapidly died off in water samples and that animal feces were not a significant source of contamination (Allsop and Stickler, 1984; Allsop and Stickler, 1985). Recently two new approaches have been used for the detection of these organisms in environmental samples. First is the enumeration of *B. fragilis* bacteriophages in which standard strains are used to propagate phage from water samples (Tartera and Jofre, 1987; Tartera et al., 1989; Cornax et al., 1990). The idea is that the phage could only originate from recent human contamination, since the *Bacteroides* do not grow (and hence could not support phage replication) outside of the human. Using this approach, it has been shown that phage can be found in about 10% of human fecal samples, but they were not found in the feces of other animals. Samples from sewage and recently contaminated river water also contained the phage, but none were found in slaughterhouse effluents or waters contaminated by wildlife. Similarly, a strategy based on the use of polymerase chain reaction (PCR) to screen for the presence of the 16S rRNA gene has shown promise (Kreader, 1995; Kreader, 1998). In this report, results similar to direct culture methods were obtained. Only 7–11% of nonhuman fecal samples were positive for the *Bacteroides* spp. probes, whereas nearly 80% of the human samples were positive. Taken together, the three methods have resulted in similar data and suggest that use of *Bacteroides* spp. as pollution indicators warrants further study.

Role of *Bacteroides* spp. in Colon Physiology

As the predominant microbial group in the large intestine, *Bacteroides* spp. are thought to contribute to a wide array of normal physiological functions in the intestinal tract. Some of the most significant activities in which *Bacteroides* spp. directly participate are polysaccharide digestion, nitrogen cycling, bile acid metabolism, and vari-

ous other transformation reactions including the production of fecal mutagens.

Polysaccharide Digestion The fermentation of polysaccharides is a major activity of the large intestine. It has been estimated that 50–70 g of substrate enter the colon and that the end products (short chain fatty acids) of this fermentation can meet about 7–10% of the human daily energy allowance (Smith and Bryant, 1979). The two major sources of fermentable substrate are dietary plant polysaccharides and host-derived polysaccharides. The plant-derived carbohydrates are primarily in the form of resistant starch that has escaped digestion in the upper gastrointestinal tract and dietary fiber composed of cellulose, hemicellulose, arabinogalactans, xylans and pectins that are not digested by the host (Macfarlane and Cummings, 1991a). Carbohydrate sources from the host come primarily from intestinal tract secretions and include mucins and mucopolysaccharides such as chondroitin sulfates. As discussed in the section Metabolism, the *Bacteroides* spp. are metabolically versatile with a wide array of polysaccharide-degrading enzymes, which make them well suited to compete for these substrates (Table 1). In one study, DNA probes used to enumerate the predominant polysaccharide-degrading *Bacteroides* spp. from feces resulted in data that were for the most part consistent with previous direct culture counts (Kuritza et al., 1986a). The somewhat less versatile organisms, *B. vulgatus* and *B. uniformis*, were found at slightly higher levels ($1.2–3.0 \times 10^{10}$) than *B. thetaiotaomicron* (1×10^{10}), which can use a wider array of host and plant polysaccharides. *Bacteroides ovatus* was below the level of detection ($<2 \times 10^{9}$). Work with ex-germ-free mice suggests that utilization of the host-derived polysaccharides may be less important than dietary sources for colonization, at least on standard mouse chow diets. In one study, *B. thetaiotaomicron* mutants lacking the ability to utilize chondroitin sulfate were not outcompeted by wildtype strains in the intestinal tract unless the mutations caused the inability to utilize *N*-acetylgalactosamine, one of the component sugars of chondroitin sulfate (Salyers et al., 1988). Further, there was no evidence for the expression of proteins in the chondroitin sulfate utilization pathway during growth of *B. thetaiotaomicron* in the intestine. Another study with *B. thetaiotaomicron* suggested that perhaps these organisms have maximized their ability to utilize small quantities of a variety of carbohydrate sources as a strategy for survival in the gut (Salyers and Pajeau, 1989). In this work, mutants lacking the ability to utilize starch or polygalacturonic acid were not outcompeted by the wild-type strains. In contrast, mutations causing a defect in utilization of the component sugars of these polysaccharides did in fact result in a colonization defect. The concept was supported by studies on the expression of disaccharidases from *B. ovatus* growing in the cecum of ex-germ-free mice (Valentine and Salyers, 1992). The authors found that disaccharidase activities were not induced as would be expected during growth on specific polysaccharides such as xylan or arabinogalactan. Rather, the level of activity of the four disaccharidases seemed to be low, suggesting that a mixture of substrates might be present in the environment. In other work with *B. ovatus*, mutants unable to utilize guar gum (galactomannan) or lacking α-galactosidase III were deficient in colonization of germ-free mice (Valentine et al., 1991). The authors interpreted these results as suggesting that the loss of even a minor substrate for *B. ovatus* was critical for its ability to compete. Overall, there is a paucity of good information on in vivo substrate utilization and this hinders sound interpretation of these mutant studies.

Protease Activity Nitrogen turnover in the colon is an efficient process with approximately similar amounts of nitrogen entering the tract from the ileum as are being excreted. Most of the nitrogen input (70–80%) is in the form of protein and peptides derived from the host or diet. By comparison, excreted nitrogen is more than 50% bacterial protein (Stephen and Cummings, 1980; Stephen, 1987; Chacko and Cummings, 1988). Thus there is a high degree of protein turnover in the colon, indicating that this must be a highly proteolytic environment. Although many of the species in the colon such as the clostridia are more proteolytic than the *Bacteroides* spp., the sheer numbers of the later species ensure them of a dominant role in protein degradation. Studies on colonic protein digestion are limited, but one study using an azocasein hydrolysis assay localized the majority of proteolytic activity to a particulate fraction containing either bacterial cells or activity tightly bound to particles (Macfarlane et al., 1986). The dominant proteolytic organisms in these samples were *Bacteroides* spp., which were present at about three orders of magnitude greater than other proteolytic genera such as *Propionibacterium*, *Clostridium* and *Enterococcus*. The protease activity of these organisms was cell bound and not measurably secreted into the medium. These results were verified using pure cultures of *B. fragilis* and *B. vulgatus*, which also had high levels of cell-bound protease activity. Similar studies with *B. thetaiotaomicron* revealed much

lower levels of protease activity (Macfarlane et al., 1986). In more detailed studies of a *B. fragilis* strain, it was found that three major proteases (34, 52 and 73 kDa) were produced and that these were largely membrane-associated, although one was released in the periplasm (Gibson and Macfarlane, 1988a). Inhibitor studies suggested that these proteases were a mixture of a serine, a cysteine, and a metallo-protease. The proteases had a limited substrate range with activity on casein, trypsin, chymotrypsin, azocasein but very little (or no) activity on collagen, azocoll, gelatin, bovine serum albumin, and elastin. The protease activity was constitutively expressed under a variety of growth conditions and throughout the growth cycle, but during stationary phase, the cells did release some activity into the supernatant (Gibson and Macfarlane, 1988b). Protease activity was optimal at alkaline pH, suggesting that it would be well suited for the descending colon where pH rises as a result of proteolytic activity of the gut microflora (Gibson and Macfarlane, 1988a). Nitrogen cycling in the large intestine goes beyond protein turnover, and the *Bacteroides* spp. have a variety of enzymes such as glutamate decarboxylase or deaminases that contribute to these functions, but there is little in the way of direct assessment of these activities in different bacterial groups.

Bile Acid Metabolism Another important metabolic activity of the colon is the transformation of bile acids and steroids. The primary bile acids, cholic and chenodeoxycholic acid conjugated on their carboxyl groups with either glycine or taurine, are synthesized in the liver from cholesterol and secreted into the small intestine. The enterohepatic circulatory system returns most of these compounds to the liver, but a sizable portion escapes to the colon, where they are immediately deconjugated (>80%), leaving the free bile acid present in the feces (Larson, 1988). The bile acid hydrolases (BAHs) are responsible for this activity, and they are produced by a number of intestinal anaerobes including *Bacteroides* spp. The enzyme activity has been found in *B. fragilis*, *B. thetaiotaomicron*, *B. ovatus* and some strains of *B. distasonis* and *B. vulgatus* (Stellwag and Hylemon, 1976; Kawamoto et al., 1989). When BAH is found in these strains, it is always accompanied by a second transformation activity, 7-α-hydroxysteroid dehydrogenase, suggesting there may be some coordinate regulation of these two enzymes (Stellwag and Hylemon, 1976). While most reports indicate that the BAHs are constitutive, one report found that in *B. fragilis*, where BAH is periplasmic, the enzyme was produced in a growth-rate-dependent manner with significant induction during the stationary phase of growth (Hylemon and Stellwag, 1976). The enzymes (subunit mol wt of 32–36 kDa) do not seem to be highly oxygen sensitive and generally have a pH optimum in the acid range. Both taurine and glycine conjugates of the primary bile acids are rapidly hydrolyzed, but some of the conjugates of secondary bile acids were not hydrolyzed (Stellwag and Hylemon, 1976; Masuda, 1981; Larson, 1988).

As mentioned, several of the *Bacteroides* spp. have 7-α-hydroxysteroid dehydrogenase, which is required (in part) for epimerization of the 7-hydroxyl group. Several types of these enzymes differ with respect to their pyridine nucleotide specificity, but interestingly *B. thetaiotaomicron* and some strains of *B. fragilis* possess both NAD- and NADP-linked enzymes (MacDonald et al., 1975). In *B. fragilis*, enzyme activity was located in the cell membrane and cytoplasmic fractions, and in one report, it was concluded that the enzyme was expressed throughout the growth cycle (Hylemon and Sherrod, 1975; Hylemon and Stellwag, 1976). In contrast, both the NAD- and NADP-linked activities of *B. thetaiotaomicron* were coordinately induced in stationary phase. None of the *Bacteroides* spp. are known to possess the 7-β-hydroxysteroid dehydrogenase activity, so they are not responsible for the complete epimerization of the molecule. At the present time, the role of these transformations in the physiology of the *Bacteroides* is not clear. It has been suggested that the enzymes may play some role in energy metabolism, but no data support this idea.

Transformations of Toxic and Mutagenic Compounds The production of toxic compounds and fecal mutagens has been a topic of considerable interest due to their implied potential role in colon cancer. It has been known for some time that the intestinal microflora have the ability to transform substrates with possible toxicological consequences and that a mutagenic potential is associated with the microflora. The *Bacteroides* exhibit a wide array of activities that can participate in these transformations, and owing to their high numbers in the colon, it is likely they play a significant role. One class of hydrolytic enzymes that is important for many transformations are the glycosidases. The diet provides a number of plant glycosides, which when hydrolyzed release aglycones, some of which are toxic or mutagenic. In one recent report, it was shown that in samples obtained from colon contents, most of the glucosidase activities were associated with the bacterial fraction and that this activity increased in the distal colon (McBain and Macfarlane, 1998). Most

probable number estimates indicated that there were approximately 10^{11} bacteria per g of contents with glucosidase activity. Screening of strains representing the colonic microflora indicated that *B. fragilis*, *B. ovatus* and *B. vulgatus* displayed some of the highest glucosidase activities (McBain and Macfarlane, 1998). This is not surprising since as discussed above (see Metabolism), the *Bacteroides* spp. possess high levels of glycosidase activity with broad substrate specificities.

Glucuronides are formed in the liver where they are important for the detoxification of xenobiotic compounds. These xenobiotic conjugates are excreted in the bile and end up in the colon where levels of β-glucuronidase of microbial origin are high (Hawksworth et al., 1971; Larson, 1988). The hydrolysis of the glucuronides can result in the production of toxic compounds in the gut, from which they can be reabsorbed rather than excreted in the feces. Glucuronidase activity has been found throughout the colon but apparently is highest in the proximal colon (McBain and Macfarlane, 1998). When normal flora isolates are examined for β-glucuronidase activity, the *Bacteroides* spp. are well represented, although not all species or strains of a given species express this activity. Strains of *B. fragilis* and *B. vulgatus* were among the most active when using *p*-nitrophenyl-D-glucuronide as the substrate (Berg et al., 1980; McBain and Macfarlane, 1998), but examination of a *B. vulgatus* strain isolated from a Crohns disease patient revealed only small amounts of β-glucuronidase (Ruseler-van Embden et al., 1989). In another study ninety-seven β-glucuronidase-positive strains were isolated from feces, and the majority of these were *Bacteroides* spp., but the highest activities were found in *Peptostreptococcus* spp. and *Clostridium* spp. (Nanno et al., 1986). Further, it also was shown that the β-glucuronidase activity of the *Bacteroides* isolates could in fact release mutagenic metabolites from benzo(a)pyrene conjugates.

The *Bacteroides* are host to a variety of other enzymatic activities that might contribute to the toxic or mutagenic potential of feces including azo-reductases and nitro-reductases, but little data are available on the distribution of these enzymes (Chung et al., 1978; Kinouchi et al., 1982). However, several *Bacteroides* spp. have been directly implicated in production of fecal mutagens in the fecapentaene class. These are highly potent, 12 or 14 carbon glyceryl ether lipids with a conjugated pentaene chain, and they are strongly mutagenic in the Ames test (Gupta et al., 1983; Hirai et al., 1985). The actual precursor(s) of these compounds is not known, and not all people produce high levels of the precursor, but it is produced endogenously, requires anaerobic conditions, requires pH >6, and requires the presence of *Bacteroides* spp. (van Tassel et al., 1982; Hirai et al., 1985). In a survey of organisms capable of producing this activity, only *Bacteroides* spp. were active, and cells needed to be in stationary phase of the growth cycle (van Tassel et al., 1982). All of the *B. thetaiotaomicron* strains and 70% of *B. fragilis* were capable of producing the fecal mutagen, and several isolates of *B. ovatus* and *B. uniformis* also had the activity. Thus, there is no doubt that these mutagens are actively produced in the colon, but it is less clear whether they are clinically significant or linked to colon cancer.

Role of *Bacteroides* spp. in Development of the Intestinal Tract

It has been known for some time that when compared to conventional animals, the gastrointestinal tract of germ-free animals is markedly altered in its morphology and function (reviewed in Abrams, 1983). The cecum of germ-free mice is greatly enlarged and can account for 1/4 of the body weight. In contrast, the intestine of germ-free animals is smaller with about 15–30% less surface area and fewer villi, which are smaller in size (Gordon and Bruckner-Kardoss, 1961; Wells and Balish, 1980), and many histological differences including a poorly developed lamina propria and smaller Peyers patches that lack the characteristic germinal centers. Taken together, all of these changes result in a somewhat altered function of the tract, but association of the gastrointestinal tract with its indigenous microflora can reverse each of these changes (Abrams, 1983; Falk et al., 1998). In this regard, the analysis of intestinal epithelial sections from ex-germ-free rats monoassociated with *B. fragilis* revealed histological characteristics similar to those of conventional animals, including a thick lamina propria and normal villi (Wells and Balish, 1980).

Owing to their prominence in the normal flora, *Bacteroides* spp. are likely to be important for the normal development of the tract, but until recently, there was very little progress in deciphering the role of these or any organisms. A new model system in which genetically engineered *B. thetaiotaomicron* are used to colonize germ-free mice has been developed to elucidate specific interactions between the microbe and its host (Bry et al., 1996). Using this system, the normal pattern of production of fucosylated glycoconjugates on the surface of the intestinal epithelium was shown to be regulated at the level of transcription by *B. thetaiotaomicron* strains able to utilize fucose as a carbon source but not

by mutants disrupted in the fucose pathway (Hooper et al., 1999). It now appears that the microbe uses an inducer (FucR) to regulate its fucose utilization in response to the presence of the fucosylated glycoconjugates, and it also controls the synthesis of these via a FucR-regulated factor that modulates the synthesis of an α-1,2-fucosyltransferase in the intestinal cells. This coordinated expression program clearly benefits the microbe, but its importance to the host is less clear. The use of this model system was recently expanded in a study where transcription in intestinal epithelial cells was analyzed by DNA microarrays in response to colonization with *B. thetaiotaomicron* (Hooper et al., 2001). The results showed that a variety of mRNAs such as colipase, glutathione S-transferase, adenosine deaminase, angiogenin-3, lactase-phlorizin hydrolase, metallothionein I, and others were modulated by colonization. It was possible to determine that some of these genes were directly influenced by *B. thetaiotaomicron*, whereas others required different components of the microflora. Another study that examined the expression of matrilysin I, a matrix metalloprotease, concluded that induction of activity required colonization with *B. thetaiotaomicron* and that a soluble factor, not adherence to cells, was responsible for the appearance of matrilysin activity (Lopez-Boado et al., 2000). Overall, these new data support the idea that interactions between the gut flora and the gut are going to be exceedingly complex. Using these defined, genetically manipulable systems, it should be possible to learn more about the biochemical signals used to communicate between the host and microbe, allowing them to establish this exceptionally stable symbiosis.

Virulence and Pathogenesis

Association with Infection

The high frequency of *Bacteroides* spp. isolated from human infections underscores their pathogenic potential. These organisms account for approximately two thirds of all anaerobes isolated from clinical specimens. *Bacteroides fragilis* is a minor component of the species present in the human gut (generally <1% of the flora), but it accounts for about 50% of all anaerobes isolated from cases of intra-abdominal infections, infections of the female genital tract, deep wounds, and bacteremia (Finegold and George, 1989). The isolation of different *Bacteroides* spp. varies somewhat, but because antibiotic susceptibility patterns of the different species are heterogeneous, it is important to identify the species (Brook, 1989). In this regard, *B. fragilis* accounted for 63% of all *B. fragilis* group isolates, *B. thetaiotaomicron* for 14%, *B. vulgatus* and *B. ovatus* for 7% each, *B. distasonis* for 6%, and *B. uniformis* for 2%. The prevalence of *B. fragilis* in clinical specimens compared to the other members of the *Bacteroides* also was reviewed by Goldstein and Citron (1988). *Bacteroides fragilis* was the predominant species accounting for 45–69% of all *Bacteroides* isolated. *Bacteroides thetaiotaomicron* was the second most frequent isolate (8–20%), and the other species were the least frequently isolated (0–10%). Some recent data summarizing the distribution of *Bacteroides* spp. by site of infection are provided in Table 4. The virulence of *B. fragilis* is highlighted by its high frequency of recovery from blood cultures compared to other species of the genus. However, many factors must be considered when describing the pathogenic potential of an organism. For example, in cases of bacteremia, *B. fragilis* was isolated from more cases, though the mortality rate following *B. thetaiotaomicron* was higher (38%) compared to *B. fragilis* (24%; Brook, 1989). A controlled study to determine the true attributable mortality rate and mortality risk ratio found an excess of 19% attributable to *Bacteroides* spp. bacteremia. In addition, the presence of *Bacteroides* spp. bacteremia was independently associated with a nearly fivefold increase in relative risk of death (Redondo et al., 1995).

Bacteroides generally cause opportunistic infections that can occur any time the integrity of the mucosal wall of the intestine is compromised. Common predisposing conditions are gastrointestinal surgery, perforated or gangrenous appendicitis, perforated ulcer, diverticulitis, trauma and inflammatory bowel disease (Sheehan and Harding, 1989). Following inoculation of the site, a typical infection occurs in two phases. First is initiation, where the organisms need to adhere to a surface, resist clearing mechanisms and other host defenses, and withstand the increased oxygen tensions. Next, an abscess is formed where the organisms must be able to persist in an environment that is populated by numerous host cells and in which resources become limited owing to the metabolism of a large bacterial population. During the course of these two phases, *Bacteroides* spp. need to express a variety of different virulence factors. These will include cell surface structures such as capsular polysaccharide and lipopolysaccharide, adherence mechanisms, production of proteases, hydrolytic enzymes, neuraminidase, ability to scavenge iron from the host, production of enterotoxin in certain strains, and the ability to avoid host defense mechanisms. The specific *Bacteroides* virulence factors will be discussed next in the section Virulence Mechanisms; how-

Table 4. Distribution of the *Bacteroides fragilis* group species isolated from clinical specimens.

ever, the reader should bear in mind that many of these factors reflect work done with *B. fragilis*, since this is the most pathogenic species and the majority of work on pathogenesis has focused on this organism.

Virulence Mechanisms

Capsular Polysaccharides The capsular polysaccharide complex (CPC) is a major factor associated with virulence and pathogenicity. For example, encapsulated strains were demonstrated to be more virulent than nonencapsulated strains by their higher rate of induction of bacteremia and greater enhancement of growth compared to other bacteria in mixed infections (Brook, 1989). An abscess is the hallmark of a *Bacteroides* infection, and formation of an abscess is a pathological response of the immune system to the presence of the *B. fragilis* CPC. *Bacteroides fragilis* is the only bacterium that has been shown to induce abscess formation when present as the sole infecting organism (Onderdonk et al., 1977). Using an experimental abscess model, it has been shown that implantation of cell-free CPC into the peritoneal cavities of rats induced formation of intra-abdominal abscesses. Most bacterial polysaccharides stimulate an antibody-mediated response, but *B. fragilis* capsule stimulates a T-cell mediated response (Shapiro et al., 1986).

CPC is involved in the abscess formation in several ways. The first is adherence, which is presumed to increase resistance to peritoneal clearance. The ability of *B. fragilis* and other *Bacteroides* to adhere to rat peritoneal mesothelium was shown to be due to the presence of capsular polysaccharide, while nonencapsulated species were less adherent (Onderdonk et al., 1978). In experimental intra-abdominal infections, the adherence of *B. fragilis* group species to peritoneal mesothelium was an advantage allowing it to outcompete other intestinal species following fecal contamination (Edmiston et al., 1990). However, immunization with capsular polysaccharide failed to reduce adherence (Onderdonk et al., 1977). In contrast, purified capsular polysaccharide alone inhibited *B. fragilis* adherence to rat peritoneal mesothelium (Onderdonk et al., 1978). As can be seen by these sometimes conflicting reports, much is still

not understood about the role of capsule, but clearly it is a major virulence factor that contributes to all phases of the infections. The second role of the *B. fragilis* CPC is its direct effect on immune system cells which results in secretion of cytokines. In vitro murine resident peritoneal cells and human peritoneal blood leukocytes respond to *B. fragilis* CPC by increased production of tumor necrosis factor alpha (TNF-α) and interleukin-8 (IL-8), respectively. This leads to recruitment of polymorphonuclear leukocytes (PMNs) and significant upregulation of intercellular adhesion molecule-1 (ICAM-1) on the mesothelial cells in the location of the adherent bacteria. This leads to accumulation of PMNs and initiation of abscess formation (Gibson et al., 1996; Gibson et al., 1998). Finally, CPC can aid in phagocytosis inhibition (Simon et al., 1982).

Immunochemical studies revealed that the surface polysaccharides of *B. fragilis* populations are antigenically heterogeneous. The antigenic composition varies within a bacterial population apparently by switching the expression of epitopes (Lutton et al., 1991; Patrick et al., 1999). This antigenic variation is presumed to be relevant to the virulence of *B. fragilis* (Lutton et al., 1991). The nature of the *B. fragilis* capsular polysaccharide complex has been elucidated and is composed of distinct polysaccharide structures containing a zwitterionic motif of repeated units of positively and negatively charged groups (Tzianabos et al., 1993). It was demonstrated that the presence of these charged groups was essential to induce intra-abdominal abscess in a rat model (Tzianabos et al., 1993). Using a combination of mutational and genome analysis (Krinos et al., 2001), it was shown that *B. fragilis* produces eight distinct polysaccharides designated PSA, PSB, PSC, PSD, PSE, PSF, PSG, and PSH. These eight capsule loci utilize an unprecedented amount of bacterial genome with about 133 kb dedicated to the synthesis of capsular polysaccharides. This, in fact, comprises about 2.5% of the whole *B. fragilis* genome. Each of these capsule loci is regulated independently by an ON-OFF phase variation mechanism, which results in the expression of different combinations of the eight polysaccharides within the same population, yielding mixed phenotypes (Krinos et al., 2001). This regulation involves the inversion of each individual transcription promoter regulatory region, resulting in an ON-OFF switch for each locus. The complex phase-variation control and the exorbitant number of capsule polysaccharides demonstrate the importance of polysaccharide surface diversity with implications for the physiology, ecology and virulence of this microorganism (Krinos et al., 2001).

Studies have demonstrated that PSA seems to have the essential composition for intra-abdominal abscess formation in animals, since a PSA mutant had a drastic reduction in abscess-inducing capability compared to parent strain (Coyne et al., 2001). In this regard, PSA is conserved in all serotypes tested, and this is consistent with the ability to induce abscess. Purified PSB alone is able to induce an abscess in vivo, but disruption of the PSB or PSC operons did not abolish abscess formation compared to wildtype strain (Comstock et al., 1999; Coyne et al., 2000).

Adherence The ability of a microorganism to adhere to host tissues is an important initial step in the colonization and multiplication in a host. The adhesive properties of *B. fragilis* are considered to be an important component of its virulence mechanism. It has been shown that adherence to a host cell is mediated by surface structures such as the capsular polysaccharide or pilus (fimbriae). *Bacteroides fragilis* isolates from abscesses and blood have a strong hemagglutination activity compared to strains isolated from nonclinical strains (Guzman et al., 1997). Some studies have shown that the increased ability of *B. fragilis* to adhere to laminin in vitro might be an advantage when compared to other potentially infecting species, and this could be part of the reason why *B. fragilis* is so successful as a pathogen (Eiring et al., 1995).

Pili- or fimbriae-like structures have been associated with *B. fragilis* adherence to epithelial cells and with red blood cell hemagglutination (Pruzzo et al., 1989; Brook and Myhal, 1991); however, other studies have demonstrated that adherence to red blood cells can be mediated by either capsule or pili-like structures (Guzman et al., 1997). Perhaps both structures act together to potentiate hemagglutination activity, since elimination of either pili or capsule reduces but does not abolish adherence (Guzman et al., 1997). Adherence of piliated and encapsulated strains of *B. fragilis* and *B. ovatus* to intestinal cells and mucus was shown to be at least five times greater than adherence of their nonpiliated or nonencapsulated counterparts (Brook and Myhal, 1991). Nevertheless, reports conflict regarding the role of fimbriae in *B. fragilis*. The studies of Oyston and Handley (1991) have shown no correlation between fimbriae and hemagglutination, even though fimbriae were actually isolated from the *B. fragilis* strains used in this study (van Doorn et al., 1992).

Another factor that is still poorly understood is the production of soluble lectin-like adhesins by strains of *Bacteroides* spp. (Rogemond and Guinet, 1986). A 70-kDa lectin with affinity for

∀-D-glucosamine and D-galactosamine was purified and shown to promote formation of micro-aggregates between *B. fragilis* and *Enterococcus faecalis* or *E. coli* (Rogemond and Guinet, 1986). This may have implications in the pathogenesis of synergistic polymicrobial infections allowing adhesion to host cells and aggregation to each other. These organisms are frequently found in mixed infections, and aggregation has been demonstrated between *B. fragilis* and *E. coli* (Reid et al., 1990).

Lipopolysaccharide and Other Surface Structures The *B. fragilis* lipopolysaccharide (LPS or endotoxin) is approximately 100–1000-fold less toxic than the potent LPS from *E. coli* and *Salmonella typhimurium* (Lindberg et al., 1990). Nevertheless, studies have suggested that LPS may be considered as a virulence factor (Zalesnik et al., 1986; Poxton and Edmund, 1995), since it is able to provoke abscess formation in experimental animal models. However, the dose of LPS required is about 5 times higher than the dose required for purified capsular polysaccharide, suggesting the possibility of some minor contamination of the LPS with CPC (Zalesnik et al., 1986). *Bacteroides fragilis* LPS induces secretion of the proinflammatory cytokine TNF-α through a CD_{14}-independent pathway (Gangloff et al., 1999), but the amount of *B. fragilis* LPS required to stimulate half-maximal TNF-α secretion is at least 1,500-fold higher than the amount of LPS from an enteric organism needed to reach the same levels of TNF-α expression (Gangloff et al., 1999). The weak endotoxic activity of *B. fragilis* is attributed to differences in its structural and chemical composition compared to typical Enterobacteriaceae LPS. *Bacteroides fragilis* LPS lacks classical O-antigen structures, has reduced acyl chains (5 instead of 6), has only one phosphorylated 2-keto-3-deoxyoctulosonic acid (KDO) moiety, and has shortened carbohydrate chains (Lindberg et al., 1990; Gangloff et al., 1999).

The release of outer-membrane vesicles (OMV) from *B. fragilis* also is presumed to play a role in the pathogenesis of *B. fragilis*. The OMV are released from the surface of whole cells of *B. fragilis* and carry a variety of hydrolyzing enzymes such as alkaline and acid phosphatases, esterase lipase, phosphohydrolyase, glucosaminidase, β-glucuronidase and α- and β-galactosidase (Patrick et al., 1996). These OMV are able to agglutinate horse and human erythrocytes, and this property may be used to deliver enzymes directly to host cells with the objective of increasing tissue damage. In addition, the *B. fragilis* OM contains an unidentified component with pro-inflammatory activity. It promotes neutrophil adherence to endothelium in vitro by inducing the expression of E-selectin on human endothelial cells by a soluble CD_{14}-dependent mechanism (Sato et al., 1998).

Neuraminidase The role of neuraminidase in the attachment of *B. fragilis* to host cells is controversial. Some studies have shown that hemagglutination and adherence to colon WiDr cells were not mediated by neuraminidase activity (Namavar et al., 1994). In contrast, other studies have shown that *B. fragilis* adheres to mammalian epithelial cells but not to PMNs by the action of an adhesin in a neuraminidase dose-dependent attachment (Guzman et al., 1990). Though this matter needs further clarification, the role of neuraminidase (NanH) in *B. fragilis* pathogenicity in vivo was investigated with *nanH* mutants. The findings have shown that the *nanH* mutant had a severe growth defect compared to the parent strain in a rat pouch model and in a tissue culture monolayer (Chinese hamster ovary [CHO] cells) model (Godoy et al., 1993). In the rat pouch experiments, >90% of the *nanH* mutants reverted to $nanH^+$ genotype within 48 h postinfection as glucose concentrations fell within the pouch during bacterial growth. This selective pressure resulting in the $nanH^+$ strains indicates that neuraminidase may play an important role in acquisition of carbon sources for bacterial cell growth in vivo (Godoy et al., 1993). Thus there may be two functions for neuraminidase during the course of infection, one for adherence and one for energy metabolism.

Iron Acquisition from Host Tissues The ability of pathogenic bacteria to scavenge iron in vivo from host tissues is an important virulence mechanism. Iron in mammalian tissues is tightly bound to proteins such as hemoglobin, transferrin or ferritin. Consequently, many aerobic bacteria and pathogens, in particular, will not grow in the presence of these proteins unless they possess specific iron-acquisition mechanisms. Although these mechanisms have been extensively investigated in aerobic bacteria, iron uptake systems in *B. fragilis* have been largely overlooked. Much of the iron requirement may be obtained from hemin; however, elemental iron is also required for growth even in the presence of hemin (Rocha et al., 1991). Apparently *B. fragilis* does not take up iron through the production of siderophores (Otto et al., 1988), but it can utilize iron from iron-bound transferrin, heme, hemoglobin and haptoglobin-hemoglobin complex (Verweij-van Vught et al., 1988; Otto et al., 1994). Furthermore, *B. fragilis* is able to overcome hemopexin-mediated heme limitation

by degradation of hemopexin, a heme-binding plasma protein, to make the protein-bound heme available for uptake (Rocha et al., 2001). This ability may enable *B. fragilis* to overcome the inhibitory effect of serum, which is commonly seen with many of the other *Bacteroides* species and can be overcome by the addition of hemin or protoporphyrin IX plus iron (Verweij-van Vught et al., 1986b). *Bacteroides fragilis* is better adapted to survive in low iron conditions than the less virulent species of the genus, and its enhanced virulence may be related to its ability to grow in serum with low free iron. The mechanisms of iron acquisition have not yet been worked out, but under iron-limited conditions, *B. fragilis* expresses four iron-repressible outer-membrane proteins (IROMP) of 89, 49, 44 and 23.5 kDa (Otto et al., 1988). It has been demonstrated that the 44-kDa IROMP is involved in the heme acquisition and is expressed in vivo (Otto et al., 1991). Other IROMP may be involved with other aspects of iron and/or heme uptake.

Enterotoxin Enterotoxigenic strains of *B. fragilis* (ETBF) are associated with diarrhea in humans and animals (Border et al., 1985; Myers and Shoop, 1987; Myers et al., 1989). Epidemiological studies have demonstrated that the presence of ETBF is significantly higher in adults and children with diarrhea (but with no other known etiological agents) when compared to the numbers of ETBF isolated from healthy controls (Kato et al., 1996; Zhang et al., 1999). The purified *B. fragilis* toxin (BFT) is a 20,000-Da zinc-containing metalloprotease capable of hydrolyzing gelatin, actin, tropomyosin and fibrinogen (Moncrief et al., 1995). Several studies have demonstrated that BFT induces physiological and morphological changes in intestinal epithelial cells both in vitro and in vivo leading to diarrhea and inflammation of the mucosa (Myers et al., 1989; Obiso et al., 1995; Saidi et al., 1997; Sanfilippo et al., 1998; Riegler et al., 1999). Three isoforms of the toxin gene have been described: *bft-1*, *bft-2* and *bft-3* (Chung et al., 1999a). Studies on the frequency of distribution of the genes have shown that the isoform *bft-1* is most common among adults with or without diarrhea, while *bft-1* and *bft-2* are equally distributed among children (D'Abusco et al., 2000). Interestingly, ETBF strains produce only one toxin, even though more than one *bft* gene may be present in the chromosome. As described in the section Genome Structure, molecular analysis has shown that a *bft* gene and a second metalloprotease gene are contained in a 6-kb DNA fragment, denoted as a pathogenicity island, which is present in all ETBF strains (Moncrief et al., 1998; Franco et al., 1999). In some cases, duplication of the whole pathogenicity island has been documented; however, this does not seem to affect expression of the *bft* genes.

The proposed mechanism of action for BFT is unique for a bacterial enterotoxin. BFT specifically cleaves the extracellular domain of the zonula adherens protein E-cadherin, altering cellular morphology and physiology and leading to increased intestinal permeability (Wu et al., 1998). However, the intestinal epithelial cells affected by BFT also seem to influence the modulation of the intestinal mucosal inflammatory response and tissue repair by inducing expression of the cytokines IL-8 and transforming growth factor beta (TGF-β), respectively (Sanfilippo et al., 2000; Kim et al., 2001).

The role of BFT is not clear, but studies comparing the frequencies of enterotoxigenic and nonenterotoxigenic strains isolated from various nonintestinal infection sites have found enterotoxigenic strains at higher frequencies in bacteremia (Kato et al., 1996; Chung et al., 1999a). It has been postulated that BFT facilitates the release of *B. fragilis* from the abscesses or other sites of infection, allowing them to disseminate into the bloodstream (Kato et al., 1996).

Proteases and Hydrolytic Enzymes The production of extracellular enzymes by pathogenic anaerobic bacteria is important for tissue damage during the course of an infection to supply nutrients for growth (Duerden, 1994). These enzymes also may contribute to the metabolic interdependency of *B. fragilis* and facultative species in polymicrobial infections (Duerden, 1994). *Bacteroides* spp. produce several enzymes such as hyaluronidase, heparinase, chondroitin sulfatase, phosphorylase, DNase, and fibrinogen-degrading protease (Rudek and Haque, 1976; Stefen and Hentges, 1981). Apparently these may contribute to the establishment and development of the infectious process, but very little experimental evidence exists to support their significance in *Bacteroides* spp. infections.

Inhibition of Neutrophil Function It is well established that in vitro anaerobic bacteria inhibit the phagocytic killing function of neutrophils. The phagocytic uptake and killing of several aerobic bacteria such as *E. coli* and *Proteus* sp. is diminished by the ability of *Bacteroides* species to compete for opsonins (Ingham et al., 1981; Jones and Gemmell, 1982; Namavar et al., 1983). Both heat-stable and heat-labile opsonins are depleted from serum incubated with *Bacteroides* species. This results in impairment of opsonization of the aerobic bacteria (Tofte et al.,

1980). Another mechanism of PMN inhibition may be mediated by the production of fermentation end products. It has been shown that short chain fatty acids inhibit PMN chemotaxis and activation of the respiratory burst function (Botta et al., 1985; Rotstein et al., 1985). Several studies have shown that the major product of *Bacteroides* fermentative metabolism, succinate, inhibits neutrophil migration and killing activity at acid pH but not neutral pH (Rotstein et al., 1985; Rotstein and Kao, 1988a). At an extracellular pH of 5.5, succinic acid is protonated, and in this form, it is able to cross the neutrophil plasma membrane and consequently lower the intracellular pH causing impairment of enzyme activity, leading to neutrophil dysfunction (Rotstein and Kao, 1988a; Rotstein et al., 1988b). More recently, Stehle et al. (2001) have shown that succinic acid at high concentrations (30 mM) significantly accelerates PMN apoptosis in vitro.

Synergy in Polymicrobial Infections

Intra-abdominal infections usually occur when gastrointestinal- or genitourinary-tract microorganisms enter into the peritoneal space as the result of a breach in the mucosal barrier (Johnson et al., 1997). The majority of intra-abdominal infections are polymicrobial associations containing facultative and anaerobic organisms, mainly *Bacteroides fragilis* and *E. coli*, as the predominant pathogens (Lorber and Swenson, 1975; Brook and Frazier, 2000). The importance of *Bacteroides* spp., particularly *B. fragilis* and *B. thetaiotaomicron*, in polymicrobial infections of abdominal, pelvic, skin and soft tissue areas was shown in a report from Brook (1989). The specific virulence factors that are involved in the pathogenesis of these mixed infections are dependent on the combination of species present at the site and the interactions of the different virulence factors of these species (Duerden, 1994). Some of these interactions have been described and are discussed next.

Bacterial synergy between anaerobic and aerobic bacteria has been demonstrated experimentally in animal models. The results have shown that this synergistic association increases mortality and abscess formation (Onderdonk et al., 1976; Dunn et al., 1984; Verweij-van Vught et al., 1986a; Rotstein and Kao, 1988a). Although the mechanisms involved in the interactions are not completely understood, several factors are known to play significant roles in the overall outcome. These factors include

1) The ability of *E. coli* to reduce intraperitoneal pO_2 and pH, creating favorable redox conditions that allow anaerobic growth and promote abscess formation (Sawyer et al., 1991). Extracellular acid pH and low oxygen tension have also been shown to alter leukocyte-killing mechanisms (Park et al., 1992). Moreover, low pH potentiates the inhibition of neutrophil functions by *B. fragilis* metabolic by-product succinate (Rotstein et al., 1988b)

2) *Bacteroides fragilis* inhibits phagocytosis and killing of *E. coli* by PMN. *Bacteroides fragilis* efficiently competes for opsonins and reduces aerobic bacteria opsonization and uptake by PMNs (Tofte et al., 1980; Jones and Gemmell, 1982)

3) Production of hemolysin by *E. coli* alters the host's ability to eliminate *E. coli* itself and other bacteria such as *B. fragilis* in experimental peritonitis (May et al., 2000)

4) Nutritional interactions in which the *E. coli* hemolysin and hemoglobin protease were shown to increase synergy of abscess formation in experimental models possibly by facilitating *B. fragilis* access to essential nutrients such as heme-iron from hemoglobin (May et al., 2000; Otto et al., 2002), and

5) The ability of *Bacteroides* species to induce local fibrin deposition impairs clearance of the bacteria in polymicrobial infections (Rotstein, 1993).

Antibiotic Susceptibility and Resistance

Susceptibility Profiles

The *Bacteroides* spp. are highly drug resistant owing to a combination of inherent resistance traits and acquired resistance determinants. For example, inherent resistance to aminoglycosides is nearly universal among anaerobic bacteria because of the inability to transport these drugs into the cell (Bryan et al., 1979) and because resistance to tetracycline, a front-line drug in the 1960s, has now reached >80% of isolates, due primarily to the dissemination of the *tetQ* gene (Salyers et al., 1995b; Shoemaker et al., 2001). Antimicrobial therapy plays an important role in the treatment of infections caused by *Bacteroides* spp.; therefore, susceptibility patterns have been watched closely to monitor the emergence of resistant strains. Summarized in Table 5 are the results from several antibiotic-resistance surveys of recent isolates. Over the years, metronidazole and chloramphenicol have remained effective antibiotics against the *Bacteroides*, with the finding of only an occasional chloramphenicol resistant strain and absence of metronidazole resistance in the United States (although occasional resistance has been noted on the European and Asian continents; Sebald et al., 1990). In contrast, *Bacteroides* spp. are resistant to most

Table 5. Summary of several susceptibility studies for *Bacteroides* spp. isolated between 1995 and 1999.

Abbreviations: MIC_{90}, minimal inhibitory concentation for 90% of strains tested; nd, no data; Pen, penicillin; Cfxime, ceftizoxime; Cfox, cefoxitin; Im, imipenem; Mer, meropenem; Pip, piperacillin; Pip + taz, piperacillin + tazobactam; Amp + sul, ampicillin + sulbactam; Cipro, ciprofloxacin; Trov, trovafloxacin; Clin, clindamycin; Met, metronidazole; and Cm, chloramphenicol.

[a]The MIC_{90} values are given in μg per ml and the % resistance refers to breakpoints of resistant strains recommended by the National Committee for Clinical Laboratory Standards (NCCLS). For the "*B. fragilis* group," values for the MIC_{90} and the % resistant strains are provided. The values given for the individual species are for % resistant strains only.

Data were from the following studies: Am1 (Aldridge et al., 2001), Am2 (Snydman et al., 1999), Spa (Betriu et al., 1999a), Sp2 (Betriu et al., 1999b), and SA (Lubbe et al., 1999).

cephalosporins and penicillins owing to the production of a variety of β-lactamases (Edwards, 1997). One exception is cefoxitin, which has shown good activity on all *Bacteroides* spp., although resistance rates up to 16% have been observed (Cuchural and Tally, 1986; Cornick et al., 1990). The carbapenems and the β-lactam + inhibitor combinations have retained outstanding activity and are the best of the β-lactam group (Table 5), but β-lactamases that destroy these drugs have been described. For the most part, the quinolone family of antibiotics has poor activity on *Bacteroides* spp. except for trovafloxacin, but significant resistance to this newer quinolone has been observed. Although the lincosamide, clindamycin, has been a very effective drug, resistance rates have risen dramatically reducing the utility of this drug in many hospitals.

Except for its resistance to imipenem, *B. fragilis* seems to be somewhat more antibiotic sensitive than other species or the genus as a whole. *Bacteroides thetaiotaomicron* and *B. ovatus* species generally are the most resistant and display the highest mean resistance rates for all antibiotics, but especially the β-lactam drugs (Snydman et al., 1999; Aldridge et al., 2001). On the other hand, high-level resistance

to carbapenems has been restricted primarily to *B. fragilis* isolates, which contain the *cfiA* β-lactamase gene and will be discussed in the section Mechanisms of Resistance. Resistance rates to clindamycin and trovafloxacin are highest among *B. vulgatus* strains (Snydman et al., 1999). No other trends have been noted, although one study suggested that with the exception of its resistance to clindamycin, the antibiotic resistance of *Bacteroides* spp. has decreased slightly (Snydman et al., 1999). It remains to be seen whether this is a sustainable trend.

Mechanisms of Resistance

Resistance to all major classes of antibiotics has been observed in the *Bacteroides* spp., and the physiological mechanisms of resistance cover the full array of mechanisms from target site alteration to antibiotic destruction. Clindamycin resistance and other MLS resistance are generally mediated by genes closely related to *ermF*, but recently two other MLS genes, *ermG* and *ermB*, have been found in *Bacteroides* spp. (Shoemaker et al., 2001; Table 6). These genes encode methyltransferase enzymes that methylate specific adenine residues on the 23S rRNA to inhibit binding of the drug to the ribosome target. This mechanism provides cross-resistance to most all macrolide, lincosamide, and streptogramin B type drugs. The *ermF* genes were first found on transmissible plasmids, and on these plasmids, they were present within three related compound transposons (Odelson et al., 1987; Smith et al., 1998; Table 6). The transposons each contained copies of IS*4351* in direct orientation that were adjacent to the *ermF* gene and responsible for its transcription. Tn*4351* and Tn*4400* were nearly identical, but Tn*4551* was twice the size and encoded a different set of genes downstream of *ermF*. The *ermF* genes are not closely related to any other *erm* genes and in fact have at most only 35% identity at the amino acid level. The *ermF* genes have been mainly found in different *Bacteroides* spp. and seem to be the major resistance gene in this genus. Recently, the *ermG* gene was found on a CTn, and in contrast to *ermF*, it was nearly identical to an MLS gene from *Bacillus sphaericus*, suggesting that it was a recent acquisition by the *Bacteroides*. Between 0 and 21% of recent MLS isolates (since 1996) had *ermG* (Cooper et al., 1996; Shoemaker et al., 2001). The *ermB* gene originally isolated from *Clostridium perfringens* also has been found in recent *Bacteroides* spp. isolates, indicating that the spread of MLS resistance continues to be a very dynamic process.

The most important form of β-lactam resistance continues to be the production of β-lactamase enzymes. Since 1955, the *Bacteroides* have been known for their production of penicillin inactivating enzymes, β-lactamases, and now nearly 100% of isolates tested have some measurable β-lactamase activity (Edwards, 1997; Rasmussen et al., 1997). By far the largest majority of these enzymes fall into the Bush class 2e, which are serine active-site cephalosporinases that are inhibited by clavulanate (Rasmussen et al., 1997). Each of the *Bacteroides* species has a specific or indigenous β-lactamase of this class. In the two cases where the β-lactamase genes have been sequenced (*B. fragilis cepA* and *B. uniformis cblA*), it was found that they are in the Ambler molecular Class A (Rogers et al., 1993; Smith et al., 1994; Mastrantonio et al., 1996). None of these enzymes can degrade cefoxitin, and the strains are sensitive to carbapenems as well. Although most species produce low levels of β-lactamase activity, in some cases the enzyme levels are upregulated and this results in resistance to all classes of β-lactam except for carbapenems, cephamycins, and inhibitor combinations (Rogers et al., 1994). For the *cepA* gene of *B. fragilis*, this activation resulted from the insertion of an IS element into the –35 region of the *cepA* promoter and resulted in high levels of *cepA* transcription. None of these species-specific β-lactamases are known to be transmissible. One unique class 2e β-lactamase was encoded by the *cfxA* gene and was found to be responsible for widespread, transmissible, cefoxitin resistance in a variety of *Bacteroides* spp. including *B. fragilis*, *B. vulgatus*, *B. uniformis* and *B. ovatus* (Parker and Smith, 1993). The CfxA β-lactamase slowly degraded cefoxitin but was otherwise typical of the Bush class 2e. Several other class 2e type enzymes have been described for the genus, but these have not yet been analyzed at the molecular level (Bush et al., 1995).

The other significant class of β-lactamases in the *Bacteroides*, the metallo-β-lactamases (which are in the Bush class 3), is responsible for imipenem resistance (Bush et al., 1995; Edwards, 1997). These are significant enzymes capable of hydrolyzing nearly all β-lactams including carbapenems and cephamycins, and they are not inhibited by clavulanate or sulbactam. DNA sequence analysis has shown that the *cfiA* gene or closely related homologs encode this potent β-lactamase, but it is only found in about 2% of *B. fragilis* clinical isolates, and in more than 60% of these strains, the gene is not expressed (Rasmussen et al., 1990; Thompson and Malamy, 1990; Podglajen et al., 1992; Podglajen et al., 2001). Strains that are imipenem resistant contain *cfiA*, which is transcriptionally activated by any one of several IS elements and is able to produce significant levels of the enzyme (Rasmussen and Kovacs, 1991; Podglajen et al., 1992; Podglajen et al., 1994; Edwards and Read,

2000; Table 6). Interestingly, *cfiA* seems to be restricted to a subgroup of the *B. fragilis* strains referred to as "*B. fragilis* DNA homology group II," whereas *cepA* is found in the more prevalent homology group I strains represented by the type strain ATCC 25285 (Podglajen et al., 1995). In association with this finding, it was shown that the IS elements known to activate *cfiA* also appear to be primarily associated with homology group II strains. These findings in part explain why imipenem resistance has been restricted to a small group of *B. fragilis* strains, but it remains to be seen whether these genes will become associated with transmissible elements and hence more widespread.

Two other mechanisms also may contribute to β-lactam resistance: reduced permeability of the drugs and reduced affinity of the penicillin-binding proteins (PBPs) for the drugs (Piddock and Wise, 1987; Cuchural et al., 1988; Edwards, 1997). Permeation studies of cephalosporins through the outer membrane of *B. fragilis* showed that values were about 1/10 of those seen for *E. coli* (Yotsuji et al., 1988a). Further studies yielded similar results and supported the general idea that hydrophilicity of the drugs was less a factor in permeation in *B. fragilis* than in enteric bacteria (Yotsuji et al., 1988a). The *Bacteroides* spp. appear to have at least three high mol wt PBPs (58,000–90,000 Da) and several smaller sized PBPs as estimated by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE; Piddock and Wise, 1986; Piddock and Wise, 1987; Yotsuji et al., 1988b; Wexler and Halebian, 1990). The high mol wt PBPs have been correlated with similar proteins in *E. coli*, and each *Bacteroides* spp. has its own distinctive pattern, although even within species there were differences. These differences may account for some cases of β-lactam resistance. In two studies, cefoxitin resistance of *B. fragilis* and *B. thetaiotaomicron* strains appeared to involve decreased affinity of the PBPs for the drug and a similar study of a cephalothin-resistant *B. fragilis* strain showed that both reduced permeation and PBP affinity were responsible for resistance (Piddock and Wise, 1986; Yotsuji et al., 1988b; Wexler and Halebian, 1990).

Thus far, only two tetracycline-resistance genes, *tetQ* and *tetX*, have been found in the *Bacteroides* spp. (Table 6). The *tetX* gene encodes a novel NADP-linked oxidoreductase that inactivates tetracycline; however, this enzymatic activity requires aerobic conditions and does not seem to be active under anaerobic conditions (Guiney et al., 1984b; Speer et al., 1991). This gene has been found on a number of transposons that contain an *erm* gene but otherwise does not appear widespread. The *tetQ* gene on the other hand is responsible for the >80% tetracycline-resistance rates now seen in the genus and was found in 100% of tetracycline-resistant *Bacteroides* spp. (Nikolich et al., 1992; Shoemaker et al., 2001). This dissemination is in large part due to its presence on virtually all CTns. It is interesting to note that *tetQ* has not been found associated with plasmids in *Bacteroides* spp., but in the closely related *Prevotella ruminicola*, this gene was located on a plasmid (Flint et al., 1988). The available evidence suggests that the spread of *tetQ* is recent on the basis of the >96% nucleotide sequence identity among 33 *tetQ* genes isolated from strains representing all of the *Bacteroides* spp. (Shoemaker et al., 2001). The TetQ protein is in the TetM family of tetracycline-resistance determinants whose mode of action is ribosome protection. It appears that TetM is related to elongation factor G (EF-G), and in the presence of GTP, TetM reduces the amount of tetracycline bound to ribosomes (Burdett, 1991; Burdett, 1996; Trieber et al., 1998).

Resistance to metronidazole and other 5-nitroimidazoles has been attributed to two major mechanisms. Until the 1980s, resistant strains were infrequently isolated, often from patients undergoing extended treatment regimens (Ingham et al., 1978). Analyses of this class of resistant strain indicated that resistance was mediated by a global change in metabolism that resulted in a decreased reducing environment in the cell thus preventing activation of the drugs. This was thought to be accomplished by a reduction in pyruvate:ferredoxin oxidoreductase activity and a subsequent increase in lactate dehydrogenase, which balances the fermentation products (Narikawa et al., 1991). More recently, transmissible resistance to as much as 64 μg/ml of metronidazole has been observed in several European countries. This resistance phenotype has been associated with four *nim* genes that share between 67 and 90% sequence similarity at the protein level but do not match anything else in the public databases (Reysset et al., 1992; Trinh et al., 1995; Trinh and Reysset, 1996a; Trinh et al., 1996b). The genes have been found on a variety of different small mobilizable plasmids, as well as on what appears to be a mobilizable transposon. In nearly every case these genes are silent unless activated by IS elements, which in many cases are the same IS elements known to activate the *cfiA* genes (Haggoud et al., 1994; Trinh et al., 1995; Table 6). The mechanism of metronidazole resistance appears to rely on the ability of the Nim protein to reduce the drugs to their amine form, which precludes the reductive formation of the toxic nitroso-radical anions that form the basis of killing by the 5-nitroimidazoles (Carlier et al., 1997). Thus it is thought that the *nim* genes encode a 5-nitroimidazole reductase.

The intrinsic resistance of *Bacteroides* spp. to most quinolone and fluoroquinolone drugs is striking, but in addition there are reports that even the use of effective fluoroquinolones such as trovafloxacin or sparfloxacin can be compromised by the rapid emergence of resistant strains following 24 h of exposure to the drugs (Peterson et al., 1999). Also, *B. fragilis* isolates from Japan showed a significant increase in all fluoroquinolone minimal inhibitory concentrations (MICs) from 1983 to 1987 (Kato et al., 1988). It is likely that resistance to these drugs arises as a combination of active efflux and mutations in the *gyrA* gene that encodes a subunit of DNA gyrase that is the antibiotic target. Studies on the accumulation of norfloxacin in *B. fragilis* revealed the presence of an active efflux pump that was sensitive to inhibition by the proton conductor carbonyl cyanide *m*-chlorophenylhydrazone (Miyamae et al., 1998; Ricci and Piddock, 2000). Further, the rate of efflux was dramatically increased by a single-step spontaneous mutation that resulted in simultaneous increases in the MICs for several fluoroquinolones, ethidium bromide, and puromycin (Miyamae et al., 1998). These data suggested the presence of a multidrug efflux pump, and in *B. thetaiotaomicron*, the gene for an efflux pump (designated *bexA*) was cloned and found to be in the multidrug and toxic compound extrusion (MATE) family. The presence of *bexA* was shown to impart increased resistance to fluoroquinolones and ethidium bromide (Miyamae et al., 2001). Comparison of the BexA protein to the *B. fragilis* genome sequence revealed the presence of at least three similar proteins (Miyamae et al., 2001).

Mutation of the DNA gyrase in the quinolone-resistance determining region (QRDR) also was shown to be responsible for the spontaneous resistance to levofloxacin of a *B. fragilis* mutant (Onodera and Sato, 1999). In a more extensive study, about half of the naturally occurring clinafloxacin-resistant strains (including *B. fragilis*, *B. thetaiotaomicron*, *B. ovatus*, *B. uniformis* and *B. vulgatus*) exhibited *gyrA* mutations in the QRDR (Oh et al., 2001). These data suggest that while GyrA mutations are important for quinolone resistance, other mechanisms such as active efflux may also play a role.

As mentioned briefly above, aminoglycoside antibiotics are not effective against *Bacteroides* spp. There is an exception to this observation, and that is trospectomycin, an amino-cyclitol similar to spectinomycin that is very active against all *Bacteroides* spp. with MIC_{90} (MIC for 90% of strains tested) of ~8 μg/ml (Jacobus and Tally, 1988; Chisari et al., 1995). Studies on the mechanism of aminoglycoside resistance have shown that the ribosomes of *B. fragilis* are in fact sensitive to streptomycin and gentamycin, but the drugs do not accumulate in the cells (Bryan et al., 1979). This suggests that the lack of aminoglycoside transport is responsible for inherent resistance. It is interesting to note that one aminoglycoside-resistance gene, *aadS*, has been found in *Bacteroides* spp. (Smith et al., 1992b). This *aadS* gene encodes a streptomycin-dependent adenyltransferase and has been found on Tn*4551* and CTn*DOT*. The gene is actually expressed in *B. fragilis*, resulting in MIC values of >10 mg/ml of streptomycin, but its significance in *Bacteroides* antibiotic resistance really is not clear.

The Role of *Bacteroides* spp. in Interspecies Resistance Transfer

The extraordinary high numbers of the *Bacteroides* in the intestinal tract allows these organisms to interact physically with a variety of the 500 or so indigenous species, as well as with the constant parade of transients passing through the tract. Contact with such diverse species provides the opportunity for genetic exchange in both directions, so *Bacteroides* spp. could be an ideal reservoir or perhaps more accurately a clearing-house of antibiotic-resistance genes. The CTns help propel this gene transfer, and their widespread dissemination may in part explain the proliferation of mobilizable plasmids and transposons, which are in >70% of all *Bacteroides* spp. (Callihan et al., 1983; Smith et al., 1998; Wang et al., 2000). The mobilizable transposons in particular have a potentially wide host range and could at the least provide a mechanism to introduce new antibiotic-resistance genes into a variety of organisms.

A significant amount of data indicates that the *Bacteroides* can transfer antibiotic-resistance determinants to diverse species. First, resistance genes (*tetQ*) are transferred directly between the *Bacteroides* spp. and Gram-negative organisms in the oral cavity such as *Prevotella* (seven species) and *Porphyromonas gingivalis* (Leng et al., 1997; Roberts, 1998; Chung et al., 1999b). More recently, a penicillin-resistant isolate of the oral microbe *Prevotella intermedia* was found to have a β-lactamase gene >98% identical to the *cfxA* gene of *B. vulgatus*, and sequences homologous to Tn*4555* transposition genes also were found (Madinier et al., 2001). A significant number of tetracycline-resistant *Prevotella* in the rumen of cattle also have been shown to harbor *tetQ* (Nikolich et al., 1994). In fact, *tetQ* has now turned up in a number of different Gram-positive and Gram-negative anaerobes from a variety of human sources, and direct transfer of the gene from diverse donors to *Enterococcus*

faecalis recipients has been demonstrated (Leng et al., 1997; Chung et al., 1999b). This shows not only that broad, heterologous expression of these genes can be achieved but also that these genes can cross very broad species barriers. Other data sets reveal complex patterns of *erm* gene transfer. As mentioned above, an identical *ermG* gene (three nucleotides differ) was found in *Bacillus* and on a *Bacteroides* CTn (Cooper et al., 1996). Also, new data on the distribution of *ermF* have shown that this resistance determinant has entered into *Treponema denticola* (Roberts et al., 1996) and *Neisseria* species including *N. gonorrhoeae* (Roberts et al., 1999).

Isolation and Identification

The majority of anaerobes isolated from clinical specimens are Gram-negative anaerobic bacilli, mainly *Bacteroides*, *Fusobacterium*, *Prevotella* and *Porphyromonas*. It is recommended that anaerobes isolated from sterile sites and from serious infections should always be completely identified to species level (Citron and Appelbaum, 1993). This recommendation is particularly relevant to the *Bacteroides* group because of their virulence and resistance to many antimicrobial agents.

The procedures recommended for appropriate processing of clinical specimen collection, transport, and anaerobic growth techniques follow the same procedures for general anaerobic bacteriology described elsewhere (Summanen et al., 1993).

Methods of Isolation, Examination, and Identification

Direct Examination Direct examination of Gram-stained smears of clinical material is a simple method that provides useful information on bacterial morphology, which for the most part is similar for aerobic organisms and anaerobes. The typical *Bacteroides* cellular morphology is the presence of pleomorphic, pale, Gram-negative forms with round-ends, occurring singly or in pairs, with vacuoles (Holdeman et al., 1977).

The methodology of fluorescent polyvalent antibody conjugates for rapid identification of the *Bacteroides* group is commercially available and gives reliable results within a few hours (Wills et al., 1982). The immunological detection of *B. fragilis* and *Bacteroides* spp. from clinical specimens by fluorescence microscopy is in the range of 81 to 97% when compared to culture results (Slack et al., 1981; Viljanen et al., 1988; Patrick et al., 1995). Antibodies prepared against the common polysaccharide antigen of *B. fragilis* and related species are more suitable for the immunodetection of *B. fragilis* from clinical samples compared to monoclonal antibodies specific for the variable surface polysaccharide (Patrick et al., 1995). Though fluorescent antibody procedures for the identification of *Bacteroides* spp. have been useful in reference laboratories, they are not routinely used in the clinical microbiology laboratory.

Direct gas-liquid chromatography analysis of clinical specimens for the detection of short-chain fatty acid end products of anaerobic bacteria metabolism is a presumptive indicator of the presence of anaerobes in the infectious site (Gorbach et al., 1976). The presence of succinic acid was suggested to be a good indicator for the presence of *Bacteroides* in the infected material, but this has not been consistently reported (Gorbach et al., 1976; Watt et al., 1982).

Preliminary Identification Initial processing procedures for examination and inoculation of the specimen require an appropriate combination of enriched, nonselective, selective and differential media. The differential isolation and identification of the species belonging to Gram-negative anaerobic bacilli groups other then *Bacteroides* are dealt with in detail by Summanen et al. (1993) and Jousimies-Somer et al. (1999).

The nonselective recovery of *Bacteroides* can be carried out on various basal media, which include Brucella agar, brain-heart infusion agar, Columbia agar and Wilkins-Chalgren agar supplemented with 5–10% horse or sheep blood and hemin (5 μg/ml). Primary selective isolation of *Bacteroides* from human origin can be accomplished on either kanamycin-vancomycin laked blood Brucella (KVLB) agar (Summanen et al., 1993) or bile-containing media such as *Bacteroides* bile esculin (BBE) agar (Livingston et al., 1978). KVLB agar inhibits most facultative anaerobic bacteria but permits selective isolation mainly of *Prevotella* spp. and *Bacteroides* spp., while BBE is selective for *Bacteroides* spp.

The use of selective media allows rapid presumptive identification of *Bacteroides* spp. from clinical and nonclinical sources. Specimens inoculated on plates containing BBE can be examined following 18–24 h anaerobic incubation. *Bacteroides* spp. will typically form colonies >1 mm diameter and will be surrounded by a brown-black zone due to esculin hydrolysis. *Bacteroides vulgatus* is an exception owing to its esculin-negative phenotype (Summanen et al., 1993). As a general rule, any colony picked off BBE agar plates for further characterization must be subcultured in an enriched medium with

no antibiotic and incubated in an aerobic incubator to determine whether the isolate is an obligate anaerobe or a facultative anaerobe. Enterobacteriaceae resistant to gentamycin are able to form colonies on BBE agar. Other anaerobic Gram-negative rods species such as *Fusobacterium mortiferum* and *Bilophila* spp. also can form colonies on BBE. The former can be differentiated from *Bacteroides* by its sensitivity to kanamycin and colistin and resistance to rifamycin. The latter is nitrate positive (Summanen et al., 1993; Jousimies-Somer et al., 1999).

Definitive Identification The standard conventional methods for the identification and differentiation of the *Bacteroides* group species are largely based on the schemes proposed by Holdeman et al. (Holdeman et al., 1977; Holdeman et al., 1986) and involve the utilization of pre-reduced anaerobically sterilized media for the determination of sugar fermentation, biochemical tests and the detection of fermentative end products by gas/liquid chromatography (Table 7). A simplified and rapid scheme for biochemical and fermentative identification of bile resistant *Bacteroides* allows speciation of the group within 24 h after obtaining a pure culture (Citron et al., 1990). Another simplified identification scheme based on conventional methodology and that provides convenient identification at a reasonable cost is the use of Presumpto plates (Whaley et al., 1995). Generally a set of three quadrant plates containing four conventional media to generate 21 tests is used to separate most of the clinically relevant anaerobes with rapid recognition of five *Bacteroides* species.

Several rapid identification systems for anaerobic bacteria also are available and include the API 20A, Minitek, An-Ident, RapID-ANAII, and API ZYM systems. Most of these systems involve the use of several chromogenic substrates for the detection of constitutive enzymes. Generally, the investigator is able to obtain adequate identification of *Bacteroides* species, but additional tests are often required since some species in this genus are not easily distinguished by these phenotypic tests.

Whole-cell carbohydrate analysis by capillary gas chromatography provides rapid and accurate identification of *Bacteroides* spp. (Engelhard and Mutters, 1991). Identification of the strains can be performed within 4–6 hours after primary isolation, and the time-consuming conventional anaerobic identification procedures can be avoided.

Molecular Approaches

Nucleic Acid Probes A variety of identification schemes based on restriction endonuclease digestion, DNA or RNA hybridization, PCR or a combination of these technologies have been used for the identification of *Bacteroides* spp. Most uses of these approaches have been in research laboratories, but some of these technologies may be adapted to the clinical laboratories in the near future. The simplest hybridization approach is to take whole-chromosome DNA samples, transfer these to a hybridization membrane, and then probe the membranes with labeled chromosomal DNA from the type strains of the species (Morotomi et al., 1988) or species-specific DNA fragments (Kuritza et al., 1986b). Using this procedure, accurate identification was obtained for *B. fragilis* in experimental blood cultures, and quantification was obtained of *B. thetaiotaomicron*, *B. uniformis*, *B. distasonis*, *B. ovatus*, *Bacteroides* group 3452A and *B. vulgatus* from fecal samples. Groves and Clark (1987) utilized specific radiolabeled RNA probes, obtained from randomly cloned chromosomal DNA from the *B. fragilis* type strain, to detect chromosomal DNA from clinical isolates of *B. fragilis* blotted on nitrocellulose membrane. These are highly accurate tests, but the use of radiolabeled probe has limited their use in the clinical laboratory.

Restriction Endonuclease Analysis Restriction endonuclease analysis (REA) of the bacterial chromosome also has been used in determining the genetic relationship of microorganisms. This approach offers the advantage of being highly reproducible and accurate. To generate a fingerprint of the chromosome, total genomic DNA is digested with an appropriate restriction endonuclease and electrophoresed on an agarose gel. The resulting patterns are species specific owing to RFLP. Often the RFLP patterns are simplified by coupling them to hybridization techniques that use specific DNA probes. For example, a ribotype, shown to have taxonomic and epidemiological values, can be obtained by using labeled ribosomal operons for 16S rRNA or 23S rRNA (Tang et al., 1997). Using this approach, distinct patterns were observed for all of the *Bacteroides* spp. and each could be easily differentiated (Smith and Callihan, 1992a). In another study, *B. fragilis* isolated from blood and feces was differentiated on the basis of REA and ribotype profiles of genomic DNA digested with *Bam*HI and *Eco*RI, respectively (Kleivdal and Hofstad, 1995). This analysis of REA and rRNA gene profiles of *B. fragilis* revealed some genetic heterogeneity among the isolates and concluded that no particular ribotype profile could be associated with systemic infection. Ribotype profiles of *B. fragilis* may be useful for phylogenetic and epidemiological studies, but

Table 7. Biochemical reactions of the *Bacteroides* group.

Species	Growth in 20% bile	Esculin hydrolysis	Indole	Catalase	Fermentation of									*a*-Fucosidase	Products from PYG

the complex patterns and heterogeneity make it difficult for routine taxonomic studies (Eribe and Olsen, 2000).

Comparison of the complex REA of chromosomal DNA profiles is difficult because of the hundreds of fragments generated by conventional methods. To address this, differentiation of *Bacteroides* has been obtained by pulse field gel electrophoresis (PFGE), which has the ability to separate the large DNA fragments typically generated with rare-cutting restriction endonucleases (Shaheduzzaman et al., 1997; Tang et al., 1997). In one study, *Bacteroides* spp. were identified on the basis of total genome size and the number and molecular size of restriction fragments generated with the rare-cutting restriction enzyme I-*Ceu*I. Restriction with I-*Ceu*I provided distinct species-specific RFLP profiles, and these profiles have a significant correlation with the classification based on 16S rRNA (Shaheduzzaman et al., 1997). PFGE is a simple and powerful technique for studying bacterial genome organization and may be useful for further studies on the phylogeny of the genus.

Polymerase Chain Reaction The use of PCR methodology has proven to be useful in the identification of *B. fragilis* and *B. thetaiotaomicron* directly from clinical specimens. PCR amplification of the neuraminidase, *nanH*, and glutamine synthase genes allowed direct detection of *B. fragilis* from clinical specimens containing other aerobic and anaerobic bacteria (Yamashita et al., 1994; Jotwani et al., 1995). It was shown that the presence of a specific PCR amplified *nanH* product completely correlated with positive cultures for *B. fragilis*. *Bacteroides thetaiotaomicron* also could be identified in clinical specimens by PCR amplification of a specific 721-bp chromosomal DNA sequence (Teng et al., 2000).

Restriction endonuclease analysis of PCR-amplified DNA also has been applied to *Bacteroides* species identification. Analysis of the RFLP pattern generated from PCR-amplified 16S rDNA digested with *Hpa*II and *Taq*I produced profiles that allowed identification of all *Bacteroides* species type strains and unequivocal identification of 93% of the *Bacteroides* clinical strains tested, compared to conventional methods (Stubbs et al., 2000). The application of 16S rDNA PCR-RFLP to species identification offers a rapid and accurate approach for identification of *Bacteroides* to the species level. A similar strategy was used by Kuwahara et al. (2001) to examine the 16S and 23S rRNA internal transcribed spacer region among *Bacteroides* spp. Amplification products of the spacer region digested with *MspI* produced distinctive species-specific RFLP patterns, and it was possible to differentiate 90 strains to the species level, including *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. eggerthii*, *B. thetaiotaomicron*, *B. uniformis* and *B. vulgatus*.

PCR methodology has been used not only for the detection of *B. fragilis* in clinical specimens but also for epidemiological studies. For example, a nested PCR amplification of the *bft* gene was developed to trace enterotoxigenic strains of *B. fragilis* in human and animal feces (Shetab et al., 1998). Moreover, detection of *B. fragilis* enterotoxigenic strains by PCR was instrumental in a study on the geographical distribution of ETBF, which led to the isolation and detection of a new *bft*-isoform (*bft*-3) in Korea (Chung et al., 1999a). Comparison of PCR fingerprint profiles of clinical isolates of *B. fragilis* and *B. thetaiotaomicron* showed that all *B. fragilis* strains isolated from Germany belong to the DNA homology group I, and all *B. thetaiotaomicron* isolates are genetically homologous to the type strain. In contrast, *B. fragilis* and *B. thetaiotaomicron* strains isolated from the United States showed a higher degree of genetic heterogeneity (Carlos et al., 1997).

DNA homology studies in 1978 suggested the likelihood of two genetically distinct *B. fragilis* groups since they shared only 69% identical sequences (Johnson, 1978a). These two *B. fragilis* DNA homology groups are phenotypically homogeneous and their metabolic features do not offer enough information to differentiate these groups by conventional identification tests (Johnson and Ault, 1978b). In an example of the utility of molecular typing approaches, these genetically distinct groups have been separated by means of ribotyping, 16S rRNA sequence analysis, PCR amplification of the β-lactamase genes *cepA* and *cfiA*, RFLP, and multi-locus enzyme electrophoresis profiles (Podglajen et al., 1995; Ruimy et al., 1996; Gutacker et al., 2000). Presence of the *cepA* gene in DNA homology group I (*cfiA* is absent) and the presence of *cfiA* in the group II strains (*cepA* is absent) provide a PCR strategy by which the two groups can be easily distinguished. Cluster analysis based on multi-locus electrophoretic profiles of 15 genetic loci separated DNA homology group I into 81 distinct electrophoretic profile types associated with the presence of *cepA* gene, whereas 9 electrophoretic profiles were detected for strains belonging to group II carrying the *cfiA* gene (Gutacker et al., 2000). The differentiation of *B. fragilis* strains belonging to genetic group I or group II is useful for taxonomic and epidemiological studies, but there is no association between these groups and any clinical manifestations such as sepsis, abscesses, or diarrhea, geographical origin, or human or animal origin.
