Preface

The 32nd International Colloquium on Automata, Languages and Programming (ICALP 2005) was held in Lisbon, Portugal from July 11 to July 15, 2005. These proceedings contain all contributed papers presented at ICALP 2005, together with the papers by the invited speakers Giuseppe Castagna (ENS), Leonid Libkin (Toronto), John C. Mitchell (Stanford), Burkhard Monien (Paderborn), and Leslie Valiant (Harvard). The program had an additional invited lecture by Adi Shamir (Weizmann Institute) which does not appear in these proceedings.

ICALP is a series of annual conferences of the European Association for Theoretical Computer Science (EATCS). The first ICALP took place in 1972. This year, the ICALP program consisted of the established track A (focusing on algorithms, automata, complexity and games) and track B (focusing on logic, semantics and theory of programming), and innovated on the structure of its traditional scientific program with the inauguration of a new track C (focusing on security and cryptography foundation).

In response to a call for papers, the Program Committee received 407 submissions, 258 for track A, 75 for track B and 74 for track C. This is the highest number of submitted papers in the history of the ICALP conferences. The Program Committees selected 113 papers for inclusion in the scientific program. In particular, the Program Committee for track A selected 65 papers, the Program Committee for track B selected 24 papers, and the Program Committee for track C selected 24 papers. All the work of the Program Committees was done electronically.

ICALP 2005 was held in conjunction with the Annual ACM International Symposium on Principles and Practice of Declarative Programming (PPDP 2005). Additionally, the following workshops were held as satellite events of ICALP 2005: the 2nd Workshop on Automated Reasoning for Security Protocol Analysis (ARSPA), the 1st International Workshop on Verification of Concurrent Systems with dynamic Allocated Heaps (COSMICAH), the 1st International Workshop on New Developments in Computational Models (DCM), the 4th International Workshop on Parallel and Distributed Methods in Verification (PDMC), the 4th International Workshop on Proof Theory, Computation, Complexity (PCC), the Workshop on Structures and Deduction — The Quest for the Essence of Proofs (DS), the 2nd Workshop on Structural Operational Semantics (SOS), and the Workshop on Semigroups and Automata (WSA).

We wish to thank all authors who submitted papers for consideration, the Program Committees for their hard work, as well as the external reviewers who assisted the Program Committees in the evaluation process.

We thank the sponsors and the Gulbenkian Foundation of Lisbon for hosting ICALP 2005. We are also grateful to the Department of Informatics of the

Faculty of Sciences and Technology, New University of Lisbon, in particular the administrative office and the technical support service.

Last but not least, we would like to thank Andrei Voronkov for providing the conference management software EasyChair. It was of great help in handling the submissions and the electronic PC meeting.

Organization

Program Committee

Track A

Lars Arge, Duke University, USA
Giorgio Ausiello, University of Rome “La Sapienza”, Italy
Surender Baswana, Max-Planck-Institut für Informatik, Saarbrücken,
Germany
Hans Bodlaender, University of Utrecht, The Netherlands
Véronique Bruyère, University of Mons-Hainaut, Belgium
Adam Buchsbaum, AT&T Labs Research, USA
Josep Diaz, Universitat Politècnica de Catalunya, Spain
David Eppstein, University of Irvine, USA
Andrew Goldberg, Microsoft, USA
Monika Henzinger, Google and ETH Lausanne, Switzerland
Giuseppe F. Italiano, University of Rome “Tor Vergata”, Italy (Chair)
Marios Mavronicolas, University of Cyprus, Cyprus
Peter Bro Miltersen, University of Aarhus, Denmark
Mike Paterson, University of Warwick, UK
Dominique Perrin, Université de Marne la Vallée, France
Seth Pettie, Max-Planck-Institut für Informatik, Saarbrücken, Germany
Yuval Rabani, Technion, Israel
Antonio Restivo, University of Palermo, Italy
José Rolim, University of Geneva, Switzerland
Dorothea Wagner, University of Karlsruhe, Germany
Tandy Warnow, University of Texas at Austin, USA
Christos Zaroliagis, CTI and University of Patras, Greece

Track B

Kenichi Asai, Ochanomizu University, Japan
Jos Baeten, Eindhoven University of Technology, The Netherlands
Peter Buneman, University of Edinburgh, UK
Zoltan Esik, University of Szeged, Hungary and Rovira University, Spain
Javier Esparza, University of Stuttgart, Germany
Marcelo Fiore, Christ’s College and University of Cambridge, UK
Manuel Hermenegildo, Universidad Politècnica de Madrid, Spain
Delia Kesner, Université Paris VII, France
Kim Guldstrand Larsen, University of Aalborg, Denmark
Gopalan Nadathur, University of Minnesota, USA

VIII Organization

Uwe Nestmann, EPFL, Switzerland
Catuscia Palamidessi, INRIA, France (Chair)
Amr Sabry, University of Indiana, USA
Davide Sangiorgi, Università di Bologna, Italy
Roberto Segala, Università di Verona, Italy
Harald Søndergaard, University of Melbourne, Australia

Track C

David Basin, ETH Zurich, Switzerland
Christian Cachin, IBM Research, Switzerland
Alfredo De Santis, Università di Salerno, Italy
Cynthia Dwork, Microsoft Research, USA
Matt Franklin, U.C. Davis, USA
Michael Goodrich, U.C. Irvine, USA
Andrew D. Gordon, Microsoft Research, UK
Roberto Gorrieri, Università di Bologna, Italy
Yuval Ishai, Technion, Israel
Phil MacKenzie, DoCoMo Labs, USA
Tatsuaki Okamoto, NTT Labs, Japan
David Pointcheval, ENS Paris, France
Tal Rabin, IBM Research, USA
Omer Reingold, Weizmann Institute, Israel
Adi Rosen, Technion, Israel
Amit Sahai, UCLA, USA
Andre Scedrov, University of Pennsylvania, USA
Igor Shparlinski, Macquarie University, Australia
Nigel Smart, University of Bristol, UK
Moti Yung, Columbia University and RSA Laboratories, USA (Chair)

Organizing Committee

Table of Contents

Invited Lectures

Holographic Circuits <i>Leslie G. Valiant</i>	1
Probabilistic Polynomial-Time Semantics for a Protocol Security Logic <i>Anupam Datta, Ante Derek, John C. Mitchell, Vitaly Shmatikov, Mathieu Turuani</i>	16
A Gentle Introduction to Semantic Subtyping <i>Giuseppe Castagna, Alain Frisch</i>	30
Logics for Unranked Trees: An Overview <i>Leonid Libkin</i>	35
Nash Equilibria, the Price of Anarchy and the Fully Mixed Nash Equilibrium Conjecture <i>Martin Gairing, Thomas Lücking, Burkhard Monien, Karsten Tiemann</i>	51

Data Structures I

The Tree Inclusion Problem: In Optimal Space and Faster <i>Philip Bille, Inge Li Gørtz</i>	66
Union-Find with Constant Time Deletions <i>Stephen Alstrup, Inge Li Gørtz, Theis Rauhe, Mikkel Thorup, Uri Zwick</i>	78
Optimal In-place Sorting of Vectors and Records <i>Gianni Franceschini, Roberto Grossi</i>	90
Towards Optimal Multiple Selection <i>Kanella Kaligosi, Kurt Mehlhorn, J. Ian Munro, Peter Sanders</i>	103

Cryptography and Complexity

Simple Extractors via Constructions of Cryptographic Pseudo-random Generators <i>Marius Zimand</i>	115
--	-----

Bounds on the Efficiency of “Black-Box” Commitment Schemes
Omer Horvitz, Jonathan Katz 128

On Round-Efficient Argument Systems
Hoeteck Wee 140

Computational Bounds on Hierarchical Data Processing with
 Applications to Information Security
Roberto Tamassia, Nikos Triandopoulos 153

Data Structures II

Balanced Allocation and Dictionaries with Tightly Packed Constant
 Size Bins
Martin Dietzfelbinger, Christoph Weidling 166

Worst Case Optimal Union-Intersection Expression Evaluation
*Ehsan Chiniforooshan, Arash Farzan,
 Mehdi Mirzazadeh* 179

Measure and Conquer: Domination – A Case Study
Fedor V. Fomin, Fabrizio Grandoni, Dieter Kratsch 191

Cryptography and Distributed Systems

Optimistic Asynchronous Atomic Broadcast
Klaus Kursawe, Victor Shoup 204

Asynchronous Perfectly Secure Communication over One-Time Pads
Giovanni Di Crescenzo, Aggelos Kiayias 216

Single-Prover Concurrent Zero Knowledge in Almost Constant Rounds
Giuseppe Persiano, Ivan Visconti 228

Graph Algorithms I

LCA Queries in Directed Acyclic Graphs
Miroslaw Kowaluk, Andrzej Lingas 241

Replacement Paths and k Simple Shortest Paths in Unweighted
 Directed Graphs
Liam Roditty, Uri Zwick 249

Deterministic Constructions of Approximate Distance Oracles and Spanners <i>Liam Roditty, Mikkel Thorup, Uri Zwick</i>	261
An $\tilde{O}(m^2n)$ Randomized Algorithm to Compute a Minimum Cycle Basis of a Directed Graph <i>Telikepalli Kavitha</i>	273
Security Mechanisms	
Basing Cryptographic Protocols on Tamper-Evident Seals <i>Tal Moran, Moni Naor</i>	285
Hybrid Trapdoor Commitments and Their Applications <i>Dario Catalano, Ivan Visconti</i>	298
On Steganographic Chosen Coverttext Security <i>Nicholas Hopper</i>	311
Classification of Boolean Functions of 6 Variables or Less with Respect to Some Cryptographic Properties <i>An Braeken, Yuri Borissov, Svetla Nikova, Bart Preneel</i>	324
Graph Algorithms II	
Label-Guided Graph Exploration by a Finite Automaton <i>Reuwen Cohen, Pierre Fraigniaud, David Ilcinkas, Amos Korman, David Peleg</i>	335
On the Wake-Up Problem in Radio Networks <i>Bogdan S. Chlebus, Leszek Gąsieniec, Dariusz R. Kowalski, Tomasz Radzik</i>	347
Distance Constrained Labelings of Graphs of Bounded Treewidth <i>Jiří Fiala, Petr A. Golovach, Jan Kratochvíl</i>	360
Optimal Branch-Decomposition of Planar Graphs in $O(n^3)$ Time <i>Qian-Ping Gu, Hisao Tamaki</i>	373
Automata and Formal Languages I	
NFAs With and Without ε -Transitions <i>Juraj Hromkovič, Georg Schnitger</i>	385

On the Equivalence of \mathbb{Z} -Automata
Marie-Pierre Béal, Sylvain Lombardy, Jacques Sakarovitch 397

A Tight Linear Bound on the Neighborhood of Inverse Cellular Automata
Eugen Czeizler, Jarkko Kari 410

Groupoids That Recognize Only Regular Languages
Martin Beaudry, François Lemieux, Denis Thérien 421

Signature and Message Authentication

Append-Only Signatures
Eike Kiltz, Anton Mityagin, Saurabh Panjwani, Barath Raghavan 434

Hierarchical Group Signatures
Mårten Trolin, Douglas Wikström 446

Designated Verifier Signature Schemes: Attacks, New Security Notions and a New Construction
Helger Lipmaa, Guilin Wang, Feng Bao 459

Single-Key AIL-MACs from Any FIL-MAC
Ueli Maurer, Johan Sjödin 472

Algorithmic Game Theory

The Efficiency and Fairness of a Fixed Budget Resource Allocation Game
Li Zhang 485

Braess’s Paradox, Fibonacci Numbers, and Exponential Inapproximability
Henry Lin, Tim Roughgarden, Éva Tardos, Asher Walkover 497

Automata and Logic

Weighted Automata and Weighted Logics
Manfred Droste, Paul Gastin 513

Restricted Two-Variable FO + MOD Sentences, Circuits and Communication Complexity
Pascal Tesson, Denis Thérien 526

Computational Algebra

Suitable Curves for Genus-4 HCC over Prime Fields: Point Counting Formulae for Hyperelliptic Curves of Type $y^2 = x^{2k+1} + ax$ <i>Mitsuhiro Haneda, Mitsuru Kawazoe, Tetsuya Takahashi</i>	539
Solvability of a System of Bivariate Polynomial Equations over a Finite Field <i>Neeraj Kayal</i>	551

Cache-Oblivious Algorithms and Algorithmic Engineering

Cache-Oblivious Planar Shortest Paths <i>Hema Jampala, Norbert Zeh</i>	563
Cache-Aware and Cache-Oblivious Adaptive Sorting <i>Gerth Stølting Brodal, Rolf Fagerberg, Gabriel Moruz</i>	576
Simulated Annealing Beats Metropolis in Combinatorial Optimization <i>Ingo Wegener</i>	589

On-line Algorithms

Online Interval Coloring and Variants <i>Leah Epstein, Meital Levy</i>	602
Dynamic Bin Packing of Unit Fractions Items <i>Wun-Tat Chan, Tak-Wah Lam, Prudence W.H. Wong</i>	614
Reordering Buffer Management for Non-uniform Cost Models <i>Matthias Englert, Matthias Westermann</i>	627

Security Protocols Logic

Combining Intruder Theories <i>Yannick Chevalier, Michaël Rusinowitch</i>	639
Computationally Sound Implementations of Equational Theories Against Passive Adversaries <i>Mathieu Baudet, Véronique Cortier, Steve Kremer</i>	652
Password-Based Encryption Analyzed <i>Martín Abadi, Bogdan Warinschi</i>	664

Random Graphs

On the Cover Time of Random Geometric Graphs <i>Chen Avin, Gunes Ercal</i>	677
On the Existence of Hamiltonian Cycles in Random Intersection Graphs <i>Charilaos Efthymiou, Paul G. Spirakis</i>	690
Optimal Cover Time for a Graph-Based Coupon Collector Process <i>Nedialko B. Dimitrov, C. Greg Plaxton</i>	702
Stability and Similarity of Link Analysis Ranking Algorithms <i>Debora Donato, Stefano Leonardi, Panayiotis Tsaparas</i>	717

Concurrency I

Up-to Techniques for Weak Bisimulation <i>Damien Pous</i>	730
Petri Algebras <i>Eric Badouel, Jules Chenou, Goulven Guillou</i>	742
A Finite Basis for Failure Semantics <i>Wan Fokkink, Sumit Nain</i>	755
Spatial Logics for Bigraphs <i>Giovanni Conforti, Damiano Macedonio, Vladimiro Sassone</i>	766

Encryption and related Primitives

Completely Non-malleable Schemes <i>Marc Fischlin</i>	779
Boneh-Franklin Identity Based Encryption Revisited <i>David Galindo</i>	791
Single-Database Private Information Retrieval with Constant Communication Rate <i>Craig Gentry, Zulfikar Ramzan</i>	803
Concurrent Zero Knowledge in the Public-Key Model <i>Giovanni Di Crescenzo, Ivan Visconti</i>	816

Approximation Algorithms I

A Faster Combinatorial Approximation Algorithm for Scheduling Unrelated Parallel Machines <i>Martin Gairing, Burkhard Monien, Andreas Woclaw</i>	828
Polynomial Time Preemptive Sum-Multicoloring on Paths <i>Annamária Kovács</i>	840
The Generalized Deadlock Resolution Problem <i>Kamal Jain, MohammadTaghi Hajiaghayi, Kunal Talwar</i>	853

Holographic Circuits

Leslie G. Valiant*

Division of Engineering and Applied Sciences,
Harvard University, Cambridge,
MA 02138, USA

Abstract. Holographic circuits are defined here to be circuits in which information is represented as linear superpositions. Holographic circuits when suitably formulated can be emulated on classical computers in polynomial time. The questions we investigate are those of characterizing the complexity classes of computations that can be expressed by holographic circuits.

1 Introduction

A holographic reduction [V04] between two computational problems is a reduction that preserves the sum of the solutions without preserving any correspondences among the individual solutions. A polynomial time holographic algorithm is an algorithm derived by applying a polynomial time holographic reduction to a problem having a classical polynomial time algorithm. Such holographic algorithms have been derived for several counting problems for which no polynomial time algorithms had been known before. This previous work used the Fisher-Kasteleyn-Temperley (FKT) algorithm for counting perfect matchings in planar graphs as the starting classical algorithm, which itself may be viewed as a classical reduction to the problem of computing the Pfaffian of an antisymmetric matrix.

This present paper develops holographic computation in two directions. First, the object of evaluation is now a computation or circuit, rather than a combinatorial problem. Second, it uses the Pfaffian itself as the starting point, and bypasses the FKT construction and the constraint of planarity.

2 Universal Operations Sets for Complexity Classes

Holographic circuits offer a new approach to computation in the following sense. Suppose we view a conventional computation as an acyclic circuit embedded in a plane. Then one possible listing of the atomic constituents of computation is:

* This research was supported in part by grants NSF-CCR-03-10882, NSF-CCR-98-77049, NSF-CCF-04-27129 and by the National Security Agency (NSA) and Advanced Research and Development Activity (ARDA) under Army Research Office (ARO) contract DAAD19-01-1-0506.

- (i) Inputs of constants 0 or 1,
- (ii) Boolean gates AND, OR, and NOT,
- (iii) Fanout or replication,
- (iv) Crossovers of wires in the planar embedding,

For nondeterministic computation we would add:

- (v) Nondeterministic generation of 0 or 1 as inputs, and
- (vi) Summation of circuit values over all generated input vectors.

In the holographic framework the sum (vi) over all possible computations of a circuit will be, by design, computable in polynomial time. This becomes meaningful if (v), or some similar nondeterministic operation, is available, since that offers polynomial time simulation of nondeterministic computations. In classical computation, of course, (i)–(iv) are trivial, while nondeterministic summation (vi) appears highly problematic. In the holographic formulation, it is the other way around: nondeterministic summation (vi) is easy but (i)–(iv), or (v), may be problematic. As we shall show, we can realize various subsets of (i)–(v) consistently. If all five could be so realized then $P^{\#P} = P$ would follow. By consistently we mean here that they can be realized with a *common basis*, as explained in the following sections.

We note that there are numerous other possible listings of the atomic constituents of computation besides the one above. For complexity classes X, Y we define such a *universal operations set for X with respect to Y* , (or a *UOS for X with respect to Y*) to be a list of operations such that if they can be realized in a common basis then $X = Y$ is implied. In this paper we shall restrict attention to and assume the case that $Y = NC2$. It is clearly interesting then to investigate such UOS's for $X = NP$, $X = \oplus P$, and $X = \#P$, among others.

The present paper is therefore oriented towards the simulation of computational circuits as opposed to the solution of particular combinatorial problems. We have to emphasize that known algebraic relations, the matchgate identities [V02a, V02b], present obstacles to some of the more obvious attempts at encoding general classes of computations, such as NP or BQP, in this manner at least when using the smallest bases. However, the question of whether these obstacles can be overcome, perhaps by means of larger bases, remains open.

3 Matchgates and Matchcircuits

We start with some standard graph-theoretic notions and their relation to the Pfaffian of a matrix [BR91, M00]. We then go on to define the notions of PfaffianSum, matchgates, character matrices, and matchcircuits, closely following the treatment in [V02a, V02b].

A weighted undirected graph, or simply a *graph*, G is a triple (V, E, W) where V is a set of *vertices* each represented by a distinct positive integer, E is a set of *edges* or unordered pairs (i, j) of the vertices $i, j \in V$, and W is the set of *weights*, each weight $w(i, j)$ corresponding to the edge $(i, j) \in E$.

An $n \times n$ matrix B is *skew-symmetric* if for all i, j ($1 \leq i, j \leq n$) $B(i, j) = -B(j, i)$. The *matrix of the graph* $G = (V, E, W)$ where $V = \{1, 2, \dots, n\}$ is the $n \times n$ matrix $M(G)$ where the (i, j) entry $M(G)(i, j)$ is defined to equal:

- (i) $w(i, j)$ if $i < j$,
- (ii) $-w(i, j)$ if $i > j$, and
- (iii) 0 otherwise.

In the more general case that $V = \{k_1, k_2, \dots, k_n\}$ where $k_1 < k_2 < \dots < k_n$, weight $w(k_i, k_j)$ replaces $w(i, j)$ in (i) and (ii) in this definition. For brevity we shall abbreviate $M(G)$ by G whenever it is clear that a matrix is intended.

The Pfaffian of an $n \times n$ skew-symmetric matrix B is defined to be zero if n is odd, one if $n = 0$, and if n is even with $n = 2k$ and $k > 0$ then it is defined as:

$$\text{Pf}(B) = \sum_{\pi} \epsilon_{\pi} w(i_1, i_2) w(i_3, i_4) \dots w(i_{2k-1}, i_{2k})$$

where

- (i) $\pi = [i_1, i_2, i_3, \dots, i_{2k}]$ is a permutation on $[1, 2, \dots, n]$,
- (ii) summation is over all such permutations π where further
 - $i_1 < i_2, i_3 < i_4, \dots, i_{2k-1} < i_{2k}$, and
 - $i_1 < i_3 < i_5 < \dots < i_{2k-1}$, and
- (iii) $\epsilon_{\pi} \in \{-1, 1\}$ is the sign of the permutation π , i.e., it is -1 or $+1$ according to whether the number of transpositions or swaps of pairs of distinct elements i_j, i_k , needed to reorder π to the identity permutation is odd or even. (An equivalent definition in this context is that it is the sign or parity of the number of overlapping pairs, where a pair of edges $(i_{2r-1}, i_{2r}), (i_{2s-1}, i_{2s})$ is *overlapping* iff $i_{2r-1} < i_{2s-1} < i_{2r} < i_{2s}$ or $i_{2s-1} < i_{2r-1} < i_{2s} < i_{2r}$. Note that it is implicit here that $i_{2r-1} < i_{2r}$ and $i_{2s-1} < i_{2s}$.)

A *matching* $E^* \subseteq E$ of G is a set of edges such that if $(i, j), (r, s)$ are distinct edges in E^* then i, j, r, s are all distinct vertices. In a graph with an even number $2k$ of nodes a matching E^* is *perfect* if it contains k edges. (Then every $i \in V$ is an endpoint of, or is *saturated* by, some edge in E^* .)

We shall use the following graph-theoretic interpretation of the Pfaffian. If B is the matrix of the graph G then there is a one-to-one correspondence between monomials in the Pfaffian of B and the perfect matchings in G . The monomial $w(i_1, i_2) w(i_3, i_4) \dots w(i_{2k-1}, i_{2k})$ in $\text{Pf}(G)$ corresponds to the perfect matching $\{(i_1, i_2), (i_3, i_4), \dots, (i_{2k-1}, i_{2k})\}$ in G . The coefficient ϵ_{π} of this monomial will be the parity of the numbers of overlapping pairs of edges, in the sense defined above.

For an $n \times n$ matrix B and any set $A = \{i_1, \dots, i_r\} \subseteq \{1, \dots, n\}$ we denote by $B[A]$ the $(n-r) \times (n-r)$ matrix obtained by deleting from B all the rows and columns indexed by A . The following is from [V02a]:

Definition. The *PfaffianSum* of an $n \times n$ skew-symmetric matrix B is the polynomial over indeterminates $\lambda_1 \dots \lambda_n$

$$\text{PfS}(B) = \sum_A \left(\prod_{i \in A} \lambda_i \right) \text{Pf}(B[A]).$$

Summation here is over the various principal minors obtained from B by deleting some subset A of the indices. In this paper we shall only need the instances in which each λ_i is fixed to be 0 or 1. The i for which $\lambda_i = 0$ can be thought of as the *unomittable* indices, and those with $\lambda_i = 1$ as the *omittable* indices. Then for this $(0,1)$ -case the PfaffianSum is simply the sum of the $\text{Pf}(B[A])$ over those A that contain only omittable indices.

We shall simulate each gate of a computation by what we call a matchgate. A *matchgate* Γ is a quadruple (G, X, Y, T) where G is a graph (V, E, W) , $X \subseteq V$ is a set of *input* vertices, $Y \subseteq V$ is a set of *output* vertices, and $T \subseteq V$ is a set of *omittable* vertices such that (i) X, Y and T are all disjoint, and (ii) $\forall i \in T$ if $j \in X$ then $j < i$ and if $j \in Y$ then $j > i$. A matchgate is an (m, n) -*matchgate* if it has m input nodes and n output nodes. It is an *input gate* if $n = 0$ and an *output gate* if $m = 0$. It is an *even gate* if it has no omittable nodes.

The matchings we consider will be those that saturate all the unomittable nodes, i.e. $V - T$, and also some, possibly empty, subset of T . Whenever we refer to the PfaffianSum of a matchgate fragment, such as G' in the following paragraph, we shall assume the substitutions $\lambda_i = 1$ if $i \in T$, and $\lambda_i = 0$ otherwise.

We call $X \cup Y$ the *external* nodes. For $Z \subseteq X \cup Y$ we consider the matchings of a larger graph that contains G as a subgraph such that the Z nodes are matched by edges external to G , and the remaining elements of $X \cup Y$ by edges of G . We define the *character* $\chi(\Gamma, Z)$ of Γ with respect to $Z \subseteq X \cup Y$ to be the product

$$\mu(\Gamma, Z) \text{PfS}(G')$$

where: (a) $G' = (V - Z, E', W')$ where further E' is the restriction of E to edges with both endpoints in $V - Z$, and W' is the corresponding restriction of W , and (b) the *modifier* $\mu(\Gamma, Z) \in \{-1, 1\}$ counts the parity of the number of overlaps between matched edges in E' and matched external edges. We consider there to exist one matched external edge from each node in $X \cap Z$ and from each node in $Y \cap Z$. The other endpoint of each of the former is some node of lower index than any in V , and of each of the latter is some node of index higher than any in V .

The character of a matchgate, therefore, characterizes the contribution of G to the PfaffianSum of a larger graph, and takes into account overlaps between its internal edges and the external edges that link its external nodes to the rest of the graph. The significance of condition (ii) in the definition of matchgates is that it guarantees that the modifier $\mu(\Gamma, Z)$ is always well defined: for any fixed Z the external edges that arise are uniquely defined, but it has to be guaranteed that the parity of the overlap of any one such external edge with *every* matching of E' that saturates all the unomittable nodes is the same. Condition (ii) ensures this by not allowing an omittable node in the gate to be numbered intermediate between the endpoints of an external edge. (That case might produce different overlap parity for the given external edge and the various internal matchings depending on whether the omittable node was in the matching.) To verify this, note that if for $i \in X \cap Z$ there are r nodes $j < i$ where $j \in V - Z$, then the parity of the overlap of the external edge from i with the internal edges is the parity of r .

We define the *character* $\chi(\Gamma)$ of Γ as the $2^{|X \cup Y|}$ values of $\chi(\Gamma, Z)$ for the various $2^{|X \cup Y|}$ possible choices of Z . In particular, we think of the character as a $2^{|X|} \times 2^{|Y|}$ matrix where the rows represent the subsets of the inputs X , and the columns the subsets of the outputs Y . Matchgates with $|X| = |Y| = k$ can then be regarded as matrix transformations defined by a square character matrix. For example $k = 1$ corresponds to one-bit 2×2 matrix transformations, and $k = 2$ corresponds to two-bit 4×4 transformations. In all cases we need to specify a correspondence between subsets of X and the rows of the matrix, and another correspondence between subsets of Y and the columns of the matrix. In this paper we shall specify these correspondences as necessary. In general, here as in [Va02a] and [Va02b] we assume what we call a *normal ordering* in which both the rows and columns are in increasing order when the subsets of externally matched nodes Z are represented in binary in the sense of the following example. Suppose $X = \{1, 2, 3\}$ and $Y = \{7, 8, 9\}$. Then the rows will be ordered $1, 2, \dots, 8$, as Z ranges over $\emptyset, \{1\}, \{2\}, \{1, 2\}, \{3\}, \{1, 3\}, \{2, 3\}, \{1, 2, 3\}$. The columns are in the same order if 1 is identified with 9, 2 with 8, and 3 with 7. (N.B. The definition for this in [Va02b] was inaccurate.)

We say that matchgate $\Gamma = (G, X, Y, T)$ with $G = (V, E, W)$ has *normal numbering* if the numbering of V is consecutive and X, Y have minimal and maximal numbers respectively. Formally, $V = \{1, 2, \dots, |V|\}$ and $\forall i \in X, \forall j \in Y$ and $\forall k \notin X \cup Y$ it is the case that $i < k < j$.

We shall construct matchcircuits by composing normally numbered matchgates in the manner of Figure 1. This is the same as in [V02a] except that we are making the input and output gates more general. The purpose of the construction is to ensure that the PfaffianSum properties of the circuit conform to the composition of the corresponding properties of the individual matchgates, without interfering sign effects. Then for any input vector generated by the in-

Fig. 1. An example of a matchcircuit composed of five input gates on the left, four output gates on the right, and three intermediate gates G_1, G_2, G_3 . The internal nodes and edges in the gates are not shown. The nodes are numbered in increasing order from left to right. The bold edges show an example of the edges in a perfect matching of the circuit, excluding any matched edges internal to the individual gates

put gates the remaining circuit will compute a *value* equal to the composition of the functions computed by the gates. The proof there of the Main Theorem supports the following more general statement.

Main Theorem. *Consider a matchcircuit Γ composed of gates as shown in Figure 1. Suppose that every gate is:*

- (i) *a gate with diagonal character matrix,*
- (ii) *an even gate applied to consecutive bits $x_i, x_{i+1}, \dots, x_{i+j}$ for some $j > 0$,*
- (iii) *an arbitrary gate applied to bits x_1, \dots, x_j for some $j > 1$, or*
- (iv) *input or output gates on consecutive bits $x_i, x_{i+1}, \dots, x_{i+j}$ for some $j > 0$.*

Then the PfaffianSum of Γ equals the sum over all the input vectors generated by the input gates of the value of the circuit defined by the remaining gates.

4 Bases

A *basis* \mathbf{b} of size k is a set of distinct nonzero vectors of length 2^k with entries from a field F . In this paper the set will always consist of two vectors corresponding to the Boolean 1 and 0, and denoted by p and n respectively. Each of the 2^k components of p or n is interpreted as corresponding to an element of $\{0, 1\}^k$, where the 1's represent the subset of the input or output nodes in a matchgate that are to be matched by external edges. We denote the size k of \mathbf{b} by $|\mathbf{b}|$, and a basis of size k is also called a k -*basis*. If q, r are two vectors of length l_1, l_2 we denote by $s = q \otimes r$ their tensor product, which is of length $l_1 l_2$ and in which $s_{il_2+j} = q_i r_j$ for $0 \leq i < l_1$ and $0 \leq j < l_2$.

The *standard basis* is the one with $k = 1, p = (0, 1), n = (1, 0)$. An *even basis* is one in which every component p_i and n_i is zero if i corresponds to an odd number of nodes being matched externally. Note that an *even 2-basis* has nonzero components in p, n , only for the vector components representing 00 and 11. A special case of an even 2-basis is the *two-rail basis*, in which the only nonzero component in p is for 11, and the only nonzero component in n is for 00.

We shall seek to construct matchgates that perform various operations over various bases. For example, we say that a 2-input 1-output matchgate performs the AND operation over basis \mathbf{b} if for the four combinations of inputs $n \otimes n, n \otimes p, p \otimes n$, and $p \otimes p$, the outputs are n, n, n , and p , respectively. Also, we shall use the name of an operation, such as AND, to represent the set of bases for which there exists a matchgate to realize that operation. Further, we shall denote by X^* (e.g., AND* if the operation is AND) the set of bases for which there is an even matchgate that realizes operation X .

5 Basis Classes

We shall seek to use matchgates to simulate Boolean circuits. Thus we shall endeavor to simulate such basic functions as "and", "swap", "fanout" and "cnot"

gates. In the definitions below we shall assume that $\mathbf{b} = (n, p)$ is a basis of size k , and hence that n, p , are of length 2^k .

We shall now define some basis classes that each correspond to something that can be viewed as a primitive constituent of computation. Interspersed with the definitions will be statements of some of their simpler properties.

(i) **Generating Constants**

Defn. GEN0: Set of \mathbf{b} such that there is a $(0, |\mathbf{b}|)$ -matchgate with $\chi = n$.

Defn. GEN1: Set of \mathbf{b} such that there is a $(0, |\mathbf{b}|)$ -matchgate with $\chi = p$.

Defn. GEN01: Set of \mathbf{b} such that there is a $(0, |\mathbf{b}|)$ -matchgate with $\chi = n$ and another with $\chi = p$. (Clearly $\text{GEN01} = \text{GEN0} \cap \text{GEN1}$.)

Defn. GEN0+1: Set of \mathbf{b} such that there is a $(0, |\mathbf{b}|)$ -matchgate with $\chi = n + p$.

Proposition 1. *GEN0, GEN1, GEN01, GEN0+1 each contain all the 1-bases and 2-bases for any field.*

Proof. This can be deduced from Proposition 1 in [V02a], or proved more directly as follows. For 2-bases consider the following matchgate where node 1 is omittable, and the output nodes are $\{3, 4\}$.

Suppose we wish to generate the 1×4 character matrix (a_1, a_2, a_3, a_4) where ordering $(\emptyset, \{4\}, \{3\}, \{3,4\})$ is implied on the matrix columns. Then, by inspection,

$$\begin{aligned} a_1 &= zu - vy + xw, \\ a_2 &= u, \\ a_3 &= -v, \\ a_4 &= x. \end{aligned}$$

For example, by the definition of the character matrix, a_3 is the Pfaffian of the graph with node set $\{3\}$ omitted, adjusted by the multiplicative modifier $\mu = -1$, since this is the overlap between the internal and external edges (i.e. between the internal edge $(2,4)$ and the external edge from 3.)

Clearly we can set a_2, a_3, a_4 to arbitrary values by setting u, v, x appropriately. If at least one of a_2, a_3, a_4 is nonzero then we can also set a_1 arbitrarily by setting z, y, w appropriately. In the special case that $a_2 = a_3 = a_4 = 0$, we modify the matchgate so that node 1 is not omittable and $x = 0$. This sets

$a_2 = a_3 = a_4 = 0$. Also $a_1 = zu - vy$ can then be set arbitrarily. Finally, for 1-bases consider the output nodes to be just $\{4\}$. \square

(ii) **Swapping**

Defn. SWAP: Set of bases \mathbf{b} such that there is a $(2|\mathbf{b}|, 2|\mathbf{b}|)$ -matchgate where $(p \otimes p)\chi = p \otimes p, (n \otimes p)\chi = p \otimes n, (p \otimes n)\chi = n \otimes p, (n \otimes n)\chi = n \otimes n$.

Proposition 2. *Every even basis belongs to SWAP* for any field.*

Proof. Suppose the basis is a k -basis. We imagine $2k$ parallel wires. The task is to interchange the contents of the top k wires with the contents of the bottom k wires. To do this we use the matrix

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

as a “pseudoswap” for pairs of bits on adjacent wires. To implement a SWAP gate between two sets of k wires we have the two sets of k wires cross and place a pseudoswap gate at all the k^2 intersections. Since we have an even basis, in every situation that contributes to the Pfaffian, an even number of the wires in each group of k will have a 1 bit on it. Hence 1 values will need to be “interchanged” with 0 values an even number of times. Hence an even number of the pseudoswap gates will have their -1 entry invoked, and hence the overall contribution will always be +1. Finally note that this is realizable by a matchgate over the standard basis by virtue of Proposition 4 in [V02a], and in particular by the following matchgate with input ordering $(\emptyset, \{1\}, \{2\}, \{1,2\})$ and output ordering $(\emptyset, \{4\}, \{3\}, \{3,4\})$. \square

Proposition 3. *Every basis over any field of characteristic 2 belongs to SWAP*.*

Proof. Immediate. \square

Proposition 4. *There is no independent 1-basis for SWAP for the complex numbers.*

Proof. This can be deduced from the definition of SWAP by solving the set of equations that define SWAP, together with the five matchgate identities [V02a], using a polynomial solver such as Singular [GPS01]. \square

(iii) **Fanout**

The replication of influence, or fanout, is a very basic constituent of computation.

Defn. FANOUT: Set of \mathbf{b} such that there is a $(|\mathbf{b}|, 2|\mathbf{b}|)$ -matchgate with $n\chi = n \otimes n$ and $p\chi = p \otimes p$.

Perhaps surprisingly, there does exist a 1-basis for FANOUT.

Proposition 5. *For any field with characteristic different from 2 there exists a 1-basis for FANOUT*.*

Proof. Consider the one bit basis $n, p = (1, -1), (1, 1)$. It can be verified that

$$\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 \end{pmatrix}$$

and that the second matrix is realized by the matchgate with $V = \{1, 2, 3, 4\}$, with input $\{1\}$, outputs $\{3, 4\}$, and $V = \{(1, 2), (2, 3), (2, 4), (3, 4)\}$ where all the edges have weight one except for $(2, 4)$ which has weight -1 . \square

Proposition 6. *There is no independent 1-basis of characteristic 2 for FANOUT.*

Proof. From the matchgate identities. \square

Propositions 4 and 6 show that for 1-bases $\text{SWAP} \cap \text{FANOUT} = \emptyset$ for any field. We therefore go on to consider notions of replication that are no stronger, and possibly more restricted than fanout. These are GENEQ and GENOPP which output pairs of equal or opposite values, but take no inputs.

Defn. GENEQ: Set of \mathbf{b} such that there is a $(0, 2|\mathbf{b}|)$ -matchgate with $\chi = p \otimes p + n \otimes n$.

Defn. GENOPP: Set of \mathbf{b} such that there is a $(0, 2|\mathbf{b}|)$ -matchgate with $\chi = p \otimes n + n \otimes p$.

Proposition 7. *There is no independent even 2-basis for GENEQ* for any field.*

Proof. Consider an even 2-basis $(a, 0, 0, b), (c, 0, 0, d)$. Then any $(0, 4)$ -matchgate for GENEQ has to generate the (1×16) -character matrix

$$(a^2 + c^2, 0, 0, ab + cd, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, ab + cd, 0, 0, b^2 + d^2).$$

But from this matchgate one can easily construct a (2,2)-matchgate with (4×4) character matrix

$$\begin{pmatrix} a^2 + c^2 & 0 & 0 & ab + cd \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ ab + cd & 0 & 0 & b^2 + d^2 \end{pmatrix}$$

The construction requires the creation of 2 new input nodes each connected by chains of 2 edges to the first two output nodes, which are no longer considered as output nodes.

But the first matchgate identity then implies that $ad = bc$, which contradicts $(a, 0, 0, b), (c, 0, 0, d)$ being independent. \square

Proposition 8. $GEN_{0+1} \cap FANOUT \subseteq GENEQ$ for any field.

Proof. If we append, in the manner of Figure 3 in [V02a], the matchgate for FANOUT to one for GEN_{0+1} we obtain one for GENEQ. \square

Proposition 9. For any field $GENEQ$ and $GENOPP$ contain all 1-bases.

Proof. Immediate from Proposition 1 applied to 2-bases. \square

Proposition 10. There is no independent even 2-basis for $GENOPP^*$ for any field.

Proof. Similar to the proof of Proposition 7. \square

(iv) **Boolean operations**

Defn. NOT: Set of \mathbf{b} such that there is a $(|\mathbf{b}|, |\mathbf{b}|)$ -matchgate with $p = n\chi$ and $n = p\chi$.

Defn. AND: Set of \mathbf{b} such that there is a $(2|\mathbf{b}|, |\mathbf{b}|)$ -matchgate where $(p \otimes p)\chi = p$, and $(n \otimes n)\chi = (n \otimes p)\chi = (p \otimes n)\chi = n$.

Proposition 11. The standard basis does not belong to AND^* , nor does any independent 1-basis over a field of characteristic 2.

Proposition 12. There is a 1-basis for AND^* over any field with characteristic different from 2.

Proof. $k = 1 : n, p = (1, 1), (2, 0)$,

$$\chi = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \\ 0 & \frac{1}{2} \\ \frac{1}{2} & 0 \end{pmatrix}$$

The matchgate that realizes this is (V, E) where $V = \{1, 2, 3, 4\}$, the inputs are $\{1, 2\}$, the output is $\{4\}$, $E = \{(1, 2), (1, 3), (2, 3), (3, 4)\}$ with weights $1, -1/2, 1/2, 1/2$, respectively. \square

Defn. **BOOL**: Set of \mathbf{b} such that there are AND, OR and NOT matchgates for \mathbf{b} .

Defn. **MON**: Set of \mathbf{b} such that there are AND and OR matchgates for \mathbf{b} .

Various relations are immediate. For example $\text{BOOL} \supseteq \text{NAND} \cap \text{GEN1}$ since NOT can be obtained from NAND using GEN1, and OR can be obtained from AND and NOT. Note that neither swap nor replication is needed in these classical Boolean simulations.

Proposition 13. *The 2-rail basis belongs to BOOL for any field.*

Proof. We can realize AND using $k = 2 : n, p = (1, 0, 0, 0), (0, 0, 0, 1)$. The matchgate that realizes this is (V, E) where $V = \{1, 2, 3, 4, 5, 6\}$, inputs are $\{1, 2, 3, 4\}$, outputs are $\{5, 6\}$, $E = \{(1, 6), (2, 5), (2, 3), (3, 6), (4, 5)\}$ all with weight 1. Similarly NOT and hence OR are also realizable. \square

(v) **Universality in the sense of quantum computation**

Defn. **ONEBITUNIV**: Set of \mathbf{b} such that for all complex numbers $\alpha, \beta, \gamma, \delta$, there is a $(|\mathbf{b}|, |\mathbf{b}|)$ -matchgate with $n\chi = \alpha n + \beta p$, and $p\chi = \gamma n + \delta p$.

Proposition 14. *The two rail basis belongs to ONEBITUNIV for any field.*

Proof. For realizing the mapping

$$\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}$$

in the two rail basis use the matchgate that realizes

$$\begin{pmatrix} \alpha & 0 & 0 & \beta \\ 0 & \alpha & \beta & 0 \\ 0 & \gamma & \delta & 0 \\ \gamma & 0 & 0 & \delta \end{pmatrix}.$$

If $\delta = 0$ then by inverting the input or output we first move a nonzero entry to the lower right position in the matrix. \square

Defn. **CNOT**: Set of \mathbf{b} such that there is a $(2|\mathbf{b}|, 2|\mathbf{b}|)$ -matchgate where $(n \otimes n)\chi = n \otimes n$, $(n \otimes p)\chi = n \otimes p$, $(p \otimes n)\chi = p \otimes p$, $(p \otimes p)\chi = p \otimes n$.

Defn. **ISWAP**: Set of \mathbf{b} such that there is a $(2|\mathbf{b}|, 2|\mathbf{b}|)$ -matchgate where $(n \otimes n)\chi = n \otimes n$, $(n \otimes p)\chi = ip \otimes n$, $(p \otimes n)\chi = in \otimes p$, $(p \otimes p)\chi = p \otimes p$, where i is the square root of -1 .

Defn. **UNIV**: Set of \mathbf{b} over the complex numbers such that a universal set of gates, in the sense of quantum computation, can be realized for \mathbf{b} .

Note that CNOT [BBC+95, CN01] together with the set of all one-bit gates form a universal set. The same holds for ISWAP [EWD+01] together with all one-bitgates.

Proposition 15. *There is no independent 1-basis for CNOT for the complex numbers.*

Proposition 16. *The standard basis can realize ISWAP for the complex numbers.*

Proof. ISWAP over the standard basis requires a character matrix:

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & i & 0 \\ 0 & i & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

This can be realized by the matchgate (V, E) where $V = \{1, 2, 3, 4\}$, inputs are $\{1, 2\}$, outputs are $\{3, 4\}$, $E = \{(1, 3), (2, 4)\}$ with weights $-i, -i$ respectively. \square

(vi) Translations from and to the standard basis

Defn. ENCODE: Set of \mathbf{b} such that there is a $(1, |\mathbf{b}|)$ -matchgate where the first row of χ is n and the second is p .

Proposition 17. *There is no even 2-basis for ENCODE.*

Proof. The matchgate identities preclude this. \square

Defn. DECODE: Set of \mathbf{b} such that there is a $(|\mathbf{b}|, 1)$ -matchgate with $n\chi = (1, 0)$ and $p\chi = (0, 1)$.

Proposition 18. *ENCODE, DECODE each contain all the 1-bases.*

Proof. Similar to proof of Proposition 1. \square

6 Some Universal Operations Sets

There appear to be an enormous variety of interesting universal operations sets with respect to NC2. Here we shall give examples for each of $\#P$, $\oplus P$, QBP, and P.

Our first example shows that one does not need the general FANOUT operation for universality over $\#P$ or $\oplus P$. The ability to produce complementary pairs of bits is sufficient.

Proposition 19. *(i) $\{GENOPP, SWAP^*, MON\}$ over any field of infinite characteristic is a universal operations set for $\#P$, as is also $\{GENEQ, SWAP^*, MON\}$.*

(ii) $\{GENOPP, MON\}$ over $GF[2]$ is a universal operations set for $\oplus P$.

Proof. We need to establish that fanout, of the limited form of producing pairs of opposite bits (GENOPP), is enough to give $\#P$ - and $\oplus P$ -completeness, as is also GENEQ for $\#P$ -completeness. For this we shall need that the counting and parity problems of read-twice Boolean formulae (i.e. where each variable occurs twice) are $\#P$ - and $\oplus P$ -complete. For read-twice CNF formulae $\#P$ -completeness was proved in the monotone case [BD97], and this will be sufficient

for the GENEQ result. Also, for more general formulae consisting of \wedge and \vee gates $\#P$ - and $\oplus P$ -completeness can be proved if each variable occurs just once positively and once negated [Va05]. This will give the GENOPP results. Let us therefore consider formulae F obtained in one of these two ways.

We now construct a matchcircuit to evaluate such a formula F . The circuit has no inputs and starts with the GENOPP/GENEQ gates on the left. There will be k output nodes corresponding to the k bits of the output if the basis has size k . Wires crossing are implemented by SWAP* gates, which exist over $\text{GF}[2]$ by virtue of Proposition 3. Finally the gates will be assembled in the manner of Figure 1.

We view each GENOPP/GENEQ gate as assigning a value $p \otimes n$ or $n \otimes p / p \otimes p$ or $n \otimes n$ in the first instance. For each combination of assignments to the, say m , GENOPP/GENEQ gates the Boolean gates will simulate the execution of the formula being encoded, so that the final output will have n or p according to whether the formula would have the Boolean value 0 or 1.

In the actual matchcircuit all 2^m assignments are computed simultaneously and added, so that if K of the assignments give value 1 and $2^m - K$ give value 0 then the PfaffianSum of the matchcircuit will be $Kp + (2^m - K)n$. Pick any component, say i , in which vectors n and p differ. There must be one since they are distinct. Suppose that $p_i - n_i = x$. Now delete the i^{th} output node so as to insist that the corresponding component has value 1, and make the remaining output nodes omittable. Then the PfaffianSum of the matchcircuit must equal $2^m n_i + Kx$. The number K of solutions can be obtained then immediately. (Note that the Pfaffian can be computed with the correct sign in polynomial time (e.g. [GM94, L97]).

This completes the proof except that for the case of infinite characteristic we need to explain why even gates are not necessary for MON or GENOPP/GENEQ. The main reason is that since we assume that we have even gates for SWAP*, we can ensure that all other operations are done on consecutive bits x_1, x_2, \dots, x_k so that the conditions of the Main Theorem are satisfied. We note that the GENOPP/GENEQ gates have no inputs and can be placed at the left of the circuit so that each one generates a consecutive sequence of bits (e.g. for 3-bases the second such gate could generate x_7, x_8, \dots, x_{12} .) \square

Next we observe that existing results in quantum computation are sufficient to provide the following universal operations set for BQP.

Proposition 20. *The set $\{GEN01, UNIV^*, SWAP^*\}$ over the complex numbers is a universal operations set for BQP. If GEN01 is replaced by GEN0+1 then it is a UOS for $\#P$. We note that UNIV is a broad class. For example, it has been shown that any entangling 2-bit transformation in conjunction with all 1-bit transformations is in UNIV [BD+02, BB02]. A transformation is *entangling* if it maps some tensor product of two one-bit vectors to something that cannot be expressed as a tensor product of two one-bit vectors.*

We can also formulate a question that corresponds to $P=?NC2$.

Proposition 21. *The sets $\{GEN01, FANOUT, BOOL, SWAP^*\}$ and $\{GEN01, FANOUT^*, BOOL^*\}$ over any field are universal operations sets for P . If $GEN01$ is replaced by $GEN0+1$ then over fields of characteristic zero they are UOS's for $\#P$, and over characteristic two, for $\oplus P$.*

7 Interpretation

As described in the introduction, we can regard deterministic computation as the composition of four components: Boolean operations, some form of fanout, swap, and constant inputs. Nondeterministic computation is the composition of these with the components of nondeterministic constant generation, and exponential summation. In conventional models of computation the first four components are trivial, and the last two appear to be problematic.

In our formulation each of the four components is achievable separately in some basis, and also in many combinations together. Proposition 19 identifies the three components MON, GENOPP, and SWAP as being sufficient for universality over $\#P$. Our results show that common bases exist for some interesting pairs of operations. The basis $\{(1,1),(2,0)\}$ is common to AND and GENOPP, the 2-rail basis $\{(1,0,0,0),(0,0,0,1)\}$ is common to BOOL and SWAP, and the standard basis $\{(1,0),(0,1)\}$ over $GF[2]$ is common to SWAP and GENOPP. Also, Propositions 20 and 21 give some distinct decompositions in terms of UNIV, and in terms of BOOL and FANOUT, respectively. Numerous further such decompositions can be described.

Our approach therefore gives a new methodology for searching for exotic algorithms for problems that are currently believed to be intractable. It is possible that such searches will fail but in that case there is some hope that our model will serve as a useful "restricted" model of computation for which lower bounds can be proved. If one fixes a field and the appropriate parameters then the question of whether any of the set intersections considered is nonempty, is equivalent to determining whether a fixed set of polynomial equations has a common solution. Small instances of such problems can be solved mechanically by computer algebra systems. We have shown that there is considerable richness in the properties of nonstandard bases for some fundamental computational operations, and therefore expect that exploring these further will be of interest whatever the ultimate outcome.

³ LORIA-INRIA Nancy, France

Abstract. We describe a cryptographically sound formal logic for proving protocol security properties without explicitly reasoning about probability, asymptotic complexity, or the actions of a malicious attacker. The approach rests on a new probabilistic, polynomial-time semantics for an existing protocol security logic, replacing an earlier semantics that uses nondeterministic symbolic evaluation. While the basic form of the protocol logic remains unchanged from previous work, there are some interesting technical problems involving the difference between efficiently recognizing and efficiently producing a value, and involving a reinterpretation of standard logical connectives that seems necessary to support certain forms of reasoning.

1 Introduction

Security analysis of network protocols is a successful scientific area with two important but historically independent foundations, one based on logic and symbolic computation, and one based on computational complexity theory. The symbolic approach, which uses a highly idealized representation of cryptographic primitives, has been a successful basis for formal logics and automated tools. Conversely, the computational approach yields more insight into the strength and vulnerabilities of protocols, but it is more difficult to apply and it involves explicit reasoning about probability and computational complexity. The purpose of this paper is to suggest that formal reasoning, based on an abstract treatment of cryptographic primitives, can be used to reason about probabilistic polynomial-time protocols in the face of probabilistic polynomial-time attacks.

^{*} This work was partially supported by NSF CyberTrust Grant 0430594, Collaborative research: High-fidelity methods for security protocols, by the DoD University Research Initiative (URI) program administered by the Office of Naval Research under Grant N00014-01-1-0795, by OSD/ONR CIP/SW URI through ONR Grant N00014-04-1-0725, by NSF CCR-0121403, Computational Logic Tools for Research and Education, and by the NSF Cybertrust grant to the PORTIA project. M. Turuani's activities at Stanford were also funded by a postdoctoral grant from INRIA.

We do this by proposing a new semantics for a variant of an existing logic. The new semantics brings forward some interesting distinctions that were not available in the coarser symbolic model, and also raises some apparently fundamental issues about the inherent logic of asymptotic probabilistic properties.

The *Protocol Composition Logic* [2, 7, 8, 10] uses a modal operator similar to Floyd-Hoare logic. Intuitively, the formula $\psi [P]_X \varphi$ means that if ψ is true at some point in the execution of a protocol (in the presence of a malicious attacker), then φ will be true after agent X performs the sequence P of actions. The pre- and post-conditions may describe actions taken by various principals and characterize the information that is available to or hidden from them. The semantics we explore in this paper recasts the methods of [15] in a logical setting, and reflects accepted modelling approaches used in the field of cryptography, particularly [5, 17].

Our central organizing idea is to interpret formulas as operators on probability distributions on traces. Informally, representing a probability distribution by a set of equi-probable traces (each tagged by the random sequence used to produce it), the meaning of a formula φ on a set T of traces is the subset $T' \subseteq T$ in which φ holds. This interpretation yields a probability: the probability that φ holds is the ratio $|T'|/|T|$. Conjunction and disjunction are simply intersection and union. There are several possible interpretations for implication, and it is not clear at this point which will prove most fruitful in the long run. In the present paper, we interpret $\varphi \implies \psi$ as the union of $\neg\varphi$ and the composition of ψ with φ ; the latter is also the conditional probability of ψ given φ . This interpretation supports a soundness proof for a sizable fragment of the protocol logic, and resembles the probabilistic interpretation of implication in [16]. Since the logic does not mention probability explicitly, we consider a formula “true” if it holds with asymptotically overwhelming probability.

In previous work [2, 7, 8, 10] over a symbolic semantic model, the atomic formula $\text{Has}(X, m)$ means that m is in the set of values “derivable,” by a simple fixed algorithm, from information visible to X . The simple fixed algorithm is central to what is called the Dolev-Yao model, after [9] and much subsequent work by others. In replacing the symbolic semantics with a computational semantics based on probabilistic polynomial time, we replace the predicate Has with two predicates, Possess and Indist . Intuitively, $\text{Possess}(X, m)$ means that there is an algorithm that computes the value of m with high probability from information available to X , while $\text{Indist}(X, m)$ means that X cannot feasibly distinguish m from a random value chosen according to the same distribution. However, certain technical problems discussed in Section 7 lead us to work with slightly simplified semantics of these predicates that capture our intuition most strongly when the possessing principal is assumed honest (in the sense of following the protocol) and the predicate Indist only appears with positive polarity. Fortunately, these syntactic conditions are met in many formulas expressing authentication and secrecy properties.

Several groups of researchers have either formulated connections between symbolic logic and feasible probabilistic computation, or developed relationships

between symbolic and computational models. In particular, Abadi and Rogaway [1] propose a logical characterization of indistinguishability by passive eavesdroppers that has been studied by a number of others, and Kapron and Impagliazzo suggest a formal logic for reasoning about probabilistic polynomial-time indistinguishability [13]. Some semantic connections between symbolic and computational models have been developed by a team at IBM Zurich, *e.g.*, [3], with other connections explored in a series of related papers by Micciancio, Warinschi, and collaborators [15, 18, 6]. Herzog [11, 12] shows that if a protocol attack exists in a Dolev-Yao model, there is an attack in a computational model. More recent related work also appears in [14, 6].

Section 2 presents the syntax for defining roles of a protocol, while the syntax of the logic appears in Section 3. Some axioms and proof rules are described in Section 4, followed by a short proof example in Section 5. Section 6 presents the probabilistic polynomial-time execution and attacker model. The semantics of the logic are given in Section 7, and concluding remarks in Section 8.

2 Protocol Syntax

We use a simple “protocol programming language” based on [10, 7, 8] to represent a protocol by a set of roles, such as “Initiator”, “Responder” or “Server”, each specifying a sequence of actions to be executed by a honest participant. The syntax of terms and actions is given in Table 1.

Names, sessions and threads: We use \hat{X}, \hat{Y}, \dots as *names* for protocol participants. Since a particular participant might be involved in more than one session at a time, we will give unique names to sessions and use (\hat{X}, s) to designate a particular *thread* being executed by \hat{X} . All threads of a participant \hat{X} share the same asymmetric key denoted by X . As a notational convenience, we will sometimes write \tilde{X} for an arbitrary thread of \hat{X} .

Terms, actions, and action lists: Terms name messages and their parts, such as nonces, keys, variables and pairs. For technical reasons, we distinguish *basic terms* from *terms* that may contain encryption. To account for probabilistic encryption, encrypted terms explicitly identify the randomness used for encryption.

Table 1. Syntax of protocol terms and actions

Terms:		Actions:
$N ::= \hat{X}$	(<i>name</i>)	$\mathbf{a} ::=$
$K ::= X$	(<i>key</i>)	$\mathbf{new} T, n$
$S ::= s$	(<i>session</i>)	$V := \mathbf{enc} T, t, K$
$n ::= r$	(<i>nonce</i>)	$V := \mathbf{dec} T, t, K$
$T ::= (N, S)$	(<i>thread</i>)	$\mathbf{match} T, t/t$
$V ::= x$	(<i>term variable</i>)	$\mathbf{send} T, t$
$t_B ::= V K T N n \langle t_B, t_B \rangle$	(<i>basic term</i>)	$\mathbf{receive} T, V$
$t ::= t_B \{t\}_K^n \langle t, t \rangle$	(<i>term</i>)	

Specifically, $\{t\}_K^n$ indicates the encryption of t with key K using randomness n generated for the purpose of encryption. We write $m \subseteq m'$ when m is a subterm of $m' \in t$.

Actions include nonce generation, encryption, decryption, pattern matching, and communication steps (sending and receiving). An *ActionList* consists of a sequence of actions that contain only basic terms. This means that encryption cannot be performed implicitly; explicit `enc` actions, written as assignment, must be used instead. We assume that each variable will be assigned at most once, at its first occurrence. For any $s \in \text{ActionList}$, we write $s|_X$ to denote the subsequence of s containing only actions of a participant (or a thread) X .

Strands, roles, protocols and execution: A *strand* is an *ActionList*, containing actions of only one thread. Typically we will use notation $[\text{ActionList}]_{\tilde{X}}$ to denote a strand executed by thread \tilde{X} and drop the thread identifier from the actions themselves. A *role* is a strand together with a basic term representing the initial knowledge of the thread. A *protocol* is a finite set of *Roles*, together with a basic term representing the initial intruder knowledge.

An *execution strand* is a pair $\text{ExecStrand} ::= \text{InitialState}(\mathcal{I}); \text{ActionList}$ where \mathcal{I} is a data structure representing the initial state of the protocol, as produced by the initialization phase from Section 6. In particular, this includes the list of agents and threads, the public/private keys and honesty/dishonesty tokens of each agent, and the roles played by each thread.

3 Logic Syntax

The syntax of formulas is given in Table 2. Protocol proofs will usually use modal formulas of the form $\psi[P]_{\tilde{X}}\varphi$, as explained intuitively in the introduction of the paper. Most formulas have the same intuitive meaning in the computational semantics as in the symbolic model [7, 8], except for predicates `Possess` and `Indist`. We summarize the meaning of formulas informally below, with precise semantics in the next section.

Action Predicates:

$a ::= \text{Send}(T, t) \mid \text{Receive}(T, t) \mid \text{New}(T, n)$

Formulas:

$\varphi ::= a \mid t = t \mid \text{Start}(T) \mid \text{Possess}(T, t) \mid \text{Indist}(T, t) \mid \text{Fresh}(T, t) \mid \text{Honest}(N) \mid$
 $\text{Start}(T) \mid \text{Contains}(t, t) \mid \text{ContainsOut}(t, t, t) \mid \text{DecryptsHonest}(T, t) \mid$
 $\text{Source}(T, t, t) \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \exists \text{Var}. \varphi \mid \forall \text{Var}. \varphi \mid \neg \varphi \mid \varphi \supset \varphi \mid \varphi \Rightarrow \varphi$

Modal formulas:

$\Psi ::= \varphi [\text{Strand}]_T \varphi$

Table 2. Syntax of the logic

For every protocol action, there is a corresponding action predicate which asserts that the action has occurred in the run. For example, $\text{Send}(\tilde{X}, t)$ holds in a run where the thread \tilde{X} has sent the term t . $\text{Fresh}(\tilde{X}, t)$ means that the value of t generated by \tilde{X} is “fresh” in the sense that no one else has seen any messages containing t , while $\text{Honest}(\tilde{X})$ means that \tilde{X} is acting honestly, *i.e.*, the actions of every thread of \tilde{X} precisely follows some role of the protocol. The **Source** predicate is used to reason about the source of a piece of information, such as a nonce. Intuitively, the formula $\text{Source}(\tilde{Y}, u, \{m\}_{\tilde{X}}^r)$ means that the only way for a thread \tilde{X} different from \tilde{Y} to know u is to learn u from the term $\{m\}_{\tilde{X}}^r$, possibly by some indirect path.

The predicate **Fresh** is definable by $\text{Fresh}(\tilde{X}, v) \equiv \text{New}(\tilde{X}, v) \wedge \neg(\exists u. \text{Send}(\tilde{X}, u) \wedge \text{Contains}(u, v))$ and classical implication is definable by $A \supset B \equiv \neg A \vee B$.

In the symbolic model [7, 8], the predicate **Has** states that a principal can “derive” a message or its contents from the information gathered during protocol execution. We use $\text{Possess}(\tilde{X}, t)$ to state that it is possible to derive t by Dolev-Yao rules from \tilde{X} ’s view of the run and $\text{Indist}(\tilde{X}, t)$ to state that no probabilistic polynomial-time algorithm, given \tilde{X} ’s view of the run, can distinguish t from a random value from the same distribution. Typically, we use **Possess** to say that some honest party obtained some secret, and **Indist** to say that the attacker does not have any partial information about a secret.

4 Proof System

The proof system used in this paper is based on the proof system developed in [7, 8, 2]. Some example axioms and rules are given in Table 3; the full presentation is deferred to the extended version of this paper. These axioms express reasoning principles that can be justified using complexity-theoretic reductions, information-theoretic arguments, and asymptotic calculations. However, the advantage of the proof system is that its justification using cryptographic-style arguments is a one-time mathematical effort; protocol proofs can be carried out symbolically using the proof system without explicitly reasoning about probability and complexity. Another advantage of the axiomatic approach is that different axioms and rules rest on different cryptographic assumptions. Therefore, by examining the axioms and rules used in a specific proof, we can identify specific properties of the cryptographic primitives that are needed to guarantee protocol correctness. This provides useful information in protocol design because primitives that provide weaker properties often have more efficient constructions.

Axioms: Axioms **AN2** and **AN3** capture some of the properties of nonce generation. Informally, **AN2** states that if a thread \tilde{X} generates a fresh nonce x and does not perform any additional actions, then x is indistinguishable from a random value for all other threads. The soundness of this axiom is established by a simple information-theoretic argument. The informal interpretation of axiom **S1** (also called the “Source” axiom) is that, unless a ciphertext is decrypted, a thread which does not possess the decryption key cannot extract any par-

Axioms:

$$\mathbf{AN2} : \top [\text{new } x]_{\tilde{X}} \tilde{Y} \neq \tilde{X} \Rightarrow \text{Indist}(\tilde{Y}, x)$$

$$\mathbf{AN3} : \top [\text{new } x]_{\tilde{X}} \text{Fresh}(\tilde{X}, x)$$

$$\mathbf{S1} : \text{Source}(\tilde{Y}, u, \{m\}_X^r) \wedge \neg \text{DecryptsHonest}(\hat{X}, \{m\}_X^r) \wedge \hat{Z} \neq \hat{X} \wedge \hat{Z} \neq \hat{Y} \wedge \text{Honest}(\hat{X}) \wedge \text{Honest}(\hat{Y}) \Rightarrow \text{Indist}(\tilde{Z}, u)$$

Proof rules:

$$\frac{\theta[P]_X \varphi \quad \theta' \supset \theta \quad \varphi \supset \varphi'}{\theta'[P]_X \varphi'} \quad \mathbf{G3} \qquad \frac{\theta[P_1]_X \varphi \quad \varphi [P_2]_X \psi}{\theta[P_1 P_2]_X \psi} \quad \mathbf{SEQ}$$

$$\frac{\varphi \quad \varphi \Rightarrow \psi}{\psi} \quad \mathbf{MP}$$

$$\frac{\varphi}{\forall x. \varphi} \quad \mathbf{GEN}$$

Table 3. Fragment of the proof system

tial information about the plaintext. The soundness of this axiom is proved by a complexity-theoretic reduction. Specifically, we show that if an attacker can break this property, then there is another attacker that can break the underlying IND-CCA2 secure encryption scheme [4].

Inference rules: Inference rules include generic rules from modal logics (e.g. **G3**), sequencing rule **SEQ** used for reasoning about sequential composition of protocol actions and a rule (called the honesty rule) for proving protocol invariants using induction. These rules are analogous to proof rules from our earlier work [7, 8].

First-order axioms and rules: We use two implications: a conditional implication \Rightarrow , discussed and defined precisely in section 7, and a classical implication \supset with $A \supset B \equiv \neg A \vee B$. While standard classical tautologies hold for classical implication, some familiar propositional or first-order tautologies may not hold when written using \Rightarrow instead of \supset . However, modus ponens and the generalization rule above are sound. The soundness of modus ponens relies on the simple asymptotic fact that the sum of two negligible functions is a negligible function. In future work, we hope to develop a more complete proof system for the first-order fragment of this logic.

5 Example

In this section, we present a simple protocol and state a secrecy property that can be proved using the proof system. The interested reader is referred to [10, 7, 8] for further explanation and examples. The two protocol roles are:

$$\begin{aligned} \mathbf{Init} &\equiv [\text{new } x; y := \text{enc}\langle x, \tilde{X} \rangle, Y; \text{send } \hat{X}, \hat{Y}, y]_{\tilde{X}} \\ \mathbf{Resp} &\equiv [\text{receive } z; \text{match } z / \langle \hat{X}, \hat{Y}, z' \rangle; z'' := \text{dec } z', Y]_{\tilde{Y}} \end{aligned}$$

The initiator generates a new nonce and sends it encrypted to the responder. The responder receives the message and recovers the nonce by decrypting the ciphertext. We can prove that if \tilde{X} completes the protocol with \tilde{Y} , then x will be a shared secret between them, provided both agents are honest. Formally,

$$\text{Start}(\tilde{X})[\text{Init}]_{\tilde{X}} \text{Honest}(\hat{X}) \wedge \text{Honest}(\hat{Y}) \wedge (\tilde{Z} \neq \tilde{X}) \wedge (\tilde{Z} \neq \tilde{Y}) \Rightarrow \text{Indist}(\tilde{Z}, x)$$

Since the meaning of $\text{Indist}(\tilde{Z}, x)$ (formally defined in Section 7) is that \tilde{Z} cannot distinguish the secret nonce x from a randomly chosen nonce, this formula expresses a standard form of secrecy used in the cryptographic literature.

The axiomatic proof uses **AN2**, a variant of **S1**, and modus ponens **MP**. The proof idea is that at the point the initiator produces the nonce x , by **AN2**, it is indistinguishable from random to everyone else other than \tilde{X} and \tilde{Y} . It continues to remain indistinguishable since it appears on the network under encryption with a public key whose corresponding private key is not available to the attacker. This part of the reasoning is codified by an axiom that is similar to **S1** and relies on the fact that the encryption scheme used is IND-CCA2 secure. Modus ponens is used in the general first-order reasoning involved in the proof.

6 Protocol Execution

Given a protocol, adversary, and value of the security parameter, we define a set of protocol traces, each associated with the random bits that produce this sequence of actions and additional randomness for algorithms used in the semantics of formulas about the run. The definition proceeds in two phases. In the initialization phase, we assign a set of roles to each principal, identify a subset which is honest, and provide all entities with private-public key pairs and random bits. In the execution phase, the adversary executes the protocol by interacting with honest principals, as in the accepted cryptographic model of [5].

Initialization: We fix the protocol Q , adversary A , security parameter η , and some randomness R of size polynomially bounded in η . Each principal and each thread (*i.e.*, an instance of a protocol role executed by the principal) is assigned a unique bitstring identifier. We choose a sufficiently large polynomial number of bitstrings $i \in I \subseteq \{0, 1\}^\eta$ to represent the names of principals and threads. Randomness R is split into r_i for each honest $i \in I$ (referred to as “coin tosses of honest party i ”) and R_A (referred to as “adversarial randomness”).

The adversary designates some of the principals as *honest* and the rest of the principals as *dishonest*. Intuitively, honest principles will follow one or more roles of the protocol faithfully. The adversary chooses a set of threads, and to each thread it assigns a strand (a program to be executed by that thread), under the restriction that all threads of honest principals are assigned roles of protocol Q .

The key generation algorithm \mathcal{K} of a public-key encryption scheme $(\mathcal{K}, \mathcal{E}, \mathcal{D})$ is run on $\mathbf{1}^\eta$ for each participant a using randomness r_a , and producing a public-private key pair (pk_a, sk_a) . The public key pk_a is given to all participants and to the adversary A ; the private key is given to all threads belonging to this principal and to the adversary if the principal is dishonest.

Generating Computational Traces: Following [5], we view an agent i trying to communicate with agent j in protocol session s as a (stateful) oracle $\Pi_{i,j}^s$. The state of each oracle is defined by a mapping λ from atomic symbols to bitstrings (with variables and nonces renamed to be unique for each role) and a counter c . Each oracle proceeds to execute a step of the protocol as defined by actions in the corresponding role's action list, when activated by the adversary.

We omit the details of communication between the adversary and the oracles, and focus on computational interpretation of symbolic protocol actions. Let a_c be the current action in the *ActionList* defining some role of participant i in session s , i.e., $Thread = (i', s')$ where $i = \lambda(i')$, $s = \lambda(s')$.

If $a_c = (\mathbf{new}(i', s'), v)$, then update λ so that $\lambda(v) = \mathit{NonceGen}(R_i)$, where $\mathit{NonceGen}$ is a nonce generation function (e.g., $\mathit{NonceGen}$ simply extracts a fresh piece of R_i). If $a_c = (v := \mathbf{enc}(i', s'), j, u)$, then update λ so that $\lambda(v) = \mathcal{E}(\lambda(u), pk_j, R_i)$ where $\mathcal{E}(\lambda(u), pk_j, R_i)$ is the result of executing the public-key encryption algorithm on plaintext $\lambda(u)$ with public key pk_j and fresh randomness extracted from R_i . For brevity, we omit computational interpretation of decryption and matching (pairing, unpairing, and equality-test) actions. Sending a variable $\mathbf{send}(i', s'), v$ is executed by sending $\lambda(v)$ to the adversary, and receiving $\mathbf{receive}(i', s'), v$ is executed by updating λ so that $\lambda(v) = m$ where m is the bitstring sent by the adversary.

At any time during the protocol execution, the adversary A may record any internal, private message on a special *knowledge tape*. This tape is not read by any participant of the protocol. However, its content will be made available to the test algorithms used to decide if a given security formula containing $\mathit{Indist}(\dots)$ is valid or not. Let K be $[(i_1, m_1), \dots, (i_n, m_n)]$ the list of messages m_k written by A on the knowledge tape, indexed by the number of actions i_k already executed when m_k was written (position in the protocol execution). This index will be useful to remember a previous state of the knowledge tape.

At the end of the protocol execution, the adversary A outputs a pair of integers (p_1, p_2) on an *output tape*. When the security formula is a modal formula $\theta[P]_X \varphi$, these two integers represent two positions in the protocol execution where the adversary claims that the formula is violated, i.e. that θ is true in p_1 but φ is false in p_2 , with P between p_1 and p_2 . Let O be this pair (p_1, p_2) of integers written on the output tape.

The symbolic trace of the protocol is the execution strand $e \in \mathit{ExecStrand}$ which lists, in the order of execution, all honest participant actions and the dishonest participant's \mathbf{send} and $\mathbf{receive}$ actions. This strand contains two parts: $\mathit{InitialState}(\mathcal{I})$ stores the initialization data, and the rest is an ordered list of all exchanged messages and honest participants' internal actions.

Definition 1. (*Computational Traces*) Given a protocol Q , an adversary A , a security parameter η , and a sequence of random bits $R \in \{0, 1\}^{p(\eta)}$ used by the honest principals and the adversary, a run of the protocol is the tuple $\langle e, \lambda, O, K, R \rangle$ where e is the symbolic execution strand, $\lambda : \mathit{Term}(e) \rightarrow \{0, 1\}^{p(\eta)}$ maps the symbolic terms in e to bitstrings, O is the pair of integers written on

the output tape, and K is the indexed list of messages written on the knowledge tape. Finally, $p(x)$ is a polynomial in x .

A computational trace is a run with two additional elements: $R_T \in \{0, 1\}^{p(\eta)}$, a sequence of random bits used for testing indistinguishability, and $\sigma : FVar(\varphi) \rightarrow \{0, 1\}^{p(\eta)}$, a substitution that maps free variables in a formula to bitstrings. The set of computational traces is

$$T_Q(A, \eta) = \{\langle e, \lambda, O, K, R, R_T, \sigma \rangle \mid R, R_T \text{ chosen uniformly}\}.$$

Definition 2. (*Participant's View*) Given a protocol Q , an adversary A , a security parameter η , a participant \tilde{X} and a trace $t = \langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T_Q(A, \eta)$, $View_t(\tilde{X})$ represents \tilde{X} 's view of the trace. It is defined precisely as follows:

If \tilde{X} is honest, then $View_t(\tilde{X})$ is the initial knowledge of \tilde{X} , a representation of $e_{|\tilde{X}}$ and $\lambda(x)$ for any variable x in $e_{|\tilde{X}}$. If \tilde{X} is dishonest, then $View_t(\tilde{X})$ is the union of the knowledge of all dishonest participants \tilde{X}' after the trace t (where $View_t(\tilde{X}')$ is defined as above for honest participants) plus K , the messages written on the knowledge tape by the adversary.

The following three definitions are used in the semantics of the predicate $Indist()$. Informally, based on some trace knowledge K , the distinguisher D tries to determine which of two bitstrings is the value of a symbolic term. One of the bitstrings will be the computational value of the term in the current run, while the other will be a random bitstring of the same structure, chosen in a specific way. The order of the two bitstrings presented to the distinguisher is determined by an LR Oracle using a random selector bit.

Definition 3. (*LR Oracle*) The LR Oracle [4] is used to determine the order in which two bitstrings are presented depending on the value of the selector bit, i.e. $LR(s_0, s_1, b) = \langle s_b, s_{1-b} \rangle$.

Definition 4. (*Distinguishing test input*) Let u be a symbolic term and σ be a substitution that maps variables of u to bitstrings. We construct another bitstring $f(u, \sigma, r)$, whose symbolic representation is the same as u . Here, r is a sequence of bits chosen uniformly at random. The function f is defined by induction over the structure of the term u .

- Nonce $u : f(u, \sigma, r) = r$
- Name/Key $u : f(u, \sigma, r) = \sigma(u)$
- Pair $u = \langle u_1, u_2 \rangle : f(\langle u_1, u_2 \rangle, \sigma, r_1; r_2) = \langle f(u_1, \sigma, r_1), f(u_2, \sigma, r_2) \rangle$
- Encryption $u = \{v\}_K^n : f(\{v\}_K^n, \sigma, r_1; r_2) = \mathcal{E}(f(v, \sigma, r_1), \sigma(K), r_2)$

Definition 5. (*Distinguisher*) A distinguisher D is a polynomial time algorithm which takes as input a tuple $\langle K, t, \langle s_0, s_1 \rangle, R, \eta \rangle$, consisting of knowledge K , symbolic term t , two bitstrings s_0 and s_1 , randomness R and the security parameter η , and outputs a bit b' .

The next definition is used while defining semantics of modal formulas. Given a set T of traces and a strand P of actions executed by a thread \tilde{X} , the set T_P includes only those traces from T which contain P . $Pre(T_P)$ is obtained from T_P by taking the initial segment of each trace up to the point where P starts. The precondition of a modal formula is evaluated over this set. $Post(T_P)$ is similarly defined; the only difference is now the trace is cut at the point that P ends. The postcondition of a modal formula is evaluated over this set. The begin and end positions are determined by the component O in the trace.

Definition 6. (*Splitting computational traces*) Let T be a set of computational traces and $t = \langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$. $O = \langle p_1, p_2 \rangle$, $e = \text{InitialState}(\mathcal{I})$; s , and $s = s_1; s_2; s_3$ with p_1, p_2 the start and end positions of s_2 in s . Given a strand P executed by participant \tilde{X} , we denote by T_P the set of traces in T for which there exists a substitution σ' which extends σ to variables in P such that $\sigma'(P) = \lambda(s_2|_{\tilde{X}})$. The complement of this set is denoted by $T_{\neg P}$ and contains all traces which do not have any occurrence of the strand P . We define the set of traces $Pre(T_P) = \{t[s \leftarrow s_1, K \leftarrow K_{\leq p_1}, \sigma \leftarrow \sigma'] \mid t \in T_P\}$, where $K_{\leq p}$ is the restriction of the knowledge tape K to messages written before the position p . We define the set of traces $Post(T_P) = \{t[s \leftarrow s_1; s_2, K \leftarrow K_{\leq p_2}, \sigma \leftarrow \sigma'] \mid t \in T_P\}$.

7 Computational Semantics

The semantics of a formula φ on a set T of computational traces is a subset $T' \subseteq T$ that respects φ in some specific way. For many predicates and connectives, the semantics is essentially straightforward. For example, an action predicate such as **Send** selects a set of traces in which a send occurs. However, the semantics of predicates **Indist** and **Possess** is inherently more complex.

Intuitively, an agent possesses the value of an expression (such as another agent's nonce or key) if the agent can compute this value from information it has seen, with high probability. If an agent is honest, and therefore follows the rules of the protocol, then it suffices to use a simple, symbolic algorithm for computing values from information seen in the run of a protocol. For dishonest agents, we would prefer in principle to allow any probabilistic polynomial-time algorithm. However, quantifying over such algorithms, in a way that respects the difference between positive and negative occurrences of the predicate in a formula, appears to introduce some technical complications. Therefore, in the interest of outlining a relatively simple form of computational semantics, we will use a fixed algorithm. This gives a useful semantics for formulas where $\text{Possess}(\tilde{X}, u)$ is used under the hypothesis that \hat{X} is honest. We leave adequate treatment of the general case for future work.

Intuitively, an agent has partial information about the value of some expression if the agent can distinguish that value, when presented, from a random value generated according to the same distribution. More specifically, an agent has partial information about a nonce u if, when presented with two bitstrings of the appropriate length, one the value of u and the other chosen randomly, the agent

has a good chance of telling which is which. As with **Possess**, there are technical issues associated with positive and negative occurrences of the predicate. For positive occurrences of **Indist**, we should say that *no* probabilistic polynomial-time algorithm has more than a negligible chance, where as for $\neg\text{Indist}(\dots)$ we want to say that *there exists* a probabilistic polynomial-time distinguisher. In order to present a reasonably understandable semantics, and establish a useful basis for further exploration of computational semantics of symbolic security logics, we give an interpretation that appears accurate for formulas that have only positive occurrences of **Indist** and could be somewhat anomalous for formulas that contain negative occurrences. This seems adequate for reasoning about many secrecy properties, since these are expressed by saying that at the end of any run of the protocol, a value used in the run is indistinguishable from random.

Conditional implication $\theta \Rightarrow \varphi$ is interpreted using the negation of θ and the conditional probability of φ given θ . This non-classical interpretation of implication seems to be essential for relating provable formulas to cryptographic-style reductions involving conditional probabilities. In particular, the soundness proof for the “source” axiom **S1**, not proved in this conference paper, uses the conditional aspect of this implication in a fundamental way. On the other hand, \Rightarrow coincides with \supset in formulas where **Indist** does not appear on the right hand side of the implication.

We inductively define the semantics $\llbracket \varphi \rrbracket (T, D, \epsilon)$ of a formula φ on the set T of traces, with distinguisher D and tolerance ϵ . The distinguisher and tolerance are not used in any of the clauses except for **Indist**, where they are used to determine whether the distinguisher has more than a negligible chance of distinguishing the given value from a random value. In definition 7 below, the tolerance is set to a negligible function of the security parameter and $T = T_Q(A, \eta)$ is the set of traces of a protocol Q with adversary A .

- $\llbracket \text{Send}(\tilde{X}, u) \rrbracket (T, D, \epsilon)$ is the collection of all $\langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$ such that some action in the symbolic execution strand e has the form **send** \tilde{Y}, v with $\lambda(\tilde{Y}) = \sigma(\tilde{X})$ and $\lambda(v) = \sigma(u)$. Recall that σ maps formula variables to bitstrings and represents the environment in which the formula is evaluated.
- $\llbracket \mathbf{a}(\cdot, \cdot) \rrbracket (T, D, \epsilon)$ for other action predicates \mathbf{a} is similar to $\text{Send}(\tilde{X}, u)$.
- $\llbracket \text{Honest}(\hat{X}) \rrbracket (T, D, \epsilon)$ is the collection of all $\langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$ where $e = \text{InitialState}(\mathcal{I}); s$ and $\sigma(X)$ is designated *honest* in the initial configuration \mathcal{I} . Since we are only dealing with static corruptions in this paper, the resulting set is either the whole set T or the empty set ϕ depending on whether a principal is honest or not.
- $\llbracket \text{Start}(\tilde{X}) \rrbracket (T, D, \epsilon)$ includes all traces $\langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$ where $e = \text{InitialState}(\mathcal{I}); s$ and $\lambda(s)_{|\sigma(\tilde{X})} = \epsilon$. Intuitively, this set contains traces in which \tilde{X} has executed no actions.
- $\llbracket \text{Contains}(u, v) \rrbracket (T, D, \epsilon)$ includes all traces $\langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$ such that there exists a series of decryptions with $\{\lambda(k) \mid k \in \text{Key}\}$ and projections (π_1, π_2) constructing $\sigma(v)$ from $\sigma(u)$. This definition guarantees that the result is the whole set T if v is a symbolic subterm of u .

- $\llbracket \text{ContainsOut}(u, v, t) \rrbracket (T, D, \epsilon)$ includes all traces $\langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$ such that there exists a series of projections (π_1, π_2) and decryptions with $\{\lambda(k) \mid k \in \text{Key}\}$, where $\sigma(t)$ is never decomposed, creating $\sigma(v)$ from $\sigma(u)$. This definition ensures that the result is the whole set T if v is a symbolic subterm of u but is not a subterm of t .
- $\llbracket \theta \wedge \varphi \rrbracket (T, D, \epsilon) = \llbracket \theta \rrbracket (T, D, \epsilon) \cap \llbracket \varphi \rrbracket (T, D, \epsilon)$.
- $\llbracket \theta \vee \varphi \rrbracket (T, D, \epsilon) = \llbracket \theta \rrbracket (T, D, \epsilon) \cup \llbracket \varphi \rrbracket (T, D, \epsilon)$.
- $\llbracket \neg \varphi \rrbracket (T, D, \epsilon) = T \setminus \llbracket \varphi \rrbracket (T, D, \epsilon)$.
- $\llbracket \exists x. \varphi \rrbracket (T, D, \epsilon) = \bigcup_{\beta} (\llbracket \varphi \rrbracket (T[x \leftarrow \beta], D, \epsilon)[x \leftarrow \sigma(x)])$
with $T[x \leftarrow \beta] = \{t[\sigma[x \leftarrow \beta]] \mid t = \langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T\}$, and β any bitstring of polynomial size.
- $\llbracket \theta \Rightarrow \varphi \rrbracket (T, D, \epsilon) = \llbracket \neg \theta \rrbracket (T, D, \epsilon) \cup \llbracket \varphi \rrbracket (T', D, \epsilon)$, where $T' = \llbracket \theta \rrbracket (T, D, \epsilon)$. Note that the semantics of φ is taken over the set T' given by the semantics of θ , as discussed earlier in this section.
- $\llbracket u = v \rrbracket (T, D, \epsilon)$ includes all traces $\langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$ such that $\sigma(u) = \sigma(v)$.
- $\llbracket \text{DecryptsHonest}(\tilde{Y}, \{u\}_X^r) \rrbracket (T, D, \epsilon) = \llbracket \varphi \rrbracket (T, D, \epsilon)$ with $\varphi = \text{Honest}(\hat{X}) \wedge \exists v. v := \text{dec } \tilde{Y}, \{u\}_X^r$.
- $\llbracket \text{Source}(\tilde{Y}, u, \{m\}_X^r) \rrbracket (T, D, \epsilon) = \llbracket \exists v. \forall w. \varphi \rrbracket (T, D, \epsilon)$ with :

$$\begin{aligned} \varphi = & \text{New}(\tilde{Y}, u) \wedge \text{Contains}(m, u) \\ & \wedge \text{Contains}(v, \{m\}_X^r) \wedge \text{Send}(\tilde{Y}, v) \\ & \wedge \neg \text{ContainsOut}(v, u, \{m\}_X^r) \\ & \wedge (v \neq w \wedge \text{Contains}(w, u)) \Rightarrow \neg \text{Send}(\tilde{Y}, w) \end{aligned}$$
- $\llbracket \text{Possess}(\tilde{X}, u) \rrbracket (T, D, \epsilon)$ includes all traces $t = \langle e, \lambda, O, K, R, R_T, \sigma \rangle \in T$ such that $\sigma(u)$ can be built from $\text{View}_t(\sigma(\tilde{X}))$ with the Dolev-Yao deduction rules.
- $\llbracket \text{Indist}(\tilde{X}, u) \rrbracket (T, \epsilon, D) = T$ if

$$\frac{|\{D(\text{View}_t(\sigma(\tilde{X})), u, LR(\sigma(u), f(u, \sigma, r), b), R_D, \eta) = b \mid t \in T\}|}{|T|} \leq \frac{1}{2} + \epsilon$$
and the empty set ϕ otherwise. Here, the random sequence $b; r; R_D = R_T$, the testing randomness for the trace t .
- $\llbracket \theta[P]_{\tilde{X}} \varphi \rrbracket (T, D, \epsilon) = T_{-P} \cup \llbracket \neg \theta \rrbracket (Pre(T_P), D, \epsilon) \cup \llbracket \varphi \rrbracket (Post(T_P), D, \epsilon)$ with T_{-P} , $Pre(T_P)$, and $Post(T_P)$ as given by Definition 6.

Definition 7. A protocol Q satisfies a formula φ , written $Q \models \varphi$, if $\forall A$ providing an active protocol adversary, $\forall D$ providing a probabilistic-polynomial-time distinguisher, $\forall \nu$ giving a negligible function, $\exists N, \forall \eta \geq N$,

$$|\llbracket \varphi \rrbracket (T, D, \nu(\eta))| / |T| \geq 1 - \nu(\eta)$$

where $\llbracket \varphi \rrbracket (T, D, \nu(\eta))$ is the subset of T given by the semantics of φ and $T = T_Q(A, \eta)$ is the set of computational traces of protocol Q generated using adversary A and security parameter η , according to Definition 1.

Theorem 1. (Soundness) $\forall Q, \forall \varphi, Q \vdash \varphi \Rightarrow Q \models \varphi$

8 Conclusion and Future Work

We propose a computational semantics for a variant of the Protocol Composition Logic presented in [2, 7, 8, 10]. The associated soundness theorem implies that it is possible to reason symbolically, and at a high level, about probabilistic polynomial-time security properties. Although omitted from this conference paper, the soundness proof uses a combination of information-theoretic arguments, calculations about negligible functions, and cryptographic-style reductions involving encryption. While the semantics given here has some imperfections, such as an interpretation of indistinguishability that only seems appropriate for formulas where `Indist` appears with positive polarity, the general approach seems promising. We look forward to future efforts to lift certain restrictions on the logic, explore the semantics and axiomatization of logical connectives over probabilistic polynomial-time interpretations, and extend the approach suggested here to additional cryptographic primitives, such as signatures and hash functions. One interesting research direction might be to develop a version of this semantics based on information-theoretic security, since that may provide some useful insight into problems we encountered in developing the semantics.

Acknowledgments: Thanks to Bogdan Warinschi, Andre Scedrov, and Dan Boneh for many insightful comments and suggestions.

A Gentle Introduction to Semantic Subtyping*

Giuseppe Castagna¹ and Alain Frisch²

¹CNRS, École Normale Supérieure de Paris, France

²INRIA, Rocquencourt, France

Abstract. Subtyping relations are usually defined either syntactically by a formal system or semantically by an interpretation of types into an untyped denotational model. This work shows how to define a subtyping relation semantically in the presence of boolean connectives, functional types and dynamic dispatch on types, without the complexity of denotational models, and how to derive a complete subtyping algorithm. The presentation is voluntarily kept informal and discursive and the technical details are reduced to a minimum since we rather insist on the motivations, the intuition, and the guidelines to apply the approach.

1 Introduction

Many recent type systems rely on a subtyping relation. Its definition generally depends on the type algebra, and on its intended use. We can distinguish two main approaches for defining subtyping: the *syntactic* approach and the *semantic* one. The syntactic approach—by far the more used—consists in defining the subtyping relation by axiomatising it in a formal system (a set of inductive or coinductive rules); in the semantic approach (for instance, [1, 4]), instead, one starts with a model of the language and an interpretation of types as subsets of the model, then defines the subtyping relation as the inclusion of denoted sets, and, finally, when the relation is decidable, derives a subtyping algorithm from the semantic definition.

The semantic approach has several advantages but it is also more constraining. Finding an interpretation in which types can be interpreted as subsets of a model may be a hard task. A solution to this problem was given by Haruo Hosoya and Benjamin Pierce [9, 8, 7] with the work on XDuce. The key idea is that in order to define the subtyping relation semantically one does not need to start from a model of the whole language: a model of the types suffices. In particular Hosoya and Pierce take as model of types the set of values of the language. Their notion of model cannot capture functional values. On the one hand, the resulting type system is poor since it lacks function types. On the other hand, it manages to integrate union, product and recursive types and still keep the presentation of the subtyping relation and of the whole type system quite simple.

In [6, 5], together with Véronique Benzaken, we extended the work on XDuce and reframed it in a more general setting: we show a technique to define semantic sub-

* Joint ICALP/PPDP 2005 keynote talk, short overview. The full article is included in the proceedings of PPDP '05 [3]

typing in the presence of a rich type system including function types, but also arbitrary boolean combinations (union, intersection, and negation types) and in the presence of lately bound overloaded functions and type-based pattern matching. The aim of [6, 5] was to provide a theoretical foundation on the top of which to build the language $\mathbb{C}Duce$ [2], an XML-oriented transformation language. This motivation needed a rather heavy technical development that concealed a side—but important—contribution of the work, namely a generic and uniform technique (or rather, a cookbook of techniques) to define semantic subtyping when straightforward set-theoretic interpretation does not work, in particular for arrow types. Here we concentrate on this second aspect of the work: we get rid of many features (e.g. patterns and pattern matching, full-fledged overloading, pattern variable type inference, . . .), skip many technical details, and focus on the basic intuition to gradually introduce our approach. This results in a presentation along which we explain the reader how to take her/his favourite set of type constructors (e.g. arrows, but also records, lists, pointers, channels, etc.) and add to it a complete set of boolean combinators: union, intersection and negation types.

Our hope is that this work will provide the reader with enough intuition and a detailed roadmap to decide whether it is possible/interesting to endow her/his favourite language with a set-theoretically defined subtyping relation.

2 Overview of the Approach

Our objective is to define give a semantic definition of a subtyping relation by interpreting types as sets and subtyping as set inclusion. We thus need to define a set-theoretic model of types. This model is usually defined by starting from a model of the terms of the object language. For a language with function types, we have to interpret the duality of functions as terms and as functions on terms. This yields the need to solve complicated recursive domain equations that hardly combines with a set-theoretic interpretation of types, whence the introduction of restrictions in the definition of semantic subtyping (e.g. no function types, no negation types, etc . . .).

Note however that in order to define semantic subtyping all we need is a set-theoretic *model of types*. The construction works even if we do not have a model of terms. The definition of a semantic subtyping relation needs neither an interpretation for applications (that is, an applicative model) nor the solution of complicated domain equations.

The first key idea to generalise semantic subtyping is, then, to dissociate the *model of types* from the *model of terms* and define the former independently from the latter. In other words, the interpretation of types must not forcedly be based on an interpretation of terms. More formally, what we do is first to define an interpretation function for types $\llbracket _ \rrbracket : \text{Types} \rightarrow \mathcal{P}(\mathcal{D})$, where \mathcal{P} denotes the powerset, and \mathcal{D} is some domain (which may not be expressive enough to interpret terms). Then, we define the subtyping relation as follows:

$$s \leq t \stackrel{\text{def}}{\iff} \llbracket s \rrbracket \subseteq \llbracket t \rrbracket.$$

The second key idea is that we do not need $\llbracket _ \rrbracket$ to state what types *mean*, but just to describe how types *are related*. And to this end, all that matters is when $\llbracket _ \rrbracket$ is equal to zero. Indeed,

$$s \leq t \iff \llbracket s \rrbracket \subseteq \llbracket t \rrbracket \iff \llbracket s \rrbracket \cap \overline{\llbracket t \rrbracket} = \emptyset \iff \llbracket s \rrbracket \cap \llbracket \neg t \rrbracket = \emptyset \iff \llbracket s \wedge \neg t \rrbracket = \emptyset$$

where the overbar denotes complementation in \mathcal{D} . Thus, we can concentrate our efforts just on the $\llbracket \cdot \rrbracket$ -counterimage of the empty set and disregard the behaviour of $\llbracket \cdot \rrbracket$ on the remaining types.

Types as Sets of Values. Nevertheless, to ensure type safety, the meaning of types has to be somewhat correlated with the language. A classical solution is to interpret types as sets of *values*, that is, as the results of *well-typed* computations in the language. More formally, the values of a typed language are all the terms that are well-typed, closed, and in normal form. Interpreting types as sets of values is much easier than interpreting them as sets of terms: since a closed application usually denotes a redex, then by restricting to the sole values we avoid the need to interpret application and, therefore, also the need to solve complicated domain equations. This is the solution adopted by XDuce, where values are XML documents and types are sets of documents.

But if we consider a language with arrow types, that is a language with higher order functions, then the applications come back again: arrow types must be interpreted as sets of function values, that is, as sets of well-typed closed lambda abstractions, and applications may occur in the body of these abstractions. Here is where XDuce stops and it is the reason why it does not include arrow types.

A Circularity to Break. Introducing arrow types is problematic because it slips applications back again in the interpretation of types. However this does not mean that we need a semantic interpretation for application, it just implies that we must define how application is typed. In particular, since functional values are *well-typed* lambda abstractions, then to interpret functional types we must be able to type the applications that occur in the body of lambda abstractions. Now this is not an easy task in our context: in the absence of higher order functions the set of values of type constructors such as products or records can be inductively defined from basic types without resorting to any typing relation (this is why the Hosoya Pierce approach works smoothly). With the arrow type constructor, instead, this can be done only by using a typing relation which yields to a circularity: in order to define the subtyping relation we need an interpretation of the types of the language; for this we have to define which are the values of an arrow type; this needs that we define the typing relation for applications, which in turns needs the definition of the subtyping relation.

Thus, if we want to define the semantic subtyping of arrow types we must find a way to avoid this circularity. The simplest way to avoid it is to break it. We already said that to define set-theoretic subtyping we *must* have a model of types; it is also clear that the typing relation *must* use subtyping; on the contrary it is not strictly necessary for our model to be based on the interpretation of values, this is just convenient since it ties the types with the language the types are intended for. This is therefore the weakest link and we can break it. So the idea is to start from a model (of the types) defined independently (but not too much) from the language the types are intended for (and therefore independently from its values), and then from that define the rest: subtyping, typing, set of values.

For a given type algebra and a language, the approach can be summarised as follows:

1. First, we define a notion of *set-theoretic model* of the type algebra. In such a model, set-theoretic connectives in the type algebra (that is union, intersection, and negation) must be interpreted in a set-theoretic way. Also, the notion of model must capture the essence of the type constructors, and in particular of the function types. For instance, in [6, 5], we show that an extensional interpretation of functions as binary relations is suitable for a language with overloaded functions and dynamic type dispatch.
2. There might be several models, each of them induces a specific subtyping relation on the type algebra. We only need to prove that there exists at least one model, and to pick one, which we call the *bootstrap model*. In [6, 5], we exhibit a model with an universal property: it induces the largest possible subtyping relation.
3. Now we have a (hopefully) suitable subtyping relation available, we can focus again on the language itself and consider its typing rules (which depend on the subtyping relation). The rich set-theoretic structure of models helps us to carry out the meta-theoretic study of the system, and to prove easily classical properties such as the transitivity of subtyping, subsumption elimination, and so on.
4. The typing judgement for the language produces a new natural set-theoretic interpretation of types: a type t denotes the set of values of type t . This interpretation induces a new subtyping relation, which might be different from the one we used to define the type system. However, if the definition of the models and the typing rules have been carefully chosen, then we can expect the two subtyping relations to coincide. This is the case in [6, 5].

The last step is the most critical one. It consists in “closing the circle”: even if we have used a detour to create a subtyping relation, in the end we obtain a consistent system where types are interpreted as sets of values and subtyping is exactly set-inclusion of types. The rest of the story is standard: we can define the operational semantics for the language (we consider a language whose semantics is driven by types) and prove a type preservation result by a classical syntactic argument. This proof requires a lot of intermediate properties about the subtyping relation, which can be obtained easily using the definition of model. Also, we can use set-theoretic reasoning to derive from this definition an actual algorithm to compute the subtyping relation. As for the subtyping relation, this algorithm obviously depends on the bootstrap model we have chosen.

In the full version [3] we show the details of this construction and hint at how it can be applied to other type constructors such as product, lazy, reference, and channel types.

Logics for Unranked Trees: An Overview

Leonid Libkin*

University of Toronto
libkin@cs.toronto.edu

Abstract. Labeled unranked trees are used as a model of XML documents, and logical languages for them have been studied actively over the past several years. Such logics have different purposes: some are better suited for extracting data, some for expressing navigational properties, and some make it easy to relate complex properties of trees to the existence of tree automata for those properties. Furthermore, logics differ significantly in their model-checking properties, their automata models, and their behavior on ordered and unordered trees. In this paper we present a survey of logics for unranked trees.

1 Introduction

Trees arise everywhere in computer science, and there are numerous formalisms in the literature for describing and manipulating trees. Some of these formalisms are declarative and based on logical specifications: for example, first-order logic, or monadic second-order logic, or various temporal or fixed-point logics over trees. Others are procedural formalisms such as various flavors of tree automata, or tree transducers, or tree grammars. All these formalisms have found numerous applications in verification, program analysis, logic programming, constraint programming, linguistics, and databases.

Until recently, most logical formalisms for trees dealt with *ranked* trees [18, 58]: in such trees, all nodes have the same fixed number of children (or, a bit more generally, the number of children of a node is determined by the label of that node). Over the past several years, however, the focus has shifted towards *unranked* trees, in which there are no restrictions on the number of children a node can have. Although unranked trees have been considered in the 60s and 70s, and are related to feature trees over an infinite set of features that have been investigated by computational linguists, their systematic study was initiated by the development of XML (eXtensible Markup Language). XML is a data format which has become the lingua franca for information exchange on the world wide web. XML data is typically modeled as labeled unranked trees [42].

This connection has led to a renewed interest in logical and procedural formalisms for unranked trees: one uses logical formalisms for expressing declarative queries, and procedural formalisms for evaluating them. Logics over unranked trees appeared in large numbers over the past 7–8 years, and they come in many flavors in shapes. Common to them is a close connection to automata models, and quite often to temporal and modal logics, especially when one describes properties of paths through a document.

* Complete version of this survey can be found at www.cs.toronto.edu/~libkin/publ.html.

Let us now review some of the parameters according to which logics for unranked trees can be classified.

The yardstick logic. Most formalisms are “inspired” by either *first-order logic* (FO), or *monadic second-order logic* (MSO) that extends FO by quantification over sets. Query languages and schema formalisms for XML tend to use MSO as the yardstick: for example, XML DTDs are (almost) equivalent to MSO sentences, and various language for extraction of data from XML documents have the power of MSO unary queries. On the other hand, navigational aspects of XML, in particular, logics capturing various fragments of XPath, are usually related to FO and its fragments.

Arity of queries. Most commonly one considers Boolean or unary queries. Boolean queries evaluate to *true* or *false*. Checking if an XML document conforms to a schema specification is represented by a Boolean query. Unary queries correspond to formulae in one free variable, and thus produce a set of nodes. E.g., extracting sets of nodes, or evaluating XPath expressions relative to the root naturally give rise to unary queries.

Complexity of model-checking. The model-checking problem asks whether a tree T satisfies a logical sentence φ . If φ is an MSO sentence φ , it can be evaluated in linear time in the size of T , by converting to a tree automaton. But there is a price to pay: in terms of the size of φ , the complexity becomes non-elementary. This type of trade-offs is one of the central issues in dealing with logics over trees.

Ordered vs. unordered trees. In unranked XML trees, children of the same node are ordered by a *sibling ordering*. If such an order is present, we speak of ordered unranked trees. In many cases, however, this ordering is irrelevant, and some models, such as feature trees, do not impose any ordering on siblings. There is considerable difference between the expressiveness of logics and automata models depending on the availability of sibling ordering. The presence of ordering also affects the yardstick logic, since without order often counting is needed to match the power of automata models [19].

The paper is organized as follows. After we give basic definitions in Section 2, we review logics for ordered trees in Section 3. We start with MSO-related logics, including syntactic restrictions of MSO, a datalog-based logic, and the μ -calculus. We then turn to FO-related logics, present analogs of LTL and CTL* that have been studied for expressing navigational properties, and also look at conjunctive queries over trees. In Section 4 we turn to trees that lack the sibling ordering, and show that in many logics some form of counting needs to be added to compensate for the missing ordering. In Section 5 we look at the model-theoretic approach in the spirit of automatic structures.

2 Trees, Logics, and Automata

Tree domains, trees, and operations on trees. Nodes in unranked trees are elements of \mathbb{N}^* – that is, finite strings whose letters are natural numbers. A string $s = n_0 n_1 \dots$ defines a path from the root to a give node: one goes to the n_0 th child of the root, then to the n_1 th child, etc. We write $s_1 \cdot s_2$ for the concatenation of strings s_1 and s_2 .

We need some basic binary relations on \mathbb{N}^* – the *child* and *next-sibling* relations:

$$\begin{aligned} s \prec_{\text{ch}} s' &\Leftrightarrow s' = s \cdot i \text{ for some } i \in \mathbb{N}; \\ s \prec_{\text{ns}} s' &\Leftrightarrow s = s_0 \cdot i \text{ and } s' = s_0 \cdot (i + 1) \text{ for some } s_0 \in \mathbb{N}^* \text{ and } i \in \mathbb{N}. \end{aligned}$$

We also use the *first child relation*: $s \prec_{\text{fc}} s \cdot 0$. We shall use $*$ to denote the reflexive-transitive closure of a relation. Thus, \prec_{ch}^* is the *descendant* relation (including self), and \prec_{ns}^* is a linear ordering on siblings.

Definition 1 (Tree domain). A tree domain D is a finite prefix-closed subset of \mathbb{N}^* (i.e., if $s \in D$ and s' is a prefix of s , then $s' \in D$) such that $s \cdot i \in D$ implies $s \cdot j \in D$ for all $j < i$.

Let Σ be a finite alphabet.

Definition 2 (Σ -trees). An ordered unranked Σ -labeled tree T is a structure

$$T = \langle D, \prec_{\text{ch}}^*, \prec_{\text{ns}}^*, (P_a)_{a \in \Sigma} \rangle,$$

where D is a tree domain, \prec_{ch}^* and \prec_{ns}^* are the descendant relation and the sibling ordering, and P_a 's are interpreted as disjoint sets whose union is the entire domain D .

An unordered unranked tree is defined as a structure $\langle D, \prec_{\text{ch}}^*, (P_a)_{a \in \Sigma} \rangle$.

Thus, a tree consists of a tree domain together with a labeling on its nodes: if $s \in P_a$, then the label of s is a . In this case we write $\lambda_T(s) = a$.

First-order and Monadic Second-Order Logic. We only consider relational vocabularies: finite lists (R_1, \dots, R_m) of relation symbols, each R_i with an associated arity n_i . Over trees, relation symbols are binary (e.g., \prec_{ch} , \prec_{ns} , \prec_{ch}^*) or unary (P_a 's for $a \in \Sigma$).

Formulae of *first-order* logic (FO) are built from atomic formulae $x = x'$, and $R(\bar{x})$, where x, x' are variables, and \bar{x} is a tuple of variables, using the Boolean connectives \vee, \wedge, \neg and quantifiers \exists and \forall . If a formula φ has free variables \bar{x} , we shall write $\varphi(\bar{x})$.

Formulae of *monadic second-order* logic (MSO) in addition allow quantification over sets. We shall normally denote sets of nodes by upper case letters. Thus, MSO formulae have the usual first-order quantifiers $\exists x\varphi$ and $\forall x\varphi$ as well as second-order quantifiers $\exists X\varphi$ and $\forall X\varphi$, and new atomic formulae $X(x)$, where X is a second-order variable and x is a first-order variable. An MSO formula may have both free first-order and second-order variables. If it only has free first-order variables, then it defines a relation on the universe of the structure.

Note that relations \prec_{ch} and \prec_{ns} are definable, in FO, from \prec_{ch}^* and \prec_{ns}^* . In MSO one can define \prec_{ch}^* from \prec_{ch} ; however, it is well-known that in FO this is *not* possible. This is why we chose \prec_{ch}^* and \prec_{ns}^* , rather than \prec_{ch} and \prec_{ns} , as our basic relations.

Definition 3 (Definability in logic). Given a logic \mathcal{L} , we say that a set of trees \mathcal{T} is *definable* in \mathcal{L} if there is a sentence φ of \mathcal{L} such that $T \in \mathcal{T}$ iff $T \models \varphi$. We say that a unary query \mathcal{Q} (that selects nodes from trees) is *definable* in \mathcal{L} if there is a formula $\psi(x)$ of \mathcal{L} such that $s \in \mathcal{Q}(T)$ iff $T \models \psi(s)$, for every tree T and a node s in T .

Unranked Tree Automata. An *nondeterministic unranked tree automaton*, NUTA [56, 9], over Σ -labeled trees is a triple $\mathcal{A} = (Q, F, \delta)$ where Q is a finite set of states, $F \subseteq Q$ is the set of final states, and δ is a mapping $Q \times \Sigma \rightarrow 2^{Q^*}$ such that $\delta(q, a)$ is a regular language over Q (normally represented by a regular expression over Q). A *run* of \mathcal{A} on a tree T with domain D is a function $\rho_{\mathcal{A}} : D \rightarrow Q$ such that, if s is a node with n children, and it is labeled a , then the string $\rho_{\mathcal{A}}(s \cdot 0) \cdots \rho_{\mathcal{A}}(s \cdot (n-1))$ is in $\delta(\rho_{\mathcal{A}}(s), a)$.

In particular, if s is a leaf labeled a , then $\rho_{\mathcal{A}}(s) = q$ implies that $\varepsilon \in \delta(q, a)$. A run is *accepting* if $\rho_{\mathcal{A}}(\varepsilon) \in F$, that is, the root is in an accepting state. A tree T is *accepted* by \mathcal{A} if there exists an accepting run. We let $L(\mathcal{A})$ denote the set of all trees accepted by \mathcal{A} . Such sets of trees will be called *regular*.

Binary trees and translations. A *binary tree domain* is a prefix-closed subset D of $\{0, 1\}^*$ such that if $s \cdot i \in D$, then $s \cdot (1 - i) \in D$ (that is, a node is either a leaf, or both its children are in D). A (binary) *nondeterministic tree automaton*, *NTA*, is a quadruple $\mathcal{A}_b = (Q, q_0, F, \delta)$ where Q and F are as before, q_0 is the initial state, and δ is a function $Q \times Q \times \Sigma \rightarrow 2^Q$. A run $\rho_{\mathcal{A}}$ on a binary tree T with domain D is a function from D to Q such that if s is a leaf labeled a , then $\rho_{\mathcal{A}}(s) \in \delta(q_0, q_0, a)$, and if $s \cdot 0, s \cdot 1$ belong to D , and s is labeled a , then $\rho_{\mathcal{A}}(s) \in \delta(\rho_{\mathcal{A}}(s \cdot 0), \rho_{\mathcal{A}}(s \cdot 1), a)$. A run is accepting if $\rho_{\mathcal{A}}(\varepsilon) \in F$, and $L(\mathcal{A}_b)$ is the set of all binary trees for which there exists an accepting run. Such sets are called *regular*.

There is a well-known regularity-preserving translation between ranked and unranked trees. It was used in [49] to show decidability of $S\omega S$ (but here we shall apply it only to finite tree domains). The idea of the translation is that the first successor in the binary tree corresponds to the first child, and the second successor to the next sibling. More precisely, we define a mapping $\mathcal{R} : \mathbb{N}^* \rightarrow \{0, 1\}^*$ such that $\mathcal{R}(\varepsilon) = \varepsilon$, and if $\mathcal{R}(s) = s'$, where $s = s_0 \cdot i$, then $\mathcal{R}(s \cdot 0) = s' \cdot 0$ and $\mathcal{R}(s_0 \cdot (i + 1)) = s' \cdot 1$. If D is an unranked tree domain, we let $\mathcal{R}(D)$ be $\{\mathcal{R}(s) \mid s \in D\}$ together with $\mathcal{R}(s) \cdot 1$ if s is a non-leaf last child, and $\mathcal{R}(s) \cdot 0$ if s a leaf, other than the last sibling (these additions ensure that $\mathcal{R}(D)$ is a binary tree domain). We define $\mathcal{R}(T)$ to be a tree with domain $\mathcal{R}(D)$, where $\mathcal{R}(s)$ has the same label as s , and the added nodes are labeled by a symbol $\perp \notin \Sigma$. The following is a folklore result.

Lemma 1. *For every NUTA \mathcal{A} , there is an NTA \mathcal{A}_b such that $L(\mathcal{A}_b) = \{\mathcal{R}(T) \mid T \in L(\mathcal{A})\}$, and for every NTA \mathcal{A}_b there is an NUTA \mathcal{A} such that the above holds.*

3 Ordered Trees

In this section we only deal with ordered unranked trees. We first survey MSO-based logics, and then move to FO-based ones.

3.1 MSO and Its Relatives

As we mentioned already, MSO is often used as a yardstick logic for trees, because of its close connection to regular languages. The following result belonged to folklore, and was explicitly stated in [41].

Theorem 1. *A set of unranked trees is regular iff it is definable in MSO.*

When one considers binary trees, this result says that regular sets of binary trees are precisely those MSO-definable, and if we look at strings, which may be viewed as trees without branching, we obtain that regular languages are precisely those MSO-definable. Of course these are well-known results by Büchi [10], and Thatcher, Wright [57].

There is also a close connection between automata, MSO, and a formalism for describing XML schemas, called DTDs (which are essentially extended context-free

grammars). A DTD d over an alphabet Σ is a collection of rules $a \rightarrow e_a$, where $a \in \Sigma$ and e_a is a regular expression over Σ . We shall assume there is at most one such rule for each $a \in \Sigma$. A Σ -labeled tree T satisfies d , if for each node s of T with n children, and $\lambda_T(s) = a$, the string $\lambda_T(s \cdot 0) \cdots \lambda_T(s \cdot (n-1))$ is in the language denoted by e_a .

Each DTD is easily definable by an unranked tree automaton: in fact its states just correspond to labels of nodes. This, however, is too restrictive to capture full definability in MSO, but a slight extension of DTDs does precisely that. An *extended DTD* over Σ is a triple (Σ', d', g) where $\Sigma' \supseteq \Sigma$, with g being a mapping $g : \Sigma' \mapsto \Sigma$, and d' is a DTD over Σ' . A Σ -labeled tree T satisfies (Σ', d', g) if there is a Σ' -labeled tree T' that satisfies d' such that $T = g(T')$. The following was established in [56].

Proposition 1. *A set of unranked trees is MSO definable iff it is the set of all trees satisfying some extended DTD (Σ', d', g) .*

Theorem 1 talks about MSO sentences, but it can be extended to unary MSO queries using the concept of *query automata* [44]. A (nondeterministic) *query automaton* over unranked Σ -labeled trees is a quadruple $\mathcal{QA} = (Q, F, \delta, S)$ where $\mathcal{A} = (Q, F, \delta)$ is an UNTA, and S is a subset of $Q \times \Sigma$. Such a query automaton defines a unary query $\mathcal{Q}_{\mathcal{QA}}$ that selects nodes s in T such that $(\rho_{\mathcal{A}}(s), \lambda_T(s)) \in S$ for some accepting run $\rho_{\mathcal{A}}$.

Theorem 2. (see [44, 41, 24]) *A unary query \mathcal{Q} on unranked trees is MSO-definable iff it is of the form $\mathcal{Q}_{\mathcal{QA}}$ for some query automaton.*

One can also define the semantics universally $((\rho_{\mathcal{A}}(s), \lambda_T(s)) \in S$ for all accepting runs) and the result still holds. Query automata have a deterministic counterpart; however, in the deterministic version, two passes over the tree are required; see [44].

Theorems 1 and 2 are constructive. In particular, every MSO sentence φ can be effectively transformed into an automaton \mathcal{A}_{φ} that accepts a tree T iff $T \models \varphi$. Since tree automata can be determinized, this gives us a $O(\|T\|)$ algorithm to check whether $T \models \varphi$, if φ is fixed¹. However, it is well-known that the size of \mathcal{A}_{φ} (even for string automata) cannot be bounded by an elementary function in $\|\varphi\|$ [55]. An even stronger result of [23] says that there could be no algorithm for checking whether $T \models \varphi$ that runs in time $O(f(\|\varphi\|) \cdot \|T\|)$, where f is an elementary function, unless PTIME=NP.

Nonetheless, these results do not rule out the existence of a logic \mathcal{L} that has the same power as MSO and yet permits faster model-checking algorithms. Even looking at a simpler case of FO on strings, where results of [23] also rule out $O(f(\|\varphi\|) \cdot |s|)$ algorithms for checking if a string s satisfies φ , with f being an elementary function, the logic LTL (linear-time temporal logic) has the same expressiveness as FO [33] and admits model-checking algorithm with running time $2^{O(\|\varphi\|)} \cdot |s|$.

Logic ETL. The first logic for unranked trees that has the power of MSO and model-checking complexity matching that of LTL appeared in [43] and was called ETL (*efficient tree logic*). It was obtained by putting syntactic restrictions on MSO formulae, and at the same time adding new constructors for formulae, which are not present in MSO, but are MSO-definable.

¹ We use the notation $\|T\|, \|\varphi\|$ to denote the sizes of natural encodings of trees and formulae.

The atomic formulae of ETL are the same as for MSO, except that we are allowed to use both \prec_{ch} and \prec_{ch}^* and are *not* allowed to use the next-sibling relation \prec_{ns}^* . ETL is closed under Boolean combinations (which are required to be in DNF), *guarded quantification*, and *path formulae*. The rules for guarded quantification are:

- if $\varphi(x, y, X)$ is an ETL formula, then $\exists y (x \prec_{\text{ch}} y \wedge \varphi)$ and $\exists y (x \prec_{\text{ch}}^* y \wedge \varphi)$ are ETL formulae;
- if $\varphi(x, X)$ is an ETL formula, then $\exists X (x \prec_{\text{ch}}^* X \wedge \varphi)$ is an ETL formula. Here $x \prec_{\text{ch}}^* X$ means that X only contains descendants of x . In this case φ cannot contain vertical path formulae (defined below).

Path formulae are defined as follows:

- if e is a regular expression over ETL formulae $\psi(u, v)$, then $e^\downarrow(x, y)$ is a (vertical path) ETL formula. The semantics is as follows: $T \models e^\downarrow(s, s')$ if there is a child-relation path $s = s_0, s_1, \dots, s_n = s'$ in T and a sequence of ETL formulae $\psi_i(u, v)$, $i \leq n - 1$, such that $T \models \psi_i(s_i, s_{i+1})$ for each $i \leq n - 1$, and the sequence $\psi_0 \dots \psi_{n-1}$ matches e .
- if e is a regular expression over ETL formulae $\psi(u, \bar{X})$, then $e^\rightarrow(x, \bar{X})$ is a (horizontal path) ETL formula. Then $T \models e^\rightarrow(s, \bar{X})$ if children $s \cdot i$, $i \leq k$ of s can be labeled with ETL formulae $\psi_i(u, \bar{X})$ such that $T \models \psi_i(s \cdot i, \bar{X})$ for all i , and the sequence $\psi_0 \dots \psi_k$ matches e .

Theorem 3. (see [43]) *With respect to Boolean and unary queries, ETL and MSO are equally expressive. Furthermore, each ETL formula φ can be evaluated on a tree T in time $2^{O(\|\varphi\|)} \cdot \|T\|$.*

Monadic datalog. Another approach to obtaining the full power of MSO while keeping the complexity low is based on database query language *datalog* (cf. [1]). A datalog program is a sequence of rules $H:-P_1, \dots, P_k$ where H and all P_i 's are atomic formulae. The predicate H is called the head of the rule, and every variable that appears in H is required to appear in one of the P_i 's. Given a datalog program \mathcal{P} , predicates which appear as a head of some rule are called intensional, and other predicates are called extensional. If all intensional predicates are monadic (of the form $H(x)$), then \mathcal{P} is a *monadic datalog program*. The semantics is a standard fixed-point semantics, see, e.g., [1]. An intensional unary predicate of a program \mathcal{P} defines a unary query.

For extensional predicates, we shall need *Leaf*, *LastChild*, and *Root*. Given a tree domain D , they are interpreted as $\text{Leaf} = \{s \in D \mid \neg \exists s' \in D : s \prec_{\text{ch}} s'\}$, $\text{LastChild} = \{s \cdot i \in D \mid s \cdot (i + 1) \notin D\}$ and $\text{Root} = \{\varepsilon\}$.

Theorem 4. (see [25]) *A unary query over unranked trees is definable in MSO iff it is definable in monadic datalog over extensional predicates \prec_{fc} , \prec_{ns} , Leaf, LastChild, Root, and P_a , $a \in \Sigma$. Furthermore, each monadic datalog query (\mathcal{P}, H) can be evaluated on a tree T in time $O(\|\mathcal{P}\| \cdot \|T\|)$.*

μ -calculus. Yet another way of getting a logic equivalent to MSO is suggested by a close connection between MSO and the modal μ -calculus L_μ on ranked trees, which can easily be extended to the unranked case by using the connection between ranked

and unranked trees. It was shown in [22, 47] that every property of infinite binary trees definable in MSO is also be definable in L_μ . To deal with unranked trees, we shall define L_μ over Σ -labeled structures that have several binary relations E_1, \dots, E_m , cf. [2]. Formulae of $L_\mu[E_1, \dots, E_m]$ are given by

$$\varphi := a \ (a \in \Sigma) \mid X \mid \varphi \vee \varphi \mid \neg\varphi \mid \diamond(E_i)\varphi \mid \mu X \ \varphi(X),$$

where in $\mu X \ \varphi(X)$, the variable X must occur positively in φ . Given a tree T with domain D , $s \in D$, and a valuation v for free variables (each $v(X)$ is a subset of D), we define the semantics (omitting the rules for letters $a \in \Sigma$ and Boolean connectives) by

- $(T, v, s) \models X$ iff $s \in v(X)$.
- $(T, v, s) \models \diamond(E_r)\varphi$ iff $(T, v, s') \models \varphi$ for some s' with $(s, s') \in E_r$.
- $(T, v, s) \models \mu X \ \varphi(X)$ iff s is in the least fixed point of the operator defined by φ .

An L_μ formula φ without free variables naturally defines a unary query on trees ($\{s \mid (T, s) \models \varphi\}$) and a Boolean query on trees (by checking if $(T, \varepsilon) \models \varphi$).

Using the translation into ranked trees, it is easy to show (see [3]):

Proposition 2. *The class of Boolean MSO queries on unranked trees is precisely the class of Boolean queries defined by $L_\mu[\prec_{fc}, \prec_{ns}]$.*

It is also possible to characterize unary MSO queries over unranked trees in terms of the *full* μ -calculus L_μ^{full} (cf. [59]) which adds backward modalities $\diamond(E_i^-)\varphi$ with the semantics $(T, s) \models \diamond(E_i^-)\varphi$ iff $(T, s') \models \varphi$ for some s' such that $(s', s) \in E_i$.

Proposition 3. (see [3]) *The class of unary MSO queries on unranked trees is precisely the class of queries defined by $L_\mu^{\text{full}}[\prec_{ch}, \prec_{ns}]$.*

3.2 FO and Its Relatives

While much is known about FO on both finite and infinite strings, it has not been as extensively studied for trees until recently. Recall that over strings – which we can view as trees with only unary branching – FO defines precisely the star-free languages (cf. [58]), and over both finite and infinite strings FO has exactly the power of LTL [33].

In contrast, the natural analog of star-free expressions over binary trees captures not FO but MSO [48]. One well-known equivalent logical description of FO on binary trees is Hafer-Thomas's theorem [31] stating that over finite binary trees, $\text{FO} = \text{CTL}^*$ (CTL^* is a branching time temporal logic widely used in verification, cf. [16], and it will be defined shortly). Actually, the result of [31] shows that CTL^* is equivalent to MSO with second-order quantification over paths only, but over finite trees this fragment of MSO is equivalent to FO.

The interest in logics over unranked trees whose power is equal to or subsumed by that of FO stems from the fact that navigational features of XPath can be described in FO. XPath [17] is a W3C standard for describing paths in XML documents. Thus, it is very natural to look for connections between XPath, FO on trees, and temporal logics, which are designed to talk about properties of paths.

Logics introduced in the context of studying XPath, and more generally, navigational properties of XML documents, can be roughly subdivided into two groups. Firstly, one may try to establish analogs of Kamp's theorem (stating that $\text{FO} = \text{LTL}$ over

strings) for trees. Secondly, one can try extended Hafer-Thomas's theorem (the equivalence $\text{FO} = \text{CTL}^*$) from binary to unranked trees.

XPath and Temporal Logics. First, recall the syntax of LTL over alphabet Σ :

$$\varphi, \varphi' := a, a \in \Sigma \mid \varphi \vee \varphi' \mid \neg\varphi \mid \mathbf{X}\varphi \mid \mathbf{X}^-\varphi \mid \varphi\mathbf{U}\varphi' \mid \varphi\mathbf{S}\varphi'.$$

Formulae of LTL are interpreted over finite or infinite strings over Σ . Given a string $s = a_0a_1\dots$, the semantics is as follows: $(s, i) \models a$ iff $a_i = a$, $(s, i) \models \mathbf{X}\varphi$ (“next” φ) iff $(s, i+1) \models \varphi$; $(s, i) \models \mathbf{X}^-\varphi$ iff $(s, i-1) \models \varphi$; $(s, i) \models \varphi\mathbf{U}\varphi'$ (φ “until” φ') if there exists $j \geq i$ such that $(s, j) \models \varphi'$ and $(s, k) \models \varphi$ for all $i \leq k < j$, and the semantics of the dual $\varphi\mathbf{S}\varphi'$ (φ “since” φ') is that there exists $j \leq i$ such that $(s, j) \models \varphi'$ and $(s, k) \models \varphi$ for all $j < k \leq i$. (Note: it is possible to avoid \mathbf{X} and \mathbf{X}^- by defining a strict semantics for \mathbf{U} and \mathbf{S} , without requiring φ to be true in (s, i)).

A logic TL^{tree} (*tree temporal logic*) is a minor extension of LTL:

$$\varphi, \varphi' := a, a \in \Sigma \mid \varphi \vee \varphi' \mid \neg\varphi \mid \mathbf{X}_*\varphi \mid \mathbf{X}_*^-\varphi \mid \varphi\mathbf{U}_*\varphi' \mid \varphi\mathbf{S}_*\varphi',$$

where $*$ is either ‘ch’ (child) or ‘ns’ (next sibling). We define the semantics with respect to a tree and a node in a tree: $(T, s) \models a$ iff $\lambda_T(s) = a$; $(T, s) \models \mathbf{X}_{\text{ch}}\varphi$ if $(T, s \cdot i) \models \varphi$ for some i ; $(T, s) \models \mathbf{X}_{\text{ch}}^-\varphi$ if (T, s') $\models \varphi$ for the node s' such that $s' \prec_{\text{ch}} s$; $(T, s) \models \varphi\mathbf{U}_{\text{ch}}\varphi'$ if there is a node s' such that $s \prec_{\text{ch}}^* s'$, $(T, s') \models \varphi'$, and for all $s'' \neq s'$ satisfying $s \prec_{\text{ch}}^* s'' \prec_{\text{ch}}^* s'$ we have $(T, s'') \models \varphi$. The semantics of \mathbf{S}_{ch} is defined by reversing the order in the semantics of \mathbf{U}_{ch} , and the semantics of \mathbf{X}_{ns} , \mathbf{X}_{ns}^- , \mathbf{U}_{ns} , and \mathbf{S}_{ns} is the same by replacing the child relation with the next sibling relation.

As L_μ , the logic TL^{tree} naturally defines unary and Boolean queries on trees.

Theorem 5. (see [38]) *A unary or Boolean query over unranked trees is definable in FO iff it is definable in TL^{tree} .*

In both CTL^* and XPath formalisms there are two kinds of formulae: those evaluated in nodes of trees, and those evaluated on paths in trees (these are state and path formulae of CTL^* and filter and location path expressions of XPath).

We now look at XPath-inspired logics, and present them using a slight modification of the syntax that keeps all the main XPath constructions and yet makes the connection with temporal logics more visible. The language CXPath [38] (*Conditional XPath*) is defined to have *node formulae* α and *path formulae* β given by:

$$\begin{aligned} \alpha, \alpha' &:= a, a \in \Sigma \mid \neg\alpha \mid \alpha \vee \alpha' \mid \mathbf{E}\beta \\ \beta, \beta' &:= ?\alpha \mid \text{step} \mid (\text{step}/?\alpha)^+ \mid \beta/\beta' \mid \beta \vee \beta' \end{aligned}$$

where **step** is one of the following: \prec_{ch} , \prec_{ch}^- , \prec_{ns} , or \prec_{ns}^- . Intuitively $\mathbf{E}\beta$ states the existence of a path starting in a given node and satisfying β , $?\alpha$ tests if α is true in the initial node of a path, and $/$ is the composition of paths.

Formally, given a tree T , we evaluate each node formula in a node s , and each path formula in a pair of nodes (s, s') . The main semantic rules are:

- $(T, s) \models \mathbf{E}\beta$ iff there is s' such that $(T, s, s') \models \beta$;
- $(T, s, s') \models ?\alpha$ iff $s = s'$ and $(T, s) \models \alpha$;

- $(T, s, s') \models \text{step}$ iff $(s, s') \in \text{step}$;
- $(T, s, s') \models \beta/\beta'$ iff for some s'' we have $(T, s, s'') \models \beta$ and $(T, s'', s') \models \beta'$;
- $(T, s, s') \models (\text{step}/?\alpha)^+$ if there exists a sequence of nodes $s = s_0, s_1, \dots, s_k = s', k > 0$, such that each (s_i, s_{i+1}) is in **step**, and $(T, s_{i+1}) \models \alpha$ for each $i < k$.

The language **Core_XPath** [26] is obtained by only allowing **step**⁺ as opposed to **(step/? α)**⁺ in the definition of path formulae. Notice that since **step**⁺ = **(step/?true)**, where **true** = $\bigvee_{a \in \Sigma} a$, we have **Core_XPath** \subseteq **CXPath**.

Core_XPath corresponds to **XPath** as defined by W3C [17], while **CXPath** represents an addition to **XPath** proposed by [38]. Node formulae of either **CXPath** or **Core_XPath** naturally define unary queries on trees. These can be characterized as follows.

Theorem 6. a) (see [38]) *The node formulae of CXPath have precisely the power of FO unary queries.*

b) (see [39]) *The node formulae of Core_XPath have precisely the power of unary FO² queries (that is, FO with two variables) in the vocabulary $\prec_{\text{ch}}, \prec_{\text{ch}}^*, \prec_{\text{ns}}, \prec_{\text{ns}}^*$.*

CTL*-Like Logic. CTL* is a branching time temporal logic used in verification of reactive systems. Here we define it with past connectives, using the syntax close to that of [35]. In CTL*, one also has node (normally called state) formulae and path formulae, but path formulae are evaluated on paths, not on arbitrary pairs of nodes.

We define CTL*_{past} node formulae α , and child and sibling path formulae β_* , for * being 'ch' or 'ns', as follows:

$$\begin{aligned} \alpha, \alpha' &:= a \ (a \in \Sigma) \mid \neg \alpha \mid \alpha \vee \alpha' \mid \mathbf{E}\beta_{\text{ch}} \mid \mathbf{E}\beta_{\text{ns}} \\ \beta_*, \beta'_* &:= \alpha \mid \neg \beta_* \mid \beta_* \vee \beta'_* \mid \mathbf{X}_* \beta_* \mid \mathbf{X}_*^- \beta_* \mid \beta_* \mathbf{U}_* \beta'_* \mid \beta_* \mathbf{S}_* \beta'_* \end{aligned}$$

The semantics is standard and omitted here. The following can be seen as an analog of the equivalence $\text{FO} = \text{CTL}^*$ for finite binary trees [31].

Theorem 7. (see [3]) *A unary or Boolean query over unranked trees is definable in FO iff it is definable in CTL*_{past}.*

Conjunctive Queries Over Unranked Trees. Conjunctive queries are a very important class of database queries: they correspond to the \exists, \wedge -fragment of FO. These are the same queries that can be expressed by selection, projection, and join in relational algebra, and thus they form the core of database queries. The complexity of evaluating a conjunctive query φ over a database \mathcal{D} is in NP, in terms of both the size of φ and the size of \mathcal{D} . In fact, the problem is NP-hard, and there has been a large body of work on classifying tractable cases (see, e.g., [28, 30]).

In the case of unranked trees, conjunctive queries are formulae of the form $\varphi(\bar{x}) = \exists \bar{y} R_1 \wedge \dots \wedge R_k$, where each R_i is either $P_a(z)$ or $z \prec z'$, where z, z' are variables among \bar{x}, \bar{y} , and \prec is one of $\prec_{\text{ch}}, \prec_{\text{ch}}^*, \prec_{\text{ns}},$ or \prec_{ns}^* . We write $\text{CQ}(\prec_1, \dots, \prec_m)$ to denote the class of conjunctive queries over unranked trees in which only unary predicates P_a and binary predicates among \prec_i can be used.

Theorem 8. (see [27]) *The maximal tractable classes of queries $\text{CQ}(\prec_1, \dots, \prec_m)$, where all \prec_i 's are among $\{\prec_{\text{ch}}, \prec_{\text{ch}}^*, \prec_{\text{ns}}, \prec_{\text{ns}}^*\}$, are $\text{CQ}(\prec_{\text{ch}}, \prec_{\text{ns}}, \prec_{\text{ns}}^*)$ and $\text{CQ}(\prec_{\text{ch}}^*)$; all others are NP-hard.*

4 Unordered Trees

In unordered trees, nodes can still have arbitrarily many children, but the sibling ordering \prec_{ns} is no longer available. Logics considered for unordered unranked trees typically introduce some form of *counting*, see [3, 19, 20, 21, 40, 46, 51, 53, 54].

An explanation for this comes from a modified notion of automata for unordered unranked trees. A *counting nondeterministic unranked tree automaton* is a tuple $\mathcal{A}_c = (Q, F, \delta)$, where Q is a set of states, and $F \subseteq Q$ is a set of final states. Let V_Q be the set of variables $\{v_q^k \mid q \in Q, k > 0\}$. Then the transition function δ maps each pair $(q, a) \in Q \times \Sigma$ into a Boolean function over V_Q . A *run* of \mathcal{A} on an unordered tree T with domain D is a mapping $\rho_{\mathcal{A}} : D \rightarrow Q$ such that if $\rho_{\mathcal{A}}(s) = q$ for a node s labeled a , then the value of $\delta(q, a)$ is 1, where each variable v_q^k is set to 1 if s has at least k children s' with $\rho_{\mathcal{A}}(s') = q_i$, and to 0 otherwise. A run is accepting if $\rho_{\mathcal{A}}(\varepsilon) \in F$, and the set of unordered trees accepted by \mathcal{A}_c is denoted by $L_u(\mathcal{A}_c)$.

A *counting query automaton* \mathcal{QA}_c is defined as (Q, F, δ, S) where $S \subseteq Q \times \Sigma$; it selects nodes s in a run ρ where $(\rho_{\mathcal{A}}(s), \lambda_T(s)) \in S$. The following appears not to have been stated explicitly, although it follows easily from results in [41, 44, 53].

Theorem 9. *a) A set of unordered unranked trees is MSO-definable iff it is of the form $L_u(\mathcal{A}_c)$ for a counting nondeterministic unranked tree automaton \mathcal{A}_c .*

b) A unary query over unordered unranked trees is MSO-definable iff it is definable by a counting query automaton \mathcal{QA}_c .

MSO and FO Over Unordered Trees. Define the *counting μ -calculus* C_μ (cf. [32]) as an extension of L_μ with formulae $\diamond^{\geq k}(E)\varphi$. The semantics of $(T, s) \models \diamond^{\geq k}(E)\varphi$ is as follows: there exist distinct elements s_1, \dots, s_k such that $(s, s_i) \in E$ and $(T, s_i) \models \varphi$ for every $1 \leq i \leq k$. The next result follows from [60], as was noticed in [32]:

Theorem 10. *Over unordered unranked trees, MSO and $C_\mu[\prec_{\text{ch}}]$ have precisely the same power with respect to Boolean queries.*

For first-order logic, counting extensions of both the temporal logic TL^{tree} and CTL^* give us analogs of Kamp's and Hafer-Thomas's theorems. Define $\text{TL}_{\text{count}}^{\text{tree}}$ as a version of TL^{tree} in which only modalities for the child relation are used, but in addition we have formulae $\mathbf{X}_{\text{ch}}^k \varphi$, with the semantics that $(T, s) \models \mathbf{X}_{\text{ch}}^k \varphi$ iff there are at least k children s' of s such that $(T, s') \models \varphi$.

We also extend CTL^* to a logic $\text{CTL}_{\text{count}}^*$ in which we have new state formulae $\mathbf{EX}_{\text{ch}}^k \alpha$, where α is a state formula, with the same semantics as above.

Theorem 11. (see [40, 51]) *Over unordered unranked trees, the classes of Boolean queries expressed in FO, $\text{TL}_{\text{count}}^{\text{tree}}$, and $\text{CTL}_{\text{count}}^*$ over binary relation \prec_{ch} , are the same.*

For unary queries, the equivalence $\text{FO} = \text{TL}_{\text{count}}^{\text{tree}}$ still holds [51], and FO can be shown to be equivalent to an extension of CTL^* with both counting and the past [3].

Extensions and More Powerful Counting. Consider now a scenario in which we deal with unordered trees, but in our formulae we can refer to some arbitrary ordering on siblings: after all, in any encoding of a tree, siblings will come in some order. Of course

we do not want any particular order to affect the truth value, so we want our formulae, even if they use an ordering, to be independent of a particular ordering that was used.

This is the standard setting of *order-invariance*, an important concept in finite model theory, cf. [36]. We say that an MSO sentence φ over vocabulary including \prec_{ch}^* and \prec_{ns}^* is \prec_{ns} -invariant if for every unordered tree T and every two expansions $T^{\prec_{\text{ns}}^1}$ and $T^{\prec_{\text{ns}}^2}$ with sibling-orderings \prec_{ns}^1 and \prec_{ns}^2 we have $T^{\prec_{\text{ns}}^1} \models \varphi \Leftrightarrow T^{\prec_{\text{ns}}^2} \models \varphi$. A \prec_{ns} -invariant sentence defines a Boolean query on unordered trees.

We now define MSO_{mod} [19] as an extension of MSO with *modulo quantifiers*: for each set variable X , and $k > 1$, we have set new formulae $Q_k(X)$ which are true iff the cardinality of X is congruent to 0 modulo k .

Theorem 12. (see [20]) *Over unordered unranked trees, \prec_{ns} -invariant Boolean queries are precisely the Boolean queries definable in MSO_{mod} .*

Further extensions in terms of arithmetic power have been considered [53, 54]. Recall that Presburger arithmetic refers to the FO theory of the structure $\langle \mathbb{N}, + \rangle$. Define *Presburger MSO*, or *PMSO*, as an extension of MSO over unordered trees with the following rule: if $\varphi(\bar{x}, y, \bar{X})$ is a PMSO formula and $\alpha(\bar{v})$ a Presburger arithmetic formula with $|\bar{X}| = |\bar{v}| = n$, then $[\varphi/\alpha](\bar{x}, y, \bar{X})$ is a PMSO formula. Given valuation \bar{s}, s_0, \bar{S} for free variables, with $\bar{S} = (S_1, \dots, S_n)$, let m_i be the cardinality of $\{s' \mid s_0 \prec_{\text{ch}} s' \text{ and } s' \in S_i\}$. Then $[\varphi/\alpha](\bar{s}, s_0, \bar{S})$ is true iff $\alpha(m_1, \dots, m_n)$ is true.

It is easy to see that $\text{MSO} \subsetneq \text{MSO}_{\text{mod}} \subsetneq \text{PMSO}$ over unordered trees. Still, PMSO is captured by a decidable automaton model.

Define Presburger unordered tree automata just as counting automata except that δ maps pairs from $Q \times \Sigma$ into Presburger formulae over v_q , for $q \in Q$. We interpret v_q as the number of children in state q , and a transition is enabled if the corresponding Presburger formula is true in this interpretation.

Theorem 13. (see [53]) *Presburger unordered tree automata and PMSO are equivalent. Furthermore, both emptiness and universality are decidable for Presburger unordered tree automata.*

Further extensions with counting have been considered for fixed-point logics [54] and the μ -calculus with modulo-quantifiers [3].

Edge-Labeled Unordered Trees. There are several areas where edge-labeled trees play a prominent role, and traditionally logical formalisms have been designed for such data. For example, there are feature logics, used extensively in computational linguistics [15], or spatial logics used for describing networks and mobile agents [14]: in both cases one deals with unordered edge-labeled trees.

In the setting of feature trees, one has an infinite set of features \mathcal{F} , and in an unordered unranked tree every edge is labeled by an element $f \in \mathcal{F}$ such that each node s has at most one outgoing edge labeled f for each $f \in \mathcal{F}$. Furthermore, nodes may be labeled by elements of some alphabet Σ , as before. It is thus natural to model feature trees as structures $\langle D, (E_f)_{f \in \mathcal{F}}, (P_a)_{a \in \Sigma} \rangle$ such that the union of all E_f 's forms the child relation of a tree, and no node has two outgoing E_f -edges. In the context of computational linguistics, one commonly used [5] logic for feature trees is the propositional

modal logic that, in the context of feature structures (not necessarily trees), is also often supplemented with path-equivalence [50], as well as regular expressions [34].

Ambient logics are modal logics for trees that have been proposed in the context of mobile computation [14] and later adapted for tree-represented data [12, 13]. One views trees as edge-labeled and defines them by the grammar

$$T, T' := \Lambda \mid T|T' \mid a[T], a \in \Sigma,$$

with the equivalences that $|$ is commutative and associative, and that $T|\Lambda \equiv T$. Here Λ is the empty tree, $|$ is the parallel composition, and $a[T]$ adds an a -labeled edge on top of T . If we extend \equiv to a congruence in the natural way, then every tree is equivalent to one of the form $a_1[T_1]| \dots | a_m[T_m]$, which is viewed as a tree whose root has m outgoing edges labeled a_1, \dots, a_m , with subtrees rooted at its children being T_1, \dots, T_m .

There were several similar logics proposed in [11, 12, 13, 14, 21]. Here we consider the logic from [11] whose formulae are given by

$$\varphi, \varphi' := \perp \mid \Lambda \mid \varphi \wedge \varphi' \mid \neg\varphi \mid \varphi|\varphi' \mid \varphi \triangleright \varphi' \mid a[\varphi] \mid \varphi@a, \quad a \in \Sigma.$$

The semantics is as follows: \perp is *false*; Λ is only true in a tree equivalent to Λ , $T \models \varphi_1|\varphi_2$ iff $T \equiv T_1|T_2$ with $T_i \models \varphi_i$, $i = 1, 2$; $T \models \varphi \triangleright \varphi'$ if for every $T' \models \varphi$ we have $T|T' \models \varphi'$; $T \models a[\varphi]$ iff $T \equiv a[T']$ with $T' \models \varphi$, and $T \models \varphi@a$ iff $a[T] \models \varphi$.

The study of ambient logics for trees took a different path compared to other logics seen in this survey; in particular, the focus was on type systems for tree languages and thus on proof systems for logics, rather than model-checking, its complexity, automata models, and comparison with other logics.

However, the ambient logic above does not take us outside of the MSO expressiveness: this can be seen by going from edge-labeled trees to node-labeled ones. The translation is simple: the label of each edge (x, y) becomes the label of y . The root will have a special label *Root* that cannot occur as a label of any other node. The only modification in the logic is that now we have formulae Λ_a for $a \in \Sigma$, which are true in a singleton-tree labeled a . The resulting logic is easily translated into MSO. For example, $\varphi|\varphi'$ states that the children of the root can be partitioned into two sets, X and X' , such that the subtree that contains all the X -children satisfies φ and the subtree that contains all the X' -children satisfies φ' . For $\varphi \triangleright \varphi'$, one can consider $\neg(\varphi \triangleright \varphi')$ saying that there exists a tree T' such that $T' \models \varphi$ and $T|T' \models \neg\varphi'$, and use nondeterministic counting automata to guess this tree T' .

5 Automatic Structures

In this section we look at a different kind of logics for unranked trees, using the standard approach of model theory. Let $\text{TREE}(\Sigma)$ be the set of all Σ -labeled unranked trees. We consider structures of the form $\mathfrak{M} = \langle \text{TREE}(\Sigma), \Omega \rangle$ where Ω is a set of relation, constant, and function symbols.

Let $\text{Def}_n(\mathfrak{M})$ be the family of n -dimensional definable sets over \mathfrak{M} : that is, sets of the form $\{\bar{T} \in \text{TREE}(\Sigma)^n \mid \mathfrak{M} \models \varphi(\bar{T})\}$, where $\varphi(x_1, \dots, x_n)$ is an FO formula in the vocabulary Ω . We shall be looking at structures \mathfrak{M} so that definable sets would be

relations definable in MSO or other logics. In particular, such relations will be given by automata, and thus structures \mathfrak{M} of this kind are called *automatic structures*.

Following known automatic structures for strings [4, 6], we introduce several predicates on trees: the extension predicate, node tests, and domain equality. For two trees T_1 and T_2 with domains D_1 and D_2 , we say that T_2 is an *extension* of T_1 , written $T_1 \preceq T_2$, if $D_1 \subseteq D_2$, and the labeling function of T_2 agrees with the labeling function of T_1 on D_1 . It will actually be more convenient to work with two extension relations: extension on the right \preceq_{\rightarrow} , and extension down \preceq_{\downarrow} . For $T_1 \preceq_{\rightarrow} T_2$, we require that every $s \in D_2 - D_1$ be of the form $s' \cdot i$ when $s' \cdot j \in D_1$ for some $j < i$. For $T_1 \preceq_{\downarrow} T_2$, we require that every $s \in D_2 - D_1$ have a prefix s' which is a leaf of T_1 . Define L_a to be true in a tree T if the rightmost node is labeled a . Finally, $T_1 \approx_{\text{dom}} T_2$ iff $D_1 = D_2$.

Now we have the following structures:

$$\begin{aligned} \mathfrak{T}_{\text{univ}} &= \langle \text{TREE}(\Sigma), \preceq_{\rightarrow}, \preceq_{\downarrow}, (L_a)_{a \in \Sigma}, \approx_{\text{dom}} \rangle \\ \mathfrak{T} &= \langle \text{TREE}(\Sigma), \preceq_{\rightarrow}, \preceq_{\downarrow}, (L_a)_{a \in \Sigma} \rangle \end{aligned}$$

Theorem 14. (see [37]) *a) For every $n \geq 1$, $\text{Def}_n(\mathfrak{T}_{\text{univ}})$ is precisely the class of regular n -ary relations over $\text{TREE}(\Sigma)$.*

b) $\text{Def}_1(\mathfrak{T}) = \text{Def}_1(\mathfrak{T}_{\text{univ}})$ is the class of regular unranked tree languages, but for every $n > 1$, $\text{Def}_n(\mathfrak{T}) \subsetneq \text{Def}_n(\mathfrak{T}_{\text{univ}})$.

Working with $\mathfrak{T}_{\text{univ}}$ makes it easy to write rather complicated properties of tree languages, and then Theorem 14 implies that those languages are regular. For example, if $X \subseteq \text{TREE}(\Sigma)$ is regular, then the set of trees T such that all their extensions can be extended on the right to a tree in X is regular. Indeed, this is easy to write in FO over $\mathfrak{T}_{\text{univ}}$, if we have a membership test for X , which is definable by Theorem 14. Also, conversions from formulae to automata are effective for both \mathfrak{T} and $\mathfrak{T}_{\text{univ}}$, which implies decidability of their theories.

Other logics over unranked trees can be naturally represented over these structures: for example, Boolean FO queries are precisely sets of trees definable over \mathfrak{T} if quantification is restricted to single branches [37].

A Different View of Unranked Trees. We conclude by presenting a different view of unranked trees and a different structure for them that makes it easy to talk about their extensions in which new children may be inserted between existing ones. For example, if we have a tree T with domain $D = \{\varepsilon, 0, 1\}$, and we want to add more children of the root, they would have to be added on the right, e.g. we may have an extension with domain $\{\varepsilon, 0, 1, 2, 3\}$. But what if we want to add a child on the left of 0, and two children between 1 and 2? Intuitively, we need a new tree domain $\{\varepsilon, -1, 0, \frac{1}{3}, \frac{2}{3}, 1\}$ then. We now capture this situation and present a different automatic structure that makes it easy to derive that certain relations on trees are regular.

A *rational unranked tree domain* is a finite prefix-closed subset of \mathbb{Q}^* . Relation \prec_{ch}^* is defined for rational domains just as before, and relation \prec_{ns}^* is now given by $s \cdot r \prec_{\text{ns}}^* s' \cdot r'$ iff $r \leq r'$. Then an unranked tree T over a rational unranked tree domain is, as before, a structure $T = \langle D, \prec_{\text{ch}}^*, \prec_{\text{ns}}^*, (P_a)_{a \in \Sigma} \rangle$.

Let $\text{TREE}_{\mathbb{Q}}(\Sigma)$ be the set of all unranked trees with rational unranked tree domains. Note that different elements of $\text{TREE}_{\mathbb{Q}}(\Sigma)$ may be isomorphic as trees; we denote this isomorphism relation by \cong .

Define the extension relation \preceq over trees in $\text{TREE}_{\mathbb{Q}}(\Sigma)$ as before. A *branch* is a tree $T \in \text{TREE}_{\mathbb{Q}}(\Sigma)$ such that the set $\{T' \mid T' \preceq T\}$ is linearly ordered by \preceq . It follows from the definition of rational unranked tree domains that the domain of a branch consists of all the prefixes of some string $s \in \mathbb{Q}^*$. Let $L_a(T)$ be true iff T is a branch whose leaf is labeled a , and let $T_1 <_{\text{lex}} T_2$ be true iff T_1 and T_2 are branches with leaves s_1 and s_2 , and $s_1 <_{\text{lex}} s_2$. We then define the structure

$$\mathfrak{T}_{\text{univ}}^{\mathbb{Q}} = \langle \text{TREE}_{\mathbb{Q}}(\Sigma), \preceq, <_{\text{lex}}, \approx_{\text{dom}}, (L_a)_{a \in \Sigma} \rangle.$$

Proposition 4. *The structure $\mathfrak{T}_{\text{univ}}^{\mathbb{Q}}$ is interpretable in $\mathfrak{T}_{\text{univ}}$. Furthermore, there is a definable subset of the image of $\text{TREE}_{\mathbb{Q}}(\Sigma)$ that contains exactly one representative of each \cong -equivalence class.*

That is, under the mapping $\iota : \text{TREE}_{\mathbb{Q}}(\Sigma) / \cong \rightarrow \text{TREE}(\Sigma)$, definable sets over $\mathfrak{T}_{\text{univ}}^{\mathbb{Q}}$ become precisely the regular tree languages. Hence, expressing properties of unranked trees in first-order logic over $\mathfrak{T}_{\text{univ}}^{\mathbb{Q}}$ allows us to conclude easily that certain tree languages are regular, and thus MSO-definable.

6 Other Directions and Conclusions

We present very briefly some directions for future work (for more detailed discussion, see the full version).

Among problems that need to be addressed are the following: (a) How does one compare different logics over unranked trees? One way is in terms of their succinctness [29]. (b) Connection between ambient logics and other logics presented there is not yet adequately understood. (c) We do not know much about logics over string representations of trees (which occur naturally, for example, in streaming XML applications [52]). (d) Nor do we know much about handling data values which are present in XML trees. Some early results were reported in [45, 8], complemented recently by a nice decidability result that works on strings with data values [7].

Acknowledgments. I am grateful to Cristiana Chitic, Christoph Koch, Maarten Marx, Frank Neven, Joachim Niehren, Gerald Penn, Thomas Schwentick, and Luc Segoufin for their comments.

1 Introduction

Motivation-Framework. Apparently, it is in human's nature to act selfishly. Game Theory, founded by von Neumann and Morgenstern [39, 40], provides us with *strategic games*, an important mathematical model to describe and analyze such a selfish behavior and its resulting conflicts. In a strategic game, each of a finite set of players aims for an optimal value of its *private objective function* by choosing either a *pure* strategy (a single strategy) or a *mixed* strategy (a probability distribution over all pure strategies) from its *strategy set*. Strategic games in which the strategy sets are finite are called *finite strategic games*. Each player chooses its strategy once and for all, and all players' choices are made *non-cooperatively* and *simultaneously* (that is, when choosing a strategy each player is not informed of the strategies chosen by any other player). One of the basic assumption in strategic games is that the players act *rational*, that is, consistently in pursuit of their private objective function. For a concise introduction to contemporary Game Theory we recommend [25].

One of the most widely used solution concepts for strategic games is the concept of *Nash equilibrium*. It represents a stable state in which no player wishes to leave unilaterally its own strategy in order to improve the value of its private objective function. A Nash equilibrium is called *pure* if all players choose a pure strategy, otherwise *mixed*. Many algorithms have been developed to compute a Nash equilibrium (see [27] for an overview). Though the celebrated results of Nash [30, 31] ensure the existence of a mixed Nash equilibrium, the complexity to compute such a Nash equilibrium is widely unknown. Papadimitriou [32] advocates it to be "*the most important concrete open question on the boundary of \mathcal{P} today*".

Rosenthal [33] introduced a special class of strategic games, now widely known as *congestion games*. Here, the strategy set of each player is a subset of the power set of given *resources*. The players share a private objective function, defined as the sum (over their chosen resources) of functions in the *number* of players sharing this resource. In his seminal work, Rosenthal [33] showed with help of a *potential function* that con-

* This work has been partially supported by the DFG-SFB 376 and by the European Union within the 6th Framework Programme under contract 001907 (DELIS).

** International Graduate School of Dynamic Intelligent Systems.

gestion games (in sharp contrast to general strategic games) always admit at least one pure Nash equilibrium. Later, Milchtaich [28] considered two extensions of congestion games, namely *weighted congestion games* in which the players have *weights* and thus different influence on the congestion of the resources, and congestion games with *player-specific payoff-functions* in which the players do not share a private objective function.

Another class of (weighted) congestion games are (weighted) *network congestion games* [8, 11] in which the strategy sets correspond to paths in a network. Koutsoupias and Papadimitriou [21] considered a very simple member of this class, now known as *KP-model*. The network consists of a single *source* and a single *destination* which are connected by parallel *links*. Associated with each link is a *capacity* representing the rate at which the link processes *load*, that is, the total weight of players assigned to this link. Thus, the latency functions are linear. Each of the players selfishly routes from the source to the destination by choosing a probability distribution over the links. The private objective function of a player is defined as its expected latency.

Koutsoupias and Papadimitriou [21] were not only interested in the computational complexity of Nash equilibria but also in the degradation of the social welfare of the system due to the selfish behavior of the players. In order to measure this social welfare, they introduced a global objective function, usually coined as *social cost*, which is defined as the expected maximum latency on a link, where the expectation is taken over all random choices of the players. The *price of anarchy*, also called *coordination ratio*, measures the extent to which non-cooperation approximates cooperation. It is defined as the worst-case ratio between the value of social cost in a Nash equilibrium and that of some social optimum. So, the price of anarchy represents a rendezvous of Nash equilibrium, a concept fundamental to Game Theory, with approximation, an ubiquitous concept in Theoretical Computer Science today (see, e.g., [38]).

Mavronicolas and Spirakis [26] introduced the notion of a *fully mixed* Nash equilibrium in which each player chooses every link with positive probability. Gairing *et al.* [15] conjectured that, in case of its existence, the *fully mixed* Nash equilibrium is the worst Nash equilibrium with respect to social cost. This so-called *Fully Mixed Nash Equilibrium Conjecture* is simultaneously intuitive and natural. To support intuition, observe that the fully mixed Nash equilibrium favors collisions between different players (since each player assigns its item with positive probability to every link). This increased probability of collisions should favor an increase to social cost. To support significance, note that the Fully Mixed Nash Equilibrium Conjecture identifies the worst-case Nash equilibrium of *all* instances. We stress that, in sharp contrast, the price of anarchy only determines the worst-case Nash equilibrium of *worst-case* instances.

Recently, the KP-model was extended to *restricted strategy sets* [2, 13] where the strategy set of each player is a *subset* of the links. In addition, the KP-model was extended to general latency functions and studied with respect to different definitions of social cost [1, 14]. Inspired by the arisen interest in the price of anarchy, the much older *Wardrop-model* [3, 6, 41] was re-investigated [35, 36]. In this weighted network congestion game, weight can be split into arbitrary pieces. The social welfare of the system is defined as the sum of the edge latencies. An equilibrium in the Wardrop-model can be interpreted as a Nash equilibrium in a game with infinitely many players, each carrying

an infinitesimal amount of weight. Finally, the price of anarchy found its way into congestion games [4, 11].

In this paper, we give a thorough survey on the most exciting results on finite (weighted) congestion games and the special classes mentioned above. In particular, we review the findings on the existence and computational complexity of pure Nash equilibria. Furthermore, we discuss results on the price of anarchy. Last but not least, we survey known facts on fully mixed Nash equilibria.

Overview. The rest of this paper is organized as follows. After a formal definition of (weighted) congestion games in Section 2, we turn our attention to the existence and computational complexity of pure Nash equilibria in Section 3. In Section 4, we consider the price of anarchy before we investigate fully mixed Nash equilibria in Section 5. We conclude, in Section 6, with some open problems.

2 Definitions and Notations

For all integers $k \geq 0$, we denote $[k] = \{1, \dots, k\}$.

A *weighted congestion game* Γ is a tuple

$$\Gamma = (n, E, (w_i)_{i \in [n]}, (S_i)_{i \in [n]}, (f_e)_{e \in E}).$$

Here, n is the number of *players* and E is the finite set of *resources*. For every player $i \in [n]$, w_i is the *weight* and $S_i \subseteq 2^E$ is the *strategy set* of player i . Denote $W = \sum_{i \in [n]} w_i$ and $S = S_1 \times \dots \times S_n$. For every resource $e \in E$, the *latency function* $f_e : \mathbb{R}^+ \mapsto \mathbb{R}^+$ describes the *latency* on resource e .

In a *congestion game*, the weights of all players are equal. Thus, the private cost of a player only depends on the *number* of players choosing the same resources. A congestion game is *symmetric* if the players share a strategy set.

2.1 Strategies and Assignments

A *pure strategy* for player $i \in [n]$ is some specific $s_i \in S_i$ whereas a *mixed strategy* $P_i = (p(i, s_i))_{s \in S}$ is a probability distribution over S_i , where $p(i, s_i)$ denotes the probability that player i chooses the pure strategy s_i .

A *pure assignment* is an n -tuple $\mathbf{L} = (s_1, \dots, s_n) \in S$ whereas a *mixed assignment* $\mathbf{P} = (P_1, \dots, P_n)$ is represented by an n -tuple of mixed strategies. A mixed assignment is *fully mixed* if $p(i, s_i) > 0$ for all $i \in [n]$ and $s_i \in S_i$.

2.2 Private Cost

Fix any pure assignment \mathbf{L} , and denote by $l_e(\mathbf{L}) = \sum_{i \in [n], s \ni e} w_i$ the *load* on resource $e \in E$. The *private cost* of player $i \in [n]$ is defined by

$$\text{PC}_i(\mathbf{L}) = \sum_{e \in s} f_e(l_e(\mathbf{L})).$$

For a mixed assignment \mathbf{P} , the *private cost* of player $i \in [n]$ is

$$\text{PC}_i(\mathbf{P}) = \sum_{\mathbf{L} \in S} p(\mathbf{L}) \cdot \text{PC}_i(\mathbf{L}).$$

2.3 Social Cost

Associated with a weighted congestion game Γ and a mixed assignment \mathbf{P} is the *social cost* as a measure of social welfare. We consider the following three definitions of social cost:

- Sum of private costs $SC_{\text{SUM}}(\mathbf{P}) = \sum_{i \in [n]} PC_i(\mathbf{P})$
- Maximum of private costs $SC_{\text{MAX}}(\mathbf{P}) = \max_{i \in [n]} PC_i(\mathbf{P})$
- Expected maximum latency $SC_{\infty}(\mathbf{P}) = \sum_{\mathbf{L} \in S} p(\mathbf{L}) \cdot \max_{i \in [n]} PC_i(\mathbf{L})$

Let $*$ \in $\{\text{SUM}, \text{MAX}, \infty\}$. The *optimum* associated with a weighted congestion game is defined by $\text{OPT}_* = \min_{\mathbf{P}} SC_*(\mathbf{P})$.

2.4 Nash Equilibria and Price of Anarchy

We are interested in a special class of (mixed) assignments called Nash equilibria [30, 31] that we describe here. Given a weighted congestion game and an associated mixed assignment \mathbf{P} , a player $i \in [n]$ is *satisfied* if it can not improve its private cost by unilaterally changing its strategy. Otherwise, player i is *unsatisfied*. The mixed assignment \mathbf{P} is a *Nash equilibrium* if and only if all players $i \in [n]$ are satisfied. Depending on the type of assignment, we differ between *pure*, *mixed* and *fully mixed* Nash equilibria.

The *mixed price of anarchy*, also called *coordination ratio* and denoted $\text{PoA}_{\text{mixed}}$, is the maximum value, over all instances Γ and Nash equilibria \mathbf{P} , of the ratio $\frac{SC_*(\mathbf{P})}{\text{OPT}_*}$. If we restrict to pure Nash equilibria, then we speak of the *pure price of anarchy* and denote it by PoA_{pure} .

2.5 Selfish Steps

Fix any pure assignment \mathbf{L} . In a *selfish step*, exactly one unsatisfied player is allowed to change its pure strategy such that its private cost decreases. A selfish step is *greedy* if the player chooses its best strategy. Clearly, selfish steps define a neighborhood of pure assignments that can be reached from \mathbf{L} . The assignment \mathbf{L} has an empty neighborhood if and only if \mathbf{L} is a Nash equilibrium. Thus, a pure Nash equilibrium corresponds to a local optimum. This stresses the close relationship of selfish steps on the one hand and local search processes on the other hand.

2.6 Special Weighted Congestion Games

Weighted Network Congestion Games. In a *weighted network congestion game* the strategies of a player correspond to paths from a source to a destination in a network. Thus, this class of games can be interpreted as *routing games*. If the players share the same source and destination, then we have a weighted *single-commodity* network congestion game, otherwise a weighted *multi-commodity* network congestion game. The underlying network of a weighted single-commodity network congestion game is called *l-layered* if all paths from source to destination have length l .

KP-Model. Koutsoupias and Papadimitriou [21] considered a special weighted network congestion game, now widely known as the *KP-model*. In this model, each of the n players is allowed to use exactly one of m resources (here called *links*), that is, $S_i = [m]$ for all $i \in [n]$. The players are called *identical* if all weights are equal, otherwise *arbitrary*. Associated with each link $j \in [m]$ is a *capacity* c_j representing the rate at which link j processes *load*. Clearly, the latency on link j is $f_j(l_j) = \frac{l_j}{c_j}$, showing that the latency functions are linear. If c_1, \dots, c_m are equal, then the resources are *identical*, otherwise *related*. Denote $C = \sum_{j \in [m]} c_j$. In order to measure the social welfare of the system, Koutsoupias and Papadimitriou [21] considered the expected maximum latency.

A natural goal is to identify a Nash equilibrium with worst social cost for a given instance. For the model of related links, Gairing *et al.* [15] conjectured that, in case of its existence, the fully mixed Nash equilibrium is the worst Nash equilibrium with respect to social cost.

Fully Mixed Nash Equilibrium Conjecture ([15]). *Consider the model of arbitrary players and related links. Then, for any instance such that a fully mixed Nash equilibrium \mathbf{F} exists, and for any associated Nash equilibrium \mathbf{P} , $\text{SC}_\infty(\mathbf{P}) \leq \text{SC}_\infty(\mathbf{F})$.*

Routing Games on Parallel Links. We also consider variants of the KP-model to which we refer as *routing games on parallel links*. In particular, we investigate *restricted strategy sets* in which the players are only allowed to choose from a subset of links, that is, $S_i \subseteq [m]$ for all $i \in [n]$.

2.7 Exact Potential Games

A function $\Phi : (S_1 \times \dots \times S_n) \mapsto \mathbb{R}$ is an *exact potential function* for a game Γ if for every pure strategy profile $\mathbf{L} = (s_1, \dots, s_n)$, for every player $i \in [n]$ and for every strategy $s'_i \in S_i$, $\text{PC}_i(\mathbf{L}') - \text{PC}_i(\mathbf{L}) = \Phi(\mathbf{L}') - \Phi(\mathbf{L})$, where $\mathbf{L}' = (s_1, \dots, s_{i-1}, s'_i, s_{i+1}, \dots, s_n)$. In this case, Γ is an *exact potential game*. Since all exact potential games admit a pure Nash equilibrium (see e.g. [29]) these games are of interest in this paper.

3 Existence and Computation of Pure Nash Equilibria

Even though Nash was able to show that every finite game possesses a mixed Nash equilibrium, the question which class of games admits a pure Nash equilibrium remains open. In the case of its existence, it is of interest whether it is possible to compute a pure Nash equilibrium in polynomial time. In this section, we give some positive and some negative answers to both questions concerning the existence and the polynomial time computation. We start in Section 3.1 with routing games on parallel links and continue in Sections 3.2 and 3.3 with congestion games and weighted congestion games.

3.1 Routing Games on Parallel Links

We begin our survey with results on the KP-model. Afterwards we focus on games with restricted strategy sets.

KP-model. We first turn our attention to the problem of computing a pure Nash equilibrium. Basically, two different approaches can be found in the literature.

The first approach is to directly compute a pure Nash equilibrium. Fotakis *et al.* [10] showed that the LPT algorithm, first explored by Graham [16], yields some pure Nash equilibrium. Clearly, this holds for parallel links with *arbitrary non-decreasing* latency functions. For related links, the social cost of the Nash equilibrium computed by LPT approximates the social cost of an optimal assignment by a factor between 1.52 and 1.67 [12].

The second approach is to convert a given pure assignment into a Nash equilibrium without increasing the social cost. This conversion process is called *nashification*. Since selfish steps do not increase the social cost and any sequence of selfish steps eventually reaches a pure Nash equilibrium, selfish steps seem to be suitable for nashification. However, we have to use them carefully since the number of selfish steps may be exponential in the number of players before reaching a pure Nash equilibrium.

Theorem 1 ([7]). *Consider the model of arbitrary players and identical links. Then, there exists an instance and associated pure assignment for which the maximum length of a sequence of greedy selfish steps is at least*

$$\frac{\left(\frac{n}{m-1}\right)^{m-1}}{2(m-1)!}.$$

Though there exist sequences of greedy selfish steps of exponential length, it is possible to use selfish steps to compute a Nash equilibrium in polynomial time if the links are identical. In particular, always moving an unsatisfied player with maximum weight to its best link requires at most n greedy selfish steps [15]. For related links, it is unknown whether selfish steps can be used to implement nashification in polynomial time. Feldmann *et al.* [9] chose a different approach not only based on selfish steps. Their algorithm relies on the following crucial observation.

Lemma 1 ([9]). *Consider the model of arbitrary players and related links. Then, for any pure assignment, a greedy selfish step of an unsatisfied player $i_1 \in [n]$ with weight w_{i_1} from a link $j_1 \in [m]$ to a link $j_2 \in [m]$ with $c_{j_1} \leq c_{j_2}$ makes no satisfied player $i_2 \in [n]$ with weight $w_{i_2} \geq w_{i_1}$ unsatisfied.*

The algorithm of Feldmann *et al.* [9] works in two phases. In the first phase, it fills up links with small capacities with players with small weight as close to $SC_{\text{MAX}}(\mathbf{L})$ as possible (but without exceeding $SC_{\text{MAX}}(\mathbf{L})$), and it collects all these users in a set \mathcal{U} . In the second phase, the algorithm performs greedy selfish steps for unsatisfied players in \mathcal{U} in non-increasing order of the weights. Lemma 1 allows to show that this procedure results in a pure Nash equilibrium. Implementing the algorithm in a proper way, we get:

Theorem 2 ([9]). *Consider the model of arbitrary players and related links. Then, for any pure assignment \mathbf{L} , a pure Nash equilibrium \mathbf{L}' with $SC_{\infty}(\mathbf{L}') \leq SC_{\infty}(\mathbf{L})$ can be computed using $O(m^2n)$ time.*

Thus, we can apply the PTAS of Hochbaum and Shmoys [17] for scheduling *jobs* on related *machines* and then convert the computed assignment into a pure Nash equilibrium in polynomial time, and we get:

Corollary 1. *There is a PTAS for computing a best pure Nash equilibrium.*

Restricted Strategy Sets. Gairing *et al.* [13] considered a variant of the routing game on parallel links where there exists at least one player $i \in [n]$ with $S_i \subsetneq [m]$. So, the strategy sets of the players are *restricted*.

Gairing *et al.* [13] combined ideas from blocking flows and the generic PREFLOW-PUSH algorithm to derive a nashification algorithm for games with restricted strategy sets on identical links.

Theorem 3 ([13]). *Consider the model of arbitrary players with restricted strategy sets and identical links. Then, for any pure assignment \mathbf{L} , a pure Nash equilibrium \mathbf{L}' with $SC_\infty(\mathbf{L}') \leq SC_\infty(\mathbf{L})$ can be computed from \mathbf{L} using $O(rmA(\log W + m^2))$ time, where r is the number of distinct weights and $A = \sum_{i \in [n]} |S_i|$.*

Lenstra *et al.* [23] showed that an optimum assignment can be approximated within a factor of 2. It is worth mentioning that the nashification algorithm of Gairing *et al.* [13] improves this result since, for *any* given assignment \mathbf{L} , it computes a pure Nash equilibrium \mathbf{L}' with $SC_\infty(\mathbf{L}') \leq (2 - \frac{1}{w_1}) \cdot OPT_\infty$. Note that we can not hope to approximate an optimum assignment with factor less than $\frac{3}{2}$ unless $\mathcal{P} = \mathcal{NP}$ [23].

3.2 Congestion Games

In his seminal paper, Rosenthal [33] proved that $\Phi(\mathbf{L}) = \sum_{e \in E} \sum_{j=1}^l(\mathbf{L}) f_e(j)$ is an exact potential function for congestion games. An immediate consequence follows:

Theorem 4 ([33]). *Every congestion game possesses a pure Nash equilibrium.*

Rosenthal's argumentation implies that every congestion game is an exact potential game. A result by Monderer and Shapley [29] shows that every exact potential game is closely related to a congestion game.

Theorem 5 ([29]). *Every finite exact potential game is isomorphic to a congestion game.*

Since every congestion game Γ possesses a pure Nash equilibrium the natural question arises whether it is possible to compute a pure Nash equilibrium for Γ in polynomial time. It is easy to see that this computational problem is in *PLS*. The class *PLS* (polynomial-time local search) introduced in [19] consists of local search problems for which local optimality can be verified in polynomial time. Many local search problems were shown to be complete for this class (see e.g. [19, 22, 37]), including graph partitioning, weighted satisfiability and traveling salesman problems. For none of these *PLS*-complete problems an algorithm is known that is able to compute a local optimum in polynomial time.

Using a sophisticated *PLS-reduction* Fabrikant *et al.* [8] proved that the computation of a pure Nash equilibrium for symmetric congestion games and asymmetric network congestion games is *PLS*-complete (see Figure 1). However, they showed that it is possible to calculate a pure Nash equilibrium for a symmetric network congestion game in polynomial time by using a min-cost flow algorithm.

	Symmetric	Asymmetric
Congestion Games	PLS-complete	PLS-complete
Network Congestion Games	Polynomial time	PLS-complete

Fig. 1. Complexity of computing pure Nash equilibria in congestion games [8]

We now switch to the class of *congestion games with player-specific payoff-functions* introduced by Milchtaich [28]. Here, a player always selects exactly one resource, that is, $S_1 = \dots = S_n = E$. Furthermore, the private cost of a player $i \in [n]$ on a resource $e \in E$ is described by a load dependent non-increasing latency function $f_e^i : \mathbb{R}^+ \mapsto \mathbb{R}^+$ that may be different from the latency function f_e^j for another player $j \neq i$. Milchtaich [28] considered these games with respect to pure Nash equilibria and sequences of selfish step. He showed:

Theorem 6 ([28]). *Every congestion game with player-specific payoff-function possesses a pure Nash equilibrium.*

Theorem 7 ([28]). *There exists a finite congestion game with player-specific payoff-function that admits a cycle of selfish steps, that is, a sequence of selfish steps starting and ending in the same assignment.*

It follows from the last theorem that games with player-specific payoff-functions do not admit an exact potential function.

3.3 Weighted Congestion Games

In this section we deal with weighted congestion games where the players may have different weights. Fotakis *et al.* [11] showed that there are such games that possess no pure Nash equilibrium. Moreover, they were able to proof that there is a subclass of games for which the existence of pure Nash equilibria is guaranteed.

Theorem 8 ([11]). *There exist instances of weighted single-commodity network congestion games for which there is no pure Nash equilibrium.*

Theorem 9 ([11]). *For any weighted multi-commodity network congestion game with linear latency functions, at least one pure Nash equilibrium exists.*

4 Price of Anarchy

The *mixed price of anarchy*, also known as *coordination ratio*, has been defined in the seminal work by Koutsoupias and Papadimitriou [21] as a measure of the extent to which non-cooperation approximates cooperation. Recall that it is defined as the worst-case ratio between the value of social cost in a Nash equilibrium and that of a social

optimum. We present results on the pure and the mixed price of anarchy for routing games on parallel links in Section 4.1, for congestion games in Section 4.2, and for weighted congestion games in Section 4.3.

4.1 Routing Games on Parallel Links

We start with results on the KP-model. We then focus on the extension of this model to restricted strategy sets. Finally, we investigate routing games on parallel links with social cost defined as the sum of the private costs of the players.

KP-model. In the KP-model, latency functions are linear, social cost is defined as the expected maximum latency and the players may choose any link. For the case of identical links the pure price of anarchy is upper bounded by a constant. This does not hold for related links or mixed Nash equilibria. The bounds for mixed Nash equilibria are shown by first bounding the maximum expected load on a link and then applying a Hoeffding inequality [18]. All bounds are summarized in Figure 2.

	Pure Price of Anarchy	Mixed Price of Anarchy
Identical Links	$2 - \frac{2}{m+1}$ [15]	$\Theta\left(\frac{\log m}{\log \log m}\right)$ [5, 20]
Related Links	$\Theta\left(\frac{\log m}{\log \log m}\right)$ [5]	$\Theta\left(\frac{\log m}{\log \log \log m}\right)$ [5]

Fig. 2. Pure and mixed price of anarchy for the KP-model

Restricted Strategy Sets. In case of restricted strategy sets, even for identical links, the pure price of anarchy cannot be bounded by a constant. This also holds if the weights are identical. Figure 3 shows bounds on the pure price of anarchy. Note, that the bound for identical players and related links is only tight if $n = m$. Awerbuch *et al.* [2] further extended their result to mixed Nash equilibria.

Theorem 10 ([2]). Consider the model of arbitrary players with restricted strategy sets and identical links. Then,

$$\text{PoA}_{\text{mixed}} = \Theta\left(\frac{\log m}{\log \log \log m}\right).$$

	Identical Players	Arbitrary Players
Identical Links	$\Theta\left(\frac{\log m}{\log \log m}\right)$ [2, 13]	$\Theta\left(\frac{\log m}{\log \log m}\right)$ [2, 13]
Related Links	$O\left(\frac{\log n}{\log \log n}\right)$ [13]	$m - 1 \leq \text{PoA}_{\text{pure}} \leq m$ [13]

Fig. 3. Pure price of anarchy for the KP-model with restricted strategy sets

Social Cost as Sum of Private Costs. Gairing *et al.* [14] considered another routing game on parallel links. In contrast to the KP-model, social cost is defined as the sum of the private costs of the players. This good natured definition of social cost makes the analysis significantly simpler and allows the investigation of general non-decreasing non-constant latency functions. For identical players, Gairing *et al.* [14] carried over an upper bound on the pure price of anarchy from the Wardrop-model [35] to the discrete setting.

Proposition 1 ([14]). *Consider the model of identical players and arbitrary links with non-decreasing and non-constant latency functions. If $x f_j(x) \leq \alpha \sum_{t=1}^x f_j(t)$ for all $x \in [n]$ and $j \in [m]$, then for any pure Nash equilibrium \mathbf{L} , $SC_{\text{SUM}}(\mathbf{L}) \leq \alpha \cdot \text{OPT}_{\text{SUM}}$.*

Corollary 2 ([14]). *Consider the model of identical players and arbitrary links. If the latency functions are polynomials with non-negative coefficients and maximum degree d , then the pure price of anarchy is bounded by $d + 1$.*

In case that all links have the same latency function $f(x) = x^d$, one can show the following bound on the mixed price of anarchy. B_k is the k 'th Bell number and counts the number of ways that a set of k elements can be partitioned into non-empty subsets.

Theorem 11 ([14]). *Consider the model of identical players and identical links with latency function $f(x) = x^d$, $d \in \mathbb{N}$. Then,*

$$\sup_{\mathbf{w}, \mathbf{P}} \frac{SC_{\text{SUM}}(\mathbf{P})}{\text{OPT}_{\text{SUM}}} = B_{d+1} .$$

4.2 Congestion Games

Recently, the pure price of anarchy found its way into congestion games [1, 4]. We restrict to results of Christodoulou and Koutsoupias [4] since only the abstract of the paper of Awerbuch *et al.* [1] was available (note that the latter paper also considers *weighted* congestion games). For congestion games with linear latency functions, Figure 4 summarizes results (both upper and lower bounds) on the pure price of anarchy. For the case of symmetric congestion games and social cost as the maximum of the private costs there is still a gap between the upper and the lower bound.

Christodoulou and Koutsoupias [4] also considered polynomial latency functions of degree d with non-negative coefficients. Figure 5 shows the corresponding bounds.

Both linear and polynomial latency functions were also considered in the Wardrop-model. Recall that in this model the social welfare of the system is defined as the sum

	SC_{SUM}	SC_{MAX}
Symmetric	$\frac{5n-2}{2n+1}$	$\frac{5n-2}{2n+1} \leq \text{PoA}_{\text{pure}} \leq \frac{5}{2}$
Asymmetric	$\frac{5}{2}$	$\Theta(\sqrt{n})$

Fig. 4. Pure price of anarchy for congestion games with linear latency functions [4]

	SC _{SUM}	SC _{MAX}
Symmetric	$d^{\Theta(d)}$	$d^{\Theta(d)}$
Asymmetric	$d^{\Theta(d)}$	$\Omega(n^{d/(d+1)}), O(n)$

Fig. 5. Pure price of anarchy for congestion games with polynomial latency functions [4]

of the edge latencies. The pure price of anarchy for linear latency functions is $\frac{4}{3}$ [35] whereas the pure price of anarchy for polynomial latency functions of degree d turned out to be $\Theta(\frac{d}{\log d})$ [34].

4.3 Weighted Congestion Games

The mixed price of anarchy was also studied in weighted congestion games. Fotakis *et al.* [11] considered l -layered networks with identical edges each having the same linear latency function and social cost defined as the expected maximum latency.

Theorem 12 ([11]). *For weighted l -layered network congestion games with latency function $f_e(x) = x$ for all $e \in E$, the mixed price of anarchy for social cost as expected maximum latency is $O\left(\frac{\log m}{\log \log m}\right)$.*

This result is particularly interesting in comparison with the corresponding bound for the parallel link network (see Figure 2). It shows that under all l -layered networks the parallel link network has worst mixed price of anarchy.

5 Fully Mixed Nash Equilibria for Routing Games on Parallel Links

In routing games on parallel links, a *fully mixed* Nash equilibrium is a special Nash equilibrium, where each player chooses each link with strictly positive probability. Such a Nash equilibrium does not always exist. In this section, we give a characterization of instances with a fully mixed Nash equilibrium, we show its uniqueness and we study the Fully Mixed Nash Equilibrium Conjecture. We do this for two different routing games on parallel links. We would like to point out that there exist routing games on parallel links for which the Fully Mixed Nash Equilibrium Conjecture was disproved [24].

KP-model. Mavronicolas and Spirakis [26] were the first to consider fully mixed Nash equilibria. They showed for the KP-model, that if a fully mixed Nash equilibrium exists, it is unique and can be easily computed.

Theorem 13 ([26]). *Consider the model of arbitrary players and related links. Then, there exists a fully mixed Nash equilibrium \mathbf{F} if and only if*

$$f_{ij} = \left(1 - \frac{mc_j}{C}\right) \cdot \left(1 - \frac{W}{(n-1)w_i}\right) + \frac{c_j}{C} \in (0, 1)$$

for all $i \in [n]$ and $j \in [m]$. If \mathbf{F} exists, then \mathbf{F} is unique and $\mathbf{F} = (f_{ij})_{i \in [n], j \in [m]}$.

In particular, this implies that for the case of identical links the fully mixed Nash equilibrium uniquely exists and has probabilities $f_{ij} = \frac{1}{m}, \forall i \in [n], j \in [m]$.

In [15], the Fully Mixed Nash Equilibrium Conjecture was first explicitly stated for the KP-model, where social cost is defined as the expected maximum latency. Here, the ultimate settlement of this conjecture would reveal an interesting complexity-theoretical contrast between the worst-case pure and the worst-case mixed Nash equilibria. On the one hand, if the conjecture is valid, then the identification of the worst-case mixed Nash equilibrium is immediate in the cases where the fully mixed Nash equilibrium exists. On the other hand, Gairing *et al.* [15] showed that the worst-case pure Nash equilibrium is not $(2 - \frac{2}{m+1} - \varepsilon)$ -approximable even on identical links.

Theorem 14 ([15]). *Consider the model of arbitrary players and identical links. If, for any ε with $0 < \varepsilon \leq 1 - \frac{2}{m+1}$, the worst-case pure Nash equilibrium is $(2 - \frac{2}{m+1} - \varepsilon)$ -approximable, then $\mathcal{P} = \mathcal{NP}$.*

This result also unfolds an interesting contrast between best and worst-case pure Nash equilibria. For any $\varepsilon > 0$, a pure Nash equilibrium \mathbf{L} with $\text{SC}_\infty(\mathbf{L}) \leq (1 + \varepsilon) \cdot \text{OPT}_\infty$ can be computed in polynomial time whereas the computation of a pure Nash equilibrium \mathbf{L}' with $\text{SC}_\infty(\mathbf{L}') \geq (1 + \varepsilon) \cdot \text{OPT}_\infty$ is \mathcal{NP} -hard.

So far, the Fully Mixed Nash Equilibrium Conjecture has been proved only for some special cases, namely, two players on identical links [15], two identical players on related links and identical players on two identical links [24]. Furthermore, it was shown up to a factor of 49.02 in case of identical players and related links [10] and up to a factor of $2h(1 + \varepsilon)$ for arbitrary players on identical links, if $n = m$ sufficient large [15], where h is the factor between the maximum and the average weight of the players.

On the other hand, Gairing *et al.* [15] proved that the private costs of all players in a Nash equilibrium are upper bounded by their private costs in the fully mixed Nash equilibrium. This directly implies:

Theorem 15 ([15]). *Consider the model of arbitrary players and related links. If the fully mixed Nash equilibrium \mathbf{F} exists, then, for any mixed Nash equilibrium \mathbf{P} , we have $\text{SC}_{\text{SUM}}(\mathbf{P}) \leq \text{SC}_{\text{SUM}}(\mathbf{F})$ and $\text{SC}_{\text{MAX}}(\mathbf{P}) \leq \text{SC}_{\text{MAX}}(\mathbf{F})$.*

Social Cost as Sum of Private Costs. Fully mixed Nash equilibria were also considered for identical players and general non-decreasing and non-constant latency functions with respect to social cost defined as the sum of the private costs [14]. In order to characterize instances where the fully mixed Nash equilibrium exists, Gairing *et al.* [14] introduced two classes of links, namely *dead links* and *special links*. They showed that in any Nash equilibrium, none of the players is assigned to a dead link. Moreover, there exists at most one player who is assigned to any of the special links. Availing these results, they could give the following thorough characterization.

Theorem 16 ([14]). *Consider the model of identical players and links with non-decreasing and non-constant latency functions. Then, there exists a fully mixed Nash equilibrium \mathbf{F} if and only if there are no special and no dead links. If \mathbf{F} exists then \mathbf{F} is unique.*

For every instance define the *generalized fully mixed Nash equilibrium* as the fully mixed Nash equilibrium for the instance where the links are restricted to non-special and non-dead links. If latency functions are non-decreasing, non-constant and *convex*, then one can show, that the private cost of each player in a Nash equilibrium is upper bounded by its private cost in the generalized fully mixed Nash equilibrium. This directly implies:

Theorem 17 ([14]). *Consider the model of identical players and links with non-decreasing, non-constant and convex latency functions. Then, for any Nash equilibrium \mathbf{P} and generalized fully mixed Nash equilibrium \mathbf{F} , $SC_{\text{SUM}}(\mathbf{P}) \leq SC_{\text{SUM}}(\mathbf{F})$ and $SC_{\text{MAX}}(\mathbf{P}) \leq SC_{\text{MAX}}(\mathbf{F})$.*

6 Open Problems

The flourishing interest in weighted congestion games resulted in a multitude of results and methods, but raised even more questions remaining tantalizingly open. We only state some of them:

- Although the results of Nash [30, 31] guarantee the existence of a Nash equilibrium in strategic games, the computational complexity of computing a Nash equilibrium is open even if only two players are involved.
- Which classes of symmetric weighted network congestions games possess a pure Nash equilibrium? For which classes is it possible to compute such a pure Nash equilibrium in polynomial time?
- It is impossible to approximate a worst-case pure Nash equilibrium within a factor better than $2 - \frac{2}{m+1}$ in the KP-model with identical links [15]. To which extent is it possible to approximate a worst-case pure Nash equilibrium in the KP-model with related links or in more general settings?
- Most of the known bounds on the price of anarchy for network congestion games were shown with respect to social cost defined as sum or maximum of the private costs of the players [1, 4]. What is the price of anarchy if social cost is defined as expected maximum latency?
- For the KP-model, Gairing *et al.* [15] showed that the private costs of all players in a Nash equilibrium are bounded from above by their private costs in the fully mixed Nash equilibrium. For which classes of network congestion games does this property still hold?
- If the players are identical and the links are related, then the Fully Mixed Nash Equilibrium Conjecture holds up to a factor of $2h(1 + \varepsilon)$, where h is the factor between the maximum and the average weight of the players [15]. Does there exist an approximation factor independent of h ?

Abstract. Given two rooted, ordered, and labeled trees P and T the tree inclusion problem is to determine if P can be obtained from T by deleting nodes in T . This problem has recently been recognized as an important query primitive in XML databases. Kilpeläinen and Mannila (SIAM J. of Comp. 1995) presented the first polynomial time algorithm using quadratic time and space. Since then several improved results have been obtained for special cases when P and T have a small number of leaves or small depth. However, in the worst case these algorithms still use quadratic time and space. In this paper we present a new approach to the problem which leads to a new algorithm which uses optimal linear space and has subquadratic running time. Our algorithm improves all previous time and space bounds. Most importantly, the space is improved by a linear factor. This will make it possible to query larger XML databases and speed up the query time since more of the computation can be kept in main memory.

1 Introduction

Let T be a rooted tree. We say that T is *labeled* if each node is assigned a symbol from an alphabet Σ and we say that T is *ordered* if a left-to-right order among siblings in T is given. All trees in this paper are rooted, ordered, and labeled. A tree P is *included* in T , denoted $P \sqsubseteq T$, if P can be obtained from T by deleting nodes of T . Deleting a node v in T means making the children of v children of the parent of v and then removing v . The children are inserted in the place of v in the left-to-right order among the siblings of v . The *tree inclusion problem* is to determine if P can be included in T and if so report all subtrees of T that include P .

Recently, the problem has been recognized as an important query primitive for XML data and has received considerable attention, see e.g., [15, 16, 18, 17]. The key idea is that an XML document can be viewed as an ordered, labeled

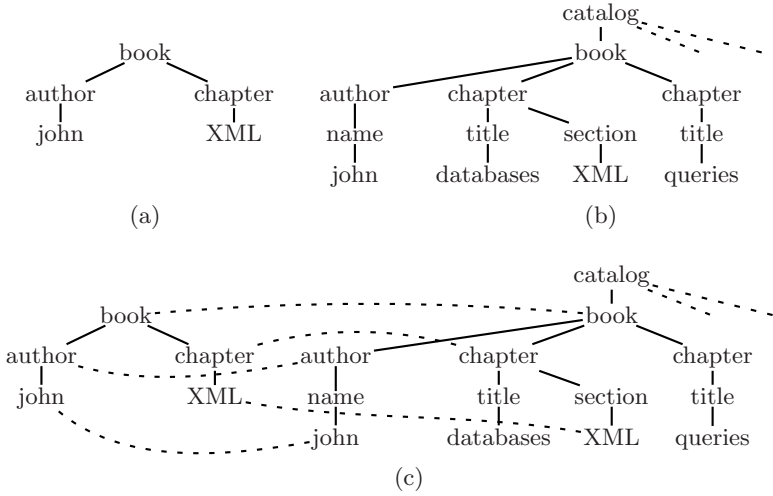

Fig. 1. Can tree (a) be included in tree (b)? Yes. The embedding is given in (c)

tree and queries on this tree correspond to a tree inclusion problem. As an example consider Fig. 1. Suppose that we want to maintain a catalog of books for a bookstore. A fragment of the tree, denoted D , corresponding to the catalog is shown in (b). In addition to supporting full-text queries, such as find all documents containing the word "John", we can also utilize the tree structure of the catalog to ask more specific queries, such as "find all books written by John with a chapter that has something to do with XML". We can model this query by constructing the tree, denoted Q , shown in (a) and solve the tree inclusion problem: is $Q \sqsubseteq D$? The answer is yes and a possible way to include Q in D is indicated by the dashed lines in (c). If we delete all the nodes in D not touched by dashed lines the trees Q and D become isomorphic. Such a mapping of the nodes from Q to D given by the dashed lines is called an *embedding* (formally defined in Sec. 3).

The tree inclusion problem was initially introduced by Knuth [11–exercise 2.3.2-22] who gave a sufficient condition for testing inclusion. Motivated by applications in structured databases [9, 12] Kilpeläinen and Mannila [10] presented the first polynomial time algorithm using $O(n_P n_T)$ time and space, where n_P and n_T is the number of nodes in a tree P and T , respectively. During the last decade several improvements of the original algorithm of [10] have been suggested [8, 1, 14, 4]. The previously best known bound is due to Chen [4] who presented an algorithm using $O(l_P n_T)$ time and $O(l_P \min\{d_T, l_T\})$ space. Here, l_S and d_S denotes the number of leaves of and the maximum depth of a tree S , respectively. This algorithm is based on an algorithm of Kilpeläinen [8]. Note that the time and space is still $\Theta(n_P n_T)$ for worst-case input trees.

In this paper we improve all of the previously known time and space bounds. Combining the three algorithms presented in this paper we have:

Theorem 1. *For trees T and P the tree inclusion problem can be solved in $O(\min(\frac{n \cdot n}{\log n}, l_P n_T, n_P l_T \log \log n_T))$ time using optimal $O(n_T + n_P)$ space.*

Hence, for worst-case input this improves the previous time and space bounds by a logarithmic and linear factor, respectively. When P has a small number of leaves the running time of our algorithm matches the previously best known time bound of [4] while maintaining linear space. In the context of XML databases the most important feature of our algorithms is the space usage. This will make it possible to query larger trees and speed up the query time since more of the computation can be kept in main memory.

Techniques. Most of the previous algorithms, including the best one [4], are essentially based on a simple dynamic programming approach from the original algorithm of [10]. The main idea behind this algorithm is following: Let $v \in V(P)$ and $w \in V(T)$ be nodes with children v_1, \dots, v_i and w_1, \dots, w_j , respectively. To decide if $P(v)$ can be included $T(w)$ we try to find a sequence of numbers $1 \leq x_1 < x_2 < \dots < x_i \leq j$ such that $P(v_k)$ can be included in $T(w_{x_k})$ for all k , $1 \leq k \leq i$. If we have already determined whether or not $P(v_s) \subseteq T(w_t)$, for all s and t , $1 \leq s \leq i$, $1 \leq t \leq j$, we can efficiently find such a sequence by scanning the children of v from left to right. Hence, applying this approach in a bottom-up fashion we can determine, if $P(v) \subseteq T(w)$, for all pairs $(v, w) \in V(P) \times V(T)$.

In this paper we take a significantly different approach. The main idea is to construct a data structure on T supporting a small number of procedures, called the *set procedures*, on subsets of nodes of T . We show that any such data structure implies an algorithm for the tree inclusion problem. We consider various implementations of this data structure which all use linear space. The first simple implementation gives an algorithm with $O(l_P n_T)$ running time. As it turns out, the running time depends on a well-studied problem known as the *tree color problem*. We show a general connection between data structures for the tree color problem and the tree inclusion problem. Plugging in a data structure of Dietz [5] we obtain an algorithm with $O(n_P l_T \log \log n_T)$ running time.

Based on the simple algorithms above we show how to improve the worst-case running time of the set procedures by a logarithmic factor. The general idea used to achieve this is to divide T into small trees or forests, called *micro trees* or *clusters* of logarithmic size which overlap with other micro trees in at most 2 nodes. Each micro tree is represented by a constant number of nodes in a *macro tree*. The nodes in the macro tree are then connected according to the overlap of the micro trees they represent. We can efficiently preprocess the micro trees and the macro tree such that the set procedures use constant time for each micro tree. Hence, the worst-case running time is improved by a logarithmic factor to $O(\frac{n \cdot n}{\log n})$.

Our results rely on a standard RAM model of computation with word size $\Theta(\log n)$. We use a standard instruction set such as bitwise boolean operations, shifts, and addition. Most of the proofs are omitted due to lack of space. They can be found in the full version of the paper [3].

2 Notation and Definitions

In this section we define the notation and definitions we will use throughout the paper. For a graph G we denote the set of nodes and edges by $V(G)$ and $E(G)$, respectively. Let T be a rooted tree. The root of T is denoted by $\text{root}(T)$. The *size* of T , denoted by n_T , is $|V(T)|$. The *depth* of a node $v \in V(T)$, $\text{depth}(v)$, is the number of edges on the path from v to $\text{root}(T)$ and the depth of T , denoted d_T , is the maximum depth of any node in T . The set of children of a node v is denoted $\text{child}(v)$. A node with no children is a leaf and otherwise an internal node. The set of leaves of T is denoted $L(T)$ and we define $l_T = |L(T)|$. We say that T is *labeled* if each node v is assigned a symbol, denoted $\text{label}(v)$, from an alphabet Σ and we say that T is *ordered* if a left-to-right order among siblings in T is given. All trees in this paper are rooted, ordered, and labeled.

Let $T(v)$ denote the subtree of T rooted at a node $v \in V(T)$. If $w \in V(T(v))$ then v is an ancestor of w , denoted $v \preceq w$, and if $w \in V(T(v)) \setminus \{v\}$ then v is a proper ancestor of w , denoted $v \prec w$. If v is a (proper) ancestor of w then w is a (proper) descendant of v . A node z is a common ancestor of v and w if it is an ancestor of both v and w . The nearest common ancestor of v and w , $\text{nca}(v, w)$, is the common ancestor of v and w of largest depth. The *first ancestor of w labeled α* , denoted $\text{fl}(w, \alpha)$, is the node v such that $v \preceq w$, $\text{label}(v) = \alpha$, and no node on the path between v and w is labeled α . If no such node exists then $\text{fl}(w, \alpha) = \perp$, where $\perp \notin V(T)$ is a special *null node*.

For any set of pairs U , let $U|_1$ and $U|_2$ denote the *projection* of U to the first and second coordinate, that is, if $(u_1, u_2) \in U$ then $u_1 \in U|_1$ and $u_2 \in U|_2$.

Lists. A *list*, X , is a finite sequence of objects $X = [v_1, \dots, v_k]$. The *length* of the list, denoted $|X|$, is the number of objects in X . The i th element of X , $X[i]$, $1 \leq i \leq |X|$ is the object v_i and $v \in X$ iff $v = X[j]$ for some $1 \leq j \leq |X|$. For any two lists $X = [v_1, \dots, v_k]$ and $Y = [w_1, \dots, w_k]$, the list obtained by *appending* Y to X is the list $X \circ Y = [v_1, \dots, v_k, w_1, \dots, w_k]$. We extend this notation such that for any object u , $X \circ u$ denotes the list $X \circ [u]$. For simplicity in the notation we will sometimes write $[v_i \mid 1 \leq i \leq k]$ to denote the list $[v_1, \dots, v_k]$. A *pair list* is a list of pairs of object $Y = [(v_1, w_1), \dots, (v_k, w_k)]$. Here the first and second element in the pair is denoted by $Y[i]_1 = v_i$ and $Y[i]_2 = w_i$. The projection of pair lists is defined by $Y|_1 = [v_1, \dots, v_k]$ and $Y|_2 = [w_1, \dots, w_k]$.

Orderings. Let T be a tree with root v and let v_1, \dots, v_k be the children of v from left-to-right. The *preorder traversal* of T is obtained by visiting v and then recursively visiting $T(v_i)$, $1 \leq i \leq k$, in order. Similarly, the *postorder traversal* is obtained by first visiting $T(v_i)$, $1 \leq i \leq k$, and then v . The *preorder number* and *postorder number* of a node $w \in T(v)$, denoted by $\text{pre}(w)$ and $\text{post}(w)$, is the number of nodes preceding w in the preorder and postorder traversal of T , respectively. The nodes to the *left* of w in T is the set of nodes $u \in V(T)$ such that $\text{pre}(u) < \text{pre}(w)$ and $\text{post}(u) < \text{post}(w)$. If u is to the left of w , denoted by $u \triangleleft w$, then w is to the *right* of u . If $u \triangleleft w$, $u \preceq w$, or $w \prec u$ we write $u \preceq w$. The null node \perp is not in the ordering, i.e., $\perp \not\triangleleft v$ for all nodes v .

Fig. 2. In (a) we have $\text{mop}(S_1, S_2, S_1, S_3, S_4) = \{(v_3, v_7)\}$ and in (b) we have $\text{mop}(S_1, S_2, S_1, S_3, S_4) = \{(v_1, v_7), (v_3, v_9)\}$

Deep Sets. A set of nodes $V \subseteq V(T)$ is *deep* iff no node in V is a proper ancestor of another node in V .

Minimum Ordered Pair. For deep sets of nodes V_1, \dots, V_k let $\Phi(V_1, \dots, V_k) \subseteq (V_1 \times \dots \times V_k)$, be the set such that $(v_1, \dots, v_k) \in \Phi(V_1, \dots, V_k)$ iff $v_1 \triangleleft \dots \triangleleft v_k$. If $(v_1, \dots, v_k) \in \Phi(V_1, \dots, V_k)$ and there is no $(v'_1, \dots, v'_k) \in \Phi(V_1, \dots, V_k)$, where either $v_1 \triangleleft v'_1 \triangleleft v'_k \trianglelefteq v_k$ or $v_1 \trianglelefteq v'_1 \triangleleft v'_k \triangleleft v_k$ then the pair (v_1, v_k) is a *minimum ordered pair*. The set of minimum ordered pairs for V_1, \dots, V_k is denoted by $\text{mop}(V_1, \dots, V_k)$. Fig. 2 illustrates mop on a small example. The following lemma shows that we can compute $\text{mop}(V_1, \dots, V_k)$ iteratively by first computing $\text{mop}(V_1, V_2)$ and then $\text{mop}(\text{mop}(V_1, V_2)|_2, V_3)$ and so on.

Lemma 1. *For any deep sets of nodes $V_1, \dots, V_k: (v_1, v_k) \in \text{mop}(V_1, \dots, V_k)$ iff there exists a v_{k-1} such that $(v_1, v_{k-1}) \in \text{mop}(V_1, \dots, V_{k-1})$ and $(v_{k-1}, v_k) \in \text{mop}(\text{mop}(V_1, \dots, V_{k-1})|_2, V_k)$.*

3 Computing Deep Embeddings

In this section we present a general framework for answering tree inclusion queries. As in [10] we solve the equivalent *tree embedding problem*. Let P and T be rooted labeled trees. An *embedding* of P in T is an injective function $f : V(P) \rightarrow V(T)$ such that for all nodes $v, u \in V(P)$,

- (i) $\text{label}(v) = \text{label}(f(v))$. (label preservation condition)
- (ii) $v \prec u$ iff $f(v) \prec f(u)$. (ancestor condition)
- (iii) $v \triangleleft u$ iff $f(v) \triangleleft f(u)$. (order condition)

Lemma 2 ([10]). *For any trees P and T , $P \sqsubseteq T$ iff there exists an embedding of P in T .*

An example of an embedding is given in Fig. 1(c). We say that the embedding f is *deep* if there is no embedding g such that $f(\text{root}(P)) \prec g(\text{root}(P))$. The *deep occurrences* of P in T , denoted $\text{emb}(P, T)$ is the set of nodes,

$$\text{emb}(P, T) = \{f(\text{root}(P)) \mid f \text{ is a deep embedding of } P \text{ in } T\}.$$

Note that $\text{emb}(P, T)$ must be a deep set in T . Furthermore, by definition the set of ancestors of nodes in $\text{emb}(P, T)$ is the set of subtrees $T(u)$ such that $P \sqsubseteq T(u)$. Hence, to solve the tree inclusion problem it is sufficient to compute $\text{emb}(P, T)$ and then, using additional $O(n_T)$ time, report all ancestors (if any) of this set.

The key idea in our algorithm for computing deep embeddings is to construct a data structure that allows a fast implementation of the following procedures, called the *set procedures*. For all $V \subseteq V(T)$, $U \subseteq V(T) \times V(T)$, $\alpha \in \Sigma$ define:

- PARENT $_T(V)$. Return the set $R := \{\text{parent}(v) \mid v \in V\}$.
- NCA $_T(U)$. Return the set $R := \{\text{nca}(u_1, u_2) \mid (u_1, u_2) \in U\}$.
- DEEP $_T(V)$. Return the set $R := \{v \in V \mid \nexists w \in V \text{ such that } v \prec w\}$.
- MOP $_T(U, V)$. Return the set of pairs R such that for any pair $(u_1, u_2) \in U$, $(u_1, v) \in R$ iff $(u_2, v) \in \text{mop}(U|_2, V)$.
- FL $_T(V, \alpha)$. Return the set $R := \{\text{fl}(v, \alpha) \mid v \in V\}$.

With the set procedures we can compute deep embeddings. The following procedure $\text{EMB}_T(v)$, $v \in V(P)$, recursively computes the set of deep occurrences of $P(v)$ in T . Fig. 3 illustrates how EMB works on a small example.

$\text{EMB}_T(v)$ Let v_1, \dots, v_k be the sequence of children of v ordered from left to right. There are three cases:

1. $k = 0$ (v is a leaf). Set $R := \text{DEEP}_T(\text{FL}_T(L(T), \text{label}(v)))$.
2. $k = 1$. Recursively compute $R_1 := \text{EMB}_T(v_1)$.
Set $R := \text{DEEP}_T(\text{FL}_T(\text{DEEP}_T(\text{PARENT}_T(R_1)), \text{label}(v)))$.
3. $k > 1$. Compute $R_1 := \text{EMB}_T(v_1)$ and $U_1 := \{(r, r) \mid r \in R_1\}$. For i , $1 \leq i \leq k$, compute $R_i := \text{EMB}_T(v_i)$ and $U_i := \text{MOP}_T(U_{i-1}, R_i)$.
Finally, compute $R := \text{DEEP}_T(\text{FL}_T(\text{DEEP}_T(\text{NCA}_T(U_k)), \text{label}(v)))$.

If $R = \emptyset$ stop and report that there is no deep embedding of $P(v)$ in T .
Otherwise return R .

Lemma 3. *For any two trees T and P , $\text{EMB}_T(v)$ computes the set of deep occurrences of $P(v)$ in T .*

Proof. By induction on the size of the subtree $P(v)$. If v is a leaf we immediately have $\text{emb}(v, T) = \text{DEEP}_T(\text{FL}_T(L(T), \text{label}(v)))$. Suppose that v is an internal node with children v_1, \dots, v_k , $k \geq 1$. We show that $\text{emb}(P(v), T) = \text{EMB}_T(v)$.

If $k = 1$, $w \in \text{EMB}_T(v)$ implies $\text{label}(w) = \text{label}(v)$ and there is a node $w_1 \in \text{EMB}_T(v_1)$ such that $\text{fl}(\text{parent}(w_1), \text{label}(v)) = w$, i.e., no node on the path between w_1 and w is labeled $\text{label}(v)$. By induction $\text{EMB}_T(v_1) = \text{emb}(P(v_1), T)$ and thus w is the root of an embedding of $P(v)$ in T . Since $\text{EMB}_T(v)$ is the deep set of all such nodes we have $w \in \text{emb}(P(v), T)$. Conversely, if $w \in \text{emb}(P(v), T)$ then $\text{label}(w) = \text{label}(v)$, there is a node $w_1 \in \text{emb}(P(v_1), T)$ such that $w \prec w_1$, and no node on the path between w and w_1 is labeled $\text{label}(v)$, that is, $\text{fl}(w_1, \text{label}(v)) = w$. Hence, $w \in \text{EMB}_T(v)$.

Fig. 3. Computing the deep occurrences of P into T depicted in (a) and (b) respectively. The nodes in P are numbered 1–4 for easy reference. (c) Case 1 of EMB. Since 3 and 4 are leaves and $\text{label}(3) = \text{label}(4)$ we have $\text{EMB}_T(3) = \text{EMB}_T(4)$. (d) Case 2 of EMB. Note that the middle child of the root(T) is not in the set since it is not a deep occurrence. (e) Case 3 of EMB: The two minimal ordered pairs of the sets of (d) and (c). (f) nca of the pairs in (e) both give the root node of T which is the only (deep) occurrence of P

Before considering case 3 we show that $U_j = \text{mop}(\text{EMB}_T(v_1), \dots, \text{EMB}_T(v_j))$ by induction on j , $2 \leq j \leq k$. For $j = 2$ it follows from the definition of MOP_T that $U_2 = \text{mop}(\text{EMB}_T(v_1), \text{EMB}_T(v_2))$. Hence, assume that $j > 2$. We have $U_j = \text{MOP}_T(U_{j-1}, \text{EMB}_T(v_j)) = \text{MOP}_T(\text{mop}(\text{EMB}_T(v_1), \dots, \text{EMB}_T(v_{j-1})), R_j)$. By definition of MOP_T , U_j is the set of pairs such that for any pair $(r_1, r_{j-1}) \in \text{mop}(\text{EMB}_T(v_1), \dots, \text{EMB}_T(v_{j-1}))$, we have $(r_1, r_j) \in U_j$ if and only if $(r_{j-1}, r_j) \in \text{mop}(\text{mop}(\text{EMB}_T(v_1), \dots, \text{EMB}_T(v_{j-1}))|_2, R_j)$. It now follows from Lemma 1 that $(r_1, r_j) \in U_j$ iff $(r_1, r_j) \in \text{mop}(\text{EMB}_T(v_1), \dots, \text{EMB}_T(v_j))$.

Consider case 3. If $k > 1$, $w \in \text{EMB}_T(v)$ implies $\text{label}(w) = \text{label}(v)$ and there are nodes $(w_1, w_k) \in \text{mop}(\text{emb}(P(v_1), T), \dots, \text{emb}(P(v_k), T))$ such that $w = \text{fl}(\text{nca}(w_1, w_k), \text{label}(v))$. Clearly, w is the root of an embedding of $P(v)$ in T . Assume for contradiction that w is not a deep embedding, i.e., $w < u$ for some node $u \in \text{emb}(P(v), T)$. Since $w = \text{fl}(\text{nca}(w_1, w_k), \text{label}(v))$ there must be nodes $u_1 \triangleleft \dots \triangleleft u_k$, such that $u_i \in \text{emb}(P(v_i), T)$, $1 \leq i \leq k$, and $u = \text{fl}(\text{nca}(u_1, u_k), \text{label}(v))$. However, this contradicts the fact that $(w_1, w_k) \in \text{mop}(\text{emb}(P(v_1), T), \dots, \text{emb}(P(v_k), T))$. If $w \in \text{emb}(P(v), T)$ a similar argument implies that $w \in \text{EMB}_T(v)$. □

When the tree T is clear from the context we may not write the subscript T in the procedure names. Note that since the $\text{EMB}_T(v)$ is a deep set we can assume that PARENT , FL , NCA , and MOP take deep sets as input.

4 A Simple Tree Inclusion Algorithm

In this section we present a simple implementation of the set procedures which leads to an efficient tree inclusion algorithm. Subsequently, we modify one of the procedures to obtain a family of tree inclusion algorithms where the complexities depend on the solution to a well-studied problem known as the *tree color problem*.

Preprocessing. To compute deep embeddings efficiently we require a data structure for T which allows us, for any $v, w \in V(T)$, to compute $\text{nca}_T(v, w)$ and determine if $v \prec w$ or $v \triangleleft w$. In linear time we can compute $\text{pre}(v)$ and $\text{post}(v)$ for all nodes $v \in V(T)$, and with these it is straightforward to test the two conditions. Using a data structure by Harel and Tarjan [7] we can answer nearest common ancestor queries in $O(1)$ time using $O(n_T)$ space and preprocessing time. Hence, our data structure uses linear preprocessing time and space.

Implementation of the Set Procedures. To answer tree inclusion queries we give an efficient implementation of the set procedures. The idea is to represent the node sets in a left-to-right order. For this purpose we introduce some helpful notation. A *node list*, X , is a list of nodes. If $v_i \triangleleft v_{i+1}$, $1 \leq i < |X|$ then X is *ordered* and if $v_1 \trianglelefteq v_{i+1}$, $1 \leq i < |X|$ then X is *semiordered*. A *node pair list*, Y , is a list of pairs of nodes. We say that Y is ordered if $Y|_1$ and $Y|_2$ are ordered, and semiordered if $Y|_1$ and $Y|_2$ are semiordered.

The set procedures are implemented using node lists and node pair lists. All lists used in the procedures are either ordered or semiordered. As noted in Sec. 3 we may assume that the input to all of the procedures, except DEEP, represent a deep set, that is, the corresponding node list or node pair list is ordered. We assume that the input list given to DEEP is semiordered. Hence, the output of all the other set procedures must be semiordered.

$\text{PARENT}_T(X)$. Return the list $Z := [\text{parent}(X[i]) \mid 1 \leq i \leq |X|]$.

$\text{NCA}(Y)$. Return the list $Z := [\text{nca}(Y[i]) \mid 1 \leq i \leq |Y|]$.

$\text{DEEP}_T(X)$. Initially, set $v := X[1]$ and $Z := []$. For each i , $2 \leq i \leq k$, compare v and $X[i]$: If $v \triangleleft X[i]$ set $Z := Z \circ v$ and $v := X[i]$. If $v \prec X[i]$, set $v := X[i]$ and otherwise ($X[i] \prec v$) do nothing. Finally, set $Z := Z \circ v$ and return Z .

$\text{MOP}_T(X, Y)$. Initially, set $Z := []$. Find the minimum j such that $X[1]_2 \triangleleft Y[j]$ and set $x := X[1]_1$, $y := Y[j]$, and $h := j$. If no such j exists, stop.

As long as $h \leq |Y|$ do the following: For each i , $2 \leq i \leq |X|$, do: Set $h := h+1$ until $X[i]_2 \triangleleft Y[h]$. Compare $Y[h]$ and y : If $y = Y[h]$ set $x := X[i]_1$. If $y \triangleleft Y[h]$ set $Z := Z \circ (x, y)$, $x := X[i]_1$, and $y := Y[h]$. Finally, set $Z := Z \circ (x, y)$ and return Z .

$\text{FL}_T(X, \alpha)$. Initially, set $Y := X$, $Z := []$, and $S := []$. Repeat until $Y := []$: For $i = 1, \dots, |Y|$ if $\text{label}(Y[i]) = \alpha$ set $Z := \text{INSERT}(Y[i], Z)$ and otherwise set $S := S \circ \text{parent}(Y[i])$. Set $S := \text{DEEP}_T(S)$, $Y := \text{DEEP}_T^*(S, Z)$, $S := []$. Return Z .

Procedure FL calls two auxiliary procedures: $\text{INSERT}(v, Z)$ takes an ordered list Z and insert the node v such that the resulting list is ordered, and $\text{DEEP}^*(S, Z)$

takes two ordered lists and returns the ordered list representing the set $\text{DEEP}(S \cup Z) \cap S$, i.e., $\text{DEEP}^*(S, Z) = [s \in S \mid \nexists z \in Z : s \prec z]$. Below we describe the implementation of FL in more detail.

We use one doubly linked list to represent all the lists Y , S , and Z . For each element in Y we have pointers Pred and Succ pointing to the predecessor and successor in the list, respectively. We also have at each element a pointer Next pointing to the next element in Y . In the beginning $\text{Next} = \text{Succ}$ for all elements, since all elements in the list are in Y . When going through Y in one iteration we simply follow the Next pointers. When FL calls $\text{INSERT}(Y[i], Z)$ we set $\text{Next}(\text{Pred}(Y[i]))$ to $\text{Next}(Y[i])$. That is, all nodes in the list not in Y , i.e., nodes not having a Next pointer pointing to them, are in Z . We do not explicitly maintain S . Instead we just save $\text{PARENT}(Y[i])$ at the position in the list instead of $Y[i]$. Now $\text{DEEP}(S)$ can be performed following the Next pointers and removing elements from the doubly linked list accordingly to procedure DEEP . It remains to show how to calculate $\text{DEEP}^*(S, Z)$. This can be done by running through S following the Next pointers. At each node s compare $\text{Pred}(s)$ and $\text{Succ}(s)$ with s . If one of them is a descendant of s then remove s from the doubly linked list.

Using this linked list implementation $\text{DEEP}^*(S, Z)$ takes time $O(|S|)$, whereas using DEEP to calculate this would have used time $O(|S| + |Z|)$.

Complexity of the Algorithm. For the running time of the node list implementation observe that, given the data structure described above, all set procedures, except FL, perform a single pass over the input using constant time at each step. Hence we have,

Lemma 4. *For any tree T there is a data structure using $O(n_T)$ space and preprocessing which supports each of the procedures PARENT , DEEP , MOP , and NCA in linear time (in the size of their input).*

The running time of a single call to FL might take time $O(n_T)$. Instead we will divide the calls to FL into groups and analyze the total time used on such a group of calls. The intuition behind the division is that for a path in P the calls made to FL by EMB is done bottom up on disjoint lists of node in T .

Lemma 5. *For disjoint ordered node lists V_1, \dots, V_k and labels $\alpha_1, \dots, \alpha_k$, such that any node in V_{i+1} is an ancestor of some node in $\text{DEEP}(\text{FL}_T(V_i, \alpha_i))$, $2 \leq i < k$, all of $\text{FL}_T(V_1, \alpha_1), \dots, \text{FL}_T(V_k, \alpha_k)$ can be computed in $O(n_T)$ time.*

The proof is omitted due to lack of space. The basic idea in the proof is to show that any node in T can be in Y at most twice during all calls to FL.

Using the node list implementation of the set procedures we get:

Theorem 2. *For trees P and T the tree inclusion problem can be solved in $O(l_P n_T)$ time and $O(n_P + n_T)$ space.*

Proof. By Lemma 4 we can preprocess T in $O(n_T)$ time and space. Let $g(n)$ denote the time used by FL on a list of length n . Consider the time used by $\text{EMB}_T(\text{root}(P))$. We bound the contribution for each node $v \in V(P)$. From

Lemma 4 it follows that if v is a leaf the cost of v is at most $O(g(l_T))$. Hence, by Lemma 5, the total cost of all leaves is $O(l_P g(l_T)) = O(l_P n_T)$. If v has a single child w the cost is $O(g(|\text{EMB}_T(w)|))$. If v has more than one child the cost of MOP, NCA, and DEEP is bounded by $\sum_{w \in \text{child}(v)} O(|\text{EMB}_T(w)|)$. Furthermore, since the length of the output of MOP (and thus NCA) is at most $z = \min_{w \in \text{child}(v)} |\text{EMB}_T(w)|$ the cost of FL is $O(g(z))$. Hence, the total cost for internal nodes is,

$$\sum_{v \in V(P) \setminus L(P)} O(g(\min_{w \in \text{child}(v)} |\text{EMB}_T(w)|)) + \sum_{w \in \text{child}(v)} |\text{EMB}_T(w)| \leq \sum_{v \in V(P)} O(g(|\text{EMB}_T(v)|)).$$

Next we bound the sum $\sum_{v \in V(P)} O(g(|\text{EMB}_T(v)|))$. For any $w \in \text{child}(v)$ we have that $\text{EMB}_T(w)$ and $\text{EMB}_T(v)$ are disjoint ordered lists. Furthermore we have that any node in $\text{EMB}_T(v)$ must be an ancestor of some node in $\text{DEEP}_T(\text{FL}_T(\text{EMB}_T(w), \text{label}(v)))$. Hence, by Lemma 5, for any leaf to root path $\delta = v_1, \dots, v_k$ in P , we have that $\sum_{u \in \delta} g(|\text{EMB}_T(u)|) \leq O(n_T)$. Let Δ denote the set of all root to leaf paths in P . It follows that, $\sum_{v \in V(T)} g(|\text{EMB}_T(v)|) \leq \sum_{p \in \Delta} \sum_{u \in p} g(|\text{EMB}_T(u)|) \leq O(l_P n_T)$.

Since this time dominates the time spent at the leaves the time bound follows. Next consider the space used by $\text{EMB}_T(\text{root}(P))$. The preprocessing of described above uses only $O(n_T)$ space. Furthermore, by induction on the size of the subtree $P(v)$ it follows immediately that at each step in the algorithm at most $O(\max_{v \in V(P)} |\text{EMB}_T(v)|)$ space is needed. Since $\text{EMB}_T(v)$ a deep embedding, it follows that $|\text{EMB}_T(v)| \leq l_T$. \square

An Alternative Algorithm. In this section we present an alternative algorithm. Since the time complexity of the algorithm in the previous section is dominated by the time used by FL, we present an implementation of this procedure which leads to a different complexity. Define a *firstlabel data structure* as a data structure supporting queries of the form $\text{fl}(v, \alpha)$, $v \in V(T)$, $\alpha \in \Sigma$. Maintaining such a data structure is known as the *tree color problem*, see e.g., [5, 13]. With such a data structure available we can compute $\text{FL}(X, \alpha)$ as the list $[\text{fl}(X[i], \alpha) \mid 1 \leq i \leq |X|]$.

Theorem 3. *Let P and T be trees. Given a firstlabel data structure using $s(n_T)$ space, $p(n_T)$ preprocessing time, and $q(n_T)$ time for queries, the tree inclusion problem can be solved in $O(p(n_T) + n_P l_T \cdot q(n_T))$ time and $O(n_P + s(n_T) + n_T)$ space.*

Proof. Constructing the firstlabel data structures uses $O(s(n_T))$ space and time $O(p(n_T))$. As in the proof of Thm. 2 we have that the total time used by $\text{EMB}_T(\text{root}(P))$ is bounded by $\sum_{v \in V(P)} g(|\text{EMB}_T(v)|)$, where $g(n)$ is the time used by FL on a list of length n . Since $\text{EMB}_T(v)$ is a deep embedding and each fl takes $q(n_T)$ we have, $\sum_{v \in V(P)} g(|\text{EMB}_T(v)|) \leq \sum_{v \in V(P)} g(l_T) = n_P l_T \cdot q(n_T)$. \square

Several firstlabel data structures are available, for instance, if we want to maintain linear space, we can use a data structure by Dietz [5] that supports firstlabel queries in $O(\log \log n_T)$ time using $O(n_T)$ space and $O(n_T)$ expected preprocessing time. Plugging in this data structure we obtain,

Corollary 1. *For trees P and T the tree inclusion problem can be solved in $O(n_P l_T \log \log n_T)$ time and $O(n_P + n_T)$ space.*

Since the preprocessing time $p(n)$ of the firstlabel data structure is expected the running time of the tree inclusion algorithm is also expected. However, the expectation is due to a dictionary using perfect hashing and we can therefore use the deterministic dictionary of [6] with $O(n_T \log n_T)$ worst-case preprocessing time instead. This does not affect the overall complexity of the algorithm.

5 A Faster Tree Inclusion Algorithm

In this section we present a new tree inclusion algorithm which has a worst-case subquadratic running time. Due to lack of space we will only give a rough sketch of the algorithm. A full description of the algorithm can be found in the full version of the paper [3].

The first step is to divide T into small connected subgraphs, called *micro trees* or *clusters*. Using a technique from [2] we can construct in linear time a *cluster partition* of T , consisting of $O(n_T / \log n_T)$ clusters each of size $O(\log n_T)$, with the property that any cluster shares at most two nodes with any other cluster. Each micro tree is represented by a constant number of nodes in a *macro tree*. The nodes in the macro tree are then connected according to the overlap of the micro trees they represent. Note that the total number of nodes in the macro tree is $O(n_T / \log n_T)$.

In linear time of the tree T we preprocess all the micro trees and the macro tree such that the set procedures use constant time for each micro tree. Using a compact node representation we can then implement all the set procedures in $O(n_T / \log n_T)$ time.

Lemma 6. *For any tree T there is a data structure using $O(n_T)$ space and $O(n_T)$ expected preprocessing time which supports all of the set procedures in $O(n_T / \log n_T)$ time.*

The proof of the lemma and all details in the implementation of the set procedures can be found in the full version of the paper. We can now compute the deep occurrences of P in T using the procedure EMB of Sec. 3 and Lemma 6. Since each node $v \in V(P)$ contributes at most a constant number of calls to set procedures it follows that,

Theorem 4. *For trees P and T the tree inclusion problem can be solved in $O(\frac{n}{\log n})$ time and $O(n_P + n_T)$ space.*

Combining the results in Theorems 2, 4 and Corollary 1 we have the main result of Theorem 1.

Acknowledgments. We thank the reviewers for the many insightful comments.

Abstract. A union-find data structure maintains a collection of disjoint sets under *makeset*, *union* and *find* operations. Kaplan, Shafir and Tarjan [SODA 2002] designed data structures for an extension of the union-find problem in which elements of the sets maintained may be deleted. The cost of a *delete* operation in their implementations is the same as the cost of a *find* operation. They left open the question whether *delete* operations can be implemented more efficiently than *find* operations. We resolve this open problem by presenting a relatively simple modification of the classical union-find data structure that supports *delete*, as well as *makeset* and *union*, operations in *constant* time, while still supporting *find* operations in $O(\log n)$ worst-case time and $O(\alpha(n))$ amortized time, where n is the number of elements in the set returned by the *find* operation, and $\alpha(n)$ is a functional inverse of Ackermann's function.

1 Introduction

A union-find data structure maintains a collection of disjoint sets under the operations *makeset*, *union* and *find*. A *makeset* operation generates a singleton set. A *union* operation takes two sets and unites them, destroying the two original sets. A *find* operation takes an element and returns a reference to the set currently containing it. The union-find problem is one of the most fundamental data structure problems. It has many applications in a wide range of areas. For an extensive list of such applications, and for a wealth of information on the problem and many of its variants, see the survey of Galil and Italiano [7].

An extremely simple union-find data structure (attributed by Aho *et al.* [1] to McIlroy and Morris), which employs two simple heuristics, *union by rank* and *path compression*, was shown by Tarjan [12] (see also Tarjan and van Leeuwen [13]) to be amazingly efficient. It performs a sequence of M *find* operations and N *makeset* and *union* operations in $O(N + M \alpha(M, N))$ total time. Here $\alpha(\cdot, \cdot)$ is an extremely slowly growing functional inverse of Ackermann's function. In other words, the *amortized* cost of each *makeset* and *union* operation is $O(1)$, while

the amortized cost of each *find* operation is $O(\alpha(M + N, N))$, only marginally more than a constant. Fredman and Saks [6] obtained a matching lower bound in the cell probe model of computation, showing that this simple data structure is essentially optimal in the amortized setting.

The union by rank heuristics on its own implies that *find* operations take $O(\log n)$ worst-case time. Here n is the number of elements in the set returned by the *find* operation. All other operations take constant worst-case time. It is possible to trade a slower *union* for a faster *find*. Smid [11], building on a result of Blum [4], gives for any k a data structure that supports *union* operations in $O(k)$ time and *find* operations in $O(\log_k n)$ time. When $k = \log n / \log \log n$, both the *union* and *find* operation take $O(\log n / \log \log n)$ time. Fredman and Saks [6] (see also Ben-Amram and Galil [3]) again show that this tradeoff is optimal, establishing an interesting gap between the amortized and worst-case complexities of the union-find problem. Alstrup *et al.* [2] present union-find algorithms with simultaneously optimal amortized and worst-case bounds.

Local Amortized Bounds. As noted by Kaplan *et al.* [8], the standard amortized bounds for *find* are global in terms of the total number N of elements ever created whereas the worst-case bounds are local in terms of the number n of elements in the current set we are finding. Obviously n may be much smaller than N . To state more local amortized bounds, we need a non-standard parameterization of the inverse Ackermann function. For integers $k \geq 0$ and $j \geq 1$, define an Ackermann function $A_k(j)$ as follows

$$A_k(j) = \begin{cases} j + 1 & \text{if } k = 0, \\ A_{k-1}^{(j+1)}(j) & \text{if } k \geq 1. \end{cases}$$

Here $f^{(i)}(x)$ is the function f iterated i times on x . Now, define the inverse of the function $\bar{\alpha}(j, i)$, for integer $i, j \geq 0$, as

$$\bar{\alpha}(j, i) = \min\{k \geq 2 \mid A_k(j) > i\}.$$

(For a technical reason, $\bar{\alpha}(j, i)$ is defined to be at least 2 for every $i, j \geq 0$.) Relating to the standard definition of α , we have $\alpha(M, N) = \Theta(\bar{\alpha}(\lceil M/N \rceil, N))$. Kaplan *et al.* [8] present a refined analysis of the classical union-find data structure showing that the amortized cost of *find*(x) operation is only $O(\bar{\alpha}(\lceil (M + N)/N \rceil, n))$. Kaplan *et al.* [8] state their results equivalently in terms of a three parameter function that we will not define here. To get a purely local amortized cost for *find*, we note that $\bar{\alpha}(\lceil (M + N)/N \rceil, n) \leq \bar{\alpha}(1, n) = O(\alpha(1, n)) = O(\alpha(n))$.

Union-Find with Deletions. In the traditional version of the union-find problem elements are created using *makeset* operations. Once created, however, elements are never destroyed. Kaplan *et al.* [8] consider a very natural extension of the union-find problem in which elements may be *deleted*. We refer to this problem as the *union-find with deletions* problem, or *union-find-delete* for short.

Using relatively straightforward ideas (see, e.g., [8]) it is possible to design a union-find-delete data structure that uses only $O(N^*)$ space, handles *make-set*, *union* and *delete* operations in $O(1)$ worst-case time, and *find* operations in $O(\log N^*)$ worst-case time and $O(\alpha(N^*))$ amortized time, where N^* is the current number of elements in the whole data structure. The challenge in the design of union-find-delete data structures is to have the time of a *find*(x) operation depend on n , the size of the set currently containing x , and not on N^* , the total number of elements currently contained in all the sets.

Using an incremental background rebuilding technique for each set, Kaplan *et al.* [8] describe a way of converting any data structure for the classical union-find problem into a union-find-delete data structure. The time bounds for *makeset*, *find* and *union* operations change by only a constant factor, while the time needed for a *delete*(x) operation is the same as the time needed for a *find*(x) operation followed by a *union* operation with a singleton set. As a *union* operation is usually much cheaper than a *find* operation, Kaplan *et al.* [8] thus show that in both the amortized and the worst-case settings, a *delete* operation is not more expensive than a *find* operation. Combined with their refined amortized analysis of the classical union-find data structure, this provides, in particular, a union-find-delete data structure that implements *makeset* and *union* operations in $O(1)$ time, and *find*(x) and *delete*(x) operations in $O(\alpha(n))$ amortized time and $O(\log n)$ worst-case time. They leave open, however, the question whether *delete* operations can be implemented *faster* than *find* operations.

Our Results. We solve the major open problem raised by Kaplan *et al.* [8] and show that *delete* operations can be performed in *constant* worst-case time, while still keeping the $O(\bar{\alpha}(\lceil(M + N)/N\rceil, n)) = O(\alpha(n))$ amortized cost and the $O(\log n)$ worst-case cost of *find* operations, and the constant worst-case cost of *makeset* and *union* operations. We recall here that N is the total number of elements ever created, M is the total number of *find* operations performed, and n is the number of elements in the set returned by the *find* operation. The data structure that we present uses linear space and is a relatively simple modification of the classical union-find data structure. It is at least as simple as the data structures presented by Kaplan *et al.* [8].

As a by-product we also obtain a very concise potential-based proof of the $O(\bar{\alpha}(\lceil(M + N)/N\rceil, n))$ bound, first obtained by Kaplan *et al.* [8], on the amortized cost of a *find* operation in the classical setting. We believe that our potential-based analysis is much simpler than the one given by Kaplan *et al.* [8].

Our Techniques. Our new union-find-delete data structure, like most other union-find data structures, maintains the elements of each set in a rooted tree. As elements can now be deleted, not all the nodes in these trees will contain active elements. Nodes that contain elements are said to be *occupied*, while nodes that do not contain elements are said to be *vacant*. When an element is deleted, the node containing it becomes vacant. If proper measures are not taken, then a tree representing a set may contain too many vacant nodes. As a result, the space needed to store the tree, and the time needed to process a *find* operation

may become too large. The new data structure uses a simple collection of local operations to *tidy up* a tree after each delete operation. This ensures that at most half of the nodes in a tree are vacant. More importantly, the algorithm employs local constant-time *shortcut* operations in which the grandparent, or a more distant ancestor, of a node becomes its new parent. These operations, which may be viewed as a local constant-time variant of the path compression technique, keep the trees relatively shallow to allow fast *find* operations.

As with the simple standard union-find, the analysis is the most non-trivial part. The analysis of the new data structure uses two different potential functions. The first potential function is used to bound the *worst-case* cost of *find* operations. Both potential functions are needed to bound the *amortized* cost of *find* operations. The second potential function on its own can be used to obtain a simple derivation of the refined amortized bounds of Kaplan *et al.* [8] for union-find without deletions.

We end this section with a short discussion of the different techniques used to analyze union-find data structures. The first tight amortized analysis of the classical union-find data structure, by Tarjan [12] and Tarjan and van Leeuwen [13], uses *collections of partitions* and the so-called *accounting method*. The refined analysis of Kaplan *et al.* [8] is directly based on this method. A much more concise analysis of the union-find data structure based on potential functions can be found in Kozen [9] and Chapter 21 of Cormen *et al.* [5]. The amortized analysis of our new union-find-delete data structure is based on small but crucial modifications of the potential function used in this analysis. As a by product we get, as mentioned above, a simple proof of the amortized bounds of Kaplan *et al.* [8]. Seidel and Sharir [10] presented recently an intriguing top-down amortized analysis of the union-find data structure. Our analysis is no less concise, though perhaps less intuitive, and has the additional advantage of bounding the cost of an amortized operation in terms of the size of the set returned by the operation.

2 Preliminaries

The Union-Find and Union-Find-Delete Problems. A classical union-find data structure supports the following operations:

- *make-set*(x): Create a singleton set containing x .
- *union*(A, B): Combine the sets A and B into a new set, destroying A and B .
- *find*(x): Return an identifier of the set containing x .

The only requirement from the identifier, or name, returned by a *find* operation is that if two elements x and y are currently contained in the same set, then the calls *find*(x) and *find*(y) return the same identifier. Kaplan *et al.* [8] studied data structures that also support *delete* operations:

- *delete*(x): Delete x from the set containing it.

A *delete* operation should not change the identifier attached to the set from which the element was deleted. It is important to note that a *delete* operation

does not receive a reference to the set currently containing x . It only receives the element x itself. As mentioned, Kaplan et al. [8] essentially showed that *delete* operations are not more expensive than *find* operations.

Standard Worst-Case Bounds for Union-Find. We briefly review here the simple standard union-find data structure that supports *makeset* and *union* operations in constant time and *find* operations in $O(\log n)$ time, as it forms the basis of our new data structure for the union-find-delete problem.

The elements of each set A are maintained in a rooted tree $T = T_A$. The identifier of the set A is the root of T . Fixing some terminology, the *height* of a node $v \in T$, denoted by $h(v)$, is defined to be 0, if v is a leaf, and $\max\{h(w) \mid w \text{ is a child of } v\} + 1$, otherwise. Let $\text{root}(T)$ denote the root of T . The height of a tree is the height of its root. For a node $v \in T$ let $p(v)$ denote the *parent* of v . A node $x \in T$ is an *ancestor* of a node $y \in T$ if x is on the path from y to the root of T —both y and the root included. A node $x \in T$ is a *descendant* of a node $y \in T$ if y is an ancestor of x .

Each node v has an assigned integer rank $\text{rank}(v)$. An important invariant is that for the parent of a node always has a strictly higher rank than the node itself. The rank of a tree is defined to be the rank of the root of the tree.

We implement the operations as follows.

find(x): Follow parent pointers from x all the way to the root. Return the root as the identifier of the set.

make-set(x): Create a new node x . Let $p(x) \leftarrow x$, $\text{rank}(x) \leftarrow 0$.

union(A, B): Recall that A and B are root nodes. Assume w.l.o.g. that $\text{rank}(A) \geq \text{rank}(B)$. Make B a child of A . If $\text{rank}(A) = \text{rank}(B)$, increase $\text{rank}(A)$ by one.

Analysis. Trivially, *makeset* and *union* operations take constant time. Since ranks are strictly increasing when following parent pointers, the time of a *find* operation applied to an element in a set A is proportional to $\text{rank}(A)$. We prove, by induction, that $\text{rank}(A) \leq \log_2 |A|$, or equivalently, that

$$|A| \geq 2^{\text{rank}(A)}. \quad (1)$$

When A is just created with *make-set*(x), it has rank 0 and $2^0 = 1$ elements. If C is the set created by *union*(A, B), then $|C| = |A| + |B|$. If C has the same rank as A , or the same rank as B , we are trivially done. Otherwise, we have $\text{rank}(A) = \text{rank}(B) = k$ and $\text{rank}(C) = k + 1$, and then $|C| = |A| + |B| \geq 2^k + 2^k = 2^{k+1}$. This completes the standard analysis of union-find with worst-case bounds.

3 Augmenting Worst-Case Union-Find with Deletions

Each set in the data structure is again maintained in a rooted tree. In the standard union-find data structure, reviewed in Section 2, the nodes of each tree were identified with the elements of the set. In the new data structure, elements are attached to nodes, not identified with them. Some nodes in a tree

are *occupied*, i.e., have an element attached to them, while others are *vacant*, i.e., have no element attached to them. An element can then be deleted by simply removing it from the node it was attached to. This node then becomes vacant. The name of a set is taken to be its root node. As the name of a set is a node, and not an element, names do not change as a result of *delete* operations.

An obvious problem with this approach is that if we never remove vacant nodes from the trees, we may end up consuming non-linear space. To avoid this, we require our union-find trees to be *tidy*:

Definition 1. *A tree is said to be tidy if it satisfies the following properties:*

- *Every vacant non-root node has at least two children,*
- *Every leaf is occupied and has rank 0.*

It is easy to tidy up a tree. First, we remove vacant leaves. When a node becomes a leaf, its rank is reduced to 0. Next, if a vacant non-root node v has a single child w , we make the parent of v the parent of w and remove v . We call this *bypassing* v . The following Lemma is now obvious.

Lemma 1. *At most half of the nodes in a tidy tree may be vacant.*

Tidy trees thus use linear space. However, tidyness on its own does not yield a sublinear time bound on *find* operations. (Note, for example, that a path of occupied nodes is tidy.) Our next goal would be to make sure that the depth of a tree is logarithmic in the number of occupied nodes contained in it. Ideally, we would want all trees to be *reduced*:

Definition 2. *A tree is said to be reduced if it is either*

- *A tree composed of a single occupied node of rank 0, or*
- *A tree of height 1 with a root of rank 1 and occupied leaves of rank 0.*

Naturally, we will not manage to keep our trees reduced at all times. Reduced trees form, however, the base case for our analysis.

Keeping the Trees Shallow During Deletions. This section contains our main technical contribution. We show how to implement deletions so that for any set A ,

$$|A| \geq (2/3)(6/5)^{\text{rank}(A)}. \quad (2)$$

Consequently, $\text{rank}(A) \leq \log_{6/5}(3|A|/2) = O(\log |A| + 1)$. As the rank of a tree is always an upper bound on its height, we thus need to follow at most $O(\log |A| + 1)$ parent pointers to get from any element of A to the root identifier.

The key idea is to associate the following value with each node v :

Definition 3. *The value $\text{val}(v)$ of a node v is defined as*

$$\text{val}(v) = \begin{cases} (5/3)^{\text{rank}(p(v))} & \text{if } v \text{ is occupied,} \\ (1/2)(5/3)^{\text{rank}(p(v))} & \text{if } v \text{ is vacant.} \end{cases}$$

Here, if v is a root, $p(v) = v$. The value of a set A is defined as the sum the values of all nodes in the tree T_A representing A : $\text{VAL}(A) = \sum_{v \in T} \text{val}(v)$.

The value $5/3$ is chosen to satisfy Equation 2 and Lemma 2, 4, and 9 below. In fact, we could have chosen any constant value in $[(1 + \sqrt{5})/2, 2)$. We are going to implement deletions in such a way that

$$VAL(A) \geq 2^{\text{rank}(A)}. \quad (3)$$

Since the tree representing a set A contains exactly $|A|$ occupied nodes, each of value at most $(5/3)^{\text{rank}(A)}$, and at most $|A|$ vacant nodes in T_A , each of value at most $(5/3)^{\text{rank}(A)}/2$, it will follow that

$$|A| \geq \frac{2^{\text{rank}(A)}}{(3/2)(5/3)^{\text{rank}(A)}} = (2/3)(6/5)^{\text{rank}(A)},$$

so (3) will imply (2).

The essential operation used to keep trees shallow is to *shortcut* from a node v , giving v a parent higher up over v in the tree. For example, path compression shortcuts from all nodes in a search path directly to the root. Since ranks are strictly increasing up through the tree, shortcutting from v increases the value of v by a factor of at least $5/3$. This suggests that we can make up for the loss of a deleted node by a constant number of shortcuts from nearby nodes of similar rank. Before proceeding, let us check that reduced trees satisfy (3).

Lemma 2. *If the tree representing a set A is reduced then $VAL(A) \geq 2^{\text{rank}(A)}$.*

Proof. If A is of height 0, then $VAL(A) = (5/3)^0 = 1$ and $2^{\text{rank}(A)} = 1$. If A is of height 1, then $VAL(A) \geq (5/3)^1 + (1/2)(5/3)^1 = 5/2$ while $2^{\text{rank}(A)} = 2$. \square

Let us for a moment assume that we have an implementation of *delete* that preserves, i.e., does not decrease, value, and let us check that the other operations preserve (3). A *makeset* operation creates a reduced tree, so (3) is satisfied by Lemma 2. Also, when we set $C := \text{union}(A, B)$, we get $VAL(C) \geq VAL(A) + VAL(B)$, and hence (3) follows just like (1).

Paying for a Deletion via Local Rebuilding. We now show how we can implement a delete operation in constant time, either without decreasing value of the set from which the element is deleted, or ending up with a reduced tree representing the set. Suppose we delete an element of A attached to a node u . As u becomes vacant, we immediately loose half its value. Before u was vacant the tree was tidy, but now we may have to tidy the tree. If u is not a leaf, the only required tidying up is to bypass u if it has a single child. If instead u was a leaf, we first delete u . If $p(u)$ is now a leaf, its rank is reduced to zero, but that in itself does not affect any value. If $p(u)$ is vacant and now has only one child, we bypass $p(u)$. This completes the tidying up.

Lemma 3. *Let v be the parent of the highest node affected by a delete, including tidying up. If $\text{rank}(v) = k$, then the maximal loss of value is at most $(9/10)(5/3)^k$.*

Proof. It is easy to see that the worst-case is when $v = p(p(u))$, where u is a deleted leaf and $p(u)$ is bypassed. Now u lost at most $(5/3)^{k-1}$ and $p(u)$ lost $(5/3)^k/2$, while the other child of $p(u)$ gained at least $((5/3)^k - (5/3)^{k-1})/2$ from the bypass. Adding up, the total loss is $(9/10)(5/3)^k$. \square

Below we show how to regain the loss from a *delete* using a pointer to v from Lemma 3. To find nearby nodes to shortcut from, we maintain two doubly linked lists for each node v ; namely $C(v)$ containing the children of v , and $G(v)$ containing the children of v that themselves have children. Thus, to find a grandchild of v , we take a child of a child in $G(v)$. Both lists are easily maintained as children are added and deleted: if a child u is added to v , it is added to $C(v)$. If u is the first child of v , we add v to $G(p(v))$. Finally, we add u to $G(v)$ if $C(u)$ is non-empty. Deleting a child is symmetric. Using these lists, we first prove

Lemma 4. *In a tidy tree, if node x has rank k and grandchildren, we can gain $\Omega((5/3)^k)$ value in $O(1)$ time.*

Proof. Using $G(x)$, find a child y of x that have children. If y is occupied, we can take any child z of y and shortcut to x . This increases the value of z by at least $(1/2)((5/3)^k - (5/3)^{k-1}) = (1/5)(5/3)^k$. We note that y may have rank much lower than $k - 1$, but that would only increase our gain. If z is the last child of y , we remove y from $G(x)$. If, on the other hand, y is vacant, we have two cases. First note that since the tree is tidy, $|C(y)| \geq 2$. If $|C(y)| > 2$, we can just take any child z of y and shortcut to x as above. Otherwise $C(y) = \{z, z'\}$. If both z and z' are occupied, we shortcut both z and z' to x and remove y . This gives a gain of at least $2((5/3)^k - (5/3)^{k-1}) - (1/2)(5/3)^k = (3/10)(5/3)^k$. Otherwise, one of them, say z is vacant. Tidyness implies that z has at least two children. If more than two, any one of them can be shortcut to x gaining at least $(1/2)((5/3)^k - (5/3)^{k-2}) = (8/25)(5/3)^k$. If exactly two, then one of them is shortcut to y and the other to x while z is removed. The gain in value is at least $(1/2)((5/3)^k + 2(5/3)^{k-2}) = (7/50)(5/3)^k$. We note that all the above shortcuts preserves tidyness. \square

The following lemma shows how we—using Lemma 4—can regain the value lost due to a deletion.

Lemma 5. *In a tidy tree with a pointer to a node v of rank k , we can increase the value by $t \cdot (5/3)^k$ or get to a reduced tree in $O(t)$ time.*

Proof. The proof is constructive. We set $x = v$ and repeat the following until either we have gained enough value, or reach the base case of a reduced tree:

1. While $G(x)$ is non-empty and there is more value to be gained, apply Lemma 4.
2. If x is not the root, set $x = p(x)$.

In case 1, we gain $\Omega((5/3)^k)$ per constant time iteration due to Lemma 4. We cannot get to case 2 twice in a row without getting to case 1, since $p(x) \in G(p(p(x)))$. Thus, in $O(t)$ time, we either gain $t \cdot (5/3)^k$ in value, or we end with x the root but with no grand children, that is, a tree of height at most 1.

If we are in the base case with a tree of height 0 or 1, we set $rank(x)$ to 0 or 1, respectively. \square

Combining Lemmas 2, 3, and 5 with $t = O(1)$, we implement a deletion in constant time so that either we have no loss, meaning that (3) is preserved, or obtaining a reduced tree that satisfies (3) directly. Thus we have proved

Theorem 1. *In union-find with deletion we can implement each makeset, union, and delete in constant time, and each find in $O(\log n)$ time.*

4 Faster Amortized Bounds

We will now show that we can get much faster amortized bounds for *find*, yet preserve the previous worst-case bounds. All we have to do is to use *path compression* followed by tidying up operations. Path compression of a path from node $v \in T$ to node $u \in T$ makes every node on the path a child of u . When we perform a *find* from a node v , we compress the path to the root. Our analysis is new and much cleaner analysis than was previously known even without deletes.

Before going further, we note that path compression consists of shortcuts that increase value of the previous section, so intuitively, the path compression can only help the deletions. Below, we first present our new analysis without the deletions, and then we observe that deletions are only helpful.

Analysis. We assign a potential $\phi(x)$ to each node x in the forest. To define the potential we need some extra functions. Define $Q = \lceil \frac{M+N}{N} \rceil$ and $\alpha'(n) = \bar{\alpha}(Q, n)$. Note that $Q \geq 2$ whenever $M > 0$. Our goal is to prove that the amortized cost of *find* is $O(\alpha'(n))$ where n is the cardinality of the set found. We also define $rank'(v) = rank(v) + Q$.

Definition 4. *For a non-root node x we define*

$$\begin{aligned} level(x) &= \max\{k \geq 0 \mid A_k(rank'(x)) \leq rank'(p(x))\} , \\ index(x) &= \max\{i \geq 1 \mid A_{level(x)}^{(i)}(rank'(x)) \leq rank'(p(x))\} . \end{aligned}$$

We have

$$0 \leq level(x) < \bar{\alpha}(rank'(x), rank'(p(x))) \leq \alpha'(rank'(p(x))) , \quad (4)$$

$$1 \leq index(x) \leq rank'(x) . \quad (5)$$

Definition 5. *The potential $\phi(x)$ of a node x is defined as*

$$\phi(x) = \begin{cases} \alpha'(rank'(x)) \cdot (rank'(x) + 1) & \text{if } x \text{ root,} \\ (\alpha'(rank'(x)) - level(x)) \cdot rank'(x) - index(x) + 1 & \text{if } x \text{ not root and } \alpha'(rank'(x)) = \alpha'(rank'(p(x))), \\ 0 & \text{otherwise.} \end{cases}$$

The potential $\Phi(x)$ of a set A is defined as the sum of the potentials of the nodes in the tree T_A representing the set A : $\Phi(A) = \sum_{x \in T} \phi(x)$.

At first sight the potential function looks very similar to the standard one from [5], but there are important differences. Using $\alpha(\text{rank}(x))$ instead of $\alpha(N)$ we get a potential function that is more locally sensitive. To get this change to work, we use the trick that the potential of a node is only positive if $\alpha'(\text{rank}'(x)) = \alpha'(\text{rank}'(p(x)))$.

From (4) and (5) it immediately follows that the potential of a node x with $\alpha'(\text{rank}'(x)) = \alpha'(\text{rank}'(p(x)))$ is strictly positive. We also note that the only potentials that can increase are those of roots. All other nodes keep their ranks while the ranks of their parents increase and that can only decrease the potential.

We will now analyze the change in potential due to the operations.

Lemma 6. *The cost of makeset is amortized as a constant per makeset plus a constant per find.*

Proof. When we create a new set A with rank 0, it gets potential $\bar{\alpha}(Q, Q)(Q + 1) = 2(Q + 1) = O((M + N)/N)$. Over N makeset operations, this adds up to a total increase of $O(M + N)$. \square

Lemma 7. *The operation $\text{union}(A, B)$ does not increase the potential.*

Proof. Suppose we make A the parent of B . If the rank of A is not increased, there is no node that increases potential, so assume that $\text{rank}'(A)$ is increased from k to $k + 1$. Then k was also the rank of B . If $\alpha'(k + 1) > \alpha'(k)$, then B gets zero potential along with any previous child of A . The potential of B is reduced by $\alpha'(k) \cdot (k + 1)$. On the other hand, the potential of A is increased by $(\alpha'(k) + 1) \cdot (k + 2) - \alpha'(k) \cdot (k + 1) = \alpha'(k) + k + 2$, which is less than $\alpha'(k) \cdot (k + 1)$, as $k \geq 2$ and $\alpha'(k) \geq 2$. (Here we use the fact that $\bar{\alpha}(j, i) \geq 2$, for every $i, j \geq 0$.)

Finally, if $\alpha'(k + 1) = \alpha'(k)$, then the potential of A increases by $\alpha'(k)$ while the potential of B decreases by at least $\alpha'(k)$, since B was a root with potential $\alpha'(k) \cdot (k + 1)$ and now becomes a child with potential at most $\alpha'(k) \cdot k$. \square

Lemma 8. *A path compression of length ℓ from a node v up to some node u decreases the potential by at least $\ell - (2 \cdot \alpha'(\text{rank}'(u)) + 1)$. In particular, the amortized cost is at most $O(\alpha'(\text{rank}'(u)))$.*

Proof. The potential of the root does not change due to the path compression. We will show that at least $\max\{0, \ell - (2 \cdot \alpha'(\text{rank}'(u)) + 2)\}$ nodes have their potential decreased by at least one.

There are at most $\alpha'(\text{rank}'(u))$ nodes x on the path that had $\alpha'(\text{rank}'(x)) < \alpha'(\text{rank}'(p(x)))$ before the operation. The potentials of these nodes do not change.

If node x had $\alpha'(\text{rank}'(x)) = \alpha'(\text{rank}'(p(x))) < \alpha'(\text{rank}'(u))$, then its potential drops to 0, and the decrease in x 's potential is therefore at least one.

It remains to account for the nodes x with $\alpha'(\text{rank}'(x)) = \alpha'(\text{rank}'(u))$. Let x be a node on the path such that x is followed somewhere on the path by a node $y \neq u$ with $\text{level}(y) = \text{level}(x) = k$. There can be at most $\alpha'(\text{rank}'(u)) + 1$ nodes

on the path that do not satisfy these constraints: The last node before u , u , and the last node on the path for each level, since $\text{level}(y) < \alpha'(\text{rank}'(u))$. Let x be a node that satisfies the conditions. We show that the potential of x decreases by at least one. Before the path compression we have $\text{rank}'(p(y)) \geq A_k(\text{rank}'(y)) \geq A_k(\text{rank}'(p(x))) \geq A_k(A_k^{(\text{index}(x))}(\text{rank}'(x))) = A_k^{(\text{index}(x)+1)}(\text{rank}'(x))$. After the path compression we have $\text{rank}'(p(x)) = \text{rank}'(p(y))$ and thus $\text{rank}'(p(x)) \geq A_k^{(\text{index}(x)+1)}(\text{rank}'(x))$, since $\text{rank}'(x)$ does not change and $\text{rank}'(p(y))$ does not decrease. This means that either $\text{index}(x)$ or $\text{level}(x)$ must increase by at least one. Thus $\phi(x)$ decreases by at least one. \square

We conclude that the amortized cost of *find* in a set A is

$$O(\alpha'(\text{rank}'(A))) = O(\bar{\alpha}(Q, \text{rank}(A) + Q + c)) = O(\bar{\alpha}(Q, \text{rank}(A))).$$

The last step follows because $\bar{\alpha}$ is defined to be at least 2. Recall that $Q = \lceil \frac{M+N}{N} \rceil$ and that $\text{rank}(A) \leq \log_2 |A|$, so without deletions, this is the desired bound.

Deletion and Path Compression. We now combine the path compression and amortized analysis with deletions. The potential used in the amortization is identical for vacant and occupied nodes. It is clear that deletions and tidying up can only decrease this potential, so they have no extra amortized cost. Likewise, a path compression can only increase value as it only performs shortcuts. However, after a path compression, there may be some cleaning to do if some vacant nodes go down to 0 or 1 children. We start the path compression from a tidy tree where each vacant node has at least two children, and the compression takes at most one child from each node on the path. Hence the only relevant tidying up is to bypass some of the nodes on the path. The tidying up takes time proportional to the length of the path, so the cost of a *find* is unchanged.

The tidying up does decrease value, but the loss turns out less than the gain from the compression.

Lemma 9. *Path compression followed by tidying up operations does not decrease the value of a tree.*

Proof. The path compression involves nodes v_0, \dots, v_ℓ starting in some occupied node v_0 and ending in the root which has some rank k . After the compression, all nodes $v_0, \dots, v_{\ell-1}$ are children of the root v_ℓ . If node v_i is not bypassed when tidying up, its value gain is at least $((5/3)^{\text{rank}(v)} - (5/3)^{\text{rank}(v+1)})/2$. If v_i is bypassed, then $0 < i < \ell$, and v_i is vacant, so the loss is $(5/3)^{\text{rank}(v+1)}/2$. However, then v_i has a child w_i which gains at least $((5/3)^{\text{rank}(v)} - (5/3)^{\text{rank}(v)})/2$, so the total change is

$$((5/3)^{\text{rank}(v)} - (5/3)^{\text{rank}(v+1)} - (5/3)^{\text{rank}(v)})/2$$

Since ranks are strictly increasing along a path, this change is positive for all but $i = \ell - 1$. On the other hand, the first node v_0 is always occupied, and has a gain of at least $(5/3)^{\text{rank}(v)} - (5/3)^{\text{rank}(v_1)}$, where $1 \leq \ell - 1$. We can use the value gained by v_0 to pay for the value lost by bypassing both v_1 and $v_{\ell-1}$. There are two cases.

If both v_{l-1} and v_1 is bypassed we must have $l \geq 4$. Combining the changes in potential for the nodes v_0 , v_1 , and v_{l-1} we get, $(5/3)^{\text{rank}(l)} - (5/3)^{\text{rank}(v_1)} - (1/2)(5/3)^{\text{rank}(v_2)} - (1/2)(5/3)^{\text{rank}(v_{-1})} > 0$.

If v_1 is not bypassed, we get that the total gain for v_0 and v_{l-1} is at least, $(5/3)^{\text{rank}(v)} - (5/3)^{\text{rank}(v_1)} - (1/2)(5/3)^{\text{rank}(v)}$, which is always positive. Thus the overall change in value is positive, or zero if the path has length 0 or 1 and no compression happens. \square

Since our values and hence (3) are preserved, for any set A , we get $\text{rank}(A) = O(\log |A|)$. Thus our amortized cost of a *find* operation is $O(\bar{\alpha}(Q, O(\log |A|))) = \Theta(\bar{\alpha}(\lceil \frac{M+N}{N} \rceil, |A|))$. Summing up, we have proved

Theorem 2. *If we do a total of M find operations on a total of N makeset operations, then the operation times can be amortized as follows. We pay only a constant for each makeset, union, and delete, and for a find on an element in a set A , we pay $O(\bar{\alpha}(\lceil \frac{M+N}{N} \rceil, |A|))$. Meanwhile, the worst-case bounds of Theorem 1 are preserved.*

Abstract. We study the problem of determining the complexity of optimal comparison-based in-place sorting when the key length, k , is not a constant. We present the first algorithm for lexicographically sorting n keys in $O(nk + n \log n)$ time using $O(1)$ auxiliary data locations, which is *simultaneously* optimal in time *and* space.

1 Introduction

We study the computational complexity of the classical problem of comparison-based sorting by considering the case in which the keys are of non-constant length, k . We aim at minimizing simultaneously the time and space bounds under the assumption that the keys are vectors $x \in \Sigma^k$ of k scalar components over a totally ordered, possibly unbounded set Σ . Denoting the i th scalar component of vector x by $x(i)$ for $1 \leq i \leq k$, we indicate the vector's *chunks* by $x(i, j)$, which are the contiguous portions of x consisting of $x(i)$, $x(i + 1)$, \dots , $x(j)$, where $1 \leq i \leq j \leq k$. The lexicographic (or alphabetic) order, $x \leq y$, is defined in terms of the scalar components: either $x(1) < y(1)$ or recursively $x(2, k) \leq y(2, k)$ for $x(1) = y(1)$. The model easily extends to k -field records in $\Sigma_1 \times \Sigma_2 \times \dots \times \Sigma_k$, but we prefer to keep the notation simple.

We are given a set $\mathcal{V} \subseteq \Sigma^k$ of n vectors stored in n *vectorial locations*, one vector of \mathcal{V} per location. We permit two kinds of operations on the vector locations: (1) exchange any two vectors in $O(k)$ time; (2) access the i th scalar component of any two vectors for comparison purposes in $O(1)$ time. Hence, determining the lexicographic order of any two vectors from scratch takes $O(k)$ time. We are also given a number of *auxiliary locations*, each location storing one integer of $O(\log n)$ bits. We employ the standard repertoire of RAM instructions on the auxiliary locations, with $O(1)$ time per operation.

The model resulting from the above rules naturally extends the comparison model to keys of non-constant length. (We obtain the comparison model by fixing $k = 1$.) We are interested in exploring algorithms using the minimal number of auxiliary locations, referring to the model using just $O(1)$ auxiliary locations as the *in-place model for vectors*. This model is useful for studying, in an abstract way, the complexity of in-place sorting and searching for a variety of keys: k -length strings, k -field records, k -dimensional points, k -digit numbers, etc.

One significant example is how to perform in-place searching on a set \mathcal{V} of n vectors. With sophisticated techniques for proving upper and lower bounds

on the complexity of searching \mathcal{V} in lexicographic order, Andersson, Hagerup, Håstad and Petersson have proved in [1] that it requires

$$\Theta\left(\frac{k \log \log n}{\log \log\left(4 + \frac{k \log \log n}{\log n}\right)} + k + \log n\right)$$

time. This bound is worse than $\Theta(k + \log n)$, obtained by searching \mathcal{V} plus $O(n)$ auxiliary locations (e.g., Manber and Myers [18]). Using permutations other than those resulting from sorting is a way to reach optimality: Franceschini and Grossi [10] have shown that for any set \mathcal{V} of n vectors in lexicographic order, there exists a permutation of them allowing for $\Theta(k + \log n)$ search time using $O(1)$ auxiliary data locations.

In-place sorting is an even more intriguing example in this scenario. Any optimal in-place sorting algorithm for constant-sized keys can be turned into an $O(nk \log n)$ -time in-place algorithm for vectors, losing optimality in this way. The lower bound of $\Omega(nk + n \log n)$ time easily derives from decision trees [14]. If the number of comparison is to be minimized, the best up-to-date result for in-place sorting is $n \log n + O(nk \log^* n)$ scalar comparisons and $n \log n + O(nk)$ vector exchanges by Munro and Raman [20]. Since each vector exchange takes $O(k)$ time, the time complexity sums up to $O(nk^2 + nk \log n)$. For the same reason, the multikey Quicksort analyzed by Bentley and Sedgewick [4] yields a non-optimal algorithm of cost $O(nk \log n)$ when adapted to run in the in-place model for vectors, since it requires $O(n \log n)$ vector exchanges. The original version of the algorithm takes $O(nk + n \log n)$ time since it can exploit $O(n)$ auxiliary locations to store the pointers to the vectors. It exchanges the pointers rather than the vectors, following the *address table sorting* suggested in Knuth [14-p.74]. Recently, Franceschini and Geffert [9] have devised an optimal in-place algorithm for constant-sized keys with $O(n)$ data moves. Subsequent results by Franceschini [7, 8] have shown how to achieve cache-obliviousness or stableness for in-place sorting. However, the $O(k)$ -time cost of each vector comparison makes these methods non-optimal in our setting. The bit encoding for vectors in Franceschini and Grossi [10] cannot help either, as it assumes that vectors are initially sorted while this is actually the major goal in this paper.

The above discussion highlights the fact that the known algorithms, to the best of our knowledge, are unable to simultaneously achieve time optimality and space optimality for sorting vectors (in place). Our main result is that of obtaining the first optimal bounds for sorting an arbitrary set of n vectors in place, taking $\Theta(nk + n \log n)$ time and using $O(1)$ auxiliary locations. An implication of our result is that we can provide optimal in-place preprocessing for efficient in-place searching [1, 10, 11, 12, 15] when the vectors are initially arranged in any arbitrary order, with a preprocessing cost of $O(nk + n \log n)$ time. Another implication is that sorting bulky records can be done optimally in place by exchanging them directly without using the $O(n)$ auxiliary locations required by Knuth's address table sorting.

2 High-Level Description

We present our in-place sorting algorithm for vectors in a top-down fashion. We describe how to reduce the original problem to a sequence of simpler sorting problems to solve. In our description, we identify the n input vectors in \mathcal{V} with their vectorial locations. At the beginning of the computation, $\mathcal{V}[i]$ represents the i th vectorial location, for $1 \leq i \leq n$, and contains the i th input vector. At the end of the computation, $\mathcal{V}[i]$ contains the vector of rank i after the sorting (ties for equal vectors are broken arbitrarily). During the intermediate steps, we solve several instances of a *general vector sorting problem*, denoted $GVSP\{m, p, h\}$ (see Figure 1). Given n vectors in \mathcal{V} , we refer to $GVSP\{m, p, h\}$ as the problem of sorting a subset of m contiguous vectors in \mathcal{V} , using

- $O(1)$ auxiliary locations,
- p vectors as *placeholders* taken from a contiguous subsequence of p locations in \mathcal{V} ,
- h *heavy* bits suitably encoded by h pairs of vectors taken from two contiguous subsequences, each consisting of h locations in \mathcal{V} ,

under the requirement that $m + p + 2h \leq n$ and that the four subsequences of h , p , m , and h vector locations, respectively, are pairwise disjoint as shown in Figure 1. Placeholders and heavy bits are defined in the rest of the section.

The general notation of $GVSP\{m, p, h\}$ is useful for expressing the various sorting instances that we get by reducing our initial problem, $GVSP\{n, 0, 0\}$, to simpler problems (with suitable values of m , p and h). Some basic instances occur just a constant number of times in the reduction and are easy to solve.

Lemma 1. *Any instance of $GVSP\{O(n/\log n), 0, 0\}$ takes $O(nk)$ time.*

Proof. We employ the in-place mergesort of [21] and pay a slowdown of $O(k)$ in the time complexity, since we run it on $O(n/\log n)$ vectors, each of length k . The cost is $O(k \times (n/\log n) \log(n/\log n)) = O(nk)$ time.

We now present the high-level structure of our reduction. In the following, for any two vectors x and y , we denote the length of their longest common prefix by $lcp(x, y) = \max(\{0\} \cup \{1 \leq \ell \leq k : x(1, \ell) = y(1, \ell)\})$.

Fig. 1. An instance of $GVSP\{m, p, h\}$. Each of the n vector locations in \mathcal{V} contains one vector. Each of the $O(1)$ auxiliary locations contains one integer of $O(\log n)$ bits

Heavy Bits (Section 3). To begin with, we reduce an instance of $GVSP\{n, 0, 0\}$ to a suitable instance of $GVSP\{n - o(n), 0, O(n/\log^2 n)\}$ plus a constant number of instances of $GVSP\{O(n/\log n), 0, 0\}$. We partition in place the sequence \mathcal{V} into contiguous subsequences \mathcal{L} , \mathcal{M} , and \mathcal{R} , such that for each $x \in \mathcal{L}$, $y \in \mathcal{M}$ and $z \in \mathcal{R}$, we have $x \leq y \leq z$. Moreover, the number of vectors in \mathcal{L} equals that of \mathcal{R} , namely, $|\mathcal{L}| = |\mathcal{R}| = O(n/\log n)$. Assuming that $\max \mathcal{L} \neq \min \mathcal{R}$ (otherwise sorting is trivial), we consider the pairs $P = \{\langle \mathcal{L}[i], \mathcal{R}[i] \rangle, \text{ for } 1 \leq i \leq |\mathcal{L}|\}$. Note that for every pair $\langle x, y \rangle \in P$, vectors x and y are distinct ($x < y$) and their first mismatching scalar component is at position $lcp(x, y) + 1$. Based on this observation we identify a subset H of the pairs in P satisfying two constraints:

1. $|H| = \Omega(n/\log^2 n)$.
2. There exists an interval $[l, r] \subseteq [1, k]$ of size $\max\{1, k/\log n\}$, such that $lcp(x, y) + 1 \in [l, r]$ for every pair $\langle x, y \rangle \in H$.

Under constraints 1-2, we can use the vectors in H for implicitly representing $O(n/\log^2 n)$ bits, called *heavy bits*, so that decoding one heavy bit requires $O(1 + k/\log n)$ time while encoding it takes $O(k)$ time. Let us see why do we need these bits. When designing an optimal in-place algorithm, the constraint on using just $O(1)$ auxiliary locations, namely, $O(\log n)$ extra bits of information, is rather stringent. Fortunately, permutations of the keys encode themselves further bits of informations. Potentially, we are plenty of $\log h!$ bits by permuting h distinct keys. Based on this idea, bit stealing [19] is a basic technique for implicitly encoding up to h bits of information by pairwise permuting h pairs of keys. In its original design, the technique encodes a bit with each distinct pair of keys x and y , such that $x < y$. The bit is of value 0 if x occurs *before* y in the permutation; it's of value 1 if x occurs *after* y in the permutation. The main drawback of this technique in our setting is that we need $O(k)$ time for encoding and decoding one bit since x and y are vectors. As we shall see, we will require an amortized number of $O(1)$ encoded bits and $O(\log n)$ decoded bits per vector, so that we have to decrease the cost of decoding to $O(1 + k/\log n)$ to stay within the claimed bounds.

At this stage, sorting \mathcal{V} reduces to sorting \mathcal{M} as an instance of $GVSP\{n - o(n), 0, O(n/\log^2 n)\}$. After that, it also reduces to sorting \mathcal{L} and \mathcal{R} as instances of $GVSP\{O(n/\log n), 0, 0\}$ solved by Lemma 1.

Buffering and Session Sorting (Sect. 4). We solve $GVSP\{n - o(n), 0, O(n/\log^2 n)\}$ reducing to $O(\log n)$ instances of $GVSP\{O(n/\log n), O(n/\log n), O(n/\log^2 n)\}$ and to $O(1)$ instances of $GVSP\{O(n/\log n), 0, 0\}$ solved by Lemma 1. We logically divide \mathcal{M} into contiguous subsequences $\mathcal{M}_1, \dots, \mathcal{M}_{s-1}, \mathcal{M}_s$, where $|\mathcal{M}_2| = \dots = |\mathcal{M}_{s-1}| \leq |\mathcal{M}_s| = O(n/\log n)$ and $s = O(\log n)$. Moreover, $|\mathcal{M}_1| = O(n/\log n)$ has a sufficiently large multiplicative constant, so that \mathcal{M}_1 can host enough vectors playing the role of placeholders. With reference to Figure 1, we sort the $m = O(n/\log n)$ vectors in each individual \mathcal{M}_i , $i \neq 1$, using the $p = O(n/\log n)$ placeholders in \mathcal{M}_1 and the $h = O(n/\log^2 n)$ heavy bits encoded by the pairs in $H \subseteq \mathcal{L} \times \mathcal{R}$.

Let us first give some motivation for using the placeholders while sorting. Having just n vector locations, we cannot rely on a temporary area of vector locations for efficiently permuting the vectors with a few moves. We therefore exploit a virtual form of temporary area using the internal buffering technique of Kronrod [16]. We designate the vectors in \mathcal{M}_1 as placeholders for “free memory” since we do not care to sort them at this stage. Hence, they can be scrambled up without interplaying with the sorting process that is running on a given \mathcal{M}_i , $i \neq 1$. When we need to move a vector of \mathcal{M}_i to the temporary area, we simulate this fact by exchanging the vector with a suitable placeholder of \mathcal{M}_1 . At the same time, we should guarantee that this exchange is somehow reversible, allowing us to put the placeholders back to the “free memory” in \mathcal{M}_1 without perturbing the sorting obtained for \mathcal{M}_i , $i \neq 1$.

Assuming to have obtained each of $\mathcal{M}_2, \dots, \mathcal{M}_{s-1}, \mathcal{M}_s$ in lexicographic order, we still have to merge them using the heavy bits in H and the placeholders in \mathcal{M}_1 . It turns out that this task is non-trivial to be performed. Just to have a rough idea, let us imagine to run the 2-way in-place mergesort for $O(\log s) = O(\log \log n)$ passes on them. This would definitively give a non-optimal time cost for the vectors since the number of vector exchanges would be $\omega(n)$, losing optimality in this way. We introduce a useful generalization of the technique in [7, 16], thus obtaining what we call *session sorting*. Let us assume that the vectors are distinct (we shall disregard this assumption in Section 4).

The main goal of session sorting is that of rearranging all the vectors in $\mathcal{M}_2, \dots, \mathcal{M}_{s-1}, \mathcal{M}_s$, so that they are not too far from their final destination. If any such vector has rank r among all the other vectors in $\mathcal{M}_2 \mathcal{M}_3 \dots \mathcal{M}_{s-1} \mathcal{M}_s$, and occupies a position $g > r$ after session sorting, we guarantee that $g - r \leq |\mathcal{M}_i|$. (Note that we do not claim anything regarding the case $g \leq r$.) Using this strong property, we show that the sequence of 2-way in-place operations for merging \mathcal{M}_i and \mathcal{M}_{i+1} for $i = 2, 3, \dots, s - 1$ (in this order) yields the sorted sequence. (We remark that this is not generally true if we do not apply session sorting.) As a result, the entire sequence $\mathcal{M}_2 \mathcal{M}_3 \dots \mathcal{M}_{s-1} \mathcal{M}_s$ is in lexicographic order with a linear number of moves.

What remains to do is sorting \mathcal{L} , \mathcal{M}_1 , and \mathcal{R} individually as instances of $GVSP\{O(n/\log n), 0, 0\}$ by Lemma 1. Merging them in place with the rest of sorted vectors is a standard task giving \mathcal{V} in sorted order. Hence, we are left with an instance of $GVSP\{O(n/\log n), O(n/\log n), O(n/\log^2 n)\}$, which corresponds to sorting a given \mathcal{M}_i , $i \neq 1$, using the placeholders initially hosted in \mathcal{M}_1 and the heavy bits encoded by the pairs in H .

Sorting Each \mathcal{M}_i Individually (Section 5). We describe this stage in general terms. For a given $i \neq 1$, let $\mathcal{M}' = \mathcal{M}_i$ and $\mathcal{M}_B = \mathcal{M}_1$, for the instance of $GVSP\{|\mathcal{M}'|, |\mathcal{M}_B|, |H|\}$ that we are going to solve with the heavy bits in H (see Figure 1). Using \mathcal{M}_B as a “free memory” area, we simulate the sorting of the $m' = |\mathcal{M}'|$ vectors by inserting them into a suitable structure that is incrementally built inside \mathcal{M}_B . Each insertion of a vector $x \in \mathcal{M}'$ into the internal structure of \mathcal{M}_B exchanges x with a placeholder. After each such exchange we permute some of the vectors inside \mathcal{M}_B , so as to dynamically maintain a set of

$O(m'/\log^2 m')$ pivot vectors in the internal structure. The pivots have buckets associated inside \mathcal{M}_B for the purpose of distributing the non-pivot vectors inserted up to that point, like in distribution sort. Each bucket contains $\Theta(\log^2 m')$ vectors that are kept *unsorted* to minimize the number of vector exchanges needed to maintain the internal structure of \mathcal{M}_B .

The pivots inside \mathcal{M}_B are kept searchable by a suitable blend of the techniques in [10, 13, 18], requiring to decode $O(\log n)$ heavy bits per inserted vector (which is fine since decoding takes $O(1 + k/\log n)$ time). In particular, we logically divide each vector x into a concatenation of $O(\log m') = O(\log n)$ equally sized chunks. We only store the *lcp* information for the chunks considered as “meta-characters,” thus obtaining an approximation of the *lcp* information for the vectors. After that the distribution completes by inserting all the vectors of \mathcal{M}' into the internal structure of \mathcal{M}_B , we sort the buckets individually by using a constant number of recursive iterations of session sorting whose parameters are suitably adapted to the buckets’ size. The base case of the recursion consists in solving $GVSP\{O(\sqrt{\log m'}), O(\sqrt{\log m'}), 0\}$, for which we design an optimal ad-hoc algorithm. After completing the individual sorting of the buckets, which still reside in \mathcal{M}_B , we exchange them with the placeholders that were temporarily moved to \mathcal{M}' . We place back the sorted buckets and their pivots to \mathcal{M}' according to their relative order, which means that the m' vectors in \mathcal{M}' are in lexicographic order. Since this stage is quite full of technicalities, we give more details in the full paper.

Known Tools. We use a few optimal algorithmic tools for atomic keys: in-place stable mergesort and in-place merge [21]; in-place selection for order statistics [17]. We apply these algorithms to vectors in a straightforward way by paying a slowdown of $O(k)$ per elementary step in their time complexity. We also use Hirschberg’s linear scanning method [11] for searching in place a set of n vectors of length k , with the simple bound of $O(k + n)$ time. We go through the convention that the last lowercase letters— \dots, x, y, w, z —denote vectors and the middle ones— \dots, i, j, k, l, \dots —are auxiliary indices or parameters.

3 Heavy Bits

We detail how to reduce the problem of sorting in place n vectors—an instance of $GVSP\{n, 0, 0\}$ —to an instance of $GVSP\{n - o(n), 0, O(n/\log^2 n)\}$ plus a constant number of instances of $GVSP\{O(n/\log n), 0, 0\}$. (The notation for $GVSP\{m, p, h\}$ is defined in Section 2 and illustrated in Figure 1.) We recall that we partition in place the sequence \mathcal{V} into \mathcal{L} , \mathcal{M} , and \mathcal{R} , where $|\mathcal{L}| = |\mathcal{R}| = p = O(n/\log n)$. We obtain this partition by performing order statistics in place [17] so as to identify the p th and the $(n - p + 1)$ st elements of \mathcal{V} in $O(nk)$ time. In the rest of the paper we assume that $w_L \neq w_R$; otherwise, \mathcal{M} is made up of all equal vectors and sorting is trivially solved by applying Lemma 1 to \mathcal{L} and \mathcal{R} .

Let us consider the set of pairs of vectors thus obtained, $P = \{\langle \mathcal{L}[i], \mathcal{R}[i] \rangle : 1 \leq i \leq p\} \subseteq \mathcal{L} \times \mathcal{R}$. Let us conceptually divide each of these vectors into chunks of $k/\ell = O(1 + k/\log n)$ scalar components, where $\ell = \min\{k, \log n\}$. We index these chunks from 1 to ℓ , in the order of their appearance inside the vector. We assign an integer label j to each pair $\langle \mathcal{L}[i], \mathcal{R}[i] \rangle$, where $1 \leq j \leq \ell$ and $1 \leq i \leq p$. Since $\mathcal{L}[i] < \mathcal{R}[i]$ by construction, label j is the index of the chunk containing the first mismatching position for $\mathcal{L}[i]$ and $\mathcal{R}[i]$; that is, it satisfies $(j-1)k/\ell \leq \text{lcp}(\mathcal{L}[i], \mathcal{R}[i]) < jk/\ell$. By the pigeon principle, there must exist a value of j for which at least $p/\ell = \Omega(n/\log^2 n)$ pairs in P are labeled j . We can identify that value by running at most ℓ in-place scans of \mathcal{L} and \mathcal{R} , with an overall cost of $O(\ell \times pk) = O(nk)$ time. With a further scan of \mathcal{L} and \mathcal{R} , we single out $h = \Theta(p/\ell) = \Theta(n/\log^2 n)$ pairs in P that have label j , moving them in place at the beginning of \mathcal{L} and \mathcal{R} , respectively. Consequently, we identify these vectors in the first h locations in \mathcal{L} and \mathcal{R} by a set of pairs, denoted H :

- $H \subseteq P$ and $|H| = h = \Theta(n/\log^2 n)$;
- $H = \{\langle \mathcal{L}[i], \mathcal{R}[i] \rangle : 1 \leq i \leq h\}$ after the preprocessing;
- there exists $j \in [1, \ell]$ such that $(j-1)k/\ell \leq \text{lcp}(x, y) < jk/\ell$ for every pair $\langle x, y \rangle \in H$.

We steal bits in H using the knowledge of j as follows. For $1 \leq i \leq h$, we encode the i th bit of value 1 by exchanging $\mathcal{L}[i]$ and $\mathcal{R}[i]$ in $O(k)$ time; namely, $\mathcal{L}[i]$ occupies now position i inside \mathcal{R} and $\mathcal{R}[i]$ does it inside \mathcal{L} . If the bit is 0, we leave them at their position (no exchange). In order to decode the i th bit, we only compare their j th chunk to find their mismatching position in the interval $[(j-1)k/\ell + 1, jk/\ell]$. In this way, we can establish whether or not the two vectors have been exchanged during encoding (and so we decode either 0 or 1). Decoding performs at most k/ℓ scalar comparisons and thus takes $O(1 + k/\log n)$ time. The non-constant cost of bit stealing motivates our choice of referring to these bits as *heavy*.

Lemma 2. *We can encode $h = \Theta(n/\log^2 n)$ heavy bits by the pairwise permutation of vectors in $H \subseteq \mathcal{L} \times \mathcal{R}$. Encoding one bit requires $O(k)$ time while decoding it requires $O(1 + k/\log n)$ time. Preprocessing requires $O(nk)$ time using $O(1)$ auxiliary locations.*

We keep \mathcal{L} and \mathcal{R} unsorted for encoding bits until the end of the algorithm. At that point, we can in-place sort \mathcal{L} and \mathcal{R} by Lemma 1, in $O(nk)$ time. Consequently we are left with the problem of sorting \mathcal{M} .

Lemma 3. *There exists an $O(nk)$ -time reduction from $GVSP\{n, 0, 0\}$ to $GVSP\{n - o(n), 0, O(n/\log^2 n)\}$, using $O(1)$ auxiliary locations.*

4 Buffering and Session Sorting

In this section, we detail how to sort the vectors in \mathcal{M} , which is an instance of $GVSP\{n - o(n), 0, O(n/\log^2 n)\}$. We logically divide \mathcal{M} into contiguous subsequences $\mathcal{M}_1, \dots, \mathcal{M}_{s-1}, \mathcal{M}_s$, called *blocks*, where $|\mathcal{M}_2| = \dots = |\mathcal{M}_{s-1}| \leq$

$|\mathcal{M}_s| = O(n/\log n)$ and $s = O(\log n)$. In the following, we assume without loss of generality that $|\mathcal{M}_s| = |\mathcal{M}_{s-1}|$ (if not, we treat \mathcal{M}_s differently, applying Lemma 1 to it). We remark that only a constant number of blocks can be sorted with the bounds of Lemma 1. Hence we should proceed otherwise. We designate the $O(n/\log n)$ vectors in \mathcal{M}_1 , for a sufficiently large multiplicative constant, to act as placeholders [16]. In this way we obtain $O(\log n)$ instances of $GVSP\{O(n/\log n), O(n/\log n), O(n/\log^2 n)\}$, plus a constant number of instances of $GVSP\{O(n/\log n), 0, 0\}$ solved by Lemma 1.

We are still missing a crucial part of the reduction performed at this stage, namely, how to obtain *all* the vectors in $\mathcal{M}_2\mathcal{M}_3\cdots\mathcal{M}_{s-1}\mathcal{M}_s$ in lexicographic order. We introduce the *right-bounded* permutations, since they rearrange the vectors so that each vector cannot occupy a position beyond a bounded distance to the right of its final position in the sorted sequence. As we will prove, the net effect of the right-bounded permutation is that we can simulate the in-place merging scheme by the following scheme: IN-PLACE-MERGE($\mathcal{M}_2, \mathcal{M}_3$); IN-PLACE-MERGE($\mathcal{M}_3, \mathcal{M}_4$); \dots ; IN-PLACE-MERGE($\mathcal{M}_{s-1}, \mathcal{M}_s$). We describe this permutation in general terms as it is of independent interest.

4.1 Right-Bounded Permutations

We are given three positive integers m, p, q , such that q divides p and p divides m , satisfying

$$\left(\frac{m}{p} - 1\right) \times (q - 1) \leq p. \quad (1)$$

Given a sequence \mathcal{B} of m vectors, we logically divide it into m/q sub-blocks of q vectors each, denoted $\mathcal{S}_1, \dots, \mathcal{S}_{m/q}$. The sub-blocks are grouped into blocks of p/q sub-blocks each, thus logically dividing \mathcal{B} into m/p blocks of p vectors each, denoted $\mathcal{B}_1, \dots, \mathcal{B}_{m/p}$. A right-bounded permutation is the arrangement of the vectors in \mathcal{B} resulting from steps P1–P2, with steps P3–P4 yielding the sequence in lexicographic order:

- P1. For $j = 1, \dots, m/p$, sort each block \mathcal{B}_j individually.
- P2. Sort *stably* the m/q sub-blocks $\mathcal{S}_1, \dots, \mathcal{S}_{m/q}$ according to their first vector (i.e., comparisons are driven by the minimum vector in each sub-block, and the rest of the vectors are considered as “satellite data”).
- P3. For $j = 1, \dots, m/p$, sort each block \mathcal{B}_j individually (note that the content of the blocks changed!).
- P4. For $j = 1, \dots, m/p - 1$, merge the vectors contained in blocks \mathcal{B}_j and \mathcal{B}_{j+1} .

Lemma 4. *For each vector $\mathcal{B}[i]$, $1 \leq i \leq m$, let g_i be the number of vectors $\mathcal{B}[j] > \mathcal{B}[i]$ such that $1 \leq j < i$ right after steps P1–P2. Then*

$$g_i \leq \left(\frac{m}{p} - 1\right) \times (q - 1). \quad (2)$$

Proof. Let us consider the arrangement of the vectors in \mathcal{B} right after steps P1–P2. In order to prove equation (2), we need to consider the intermediate arrangement of the vectors in \mathcal{B} after step P1 and before step P2. Recall that we logically divide \mathcal{B} into blocks and sub-blocks, indexing the blocks from 1 to m/p . We assign a unique type to each block based on its index, namely, block \mathcal{B}_t is assigned *type* t , where $1 \leq t \leq m/p$, since it is the t th block in \mathcal{B} . For the intermediate arrangement above, we say that a vector has type t if it belongs to \mathcal{B}_t (recall that \mathcal{B}_t is sorted). We can assign type t to the sub-blocks of each \mathcal{B}_t in the same manner, since each sub-block contains vectors of the same type t by construction. Hence the type of a sub-block is well defined. We refer to the first vector of each sub-block, which is also the minimum in it, as the *header* of the sub-block.

Let us now resume the arrangement of the vectors in \mathcal{B} right after steps P1–P2. Consider a generic vector $\mathcal{B}[i]$ belonging to a sub-block, say \mathcal{S}' of type t' , and let g_i be defined as above. We give an upper bound to g_i so as equation (2) holds. Specifically, we count the maximum number of vectors contributing to g_i . Let us discuss them by their type. By the stability of the sorting process in step P2, we know that the vectors of type t' have maintained the relative order they had in the intermediate arrangement (after step P1 and before step P2) and so they cannot contribute to g_i .

Let x be the header of the sub-block \mathcal{S}' containing $\mathcal{B}[i]$. Let us evaluate the contribution to g_i for the vectors of type $t'' \neq t'$. Consider all sub-blocks of type t'' : we claim that at most one of them, say \mathcal{S}'' , can contain vectors contributing to g_i . Precisely, \mathcal{S}'' is the sub-block of type t'' having the largest header less than or equal to x . Let $y \leq x$ be the header of \mathcal{S}'' and z be one of such contributing vectors in \mathcal{S}'' . Sub-block \mathcal{S}'' is laid out before \mathcal{S}' by construction but $z > \mathcal{B}[i]$ by definition of g_i . Note that there can be at most $q - 1$ such vectors z in \mathcal{S}'' . For any other sub-block of type t'' , we show that its vectors cannot contribute to g_i . Since the block of type t'' is sorted after step P1, there are two possibilities for its sub-blocks $\mathcal{S}''' \neq \mathcal{S}''$: (a) \mathcal{S}''' contains all vectors that are less than or equal to $y \leq x$ (i.e., \mathcal{S}''' is laid out before \mathcal{S}''); they do not contribute to g_i by transitivity since $x \leq \mathcal{B}[i]$. (b) \mathcal{S}''' contains all vectors that are greater than or equal to $z > \mathcal{B}[i] \geq x$ (i.e., \mathcal{S}''' is laid out after \mathcal{S}''); they do not contribute because the header of \mathcal{S}''' is strictly larger than x by transitivity and so \mathcal{S}''' is laid out after \mathcal{S}' . Summing up, the total contribution to g_i for the vectors of type $t'' \neq t'$ is at most $q - 1$ (a subset of the vectors in \mathcal{S}''). Since there are $\frac{m}{p} - 1$ different types other than t' , we obtain the upper bound for equation (2).

Theorem 1. *After steps P1–P4, the sequence \mathcal{B} is sorted.*

Proof. We proceed by induction on the length of prefixes of blocks in \mathcal{B} . The base case is obvious, as we know that \mathcal{B}_1 is sorted by step P3. Let us assume that the j th prefix of blocks $\mathcal{B}_1\mathcal{B}_2 \cdots \mathcal{B}_j$ is sorted by induction, for $j \geq 1$. After step P3, the upper bound in equation (2) still holds for any vector v in block \mathcal{B}_{j+1} (modulo the inner permutation due to the sorting of \mathcal{B}_{j+1}). Indeed, the number of vectors $z > v$ that are laid out before v cannot increase; those

inside \mathcal{B}_{j+1} disappear after sorting it and so the upper bound in equation (2) is anyway valid. By equation (1), we derive that p , the size of each block, is larger than the upper bound of equation (2). As a result, the number of vectors $z > v$ that belong to the j th prefix of blocks cannot exceed p . Hence, they should be contained in the last locations of block \mathcal{B}_j since $p = |\mathcal{B}_j|$ and $\mathcal{B}_1\mathcal{B}_2 \cdots \mathcal{B}_j$ is sorted by induction. This allows us to conclude that after merging \mathcal{B}_j and \mathcal{B}_{j+1} , the $(j+1)$ st prefix of blocks $\mathcal{B}_1\mathcal{B}_2 \cdots \mathcal{B}_{j+1}$ is sorted, thus proving the statement of the theorem.

4.2 Session Sorting

We apply the steps stated in Theorem 1 to sorting the vectors in \mathcal{M} into sessions. We choose \mathcal{M}_1 of size $O(n/\log n)$ for the placeholders. We then fix $q = \log^3 n$, $p = qn/\log^4 n = \Theta(n/\log n)$, and we pick m as the largest multiple of p such that $m \leq |\mathcal{M}| - |\mathcal{M}_1|$. These values satisfy equation (1). We therefore obtain the logical division of \mathcal{M} into blocks $\mathcal{M}_1, \dots, \mathcal{M}_{s-1}, \mathcal{M}_s$, as expected. We comment on how to apply steps P1–P4 to $\mathcal{M}_2, \dots, \mathcal{M}_s$ (assuming w.l.o.g. that $|\mathcal{M}_s| = |\mathcal{M}_{s-1}|$).

In steps P1 and P3, we have to solve a number of $m/p = O(\log n)$ instances of $GVSP\{O(n/\log n), O(n/\log n), O(n/\log^2 n)\}$ (see Section 5).

In step P2, we have just $m/q = O(n/\log^3 n)$ vectors to sort, which are the minimum in each sub-block. We refer to them as *headers* and to the rest of the vectors as *satellite data* (with $q - 1$ vectors each). We associate a unique implicit index in the range from 1 to m/q with the satellite data in each sub-block. We employ the heavy bits in H so as to form a sequence of m/q integers $h_1, h_2, \dots, h_{m/q}$ of $\log n$ bits each, employed to encode a permutation of these indexes. Note that we have direct access to any h_j , $1 \leq j \leq m/q$, in $O(k \log n)$ time for encoding it and $O(k + \log n)$ time for decoding it by Lemma 2.

At the beginning of step P2, we set $h_j = j$ and exchange the j th header with the j th placeholder in \mathcal{M}_1 , for $1 \leq j \leq m/q$. We then apply the in-place *stable* mergesort on the headers thus collected in \mathcal{M}_1 . Each comparison cost is $O(k)$ time while each exchange requires $O(k \log n)$ time. Indeed, when exchanging two headers inside \mathcal{M}_1 , say at position j' and j'' , we have also to swap the values of $h_{j'}$ and $h_{j''}$, involving their decoding and encoding in H . Note that the satellite data is not exchanged but $h_{j'}$ and $h_{j''}$ are correctly updated to maintain the association of the headers with their satellite data in the sub-blocks. At the end of the mergesort, we exchange the j th header in \mathcal{M}_1 with the placeholder temporarily hosted in the h_j th sub-block. The total cost is $O((m/q) \log(m/q) \times (k \log n)) = O((n/\log^3 n) \log n \times (k \log n)) = o(nk)$.

We now have to permute the sub-blocks according to the values of $h_1, \dots, h_{m/q}$ encoded in H . Specifically, the h_j th sub-block must occupy the j th position among the sub-blocks to reflect the stable sorting of their headers. We employ an additional sequence of integers $r_1, r_2, \dots, r_{m/q}$ encoded in H , initializing $r_i = j$ if and only if $h_j = i$. We proceed incrementally for $j = 1, 2, \dots, m/q - 1$ (in this order), preserving the invariant that we have correctly placed the first $j - 1$ sub-blocks, with $h_1, \dots, h_{m/q}$ and $r_1, r_2, \dots, r_{m/q}$ suitably updated to re-

flect the fact that one permutation is the inverse of the other (in particular, $h_{j'} = r_{j'} = j'$ for $1 \leq j' < j$, so the invariant is meaningful for the rest of the indexes). Note that some of the sub-blocks may have exchanged in order to place the first $j - 1$ sub-blocks. Hence, when we refer to the j th and the h_j th sub-blocks, they are taken from the current arrangement of sub-blocks. If $j = h_j$, the current sub-block is already correctly placed and the invariant is trivially preserved. Otherwise, we exchange the j th and the h_j th sub-blocks by pairwise exchanging their i th vectors for $i = 1, 2, \dots, q$. In order to preserve the invariant, we simultaneously swap the values of h_j and h_r and the values of r_j and r_h , respectively, re-encoding them in H . Since the exchange of sub-blocks requires the pairwise exchange of q vectors plus the encoding and decoding of $O(1)$ values among $h_1, \dots, h_{m/q}$ and $r_1, r_2, \dots, r_{m/q}$, the cost is $O(qk + k \log n)$. When $j = m/q - 1$, the last two sub-blocks are placed correctly and we have performed a total of $O(m/q)$ such exchanges. The final cost is $O(m/q \times (qk + k \log n)) = O(n/\log^3 n \times k \log^3 n) = O(nk)$. Hence, the total cost of step P2 is $O(nk)$.

Finally, in step P4, we use the in-place merging with comparison cost $O(k)$. As a result, we obtain a total cost of $O(m/p \times pk) = O(nk)$ for step P4 (and \mathcal{M} is sorted).

Lemma 5. *There is an $O(nk)$ -time reduction from $GVSP\{n - o(n), 0, O(n/\log^2 n)\}$ to a number of $O(\log n)$ instances of $GVSP\{O(n/\log n), O(n/\log n), O(n/\log^2 n)\}$, using $O(1)$ auxiliary locations.*

5 Sorting Each Block Individually

We have to solve an instance of $GVSP\{O(n/\log n), O(n/\log n), O(n/\log^2 n)\}$ (see Figure 1). We reformulate it as $GVSP\{m', O(m'), O(m'/\log m')\}$, where $m' = O(n/\log n)$ vectors in \mathcal{M}' should be sorted using a sufficiently large number $O(m')$ of placeholders in \mathcal{M}_B . We need to encode $O(1)$ sequences of integers of $O(\log m') = O(\log n)$ heavy bits each in $H \subseteq \mathcal{L} \times \mathcal{R}$, totalizing $O(m'/\log m')$ heavy bits. We sort \mathcal{M}' by repeatedly inserting its vectors in an internal structure maintained inside \mathcal{M}_B to mimic a distribution sort into buckets of $O(\log^2 m')$ vectors each. Each bucket is sorted by applying a constant number of recursive calls to session sorting (Section 4.2). The base case is an instance of $GVSP\{O(\sqrt{\log m'}), O(\sqrt{\log m'}), 0\}$. We first rank the vectors by linking them in a sorted list without moving the vectors (we mimic the insertion sort in a list without moving vectors). The list pointers of $O(\log \log m')$ bits each, however, are not encoded with heavy bits in this case. Since we sort one bucket at a time and have $O(\sqrt{\log m'})$ such pointers, we can keep the $O(\sqrt{\log m'} \log \log m') = o(\log n)$ bits for all the pointers in one auxiliary location. We can access any such pointer in constant time, and we can append a new pointer to them within the same complexity by using RAM operations. We apply Hirschberg's linear scanning to add a new vector to the sorted list and mimic insertion sort. Hence, the cost per vector is $O(k + \sqrt{\log m'})$. After

setting up the linked list that reflects the sorted order, we permute the vectors using the temporary buffer of $O(\sqrt{\log m'})$ placeholders. Thus the time complexity of $GVSP\{O(\sqrt{\log m'}), O(\sqrt{\log m'}), 0\}$ is bounded by $O(k\sqrt{\log n} + \log n)$. We summarize the resulting bounds, leaving several technical details to the full paper.

Lemma 6. *An instance of $GVSP\{O(n/\log n), O(n/\log n), O(n/\log^2 n)\}$ takes $O(n + nk/\log n)$ time using $O(1)$ auxiliary locations.*

Theorem 2. *An arbitrary set of n vectors of length k can be sorted in place optimally, taking $O(nk + n \log n)$ time and using $O(1)$ auxiliary locations.*

Abstract. The multiple selection problem asks for the elements of rank r_1, r_2, \dots, r_k from a linearly ordered set of n elements. Let B denote the information theoretic lower bound on the number of element comparisons needed for multiple selection. We first show that a variant of multiple quickselect — a well known, simple, and practical generalization of quicksort — solves this problem with $B + \mathcal{O}(n)$ expected comparisons. We then develop a deterministic divide-and-conquer algorithm that solves the problem in $\mathcal{O}(B)$ time and $B + o(B) + \mathcal{O}(n)$ element comparisons.

1 Introduction

We consider the problem of determining the elements of rank r_1, r_2, \dots, r_k in an ordered set S with n elements using as few comparisons as possible. The problem has been studied extensively, primarily at its extreme ends, when one either requires one or two order statistics (such as the median or the maximum and minimum) or when all ranks are to be determined, and so the set is to be sorted. The more general problem can be very helpful in statistical analyses, providing a clean summary of the data by giving elements of a chosen set of ranks. Multiple selection is also an ingredient of *sample sort* [1].

Let $\Delta_j := r_j - r_{j-1}$ where $r_0 = 0$ and $r_{k+1} = n$ and let¹

$$B = n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j - \mathcal{O}(n) = \sum_{j=1}^{k+1} \Delta_j \lg \frac{n}{\Delta_j} - \mathcal{O}(n).$$

A comparison-based multi-selection algorithm identifies the Δ_1 smallest elements, the Δ_2 next smallest elements, \dots , and hence an additional $\sum_j \Delta_j \lg \Delta_j + \mathcal{O}(n)$ comparisons suffice to sort the entire set. Thus B is a lower bound for the number of comparisons needed by any multiselection algorithm, even in the expected case [5]. Note that this lower bound takes both the input size n and the structure of the required ranks R into account.

¹ Throughout this paper, $\lg x$ stands for $\log_2 x$.

1.1 Background and Ancient History

The problem of sorting is one of the oldest and most heavily studied in computing. “Interesting” sorting algorithms date back to the 1940’s, or earlier. The information theoretic lower bound of $\lg(n!) = n \lg n - n \lg e + \mathcal{O}(\lg n)$ comparisons is missed by only about $n(\lg e - 1)$ comparisons by mergesort, when n is a power of 2. Despite such an easy approach to optimality, even Ford-Johnson [9] merge insertion and other very complex methods still leave a $\Theta(n)$ gap (with an admittedly small constant).

It seems that Charles Dodgson (Lewis Carroll) was the first to point to the unfairness of declaring the runner-up (the player losing to the last game to the winner in a single knockout competition) to be the “second best”. Hoare [8] proposed a simple $\mathcal{O}(n)$ expected case (median) selection algorithm as an addendum to his original work on Quicksort. Close to a decade later Blum, Floyd, Pratt, Rivest and Tarjan [2] provided the first median finding technique with $\mathcal{O}(n)$ worst case behavior. The result was certainly a major surprise at the time, although it is now often presented as a basic example of divide and conquer. At essentially the same time, two of those authors, Floyd and Rivest [7], gave a probabilistic method for selection using $n + \min(r_1, n - r_1) + o(n)$ comparisons in the expected case. This bound is optimal, at least up to $o(n)$ terms, as shown in [4]. We note that this lower bound exceeds that of the information theoretic argument, above, for selecting the median by $n/2$. The difference is even greater for selecting other ranks.

The contrast between the simple randomized techniques and the complex worst case approach is striking. The development of the $3n + o(n)$ worst case method of Schönhage et al. [14] and the $(2.94 \dots)n$ method of Dor and Zwick [6] further amplifies

Multiple selection problems have received much less attention. Chambers [3] proposed multiple quickselect — a natural generalization of quicksort: Pick a *pivot* element m as an estimate for the median of S and partition S into two sets $S_{\leq} = \{s \in S : s \leq m\}$ and $S_{>} = \{s \in S : s > m\}$. Output m as the element of rank $r_m := |S_{\leq}|$ if $r_m \in R$. Recurse on $(S_{\leq}, \{r \in R : r < r_m\})$ and $(S_{>}, \{r - r_m \in R : r > r_m\})$. The recursion can be broken when $R = \emptyset$.

Pohl [12] gave a slick deterministic algorithm for finding the maximum and minimum of a set in the optimal number of $\lceil 3n/2 \rceil - 1$ comparisons. Cunto and Munro [4] provided optimal and near optimal randomized techniques for finding elements of two or three ranks. The “full blown” deterministic multiselection problem that we address appears to have first been considered by Dobkin and Munro [5], who suggest a method based on median finding that solves the problem using $3B + \mathcal{O}(n)$ comparisons.

A quarter century after Chamber’s paper, there has been renewed interest in the analysis of multiple quickselect. Prodingler [13] has given an exact formula for the expected number of comparisons performed by multiple quickselect with random pivot which can be written as $2B/\lg(e) + \mathcal{O}(n)$. Panholzer [11] has derived very accurate bounds for the expected number of comparisons for the case that the pivot is the median of $2t + 1$ random sample elements and where R

is a *random* k element subset of $\{1, \dots, n\}$. These bounds show that $n \lg k + \mathcal{O}(n)$ expected comparisons are sufficient if $t = \Omega(\lg n)$. Note that for general R the lower bound B might be much smaller. For example, consider the set of ranks $R := \{\lceil n/i \rceil : i \leq n\}$. Observe further that this set has $k = \Theta(\sqrt{n})$ elements, i.e., $n \lg k = \Theta(n \lg n)$. On the other hand, $B \approx n \sum_i \frac{\ln(i(i+1))}{i(i+1)} = \Theta(n)$, i.e., there is a logarithmic factor gap between Panholzer's upper bound and the lower bound B . It is a natural question whether multiple quicksort is still a near optimal algorithm for inputs with nonuniformly spread ranks in R . For example, it was initially not clear to us whether one should choose m such that S is approximately halved, such that R is approximately halved, or some compromise between these two strategies.

1.2 The Rest of the Paper

Section 2 introduces our basic proof technique by analyzing an idealized variant of multiple quickselect that is given the exact median for free. This algorithm needs at most $n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 2n$ comparisons. In Section 3 we show that multiple quickselect with pivot selection based on random sampling can closely approximate the idealized algorithm with respect to the expected number of comparisons. The method is reasonably straightforward and so usable in practice: one uses about n comparisons to split S into elements above and below a pivot value which, with high probability, is quite close to the median. Some care is required in sampling, but as long as one does not insist on minimizing lower order terms too vigorously, this aspect of the analysis is fairly straightforward. Handling the details of the splits is a bit trickier.

Section 4 deals with the deterministic algorithm. As in the deterministic median algorithm of Blum et al. [2], we represent sets as collections of sorted sequences. Each sequence has length about $\ell = \lg(B/n)$. The number of sequences is about n/ℓ . We determine the median of the median of the sequences, call it m , and partition each sequence at m using binary search. This has cost $\mathcal{O}((n/\ell) \lg \ell)$ which is sublinear, if $B = \omega(n)$. After partitioning, we have two collections of sorted sequences on which we recurse. In each collection, we have short sequences (length less than ℓ) and long sequences (length between ℓ and 2ℓ). As long as we have two short sequences of the same length, we merge them using an optimal number of comparisons. The key insight is that the amortized cost of merging is $nH(\alpha)$ where $n\alpha$ is the rank of the pivot element and $H(\alpha) = -\alpha \lg \alpha - (1 - \alpha) \lg(1 - \alpha)$ is the binary entropy function. A simple induction shows that the total cost of merging is $B + o(B) + \mathcal{O}(n)$ and that the total cost of partitioning is $o(B) + \mathcal{O}(n)$.

2 An Idealized Algorithm

Consider multiple quickselect where we pick the exact median of the current subproblem as a pivot. Let $T(n, R)$ denote the number of comparisons needed in the partitioning steps, i.e., we disregard the cost needed for obtaining the pivot.

Theorem 1. $T(n, R) \leq n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 2n.$

Proof: The proof is by induction. For $n = 1$ the claim $0 = T(n, R) \leq 0 - 0 + 1 - 1 + 2$ is true. Now let r_i denote the largest element of R with $r_i \leq n/2$. For the induction step we distinguish two cases and substitute the induction hypothesis for the subproblems in each case.

Case $0 < i < k$:

$$\begin{aligned} T(n, R) &= n - 1 + T\left(\frac{n}{2}, \{r_1, \dots, r_i\}\right) + T\left(\frac{n}{2}, \{r_{i+1} - \frac{n}{2}, \dots, r_k - \frac{n}{2}\}\right) \\ &\leq n - 1 + n \lg \frac{n}{2} - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_i - r_1 + r_k - r_{i+1} + 2n \\ &\quad + \Delta_{i+1} \lg \Delta_{i+1} - \left(\frac{n}{2} - r_i\right) \lg \left(\frac{n}{2} - r_i\right) - \left(r_{i+1} - \frac{n}{2}\right) \lg \left(r_{i+1} - \frac{n}{2}\right) \\ &\leq n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j - r_k + r_1 + 2n \end{aligned}$$

For the last estimate we have used $n - 1 + n \lg(n/2) = n \lg n - 1 \leq n \lg n$ and Lemma 1 below with $x = n/2 - r_i$ and $y = r_{i+1} - n/2$.

Case $i = k$: (the case $i = 0$ is symmetric)

$$\begin{aligned} T(n, R) &= n - 1 + T\left(\frac{n}{2}, R\right) \\ &\leq n - 1 + \frac{n}{2} \lg \frac{n}{2} - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 2\frac{n}{2} \\ &\quad + (n - r_k) \lg(n - r_k) - \left(\frac{n}{2} - r_k\right) \lg \left(\frac{n}{2} - r_k\right) \end{aligned}$$

Now we use $n - 1 + 2n/2 \leq 2n$ and, by Lemma 1,

$$(n - r_k) \lg(n - r_k) - \left(\frac{n}{2} - r_k\right) \lg \left(\frac{n}{2} - r_k\right) \leq \frac{n}{2} \lg \frac{n}{2} + n - r_k.$$

$$T(n, R) \leq n \lg \frac{n}{2} - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 2n + n - r_k .$$

Finally, observe that $n \lg \frac{n}{2} + n - r_k = n \lg n - r_k \leq n \lg n.$ □

Lemma 1. For $x, y \geq 0$ we have $(x + y) \lg(x + y) - x \lg x - y \lg y - (x + y) \leq 0.$

Proof: Let $s = x + y$ and $x = \gamma s$, with $0 \leq \gamma \leq 1$. Then

$$\begin{aligned} s(\lg s - \gamma \lg(\gamma s) - (1 - \gamma) \lg((1 - \gamma)s) - 1) \\ = s(-\gamma \lg(\gamma) - (1 - \gamma) \lg(1 - \gamma) - 1) = s(H(\gamma) - 1) \leq 0. \end{aligned} \quad \square$$

3 The Randomized Algorithm

We now analyze a variant of quickselect where the pivot m is the median of $n^{3/4}$ sample elements chosen uniformly at random from S with replacement. Let $T(n, R)$ denote the expected number of comparisons needed to execute this of multiple quickselect.

Theorem 2. $T(n, R) \leq n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 2n + \mathcal{O}(k^{1/4}n^{3/4})$.

The remainder of this section outlines a proof for the above theorem. Most probabilistic aspects of the problem are packaged in the following lemma:

Lemma 2. *The rank of the pivot m is outside the range $[n/2 - n^{3/4}, n/2 + n^{3/4}]$ with probability at most $1/n$.*

The proof is in the full paper. It is based on Chernoff bounds and very similar to the proof used in the analysis of the Floyd Rivest algorithm [7] in [10].

Using Lemma 2 we can conclude that

$$\begin{aligned} T(n, R) &\leq n - 1 + \mathcal{O}(n^{3/4}) + \frac{1}{n}T(n, R) \\ &\quad + \left(1 - \frac{1}{n}\right) \max_{|\frac{n}{2} - n'| \leq n^{3/4}} (T(n', R') + T(n'', R'')) \end{aligned}$$

where $R' = \{r \in R : r < n'\}$, $R'' = \{r - n' : r \in R, r > n'\}$ and $n'' = n - n'$. The term $n - 1$ stems from the comparisons of elements in $S \setminus \{m\}$ with m . The term $\mathcal{O}(n^{3/4})$ accounts for the expected cost of finding m in the sample using a (randomized) linear time selection algorithm. The next term is the probability $1/n$ that m is an inaccurate estimate of the median times a conservative estimate of the cost in this case — partitioning can never make the subproblems more difficult than the original problem. Subtracting $T(n, R)/n$ and dividing by $1 - 1/n$ yields

$$T(n, R) \leq n + \mathcal{O}(n^{3/4}) + \max_{|\frac{n}{2} - n'| \leq n^{3/4}} (T(n', R') + T(n'', R'')) \quad (1)$$

We now use induction over n using the induction hypothesis

$$T(n, R) \leq n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 2n + (an^{1/4} - b)n^{3/4}$$

where a and b are constants whose value will be implied by constraints showing up in the proof. First note that for any constant n we can make this work by choosing a value for a that is sufficiently much larger than b .

For the induction step we will use the following two lemmata which encapsulate a number of calculations that we defer to the full paper.

Lemma 3. $f(\delta) := (1 + \delta) \lg(1 + \delta) + (1 - \delta) \lg(1 - \delta) \leq 2\delta^2$ for $\delta \in [-1, 1]$.

Lemma 4. For $0 \leq i \leq k$ and $-1 \leq \delta \leq 1$ we have

$$i^{1/4}(1 + \delta)^{3/4} + (k - i)^{1/4}(1 - \delta)^{3/4} \leq 2(k/2)^{1/4}$$

To simplify the max term in Eq. (1), consider a fixed value $0 \leq \delta \leq 2n^{-1/4}$ such that $n' = (1 + \delta)\frac{n}{2}$ (the case $\delta < 0$ is symmetric). Let r_i denote the largest element of R with $r_i \leq n'$. We get three cases:

Case $0 < i < k$: We use the abbreviation $I(x) := x \lg x$.

$$\begin{aligned} T(n', R') + T(n'', R'') &\leq I((1 + \delta)\frac{n}{2}) + I((1 - \delta)\frac{n}{2}) - \sum_{j=1}^{k+1} I(\Delta_j) \\ &\quad + I(\Delta_{i+1}) - I(n' - r_i) - I(r_{i+1} - n') \\ &\quad + r_i - r_1 + 2n' + (ai^{1/4} - b)n'^{3/4} \\ &\quad + r_k - r_{i+1} + 2n'' + (a(k - i)^{1/4} - b)n''^{3/4} \\ &= n \lg n - n + \frac{n}{2}(I(1 + \delta) + I(1 - \delta)) - \sum_{j=1}^{k+1} I(\Delta_j) \\ &\quad + I(\Delta_{i+1}) - I(n' - r_i) - I(r_{i+1} - n') - (r_{i+1} - r_i) \\ &\quad + 2^{-3/4}a(i^{1/4}(1 + \delta)^{3/4} + (k - i)^{1/4}(1 - \delta)^{3/4})n^{3/4} \\ &\quad - 2^{-3/4}((1 + \delta)^{3/4} + (1 - \delta)^{3/4})bn^{3/4} + r_k - r_1 + 2n \end{aligned}$$

Now we can apply a number of estimates:

$I(1 + \delta) + I(1 - \delta) \leq 2\delta^2 \leq 2(2n^{-1/4})^2 = \mathcal{O}(n^{-1/2})$ (using Lemma 3). As in the idealized case, Lemma 1 can be used to eliminate the $I(x)$ terms not in $\sum_{j=1}^{k+1} I(\Delta_j)$. Now it follows (using Lemma 4) that $i^{1/4}(1 + \delta)^{3/4} + (k - i)^{1/4}(1 - \delta)^{3/4} \leq 2(k/2)^{1/4} = 2^{3/4}k^{1/4}$. Finally, $-(1 + \delta)^{3/4} - (1 - \delta)^{3/4} \leq -2 + \mathcal{O}(n^{-1/2})$ using calculus. So

$$\leq n \lg n - n - \sum_{j=1}^{k+1} I(\Delta_j) + \mathcal{O}(\sqrt{n}) + ak^{1/4}n^{3/4} - 2^{1/4}bn^{3/4} + r_k - r_1 + 2n.$$

Substituting this back into Eq. (1) we obtain

$$T(n, R) \leq n \lg n - \sum_{j=1}^{k+1} I(\Delta_j) + \mathcal{O}(n^{3/4}) + ak^{1/4}n^{3/4} - 2^{1/4}bn^{3/4} + r_k - r_1 + 2n .$$

Since $2^{1/4} > 1$ we can use the term $b(2^{1/4} - 1)n^{3/4}$ to cancel the $\mathcal{O}(n^{3/4})$ term by choosing a sufficiently large value for b .

Case $i = k$: This case is a slight generalization of the reasoning from the idealized algorithm and from the case $0 < i < k$. Compared to the idealized case, we get various $\mathcal{O}(n^{3/4})$ terms that we need to cancel. For this purpose we use the term $ak^{1/4}((1 + \delta)\frac{n}{2})^{3/4} = 2^{-3/4}ak^{1/4}n^{3/4} + \mathcal{O}(k^{1/4}n^{1/2})$. Since $2^{-3/4} < 1$ we can choose a sufficiently large to cancel all the unwanted lower order terms.

Case $i = 0$: This case is similar to the case $i = k$ but “easier” because the non-trivial recursion is on a smaller input. We therefore omit the detailed proof. ■

4 The Deterministic Algorithm

In this section we present a deterministic algorithm for the multiple selection problem. It performs $B + o(B) + \mathcal{O}(n)$ comparisons.

The algorithm sets $\ell = \max(1, \lceil \lg(B/n) \rceil)$ and is based on the recursive procedure *multiselect*. The input to *multiselect* is a collection C of non-empty sorted sequences and a non-empty set $R = \{r_1, \dots, r_k\}$ of ranks. Each sequence in the collection has length at most 2ℓ . The procedure returns the elements of rank r_1, r_2, \dots, r_k in the input set. We solve the multiselection problem by calling *multiselect* with a collection of n sequences of length one each and our set R of desired ranks.

We call a sequence *short* if it has length less than ℓ . A collection C satisfies the length invariant if it contains no two short sequences of the same length.

Procedure *multiselect* works as follows: If the total number of elements in the sequences of C is less than $4\ell^2$, then solve the problem by sorting all the elements and if R is empty, simply return. Otherwise, we first establish the length invariant. As long as there are two short sequences of the same length, we merge them into a single sequence. Recall that two sorted sequences of length s can be merged using $2s - 1$ comparisons. After the merge step, we have a collection D of q sequences satisfying the length invariant. We determine the median of the medians of the sequences in D , call it m , and split every sequence in D at m , i.e., into the elements smaller than or equal to m and into the elements larger than m . This gives us collections C' and C'' of size p' and p'' , respectively. We have $p' \leq q$, $p'' \leq q$ and $p' + p'' \geq q$. We also split the ranks and make one or two recursive calls.

This ends the description of the algorithm. We turn to the analysis. For a sequence c we use $|c|$ to denote its length. For a collection C of sorted sequences, let $I(C) = \sum_{c \in C} |c| \lg |c|$ be the *information content* of the collection. *Multi-select* generates a recursion tree T . We use v to denote an arbitrary node of the recursion tree and introduce the following notation: $I_v = I(C)$ is the information content of the collection entering node v , $p_v = |C|$ is the number of sequences in the collection and $n_v = \sum_{c \in C} |c|$ is the total length of the sequences in the collection. $J_v = I(D)$ is the information content of the collection after the merging step and q_v is the number of sequences in the collection. $I'_v = I(C')$ and $I''_v = I(C'')$ are the information content of the sequences resulting from the

partitioning step and p'_v and p''_v are the number of sequences in these collections, respectively. Also, the total number of elements in C' is $\alpha_v n_v$. Finally, we use C_v^m for the number of comparisons spent on merging in node v and C_v^p for the number of comparisons spent on computing the median and partitioning in node v . The total number of comparisons in the calls with $n_v < 4\ell^2$ is $\mathcal{O}(n \lg \ell)$, since the calls are applied to disjoint sets of elements.

Lemma 5. $C_v^m \leq J_v - I_v + q_v - p_v$.

Proof: It takes at most $2s - 1$ comparisons to merge two sequence of length s . Also $2s \lg(2s) - 2(s \lg s) + 1 - 2 = 2s - 1$. □

Lemma 6. $J_v \leq I'_v + I''_v + n_v H(\alpha_v)$.

Proof: Let $D = \{d_1, \dots, d_q\}$ be the collection after the merging step and let $n = n_v$ and $\alpha = \alpha_v$. Each d_i is split into two sequences d'_i and d''_i and C' is formed by the non-empty sequences in $\{d'_1, \dots, d'_q\}$. C'' is defined analogously. Define α_i as $\alpha_i = d'_i/d_i$. We have (using $0 \lg 0 = 0$)

$$\begin{aligned} J_v - I'_v - I''_v &= \sum_{1 \leq i \leq q} (d_i \lg d_i - d'_i \lg d'_i - d''_i \lg d''_i) \\ &= \sum_{1 \leq i \leq q} d_i (\lg d_i - \alpha_i \lg(\alpha_i d_i) - (1 - \alpha_i) \lg((1 - \alpha_i) d_i)) \\ &= \sum_{1 \leq i \leq q} d_i H(\alpha_i). \end{aligned}$$

Next observe that $\sum_i d_i/n = 1$, $\sum_i \alpha_i d_i/n = \sum_i d'_i/n = \alpha$. Thus $\sum_i (d_i/n) H(\alpha_i)$ is a convex combination of the values of H at the arguments α_i . Since H is convex this is bounded by the value of H at the corresponding combination of the arguments, i.e., by the value at $\sum_i (d_i/n) \alpha_i$. Thus $\sum_i (d_i/n) H(\alpha_i) \leq H(\sum_i (d_i/n) \alpha_i) = H(\alpha)$. □

Lemma 7. $C_v^m \leq n_v H(\alpha_v) + I'_v + I''_v - I_v + p'_v + p''_v - p_v$.

Proof: This follows immediately from the two lemmas above and the inequality $q_v \leq p'_v + p''_v$. □

The next Lemma shows that the splitting process is reasonably balanced. A similar Lemma is used in the analysis of the deterministic median algorithm of Blum et al.

Lemma 8. *If $n_v \geq 4\ell^2$ then $1/16 \leq \alpha_v \leq 15/16$ and $H(\alpha_v) \geq 1/4$.*

Proof: We count the number of elements that are smaller than or equal to the median of the medians m after partitioning.

After the merge step, we have a collection of q_v sequences, each of length at most 2ℓ . Therefore, $q_v \geq \lceil n_v/2\ell \rceil$. Recall that by the invariant of the algorithm there are no two sequences of the same length less than ℓ . Or, in other words, there can be at most one sequence for each of the lengths $1, \dots, \ell - 1$. Consider the sequences whose median is less than or equal to m . Their number is $\lceil q_v/2 \rceil \geq n_v/4\ell$. In the worst case this collection contains one sequence from each of the lengths $1, \dots, \ell - 1$. Thus, the number of non-short sequences is at least $n_v/4\ell - (\ell - 1)$ and each of them has at least $\lceil \ell/2 \rceil$ elements that are less than or equal to m . Thus, in total they have at least $(n_v/4\ell - (\ell - 1)) \lceil \ell/2 \rceil \geq n_v/8 - \ell(\ell - 1)/2$ elements. Moreover, the number of elements contained in the short sequences that are smaller than or equal to m are $\sum_{i=1}^{\ell-1} \lceil i/2 \rceil \geq 1/2 \sum_{i=1}^{\ell-1} i = \ell(\ell - 1)/4$. Therefore, over all $\alpha_v n_v \geq n_v/8 - \ell(\ell - 1)/4$. Similarly, for the number of elements greater than m we can show that $(1 - \alpha_v)n_v \geq n_v/8 - \ell(\ell - 1)/4$ and the claim follows. \square

Consider the recursion tree T generated by the algorithm. This is a binary tree. The leaves correspond to calls with either $n_v < 4\ell^2$ or empty R_v . Interior nodes have $n_v > 4\ell^2$ and non-empty R_v . The total cost of merging is

$$\sum_{v \in T} C_v^m \leq \sum_{v \in T} (n_v H(\alpha_v) + I'_v + I''_v - I_v + p'_v + p''_v - p_v).$$

We first bound $\sum_{v \in T} n_v H(\alpha_v)$.

Lemma 9. *Let $T(n, R) = \sum_{v \in T} n_v H(\alpha_v)$. Then*

$$T(n, R) \leq \sum_{j=1}^{k+1} \Delta_j \lg \frac{n}{\Delta_j} + r_k - r_1 + 16n = n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 16n$$

whenever R is non-empty².

Proof: We use induction. If $n < 4\ell^2$ and R is non-empty, $T(n, R) = 0$ and the right hand side is at least zero. If R is non-empty, we split into subproblems (n', R') and (n'', R'') , with $n' = \alpha n$, $n'' = (1 - \alpha)n$, $R' = \{r : r \in R, r < n'\}$ and $R'' = \{r - n' : r \in R, r > n'\}$. Then $nH(\alpha) = n \lg n - n' \lg n' - n'' \lg n''$. Let $k' = |R'|$. By symmetry, we may assume $k' > 0$. Let $\Delta'_1, \dots, \Delta'_{k'+1}$ and $\Delta''_1, \dots, \Delta''_{k''+1}$ be the sequence of Δ 's for the two subproblems. Then $\Delta'_1, \dots, \Delta'_{k'}, \Delta'_{k'+1} + \Delta''_1, \Delta''_2, \dots, \Delta''_{k''+1}$ is the sequence of Δ 's in the original problem. We need to distinguish cases.

Assume first $k'' > 0$. Then we can apply the induction hypothesis to both subproblems and obtain (writing x for $\Delta'_{k'+1}$ and y for Δ''_1)

² If R is empty, $k = 0$ and $r_k = 0$ and $r_1 = n$. This will not make sense in the inductive proof.

$$\begin{aligned}
 T(n, R) &\leq nH(\alpha) + T(n', R') + T(n'', R'') \\
 &\leq n \lg n - n' \lg n' - n'' \lg n'' + n' \lg n' - \sum_{j=1}^{k'+1} \Delta'_j \lg \Delta'_j + r'_k - r_1 + 16n' \\
 &\quad + n'' \lg n'' - \sum_{j=1}^{k''+1} \Delta''_j \lg \Delta''_j + r_k - r_{k'+1} + 16n'' \\
 &= n \lg n - \sum_{j=1}^{k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 16n \\
 &\quad + (x + y) \lg(x + y) - x \lg x - y \lg y - (r_{k'+1} - r_{k'})
 \end{aligned}$$

and we have established the induction step using Lemma 1 and $x+y = r_{k'+1} - r_{k'}$.

Assume next $k'' = 0$. We apply the induction hypothesis to the first subproblem and obtain

$$\begin{aligned}
 T(n, R) &\leq nH(\alpha) + T(n', R') \\
 &\leq n \lg n - n' \lg n' - n'' \lg n'' + n' \lg n' - \sum_{1 \leq j \leq k+1} \Delta'_j \lg \Delta'_j + r_k - r_1 + 16n' \\
 &= n \lg n - \sum_{1 \leq j \leq k+1} \Delta_j \lg \Delta_j + r_k - r_1 + 16n \\
 &\quad + (\Delta'_{k+1} + n'') \lg(\Delta'_{k+1} + n'') - \Delta'_{k+1} \lg \Delta'_{k+1} - n'' \lg n'' - 16n''
 \end{aligned}$$

We have $\Delta'_{k+1} + n'' \leq n \leq 16n''$ by Lemma 8. An application of Lemma 1 completes the induction step. \square

Lemma 10. $\sum_{v \in T} (I'_v + I''_v - I_v + p'_v + p''_v - p_v) \leq n \lg(2\ell)$.

Proof: The sum telescopes to

$$-I_{\text{root}} - p_{\text{root}} + \sum_{\substack{v \in T \text{ and there is} \\ \text{no recursive call for } C'}} (I'_v + p'_v) + \sum_{\substack{v \in T \text{ and there is} \\ \text{no recursive call for } C''}} (I''_v + p''_v).$$

The collection entering the root consists of sequences of length 1 and hence $I_{\text{root}} = 0$ and $p_{\text{root}} = n$. The collections for which there is no recursive call are disjoint and hence their total length is n . Also no sequence is longer than 2ℓ and every sequence is non-empty. Thus their contribution is bounded by $n \lg(2\ell) + n$. \square

We next turn to the cost of computing the median of the medians and partitioning our sequences at the median of medians. We let β be a constant such that the median of z elements can be computed with βz comparisons.

Lemma 11. *The total cost C^p of computing the median of the medians and partitioning is bounded by*

$$\frac{4(\lg 2\ell + \beta)}{\ell} \sum_{j=1}^{k+1} \Delta_j \lg \frac{n}{\Delta_j} + \frac{4(\lg 2\ell + \beta)}{\ell} (r_k - r_1) + \mathcal{O}(n) + \mathcal{O}(\beta \ell n) + \mathcal{O}(n \ell \lg \ell).$$

Proof: We split the cost for computing medians and partitioning into two parts: the cost arising from non-short sequences and the cost arising from short sequences.

The first three terms refer to the cost of finding the median of medians and partitioning arising from the non-short sequences. The median of each sequence is known since they are sorted. At each node v the number of non-short sequences is at most $\lfloor n_v/\ell \rfloor \leq n_v/\ell$ and hence the share of the non-short sequences is $\beta n_v/\ell$ comparisons in node v . In order to partition at m we perform binary search on each sequence with cost at most $\lg 2\ell$, thus, the cost over all sequences is at most $n_v \lg 2\ell/\ell$. Therefore, the comparisons spent in node v for non-short sequences is $(\lg 2\ell + \beta)n_v/\ell$. Next observe that $1 \leq 4H(\alpha_v)$ for any vertex v and hence $(\lg 2\ell + \beta)n_v/\ell \leq 4(\lg 2\ell + \beta)H(\alpha_v)n_v/\ell$. The bound now follows from Lemma 9.

The fourth term refers to the cost contributed by the short sequences for computing the median of medians. Since we have at most $\ell - 1$ short sequences in each node, they contribute $\beta(\ell - 1)$ to the number of comparisons at each node of the recursion tree. Hence, they contribute an $\mathcal{O}(\beta \ell n)$ over all.

The last term refers to the cost of partitioning the short sequences at m . At each node this cost is at most $\sum_{i=1}^{\ell-1} \lg i \leq \ell \lg \ell$ and the bound follows. \square

Lemma 12. *The total cost for the base case of the recursion is bounded by βn .*

Proof: The collections for which there is no recursive call are disjoint and the cost of selecting the median of s elements is βs . \square

Theorem 3. *The deterministic multi-selection algorithm uses $B + o(B) + \mathcal{O}(n)$ comparisons.*

Proof: Summing the bounds in Lemmas 9, 10, 11, and 12 we obtain the following upper bound:

$$\begin{aligned} & B + \mathcal{O}(n) + \mathcal{O}(n \lg \ell) + \mathcal{O}((1 + \lg \ell)/\ell) \cdot B + \mathcal{O}(n) + \mathcal{O}(n \ell \lg \ell) \\ &= B + \mathcal{O}(n) + \mathcal{O}\left(\frac{1 + \lg \lg(B/n)}{\lg(B/n)} + \frac{\lg(B/n) \lg \lg(B/n)}{B/n}\right) \cdot B. \end{aligned}$$

This is $B + o(B) + \mathcal{O}(n)$. \square

5 Conclusion

We have shown that multiple quickselect performs an optimal number of comparisons up to a linear term. There are several ways to improve this linear term which is particularly interesting when the lower bound is linear itself. For example, when $r_k < n/2$ (or $r_1 > n/2$) it pays to choose the pivot such that its

rank is just a bit larger than r_k (or a bit smaller than r_1). It can then be shown that the linear term is reduced from $2n$ to $3n/2$. Also note that for $k = 1$ the algorithm then becomes a special case of the optimal algorithm by Floyd and Rivest [7]. Likewise, the lower bound could be further refined. However, since there is even a remaining linear size gap between upper and lower bound for sorting, completely closing the gap remains a distant possibility.

There is a long standing constant factor gap between the upper bounds for the best deterministic selection algorithms and the lower bound. Our deterministic algorithm shows that this gap becomes a lower order term for multiple selection.

Multiple quickselect is obviously highly practical. It might be quite complicated to implement our *deterministic* algorithm efficiently but at the end it might work quite well: Its cost is dominated by merging operations that are known to be quite fast. Moreover, since the algorithm executes batches of many small binary merging operations, one might execute them in parallel using multithreading or instruction parallelism. This approach might mitigate the impact of data dependencies and branch mispredictions.

Simple Extractors via Constructions of Cryptographic Pseudo-random Generators

Marius Zimand

Department of Computer and Information Sciences,
Towson University, Baltimore
<http://triton.towson.edu/~mzimand>

Abstract. Trevisan has shown that constructions of pseudo-random generators from hard functions (the Nisan-Wigderson approach) also produce extractors. We show that constructions of pseudo-random generators from one-way permutations (the Blum-Micali-Yao approach) can be used for building extractors as well. Using this new technique we build extractors that do not use designs and polynomial-based error-correcting codes and that are very simple and efficient. For example, one extractor produces each output bit separately in $O(\log^2 n)$ time. These extractors work for weak sources with min entropy λn , for arbitrary constant $\lambda > 0$, have seed length $O(\log^2 n)$, and their output length is $\approx n^{\lambda/3}$.

1 Introduction

This paper puts forward a new framework for constructing extractors based on a new connection between extractors and pseudo-random generators. A pseudo-random generator takes as input a short random string called the seed and outputs a long string that cannot be distinguished from a truly random string by any test that is computable by circuits of bounded size. An extractor has two inputs: (a) The first one comes from an imperfect (i.e., with biased bits and correlations among bits) distribution on binary strings of some length and it is called the weakly-random string; (b) the second one is a short random seed. The output is a long string that cannot be distinguished from a truly random string by *any* test. One difference between pseudo-random generators and extractors is the number of inputs (one versus two). From a technical point of view this difference is minor because the known constructions of pseudo-random generators implicitly do use an extra input which is a function that in some sense is computationally hard. The fundamental difference is in the randomness requirement for the output. Thus, while the output of a pseudo-random generator looks random in a complexity-theoretic way, the output of an extractor is random (or very close to random) in an absolute information-theoretic way. Consequently pseudo-random generators and extractors appear to belong to two very different worlds, and, for many years, the developments in the construction of pseudo-random generators and extractors went along distinct research lines.

Trevisan [Tre01] has made a breakthrough contribution in this area by observing that the (apparently superficial) similarity between extractors and pseudo-random generators extends to some of the methods to build the two kind of objects. For the reasons mentioned above, Trevisan's result has been extremely surprising. It has also been an isolated example of a transfer from the complexity theory standard arsenal of techniques to the information theoretical area. In this paper we extend Trevisan's observation and establish that, as far as construction methods are concerned, there is a truly close relationship between pseudo-random generators and extractors. Specifically, we show that the other major route (than the one followed by Trevisan) that leads to pseudo-random generators (of a somewhat different kind) can also be used to construct extractors. Some explanations are in order at this point. There are two known approaches for constructing pseudo-random generators. One approach uses as a building block a hard function f and, in one typical setting of parameters, for any given $k \in \mathbf{N}$, builds a pseudo-random generator g with outputs of length n that is secure against adversary tests computable in time n^k . The running time to compute $g(x)$ is $n^{k'}$, for some $k' > k$. This kind of pseudo-random generators can be used for derandomizing BPP computations. They cannot be used in cryptography, because in this setting, it is unwise to assume that the adversary is endowed with less computational power (n^k) than the legitimate users ($n^{k'}$). Henceforth we will call this type of pseudo-random generator a "derandomization pseudo-random generator" (also known as a Nisan-Wigderson pseudo-random generator). The second approach uses as a building block a hard object of a more sophisticated type, namely a one-way function (the hardness of such a function f consists in the difficulty to invert it, but f must satisfy an additional property, namely, it should be easy to calculate $f(x)$ given x). It is known that given a one-way function, one can construct a pseudo-random generator [HILL99]. An easier construction produces a pseudo-random generator from any one-way length-preserving permutation. This second approach has the disadvantage that is using as a building block a more demanding type of object. The advantage of the method is that a pseudo-random generator g constructed in this way can be used in cryptography because $g(x)$ can be calculated in time significantly shorter than the time an adversary must spend to distinguish $g(x)$ from a truly random string. Henceforth we will call this type of pseudo-random generator a "crypto pseudo-random generator" (also known as a Blum-Micali-Yao pseudo-random generator).

Trevisan has shown that the known methods for constructing derandomization pseudo-random generators also produce extractors. More precisely, he has shown that the constructions of pseudo-random generators from hard functions given by Nisan and Wigderson [NW94] and Impagliazzo and Wigderson [IW97] can be used almost directly to produce extractors. His method has been extended in a number of papers to build extractors with increasingly better parameters (see the survey paper by Shaltiel [Sha02]). In the paper [Tre99], the conference version of [Tre01], Trevisan has suggested that the methods to construct crypto pseudo-random generator cannot be used to build extractors. We show that in

fact they can, at least for a combination of parameters that, even though not optimal, is not trivial. Moreover, we show that the extractors constructed in this way are very simple and efficient. The first extractor built in this paper follows almost directly the classical construction of a pseudo-random generator from a one-way permutation. It runs in $O(n \log n)$ time (in the standard RAM model) and is very simple. The following is a complete description of it. The input consists of the weakly-random string X , of length $n = \tilde{n}2^{\tilde{n}}$ for some integer \tilde{n} , and of the seed $((x_1, \dots, x_\ell), r)$, with $|x_i| = \tilde{n}$, $\ell = O(\tilde{n})$, and $|r| = \ell\tilde{n}$. We view X as a function $X : \{0, 1\}^{\tilde{n}} \rightarrow \{0, 1\}^{\tilde{n}}$, and, using the standard procedure, we transform X into a circular permutation $R : \{0, 1\}^{\tilde{n}} \rightarrow \{0, 1\}^{\tilde{n}}$. For $i = 0$ to $m - 1 = n^{\Omega(1)}$, we calculate b_i as the inner product modulo 2 of r and $(R^i(x_1) \dots R^i(x_\ell))$. The output is $b_0 \dots b_{m-1}$. A type of efficiency which has received a lot of attention recently is that of sublinear time. It may be the case that in some applications we only need the i -th bit from the sequence of random bits that are extracted from the weakly-random string. We would like to obtain this bit in time polynomial in the length of the index i , which typically means polylog time in the input length (under the assumption that each input bit can be accessed in one time unit). By analogy with the case of list-decodable codes, we call an extractor with this property, a *bitwise locally computable extractor*.¹ The second extractor that we build is of this type. It relies on the same basic method used in the construction of the first extractor, combined with the idea of taking consecutive inputs of the hard function as in the extractor of Ta-Shma, Zuckerman and Safra [TSZS01]. This second extractor is even simpler and its complete description is as follows. The input consists of the weakly-random string X of length $n = \tilde{n} \cdot 2^{\tilde{n}}$, for some natural number \tilde{n} , and of the seed $((x_1, \dots, x_\ell), r)$, with $|x_i| = \tilde{n}$, for all i , $\ell = O(\tilde{n})$, and $|r| = \ell\tilde{n}$. We view X as the truth-table of a function $X : \{0, 1\}^{\tilde{n}} \rightarrow \{0, 1\}^{\tilde{n}}$. For $i = 0$ to $m - 1 = n^{\Omega(1)}$, we calculate b_i as the inner product modulo 2 of r and $(X(x_1 + i), \dots, X(x_\ell + i))$, where the addition is done modulo $2^{\tilde{n}}$. The output is $b_0 \dots b_{m-1}$.

The parameters of the extractors constructed in this paper are not optimal. Both extractors that have been described above work for weak sources having min-entropy λn , for arbitrary constant $\lambda > 0$, use a random seed of length $O(\log^2 n)$, and the output length is approximately $n^{\lambda/3}$. A variant of the second extractor has seed length $O(\log n)$ (here, for simplicity, we assume that the extractor's error parameter ϵ is a constant), but the output length reduces to $2^{O(\sqrt{\log n})}$.

Lu's extractor [Lu04] coupled with the constructions of designs from the paper of Hartman and Raz [HR03] can be seen to be also a bitwise locally computable extractor with parameters similar to those of our second extractor (note that the designs in [HR03] appear to imply extractors with seed length $\Omega(\log^2 n)$). Lu's extractor is using expander graphs and the designs from [HR03]

¹ The simpler name *locally computable extractor* is already taken by a different kind of efficient extractors, namely by extractors computable in space linear in the output length, see [Vad04], [Lu04].

need somewhat unwieldy algebraic objects. It seems to us that the extractors presented in this paper are simpler than all the extractors from the literature.² At the highest level of abstraction, our extractors follow the “reconstruction paradigm” (see [Sha02]) typical to Trevisan’s extractor and to its improvements [RRV99, TSZS01, SU01]. The major differences are that our extractors avoid (1) the use of designs (in this respect they are similar to the extractors in [TSZS01] and [SU01]), and, perhaps more strikingly, (2) the encoding of the weakly-random string with an error-correcting code having a good list-decoding property. Our extractors can be implemented very easily and are thus suitable for practical applications. For example, they can be utilized to generate one-time pad keys in cryptosystems based on the bounded-storage model (see the papers of Lu [Lu04] and Vadhan [Vad04]), or for constructions of error-correcting codes using the scheme in [TSZ01] (the extractors built in this paper are actually strong extractors—for definition see, for example [Sha02]—as required by this scheme). They may also have theoretical applications in situations where the kind of efficiency achieved by our extractors is essential.

1.1 Definitions

Notations: $x \odot y$ denotes the concatenation of the strings x and y , $|x|$ denotes the length of the string x , and $\|A\|$ denotes the cardinality of the set A . For two binary strings x and r of the same length, $b(x, r)$ denotes the inner product of x and r viewed as vectors over the field $\text{GF}(2)$. Let $n \in \mathbf{N}$. Let X_n, Y_n be two distributions on Σ^n . The statistical distance between X_n and Y_n is denoted $\Delta_{\text{stat}}(X_n, Y_n)$ and is defined by $\Delta_{\text{stat}}(X_n, Y_n) = \max_{A \subseteq \{0,1\}^n} |\text{Prob}(X_n \in A) - \text{Prob}(Y_n \in A)|$. The computational distance between X_n and Y_n relative to size S is denoted $\Delta_{\text{comp}, S}(X_n, Y_n)$ and is defined by $\Delta_{\text{comp}, S}(X_n, Y_n) = \max |\text{Prob}(C(X_n) = 1) - \text{Prob}(C(Y_n) = 1)|$, where the maximum is taken over all circuits C of size $\leq S$. Abusing notation, we identify a circuit C with the set of strings x for which $C(x) = 1$. Thus, $x \in C$ is equivalent to $C(x) = 1$. The min-entropy of a random variable taking values in $\{0, 1\}^n$ is given by $\min \left\{ \log \frac{1}{\text{Prob}(X=a)} \mid a \in \{0, 1\}^n, \text{Prob}(X = a) \neq 0 \right\}$. For each $n \in \mathbf{N}$, let U_n denote the uniform distribution over $\{0, 1\}^n$.

Definition 1.1. (Extractor) *The values n, k, d, m are integer parameters, and $\epsilon > 0$ is a real number parameter. A function $E: \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is a (k, ϵ) -extractor if for every distribution X on $\{0, 1\}^n$ with min-entropy at least k , the distribution $E(X, U_d)$ is ϵ -close to the uniform distribution U_m in the statistical sense, i.e., $\Delta_{\text{stat}}(E(X, U_d), U_m) \leq \epsilon$.*

We fix parameters n, d, m and ϵ and a function $E: \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$. Let us consider an arbitrary set $W \subseteq \{0, 1\}^m$ and a string $x \in \{0, 1\}^n$. We say

² We note that Dziembowski and Maurer [DM04] give a similarly simple construction of an object that is related to extractors.

that x hits W ϵ -correctly via E if $\left| \frac{\| \{E(x,y) | y \in \{0,1\}^m\} \cap W \|}{\| \{0,1\} \|} - \frac{\|W\|}{\| \{0,1\} \|} \right| \leq \epsilon$. The following lemma has appeared more or less explicitly in the literature (see, for example, [Sha02]).

Lemma 1.2. *Let $E: \{0,1\}^n \times \{0,1\}^d \rightarrow \{0,1\}^m$ and $\epsilon > 0$. Suppose that for every $W \subseteq \{0,1\}^m$, the number of $x \in \{0,1\}^n$ that do not hit W ϵ -correctly via E is at most 2^t , for some t . Then E is a $(t + \log(1/\epsilon), 2\epsilon)$ -extractor.*

1.2 Overview and Comparison with Trevisan's Approach

Trevisan's method is based on the constructions of pseudo-random generators from hard functions given in [NW94] and in [IW97]. These constructions use a function f as a block-box and construct from it a function g_f that stretches the input (i.e., $|g_f(x)| \gg |x|$) and which has the following property. If there exists a circuit D that distinguishes $g_f(x)$, when x is randomly chosen in the domain of g_f , from the uniform distribution, then there is a small circuit A , which uses D as a subroutine, such that A calculates f (or an approximation of f , depending on whether we are using the method in [IW97] or the one in [NW94]). Therefore if f is a hard function, there can be no circuit D as above of small size and thus g_f is a pseudo-random generator. Trevisan has observed that (1) the truth-table of f can be viewed as a string produced by a weak source that can serve as an extra input of the pseudo-random generator, and (2) the circuit A invoking D can be considered as a special type of a circuit that is endowed with D -gates. By a standard counting argument, it can be shown that, for any circuit D , regardless of its size, the set of functions that can be calculated by small circuits with D -gates is small. A circuit D can be viewed statically as a statistical test (more exactly, the statistical test associated to the circuit D is the set of strings accepted by D). In the new terminology, the fact that D distinguishes the distribution of $g_f(x)$ from the uniform distribution with ϵ bias can be restated as " f does not hit D ϵ -correctly via g ." The main property mentioned above can be restated as saying that the set of functions f that do not hit D ϵ -correctly is included in the set of functions computable by small circuits with D -gates. Since the latter set is small, the former set is small as well, and thus, by Lemma 1.2, the construction yields an extractor. In a nutshell, Trevisan's method replaces hard functions (a complexity-theoretic concept) with random functions (an information-theoretic concept) and takes advantage of the fact that a random function is hard and thus the construction carries over in the new setting.

We would like to follow a similar approach for the construction of crypto pseudo-random generators from one-way permutations. Those constructions do use a one-way permutation R as a black box to construct a pseudo-random generator g_R , and thus a truth-table of R can be considered as an extra input of the pseudo-random generator. Also, the proof is a reduction that shows that if a circuit D distinguishes $g_R(x)$ from the uniform distribution, then there is a small circuit A , invoking the circuit D , that inverts R on a large fraction of inputs. To close the proof in a similar way to Trevisan's approach, we would

need to argue that the vast majority of permutations are one-way. It seems that we hit a major obstacle because, unlike the case of hard functions, it is not currently known if even a single one-way function exists (and we are seeking an unconditional proof for the extractors that we build). We go around this obstacle by allowing algorithms to have oracle access to the function they compute. Thus, in the above analysis, the circuit A , in addition to invoking the circuit D , will also have oracle access to the permutation R . In this setting all permutations are easy to compute because, obviously, there is a trivial constant-time algorithm that, for any permutation $R : \{0, 1\}^n \rightarrow \{0, 1\}^n$, given the possibility to query R , calculates $R(x)$. We need to argue that only few permutations R are invertible by algorithms that can query R in a bounded fashion. More precisely we need to estimate the size of the set of permutations $R : \{0, 1\}^n \rightarrow \{0, 1\}^n$ that can be inverted on a set of T elements in $\{0, 1\}^n$ by circuits that can pose Q queries to R . This problem has been considered by Impagliazzo [Imp96] and by Gennaro and Trevisan [GT00]. Their techniques seem to work for the case $T \cdot Q < 2^n$ and lead to extractors that work only for sources with high min-entropy.³

We obtain better parameters by restricting the type of one-way permutations and the type of circuits that attempt to invert them. A closer look at the standard construction of Blum-Micali-Yao pseudo-random generators reveals that the circuit A with D -gates manages to determine x using only the values $R(x), R^2(x), \dots, R^m(x)$ (where m is the generator's output length). It is thus enough to consider only circuits that use this pattern of queries to the permutation R . Intuitively, for a random permutation R , the value of x should be almost independent of the values of $R(x), R^2(x), \dots, R^m(x)$, and thus, a circuit A restricted as above cannot invert but a very small fraction of permutations. If we take R to be a random circular permutation, the above intuition can be easily turned into a proof based on a Kolmogorov-complexity counting argument. A circular permutation $R : \{0, 1\}^n \rightarrow \{0, 1\}^n$ is fully specified by the sequence $(R(1), R^2(1), \dots, R^{N-1}(1))$, where $N = 2^n$. If a circuit A restricted as above inverts $R(x)$ for all x , then the permutation R is determined by the last m values in the above sequence, namely $R^{N-m}(1), R^{N-(m-1)}(1), \dots, R^{N-1}(1)$. Indeed, given the above values, the circuit A can determine $R^{N-m-1}(1)$, which is $R^{-1}(R^{N-m}(1))$, and then $R^{N-m-2}(1)$, and so on till $R(1)$ is determined. Therefore such a permutation R , given the circuit A , can be described concisely using only $m \cdot n$ bits (for specifying, as discussed, the last m elements in the above sequence). In fact, in our case, the circuit A does not invert $R(x)$ for all $x \in \{0, 1\}^n$, and, therefore, the values of R at the points where the inversion fails have to be included in the description. A further complication is that even for the successful cases, the circuit A only list-inverts $R(x)$, which means that A on input $R(x)$ produces a relatively short list of elements, one of which is x . Thus, one also has to include in the description of R the rank of x in the

³ On the other hand, these extractors have the interesting property that their output looks random even to statistical tests that have some type of access to the weakly-random string. These results will be reported in a separate paper.

list produced by A . The quantitative analysis of the standard construction of a crypto pseudo-random generator shows that if the permutation R does not hit D ϵ -correctly, then the circuit A with D -gates is only able to produce for an ϵ/m fraction of $R(x), x \in \{0, 1\}^n$, a list with m^2/ϵ^2 elements one of which is x . For interesting values of m (the pseudo generator's output length), the ϵ/m fraction is too small and needs to be amplified to a value of the form $(1 - \delta)$, for a small constant δ . This can be done by employing another technique that is well-known in the context of one-way functions. Namely, we use Yao's method of converting a weak one-way function into a strong one-way function by taking the direct product. In other words, we start with a circular permutation R , define (the direct product) $\bar{R}(x_1, \dots, x_\ell) = R(x_1) \odot \dots \odot R(x_\ell)$ (where \odot denotes concatenation), for some appropriate value of ℓ , and use \bar{R} in the definition of the extractor (instead of R in our tentative plan sketched above). It can be shown that, for $\ell = O((1/\delta) \log(1/\gamma))$, if a circuit A list-inverts (y_1, \dots, y_ℓ) , with list size $T = m^2/\epsilon^2$, for a $\gamma = \epsilon/m$ fraction of ℓ -tuples $(y_1, \dots, y_\ell) \in (\{0, 1\}^n)^\ell$, then there is a probabilistic algorithm A' that list-inverts $R(x)$ with list size $O(n \cdot T \cdot (1/\delta) \cdot (1/\gamma) \cdot \log(1/\gamma))$ for a $(1 - \delta)$ fraction of $x \in \{0, 1\}^n$. By fixing the random bits and the queries that depend on these random bits, we can obtain a brief description of R as in our first tentative plan. It follows that only few permutations R can hit D ϵ -incorrectly and, therefore, by Lemma 1.2, we have almost obtained an extractor (we also need to convert an arbitrary function $X : \{0, 1\}^n \rightarrow \{0, 1\}^n$ into a circular permutation $R : \{0, 1\}^n \rightarrow \{0, 1\}^n$, which is an easy task).

The second extractor starts from this idea and the observation that, for the sake of building an extractor, we can work with a function \bar{X} (i.e., not necessarily a permutation) and consider consecutive values $\bar{X}(\bar{x}), \bar{X}(\bar{x} + 1), \dots, \bar{X}(\bar{x} + m)$, as in the extractor of Ta-Shma, Zuckerman, and Safra [TSZS01]. That extractor (as well as all the extractors using the "reconstruction paradigm") takes \bar{X} to be the encoding of an arbitrary function X with a good list-decoding property and some other special algebraic properties. This is necessary, among other things, for the same type of amplification as in our discussion above. We use instead a direct-product construction that is much simpler to implement (however, the cost is a longer seed length).

Because of the space constraints, most of the proofs are omitted. A full version of the paper is available [Zim05].

2 An Extractor from a Crypto Pseudo-random Generator

Restricted permutations, restricted circuits

The space from where we randomly choose permutations consists of permutations of a special form. First we consider the set CIRC of all circular permutations $R : \{0, 1\}^n \rightarrow \{0, 1\}^n$. Next, for some parameter $\ell \in \mathbf{N}$, we take the ℓ -direct product of CIRC. This means that for any $R \in \text{CIRC}$, we define

$\bar{R}_\ell : \{0, 1\}^{\ell n} \rightarrow \{0, 1\}^{\ell n}$ by $\bar{R}_\ell(x_1 \odot x_2 \odot \dots \odot x_\ell) = R(x_1) \odot R(x_2) \odot \dots \odot R(x_\ell)$. We let PERM_ℓ be the set $\{\bar{R}_\ell \mid R \in \text{CIRC}\}$. We will drop the subscript ℓ when its value is clear from the context or when it is not relevant in the discussion.

We want to argue that no circuit that queries \bar{R} in a restricted way can invert a “large” fraction of $\bar{R}(\bar{x})$ except for a “small” fraction of permutations \bar{R} in PERM . In order to obtain adequate values for “large” and “small” we will impose the following restriction on the pattern of queries that the circuit can make.

Definition 2.1. *An oracle circuit C on inputs of length at least $\ell \cdot n$ is L -restricted if on any input x and for all oracles $\bar{R} \in \text{PERM}_\ell$, C only queries $x_{\text{first}}, \bar{R}(x_{\text{first}}), \bar{R}^2(x_{\text{first}}), \dots, \bar{R}^{L-1}(x_{\text{first}})$, where x_{first} is the string consisting of the first $\ell \cdot n$ bits of x .*

We will allow the circuits to attempt to invert \bar{R} in a weaker form: On input $\bar{R}(\bar{x})$, $C^{\bar{R}}$ outputs a small list of strings one of which (in case C succeeds) is \bar{x} . When this event happens, we say that $C^{\bar{R}}$ list-inverts \bar{x} . We are interested in estimating the number of permutations $\bar{R} \in \text{PERM}$ so that $C^{\bar{R}}$ list-inverts $\bar{R}(\bar{x})$ for a large fraction of \bar{x} .

Definition 2.2. *Let C be an oracle circuit. A permutation \bar{R} is (γ, T) -good for C if for at least a γ fraction of $\bar{x} \in \{0, 1\}^{\ell n}$, $C^{\bar{R}}$ on input $\bar{R}(\bar{x})$ outputs a list of T elements that contains \bar{x} .*

The next lemma shows that a permutation that is (γ, T) -good for a restricted circuit C admits a short description conditioned by C being given.

Lemma 2.3. *Let $\gamma > 0$, $n \in \mathbf{N}$, $L \in \mathbf{N}$, and $T \in \mathbf{N}$. Let $N = 2^n$. Let $\delta > 0$ and let $\ell = \lceil \frac{3}{\delta} \cdot \log(\frac{2}{\gamma}) \rceil$. Assume $\delta \geq 2e^{-n}$ and $\ell < L + 1$. Let C be an L -restricted circuit, having inputs of length ℓn , and let $\bar{R} \in \text{PERM}_\ell$ be a permutation that is (γ, T) -good for C . Then, given C and ℓ , \bar{R} can be described using a number of bits that is bounded by $2\delta Nn + Ln + N \log n + (\log 6)N + N \log(1/\delta) + N \log \log(2/\gamma) + N \log(1/\gamma) + N \log T + 18n^2 \cdot L \cdot \frac{1}{\gamma} \cdot (\frac{1}{\delta})^2 (\log \frac{2}{\gamma})^2$.*

The above lemma allows us to estimate the number of permutations that are (γ, T) -good for some L -restricted circuit C . We state the result for a particular combination of parameters that will be of interest in our application.

Lemma 2.4. *Let $n \in \mathbf{N}$, $m \in \mathbf{N}$, $\epsilon > 0$, $\delta > 0$. Let $N = 2^n$. Consider $\gamma = \epsilon/m$ and $T = m^2 \cdot (1/\epsilon^2)$. Let $\ell = \lceil (3/\delta) \log(2/\gamma) \rceil$. Assume that $\delta = O(1)$ and $m^2 \cdot (1/\epsilon) = o(N/n^4)$. Let C be an m -restricted circuit, with inputs of length ℓn . Then the number of permutations \bar{R} in PERM_ℓ that are (γ, T) -good for C is bounded by 2^h , where $h = 3\delta \cdot N \cdot n + 3N \log m + 3N \log(1/\epsilon)$.*

Analysis of the construction of pseudo-random generators from one-way permutations

We recall the classic construction (Blum and Micali [BM84] and Yao [Yao82]) of a pseudo-random generator from a one-way permutation.

The function $G_{\bar{R}}(\bar{x}, r)$ is defined by the following algorithm.

Input: \bar{R} a permutation of $\{0, 1\}^{\ell n}$, $\bar{x} \in \{0, 1\}^{\ell n}$, $r \in \{0, 1\}^{\ell n}$.

For $i = 0$ **to** $m - 1$, $b_i = b(r, \bar{R}^i(\bar{x}))$.

Output $b_0 \odot b_1 \odot \dots \odot b_{m-1}$.

The following lemma (whose proof follows closely the classical proof – see for example [Zim04]– and, in addition, analyzes the pattern of queries) establishes the properties of the above function in an information-theoretic context.

Lemma 2.5. *Let C_4 be a circuit. Then there are $2^{m+1} - 4$ circuits $C_{1,1}, \dots, C_{1,2^{-1}-4}$ such that*

- (1) *If \bar{R} is a permutation with $|\text{Prob}_{\bar{x}, r}(G_{\bar{R}}(\bar{x}, r) \in C_4) - \text{Prob}(U_m \in C_4)| > \epsilon$, (i.e., \bar{R} does not hit C_4 ϵ -correctly via G), then there is some circuit $C_{1,i}$ such that for at least a fraction $\frac{\epsilon}{m}$ of \bar{x} , $C_{1,i}^{\bar{R}}$ on input $\bar{R}(\bar{x})$ outputs a list of $m^2 \cdot (\frac{1}{\epsilon})^2$ strings that contains \bar{x} (i.e., \bar{R} is $(\epsilon/m, m^2/\epsilon^2)$ -good for $C_{1,i}$).*
- (2) *All the circuits $C_{1,i}$ are $(m - 2)$ -restricted.*

The extractor

We first build a special type of extractor in which the weakly-random string is the truth-table of a permutation in PERM .

The following parameters will be used throughout this section. Let $\epsilon > 0, \delta > 0$, and $n, m \in \mathbf{N}$ be parameters. Let $N = 2^n$. Let $\ell = \lceil (3/\delta) \log(2m \cdot (1/\epsilon)) \rceil$. We consider the set of permutations PERM_ℓ . We assume that $\delta = O(1)$ and $m^2 \cdot (1/\epsilon) = o(N/n^4)$. Let $G : \text{PERM}_\ell \times (\{0, 1\}^{\ell n} \times \{0, 1\}^{\ell n}) \rightarrow \{0, 1\}^m$ be the function defined by the following algorithm (the same as the algorithm for $G_{\bar{R}}$ from the previous section).

Parameters: $\ell \in \mathbf{N}, m \in \mathbf{N}$.

Input: $\bar{R} \in \text{PERM}_\ell$, $(\bar{x}, r) \in \{0, 1\}^{\ell n} \times \{0, 1\}^{\ell n}$.

For $i = 0$ **to** $m - 1$, $b_i = b(r, \bar{R}^i(\bar{x}))$.

Output $b_0 \odot b_1 \odot \dots \odot b_{m-1}$.

The following lemma, in view of Lemma 1.2, shows that G is an extractor for the special case of weakly-random strings that are truth-tables of permutations in PERM_ℓ .

Lemma 2.6. *Let C_4 be a test for strings of length m (i.e., $C_4 \subseteq \{0, 1\}^m$). Let $\text{GOOD}(C_4) = \{\bar{R} \in \text{PERM}_\ell \mid \bar{R} \text{ does not hit } C_4 \text{ } \epsilon\text{-correctly via } G\}$. Then $\|\text{GOOD}(C_4)\| < 2^{m+h+1}$, where $h = 3\delta Nn + 3N \log m + 3N \log(1/\epsilon)$.*

Proof. Let $C_{1,1}, \dots, C_{1,2^{-1}-4}$ be the $2^{m+1} - 4$ circuits implied by Lemma 2.5 to exist (corresponding to the test C_4). Let \bar{R} be in $\text{GOOD}(C_4)$. Then Lemma 2.5 shows that there is a circuit $C_{1,i}$ from the above list having the following property: For at least a fraction $\gamma = \epsilon/m$ of strings $\bar{x} \in \{0, 1\}^{\ell n}$, $C_{1,i}^{\bar{R}}$ on input $\bar{R}(\bar{x})$ returns a list having $T = m^2 \cdot (1/\epsilon^2)$ strings, one of which is \bar{x} . Thus, \bar{R} is (γ, T) -good for $C_{1,i}$ (recall Definition 2.2). It follows that the set of permutations $\bar{R} \in \text{PERM}_\ell$ that do not hit C_4 ϵ -correctly via G is included in

$\bigcup_1^{2^{m+1}-4} \{\overline{R} \in \text{PERM}_\ell \mid \overline{R} \text{ is } (\gamma, T)\text{-good for } C_{1,i}\}$. Lemma 2.4 shows, that, for each $i \in \{1, \dots, 2^{m+1} - 4\}$, $\|\{\overline{R} \in \text{PERM}_\ell \mid \overline{R} \text{ is } (\gamma, T)\text{-good for } C_{1,i}\}\| \leq 2^h$. \square

In order to obtain a standard extractor (rather than the special type given by Lemma 2.6), the only thing that remains to be done is to transform a random binary string X into a permutation $R \in \text{CIRC}$, which determines $\overline{R} \in \text{PERM}_\ell$ that is used in the function G given above. Note that a permutation $R \in \text{CIRC}$ is specified by $(R(1), R^2(1), \dots, R^{N-1}(1))$, which is an arbitrary permutation of the set $\{2, 3, \dots, N\}$. Consequently, we need to generate permutations of the set $\{1, 2, \dots, N - 1\}$ (which can be viewed as permutations of $\{2, 3, \dots, N\}$ in the obvious way). We can use the standard procedure that transforms a function mapping $[N - 1]$ to $[N - 1]$ into a permutation of the same type. To avoid some minor truncation nuisances, we actually use a function $X : [N] \rightarrow [N]$.

Input: $X : [N] \rightarrow [N]$.
Loop 1: for $i = 1$ to $N - 1$, $R(i) = i$.
Loop 2: for $i = 1$ to $N - 1$, $Y(i) = 1 + (X(i) \bmod i)$.
Loop 3: for $i = 1$ to $N - 1$, swap $R(i)$ with $R(Y(i))$.
Output: permutation $R : [N - 1] \rightarrow [N - 1]$.

It is easy to see that the number of functions $X : [N] \rightarrow [N]$ that map via the above procedure into a given permutation $R : [N - 1] \rightarrow [N - 1]$ is bounded by 2^{2N} .

We can now present the (standard) extractor. We choose the parameters as follows. Fix $n \in \mathbf{N}$ and let $N = 2^n$ and $\overline{N} = n \cdot 2^n$. Let $\lambda \in (0, 1)$ be a constant. Let $\alpha > 0, \beta > 0$ be constants such that $\alpha < \lambda/3, \beta < (\lambda - 3\alpha)/4$. Let $\epsilon \geq N^{-\beta}$ and $m \leq N^\alpha$. Take $\delta = (\lambda - 4\beta - 3\alpha)/4$ and $\ell = \lceil (3/\delta) \log(2m \cdot (1/\epsilon)) \rceil$.

Parameters: $n \in \mathbf{N}, \overline{N} \in \mathbf{N}, \lambda > 0, \epsilon > 0, \ell \in \mathbf{N}, m \in \mathbf{N}$, satisfying the above requirements.

Inputs: The weakly-random string $X \in \{0, 1\}^{\overline{N}}$, viewed as the truth-table of a function $X : [N] \rightarrow [N]$; the seed $y = (\overline{x}, r) \in \{0, 1\}^{\ell n} \times \{0, 1\}^{\ell n}$.

Step 1. Transform X into a permutation $\overline{R}_X \in \text{PERM}_\ell$. The transformation is performed by the above procedure which yields a permutation $R \in \text{CIRC}$, and, next, \overline{R}_X is the ℓ -direct product of R .

Step 2. Run G on input $\overline{R}_X, (\overline{x}, r)$.

We have defined a function $E : \{0, 1\}^{\overline{N}} \times \{0, 1\}^{2\ell n} \rightarrow \{0, 1\}^m$. Note that the seed length $2\ell n$ is $O(\log^2 \overline{N})$ and the output length m is \overline{N}^α , for an arbitrary $\alpha < \lambda/3$.

Theorem 2.7. *The function E is a $(\lambda \overline{N}, 2\epsilon)$ -extractor.*

Proof. Let C_4 be a subset of $\{0, 1\}^m$. Taking into account Lemma 1.2, it is enough to show that the number of strings $X \in \{0, 1\}^{\overline{N}}$ that do not hit C_4 ϵ -correctly via E is at most $2^{\lambda \overline{N} - \log(1/\epsilon)}$. Let $X \in \{0, 1\}^{\overline{N}}$ be a string that

does not hit C_4 ϵ -correctly via E . By the definition of E , it follows that \overline{R}_X does not hit C_4 ϵ -correctly via G . By Lemma 2.6, there are at most 2^{m+h+1} permutations $\overline{R} \in \text{PERM}_\ell$ that do not hit C_4 ϵ -correctly via G , where $h = 3\delta Nn + 3N \log m + 3N \log(1/\epsilon)$. Since the number of functions $X : [N] \rightarrow [N]$ that map into a given permutation $\overline{R} \in \text{PERM}_\ell$ is at most 2^{2N} , it follows that $\|\{X \in \{0, 1\}^{\overline{N}} \mid X \text{ does not hit } C_4 \text{ } \epsilon\text{-correctly}\}\| < 2^{2N} \cdot 2^{m+h+1} < 2^{\lambda \overline{N} - \log(1/\epsilon)}$, where the last inequality follows from the choice of parameters. \square

3 A Bitwise Locally-Computable Extractor

We present a bitwise locally-computable extractor: Each bit of the output string can be calculated separately in $O(\log^2 \overline{N})$, where \overline{N} is the length of the weakly-random string. The proof uses the same plan as for the extractor in Section 2, except that the weakly-random string X is viewed as the truth-table of an arbitrary function (not necessarily a permutation) and the ‘‘consecutive’’ values that are used in the extractor are $\overline{X}(\overline{x}), \overline{X}(\overline{x} + 1), \dots, \overline{X}(\overline{x} + m - 1)$ (instead of $\overline{R}(\overline{x}), \overline{R}^2(\overline{x}), \dots, \overline{R}^{m-1}(\overline{x})$ used in Section 2).

The parameter $n \in \mathbf{N}$ will be considered fixed throughout this section. We denote $N = 2^n$ and $\overline{N} = n \cdot N$. The parameter $m \in \mathbf{N}$ will be specified later (it will be a subunitary power of N). The weakly-random string X has length \overline{N} , and is viewed as the truth-table of a function $X : \{0, 1\}^{\overline{N}} \rightarrow \{0, 1\}^{\overline{N}}$. For some $\ell \in \mathbf{N}$ that will be specified later we define $\overline{X} : \{0, 1\}^{\ell n} \rightarrow \{0, 1\}^{\ell n}$ by $\overline{X}(x_1 \odot \dots \odot x_\ell) = X(x_1) \odot \dots \odot X(x_\ell)$, i.e., \overline{X} is the ℓ -direct product of X . We also denote $\overline{x} = x_1 \odot \dots \odot x_\ell$. The seed of the extractor will be $(\overline{x}, r) \in \{0, 1\}^{\ell n} \times \{0, 1\}^{\ell n}$. We define $\overline{x} + 1 = (x_1 + 1) \odot \dots \odot (x_\ell + 1)$ (where the addition is done modulo 2^n) and inductively, for any $k \in \mathbf{N}$, $\overline{x} + k + 1 = (\overline{x} + k) + 1$. The extractor is defined by

$$E(X, (\overline{x}, r)) = b(\overline{X}(\overline{x}), r) \odot b(\overline{X}(\overline{x} + 1), r) \odot \dots \odot b(\overline{X}(\overline{x} + m - 1), r). \quad (1)$$

It can be shown that, for any constants $\lambda > 0$ and $\alpha < \lambda/3$, for $m \leq N^\alpha$ and $\epsilon \geq N^{-(\lambda-3\alpha)/4}$, for some $\ell = O(n)$, E is a $(\lambda \overline{N}, 2\epsilon)$ -extractor. The proof shows that if some $X \in \{0, 1\}^{\overline{N}}$ does not hit ϵ -correctly some test $D \subseteq \{0, 1\}^m$ via E , then for ‘‘many’’ $x \in \{0, 1\}^{\overline{N}}$, $X(x)$ can be derived from $X(x - m + 1), \dots, X(x - 1)$ and from the value of X in a few additional points that do not depend on x . It is then shown that less than $2^{\lambda \overline{N} - \log(1/\epsilon)}$ elements $X \in \{0, 1\}^{\overline{N}}$ can have such a property. The conclusion follows from Lemma 1.2.

The construction scheme of the extractor given in Equation (1) allows some flexibility in the choice of parameters. We can obtain a quite simple extractor that has seed length $O(\log(\overline{N}))$, is capable to extract from sources with min-entropy $\lambda \overline{N}$, for arbitrary constant $\lambda > 0$, and has output length $\approx 2^{(1/3)\sqrt{\log(\overline{N})}}$. This extractor has a good seed length, however the output length is much smaller than the min-entropy of the source.

Bounds on the Efficiency of “Black-Box” Commitment Schemes

Omer Horvitz* and Jonathan Katz**

Department of Computer Science,
University of Maryland, College Park, MD 20742
{horvitz, jkatz}@cs.umd.edu

Abstract. Constructions of cryptographic primitives based on general assumptions (e.g., the existence of one-way functions) tend to be less efficient than constructions based on specific (e.g., number-theoretic) assumptions. This has prompted a recent line of research aimed at investigating the best possible efficiency of (black-box) constructions based on general assumptions. Here, we present bounds on the efficiency of statistically-binding commitment schemes constructed using black-box access to one-way permutations; our bounds are tight for the case of *perfectly*-binding schemes. We present the bounds in an extension of the Impagliazzo-Rudich model; that is, we show that any construction beating our bounds would imply the unconditional existence of a one-way function (from which a commitment scheme could be constructed “from scratch”). Our analysis is the first in the area to pertain directly to an information-theoretic component of the security notion.

1 Introduction

A central goal of modern cryptography has been to characterize the minimal assumptions needed to construct cryptographic tools and protocols. For example, we now know that one-way functions are sufficient for constructing pseudorandom generators (PRGs) [2, 18, 8, 9], universal one-way hash functions (UOWHFs) and digital signature schemes [14, 16], private-key encryption schemes [6] and commitment schemes [13]. In each of these cases, one-way functions are also known to be necessary [10, 16], making the characterization exact. While important from a theoretical point of view, the above constructions have had limited practical impact due to their inefficiency. In practice, more efficient constructions based on stronger assumptions tend to be used. Moreover, for all of the examples listed above, no constructions from general assumptions that improve on the efficiency of the original solutions are known.

The tension between general and efficient constructions has motivated a recent line of research, aimed at understanding the minimal assumptions needed for *efficient* constructions of various primitives. Put another way, we ask what is

* Supported by U.S. Army Research Office award DAAD19-01-1-0494.

** Supported by NSF CAREER award #0447075.

the best possible efficiency that can be achieved (for a particular primitive of interest) if we limit ourselves to constructions based on the weakest cryptographic assumptions. Initial work by Kim, Simon, and Tetali [12] demonstrated (non-tight) bounds on the efficiency of constructing universal one-way hash functions from one-way permutations. Extending their results, Gennaro, Gertner, Katz, and Trevisan [4] showed that known constructions of UOWHFs based on one-way permutations are in fact *optimal*; they also show efficiency bounds for the case of PRGs, private-key encryption schemes, and digital signatures based on one-way permutations, as well as for the case of public-key encryption schemes based on trapdoor permutations.

It is noted that in all the above bounds, analysis pertains directly to a *computational* aspect of the security notion at hand: for PRGs, it is the indistinguishability of the output from random; for UOWHFs – the computational hardness of finding a collision with a given element for a random member of the family; for encryption – the computational indistinguishability of encryptions of distinct messages; and for signatures – the computational hardness of generating a forgery. For commitment schemes, appealing to computational formulations of both the hiding and binding properties resists similar analysis. Taking either of the properties as *information-theoretic* introduces new challenges. Indeed, finding lower bounds on the efficiency of commitments from one-way permutations is left as an open problem in [4].

Our results. Here, we prove lower bounds on the efficiency of (black-box) constructions of statistically-binding, interactive commitment schemes based on one-way permutations. A commitment scheme for m -bit messages is an interactive protocol between a sender \mathcal{S} and a receiver \mathcal{R} , where \mathcal{S} takes as input a message $M \in \{0, 1\}^m$. Call the view of \mathcal{R} during an interaction with \mathcal{S} the *commitment*. Informally, a statistically-binding commitment scheme satisfies two properties (defined more formally in Section 2.2): (1) *Hiding*: the distribution over commitments to M_0 is computationally indistinguishable from the distribution over commitments to M_1 , for any M_0, M_1 and a possibly malicious receiver; and (2) (statistical) *Binding*: the probability (over coin tosses of the honest receiver \mathcal{R}) that there exist different M, M' and coins s, s' for \mathcal{S} such that the corresponding commitments to M, M' are identical is at most ε_b . When $\varepsilon_b = 0$ we say the scheme is *perfectly binding*. A permutation $\pi : \{0, 1\}^n \rightarrow \{0, 1\}^n$ is *one-way with security S* if any circuit of size $\leq S$ inverts π on a fraction $\leq 1/S$ of its inputs.

We show that any black-box construction¹ of a statistically-binding commitment scheme based on one-way permutations must have the sender query its oracle $\Omega((m - \log(1 + 2^m \cdot \varepsilon_b)) / \log S)$ times. For perfectly-binding schemes, the bound translates to $\Omega(m / \log S)$; for non perfectly-binding schemes, the bound becomes $\Omega(\log \varepsilon_b^{-1} / \log S)$ when $m > \log \varepsilon_b^{-1}$, and is essentially $\Omega(m / \log S)$ otherwise. We prove our bounds in the model of Gennaro, et al. [4] which, in turn,

¹ Using the terminology of [17] (see also [4]), our bounds hold for *weak* black-box constructions and thus rule out stronger types of black-box constructions as well.

extends the model of Impagliazzo and Rudich [11, 15] (see [4] for a detailed comparison). In particular, we show that the existence of a construction beating our efficiency bound would imply the unconditional existence of a one-way function (and hence $P \neq NP$).

For the case of perfectly-binding schemes constructed from one-way permutations, our bound matches the efficiency achieved by the construction of Blum [1] as extended by Goldreich and Levin [8] (see also [5]). For statistically-binding schemes, our bound matches the efficiency achieved by the construction of Naor [13] for single-bit messages (setting $\varepsilon_b = 2^{-S}$). Closing the gap for the case of longer messages remains an interesting open problem.

2 Preliminaries

2.1 One-Way Functions and Permutations

Let A^f denote a circuit A with oracle access to the function f . We say that a function $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$ is (S, ε) -one-way if for every circuit A of size $\leq S$ we have

$$\Pr_x[A^f(f(x)) \in f^{-1}(f(x))] \leq \varepsilon.$$

To reduce the number of parameters, we will call a function S -hard if it is $(S, 1/S)$ -one way.

Let Π_t denote the set of all permutations over $\{0, 1\}^t$. Then:

Theorem 1 ([4]). *For sufficiently large t , a random $\pi \in \Pi_t$ is $2^{t/5}$ -hard with probability at least $1 - 2^{-2^{t/2}}$.*

Let $a||b$ denote the concatenation of strings a and b . For $t < n$, let $\Pi_{t,n}$ denote the subset of Π_n such that $\pi \in \Pi_{t,n}$ iff $\pi(a||b) = \hat{\pi}(a)||b$ for some $\hat{\pi} \in \Pi_t$. A corollary to Theorem 1 is that if $t = 5 \log S_p$, then for $n > t$, a randomly chosen $\pi \in \Pi_{t,n}$ is S_p -hard with high probability.

Corollary 1 ([4]). *For sufficiently large t and $n > t$, a random $\pi \in \Pi_{t,n}$ is $2^{t/5}$ -hard with probability at least $1 - 2^{-2^{t/2}}$.*

2.2 Commitment Schemes

A *commitment scheme* for m -bit messages is defined by a pair of probabilistic, interactive algorithms $(\mathcal{S}, \mathcal{R})$. The inputs to \mathcal{S} , the *sender*, are a message $M \in \{0, 1\}^m$ and randomness s , while the input to \mathcal{R} , the *receiver*, is randomness r . Let $\langle \mathcal{S}(M; s), \mathcal{R}(r) \rangle$ denote the receiver's view of an interaction with the sender on the specified inputs; this view simply consists of the receiver's randomness and the messages it receives from the sender during the interaction (when the receiver makes queries to an oracle, the view additionally includes the answers it receives from the oracle). We call $\langle \mathcal{S}(M; s), \mathcal{R}(r) \rangle$ a *commitment*. A *decommitment* consists of a message and sender randomness. We say that a

commitment $C = \langle \mathcal{S}(M; s), \mathcal{R}(r) \rangle$ can be *decommitted* to a message M' if there exists a string s' such that $\langle \mathcal{S}(M'; s'), \mathcal{R}(r) \rangle = C$. For a message M , let

$$\langle \mathcal{S}(M), \mathcal{R} \rangle \stackrel{\text{def}}{=} \left\{ s, r \leftarrow \{0, 1\}^* : \langle \mathcal{S}(M; s), \mathcal{R}(r) \rangle \right\}.$$

We say that two distributions \mathcal{X}, \mathcal{Y} are (S, ε) -*indistinguishable*, and write $\mathcal{X} \stackrel{(S, \varepsilon)}{\approx} \mathcal{Y}$, if for every circuit A of size $\leq S$, we have

$$\left| \Pr_{x \in \mathcal{X}} [A(x) = 0] - \Pr_{x \in \mathcal{Y}} [A(x) = 0] \right| \leq \varepsilon.$$

Definition 1. Let $(\mathcal{S}, \mathcal{R})$ be a commitment scheme for m -bit messages. We say that $(\mathcal{S}, \mathcal{R})$ is (S_h, ε_h) -*hiding* if for every circuit \mathcal{R}^* of size $\leq S_h$, for all $M_0, M_1 \in \{0, 1\}^m$, we have

$$\langle \mathcal{S}(M_0), \mathcal{R}^* \rangle \stackrel{(S_h, \varepsilon_h)}{\approx} \langle \mathcal{S}(M_1), \mathcal{R}^* \rangle.$$

We say that $(\mathcal{S}, \mathcal{R})$ is ε_b -*binding* if

$$\Pr_r \left[\begin{array}{c} \exists M, M' \in \{0, 1\}^m, s, s' \text{ s.t.} \\ \langle \mathcal{S}(M; s), \mathcal{R}(r) \rangle = \langle \mathcal{S}(M'; s'), \mathcal{R}(r) \rangle \end{array} \right] \leq \varepsilon_b.$$

We say that $(\mathcal{S}, \mathcal{R})$ is ε_b -*binding* for an honest sender if for all $M \in \{0, 1\}^m$, we have

$$\Pr_{s, r} \left[\begin{array}{c} \exists M' \neq M, s' \text{ s.t.} \\ \langle \mathcal{S}(M; s), \mathcal{R}(r) \rangle = \langle \mathcal{S}(M'; s'), \mathcal{R}(r) \rangle \end{array} \right] \leq \varepsilon_b.$$

If $\varepsilon_b = 0$ we say the scheme is *perfectly-binding*. Finally, we say that $(\mathcal{S}, \mathcal{R})$ is $(S_h, \varepsilon_h, \varepsilon_b)$ -*secure* (resp., *secure for an honest sender*) if $(\mathcal{S}, \mathcal{R})$ is (S_h, ε_h) -*hiding* and ε_b -*binding* (resp., *binding for an honest sender*).

A construction of a commitment scheme for m -bit messages (based on one-way permutations) is a pair of oracle algorithms $(\mathcal{S}^{(\cdot)}, \mathcal{R}^{(\cdot)})$ such that, for all $\pi \in \Pi_n$, $(\mathcal{S}^\pi, \mathcal{R}^\pi)$ is a commitment scheme for m -bit messages. We say that $(\mathcal{S}^{(\cdot)}, \mathcal{R}^{(\cdot)})$ is $(S_p, S_h, \varepsilon_h, \varepsilon_b)$ -*secure* (resp., *secure for an honest sender*) if for every $\pi \in \Pi_n$ that is S_p -*hard*, $(\mathcal{S}^\pi, \mathcal{R}^\pi)$ is (S_h, ε_h) -*hiding* and for every $\pi \in \Pi_n$ (even those not S_p -*hard*), $(\mathcal{S}^\pi, \mathcal{R}^\pi)$ is ε_b -*binding* (resp., *binding for an honest sender*). \diamond

We note that, in the terminology of [17], our definitions of security for commitment constructions fall in the category of *weak black-box* constructions. This is evident in that in the definition of the hiding property, the distinguishing algorithm is *not* given oracle access to π . As we prove lower bounds, our results apply to stronger notions of black-box constructions as well, and in particular to *semi-* and *fully black-box* constructions (see [17] for further details.)

2.3 Pairwise-Independent Hashing

Let H be a family of functions mapping m -bit strings to m' -bit strings. We assume that the following can be done in time polynomial in m : (1) selecting a function $h \in H$ uniformly at random; (2) given $h \in H$ and $x \in \{0, 1\}^m$, evaluating $h(x)$; and (3) given h^* , deciding whether $h^* \in H$ or not. We say that H is a *pairwise-independent hash family* (following [3]) if for any distinct $x_1, x_2 \in \{0, 1\}^m$ and any $y_1, y_2 \in \{0, 1\}^{m'}$ we have:

$$\Pr_{h \in H} [h(x_1) = y_1 \wedge h(x_2) = y_2] = 2^{-2m'}.$$

3 The Lower Bound

Let $(\mathcal{S}^{(\cdot)}, \mathcal{R}^{(\cdot)})$ be an $(S_p, S_h, \varepsilon_h, \varepsilon_b)$ -secure construction of a commitment scheme for m -bit messages (based on one-way permutations). We prove that unless \mathcal{S} queries its oracle at least $\Omega((m - \log(1 + 2^m \cdot \varepsilon_b)) / \log S_p)$ times, there exists (constructively) a commitment scheme $(\bar{\mathcal{S}}, \bar{\mathcal{R}})$ secure for an honest sender which *does not* require access to any oracle (i.e., the scheme is secure unconditionally). Strengthening a result of Impagliazzo and Luby [10] (cf. Lemma 1), this implies the unconditional existence of a one-way function.

We describe here the intuition behind our proof, assuming for ease of exposition that $(\mathcal{S}, \mathcal{R})$ is a non-interactive, perfectly-binding scheme. As in [4], our starting point is that a random $\pi \in \Pi_{t,n}$ (for $t = \Theta(\log S_p)$) is S_p -hard with all but negligible probability (cf. Corollary 1). So, consider a scheme in which the sender \mathcal{S}' simulates a random $\pi \in \Pi_{t,n}$ for \mathcal{S} , using independent random coins² y . Note that decommitment here consists of both s and y .

It is quite straightforward to show that the resulting scheme still satisfies hiding. Binding, however, is another matter. Note first that we need only show binding for an *honest* sender. That is, we may assume that s and y have been chosen honestly (i.e., uniformly at random) by \mathcal{S}' . Letting P denote the pairs of t -bit prefixes of oracle queries made by \mathcal{S}' during the computation and t -bit prefixes of corresponding answers, the question then is whether there exist s', y' (with associated query/answer prefixes P') that form a decommitment of C to a different message. We first observe, informally, that having $P' = P$ will not help: this is because the original scheme is binding for any choice of π . In fact, this further implies that for any choice of P' there exists at most one message to which C can be decommitted. Said another way, this means that C can be decommitted to at most

$$2^{2t|P|} = 2^{2tq}$$

different messages (where q is the number of oracle queries made by the original sender). Although this clearly violates binding, it does limit the space of possible

² This can easily be done by selecting random t -bit answer-prefixes to new t -bit query-prefixes, as needed.

messages *somewhat* as long as $2^{2tq} < m$. We now show how to “bootstrap” this to achieve “full” binding with noticeable probability.

The idea is to modify the scheme as follows: the sender $\bar{\mathcal{S}}$ now chooses a function h uniformly at random from a pairwise-independent hash family mapping m -bit strings to m -bit strings. On message M , $\bar{\mathcal{S}}$ now runs \mathcal{S}' *twice* (simulating a random π as before), first on input M and then on input $h(M)$. The commitment also includes h . Hiding for the derived scheme follows easily, as before. As for binding, denote the two sub-commitments of $\bar{\mathcal{S}}$ by C_1 and C_2 . We have said already that for each of these commitments there are sets S_1, S_2 , each of size at most $2^{2t|P|} < 2^m$, such that C_1 might potentially be decommitted to any message from S_1 and similarly for C_2, S_2 . But now the commitment $C_1 \| C_2 \| h$ can only be decommitted as a different message if there exists an $M' \in S_1$ (with $M' \neq M$) for which $h(M') \in S_2$. The crux of our proof is to show that, with constant probability over choice of h (and for certain values of $|P|$), such an M' does not exist. This immediately implies that binding holds with constant probability.

3.1 A Technical Lemma

We begin by showing that the existence of a commitment scheme secure for honest senders implies the existence of a one-way function. Although the result can be derived from [10], we give a simple and more direct proof here.

Lemma 1. *Let $(\mathcal{S}, \mathcal{R})$ be a commitment scheme for m -bit messages which is $(S_h, \varepsilon_h, \varepsilon_b)$ -secure for an honest sender. Let $S_{\mathcal{S}}, S_{\mathcal{R}}$ be the sizes of the circuits computing \mathcal{S}, \mathcal{R} , respectively. Then for any $\ell \in \mathbb{N}$, there exists an $(S_h - \ell(S_{\mathcal{S}} + S_{\mathcal{R}}), \ell\varepsilon_h + 2\varepsilon_b^\ell)$ -one-way function.*

Proof. Via a standard hybrid argument, running ℓ independent interactions between \mathcal{S} and \mathcal{R} on the same, fixed message yields an $(S_h, \ell\varepsilon_h, \varepsilon_b^\ell)$ -secure commitment scheme for m -bit messages. Let $(\mathcal{S}_\ell, \mathcal{R}_\ell)$ denote this scheme.

Let $f(M, s, r) \stackrel{\text{def}}{=} \langle \mathcal{S}_\ell(M; s), \mathcal{R}_\ell(r) \rangle$. We claim that f is $(S_h - \ell(S_{\mathcal{S}} + S_{\mathcal{R}}), \ell\varepsilon_h + 2\varepsilon_b^\ell)$ -one-way. Assume the contrary. Then there exists a circuit B of size at most $S_h - \ell(S_{\mathcal{S}} + S_{\mathcal{R}})$ such that

$$\text{Succ}_{B,f}^{\text{owf}} \stackrel{\text{def}}{=} \Pr_{M,s,r} [B(f(M, s, r)) \in f^{-1}(f(M, s, r))] > \ell\varepsilon_h + 2\varepsilon_b^\ell.$$

We use B to construct a circuit A that violates the hiding property of $(\mathcal{S}_\ell, \mathcal{R}_\ell)$. On input (M_0, M_1, C) , A computes $(M', s', r') \leftarrow B(C)$, and checks whether $f(M', s', r') \stackrel{?}{=} C$ and whether $M' \stackrel{?}{=} M_0$. If both hold, A outputs 0; otherwise, it outputs 1. Note that $|A| = |B| + \ell(S_{\mathcal{S}} + S_{\mathcal{R}}) \leq S_h$.

Let $\text{Bad} \stackrel{\text{def}}{=} \{(M, s, r) | \exists M' \neq M, s' : \langle \mathcal{S}_\ell(M; s), \mathcal{R}_\ell(r) \rangle = \langle \mathcal{S}_\ell(M'; s'), \mathcal{R}_\ell(r) \rangle\}$. In what follows, note that if $(M', s', r') \in f^{-1}(f(M, s, r))$ then $r' = r$, as r is included in the receiver’s view. We have:

$$\begin{aligned}
& \Pr_{\substack{M_0, M_1 \\ C \in \langle \mathcal{S}(M_0), \mathcal{R} \rangle}} [A(M_0, M_1, C) = 0] \\
&= \Pr_{\substack{M_0, M_1 \\ s, r}} \left[\begin{array}{l} (M', s', r') \leftarrow B(f(M_0, s, r)) : \\ (M', s', r') \in f^{-1}(f(M_0, s, r)) \wedge M' = M_0 \end{array} \right] \\
&\geq \Pr_{\substack{M_0, M_1 \\ s, r}} \left[\begin{array}{l} (M', s', r') \leftarrow B(f(M_0, s, r)) : \\ (M', s', r') \in f^{-1}(f(M_0, s, r)) \wedge (M_0, s, r) \notin \text{Bad} \end{array} \right] \\
&= \Pr_{\substack{M_0, M_1 \\ s, r}} \left[\begin{array}{l} (M', s', r') \leftarrow B(f(M_0, s, r)) : \\ (M', s', r') \in f^{-1}(f(M_0, s, r)) \end{array} \right] \\
&\quad - \Pr_{\substack{M_0, M_1 \\ s, r}} \left[\begin{array}{l} (M', s', r') \leftarrow B(f(M_0, s, r)) : \\ (M', s', r') \in f^{-1}(f(M_0, s, r)) \wedge (M_0, s, r) \in \text{Bad} \end{array} \right] \\
&\geq \Pr_{\substack{M_0, M_1 \\ s, r}} \left[\begin{array}{l} (M', s', r') \leftarrow B(f(M_0, s, r)) : \\ (M', s', r') \in f^{-1}(f(M_0, s, r)) \end{array} \right] - \Pr_{\substack{M_0, M_1 \\ s, r}} [(M_0, s, r) \in \text{Bad}] \\
&\geq \text{Succ}_{B, f}^{\text{owf}} - \varepsilon_b^\ell > \ell \varepsilon_h + \varepsilon_b^\ell.
\end{aligned}$$

Furthermore, we have:

$$\begin{aligned}
& \Pr_{\substack{M_0, M_1 \\ C \in \langle \mathcal{S}(M_1), \mathcal{R} \rangle}} [A(M_0, M_1, C) = 0] \\
&= \Pr_{\substack{M_0, M_1 \\ s, r}} \left[\begin{array}{l} (M', s', r') \leftarrow B(f(M_1, s, r)) : \\ (M', s', r') \in f^{-1}(f(M_1, s, r)) \wedge M' = M_0 \end{array} \right] \\
&\leq \Pr_{\substack{M_0, M_1 \\ s, r}} \left[\begin{array}{l} (M', s', r') \leftarrow B(f(M_1, s, r)) : \\ (M', s', r') \in f^{-1}(f(M_1, s, r)) \wedge (M_1, s, r) \in \text{Bad} \end{array} \right] \\
&\leq \Pr_{\substack{M_0, M_1 \\ s, r}} [(M_1, s, r) \in \text{Bad}] \leq \varepsilon_b^\ell.
\end{aligned}$$

Putting everything together, we have:

$$\left| \Pr_{\substack{M_0, M_1 \\ C \in \langle \mathcal{S}(M_0), \mathcal{R} \rangle}} [A(M_0, M_1, C) = 0] - \Pr_{\substack{M_0, M_1 \\ C \in \langle \mathcal{S}(M_1), \mathcal{R} \rangle}} [A(M_0, M_1, C) = 0] \right| > \ell \varepsilon_h.$$

But this implies that there exist two messages M_0, M_1 for which A can distinguish $\langle \mathcal{S}_\ell(M_0), \mathcal{R}_\ell \rangle$ from $\langle \mathcal{S}_\ell(M_1), \mathcal{R}_\ell \rangle$ with probability $> \ell \varepsilon_h$, contradicting the hiding property of $(\mathcal{S}_\ell, \mathcal{R}_\ell)$. \blacksquare

3.2 Main Result

Theorem 2. *Let $(\mathcal{S}^{(\cdot)}, \mathcal{R}^{(\cdot)})$ be an $(S_p, S_h, \varepsilon_h, \varepsilon_b)$ -secure construction of a commitment scheme for m -bit messages that expects an oracle $\pi \in \Pi_n$. Let $t = 5 \log S_p$. If \mathcal{S} makes $q_S \leq (m - 2 - \log(1 + 2^{m+1} \cdot \varepsilon_b))/4t$ queries to its oracle, and $\varepsilon_h \leq 1/8 - 2^{-S}$, then there exists a commitment scheme for m -bit messages which is $(S_h, 1/4, 1/4)$ -secure for an honest sender (without access to any oracle).*

Applying Lemma 1, this implies the existence of a one-way function (without access to any oracle).

Proof. We construct non-interactive commitment scheme $(\bar{\mathcal{S}}, \bar{\mathcal{R}})$ for m -bit messages. The construction makes use of a procedure \mathcal{SIM} that simulates a random permutation in $\Pi_{t,n}$, as follows [4]: \mathcal{SIM} takes as input a list L . On a query $x||x'$, where $|x| = t$, \mathcal{SIM} checks whether there exists a y such that $(x, y) \in L$. If so, \mathcal{SIM} returns $y||x'$. Otherwise, it picks uniformly at random a $y \in \{0, 1\}^t \setminus \{\hat{y} \mid \exists \hat{x} : (\hat{x}, \hat{y}) \in L\}$, adds (x, y) to L , and returns $y||x'$. As usual, we let $\mathcal{SIM}(L; y)$ denote an execution of \mathcal{SIM} on input L and randomness y . We let \mathcal{SIM}_y denote $\mathcal{SIM}(\emptyset; y)$.

Let H be a pairwise-independent family of functions from m -bit strings to m -bit strings. Define $\bar{\mathcal{S}}$ as follows. On input a message $M \in \{0, 1\}^m$, $\bar{\mathcal{S}}$ chooses uniformly at random $h \in H$ and values $s_1, r_1, y_1, s_2, r_2, y_2$. It then computes $C_1 = \langle \mathcal{S}^{\mathcal{SIM}_1}(M; s_1), \mathcal{R}^{\mathcal{SIM}_1}(r_1) \rangle$ and $C_2 = \langle \mathcal{S}^{\mathcal{SIM}_2}(h(M); s_2), \mathcal{R}^{\mathcal{SIM}_2}(r_2) \rangle$. The resulting commitment is $C_1||C_2||h$.³ Decommitment consists of all the random coins used by $\bar{\mathcal{S}}$. We claim that $(\bar{\mathcal{S}}, \bar{\mathcal{R}})$ is $(S_h, 1/4, 1/4)$ -secure for an honest sender. This follows from the following two lemmata.

Lemma 2. $(\bar{\mathcal{S}}, \bar{\mathcal{R}})$ is $(S_h, 1/4)$ -hiding.

Proof (of lemma). The hiding property of $(\mathcal{S}^{(\cdot)}, \mathcal{R}^{(\cdot)})$ guarantees that for any $\pi \in \Pi_n$ that is S_p -hard, for any circuit B of size $\leq S_h$, and for any $M_0, M_1 \in \{0, 1\}^m$, we have

$$\left| \Pr_{C \in \langle \mathcal{S}^{(M_0)}, \mathcal{R} \rangle} [B(C) = 0] - \Pr_{C \in \langle \mathcal{S}^{(M_1)}, \mathcal{R} \rangle} [B(C) = 0] \right| \leq \varepsilon_h.$$

A straightforward hybrid argument shows that for any $\pi_1, \pi_2 \in \Pi_n$ that are S_p -hard, for any circuit B of size $\leq S_h$, and for any $M_0, M_1 \in \{0, 1\}^m$, we have

$$\left| \Pr_{\substack{C_1 \in \langle \mathcal{S}^1(M_0), \mathcal{R}^1 \rangle \\ C_2 \in \langle \mathcal{S}^2(h(M_0)), \mathcal{R}^2 \rangle}} [B(C_1||C_2||h) = 0] - \Pr_{\substack{C_1 \in \langle \mathcal{S}^1(M_1), \mathcal{R}^1 \rangle \\ C_2 \in \langle \mathcal{S}^2(h(M_1)), \mathcal{R}^2 \rangle}} [B(C_1||C_2||h) = 0] \right| \leq 2\varepsilon_h.$$

Corollary 1 shows that a random $\pi \in \Pi_{t,n}$ is S_p -hard except with probability at most $2^{-S^{5/2}} \leq 2^{-S}$. Using the union bound and a simple averaging argument, we get that for any circuit B of size $\leq S_h$ and for any $M_0, M_1 \in \{0, 1\}^m$,

³ The permutations simulated by \mathcal{SIM} in the computations of C_1, C_2 may be different. The theorem can be strengthened (improving the bounds on ε_h) by having \mathcal{SIM} provide a consistent simulation for both computations. We forgo this for simplicity.

$$\left| \Pr_{\substack{\pi_1, \pi_2 \in \Pi \\ h \in H \\ C_1 \in \langle \mathcal{S}^1(M_0), \mathcal{R}^1 \rangle \\ C_2 \in \langle \mathcal{S}^2(h(M_0)), \mathcal{R}^2 \rangle}} [B(C_1 \| C_2 \| h) = 0] - \Pr_{\substack{\pi_1, \pi_2 \in \Pi \\ h \in H \\ C_1 \in \langle \mathcal{S}^1(M_1), \mathcal{R}^1 \rangle \\ C_2 \in \langle \mathcal{S}^2(h(M_1)), \mathcal{R}^2 \rangle}} [B(C_1 \| C_2 \| h) = 0] \right| \leq 2\varepsilon_h + 2^{1-S}.$$

Since $\mathcal{S}IM$ perfectly simulates a random $\pi \in \Pi_{t,n}$, we have

$$\left| \Pr_{\substack{y_1, y_2 \\ h \in H \\ C_1 \in \langle \mathcal{S}^{SIM}_1(M_0), \mathcal{R}^{SIM}_1 \rangle \\ C_2 \in \langle \mathcal{S}^{SIM}_2(h(M_0)), \mathcal{R}^{SIM}_2 \rangle}} [B(C_1 \| C_2 \| h) = 0] - \Pr_{\substack{y_1, y_2 \\ h \in H \\ C_1 \in \langle \mathcal{S}^{SIM}_1(M_1), \mathcal{R}^{SIM}_1 \rangle \\ C_2 \in \langle \mathcal{S}^{SIM}_2(h(M_1)), \mathcal{R}^{SIM}_2 \rangle}} [B(C_1 \| C_2 \| h) = 0] \right| \leq 2\varepsilon_h + 2^{1-S}.$$

But that precisely means that

$$\left| \Pr_{C \in \langle \mathcal{S}(M_0), \mathcal{R}^* \rangle} [B(C) = 0] - \Pr_{C \in \langle \mathcal{S}(M_1), \mathcal{R}^* \rangle} [B(C) = 0] \right| \leq 2\varepsilon_h + 2^{1-S} \leq 1/4$$

for any \mathcal{R}^* and any B of size $\leq S_h$, where the last inequality uses the assumption that $\varepsilon_h \leq 1/8 - 2^{-S}$. The hiding property therefore holds as claimed. \square

Lemma 3. $(\bar{\mathcal{S}}, \bar{\mathcal{R}})$ is 1/4-binding for an honest sender.

Proof (of lemma). (See also Fig. 1.) Fix an arbitrary $M \in \{0, 1\}^m$. Define

$$C(M, s, r, y) \stackrel{\text{def}}{=} \langle \mathcal{S}^{SIM}(M; s), \mathcal{R}^{SIM}(r) \rangle.$$

Since $(\bar{\mathcal{S}}, \bar{\mathcal{R}})$ is non-interactive, we are interested in the following probability:

$$\text{NoBind} \stackrel{\text{def}}{=} \Pr_{\substack{h \in H \\ s_1, r_1, y_1 \\ s_2, r_2, y_2}} \left[\begin{array}{l} \exists M' \neq M, s'_1, y'_1, s'_2, y'_2 \text{ s.t.} \\ C(M', s'_1, r_1, y'_1) = C(M, s_1, r_1, y_1), \\ C(h(M'), s'_2, r_2, y'_2) = C(h(M), s_2, r_2, y_2) \end{array} \right]$$

(here, we use the fact that r_1, r_2 and h are explicit in the receiver's view).

Let Perm_t^q denote the set of injective functions from t -bit strings to t -bit strings over domains of size q . Let $\text{queries}_{\mathcal{S}}(M, s, r, y) \in \text{Perm}_t^{q_{\mathcal{S}}}$ denote the t -bit prefixes of the queries/answers made by \mathcal{S} to its oracle during the execution of $C(M, s, r, y)$ (i.e., an oracle query $a \| a'$ by \mathcal{S} is answered with $b \| a'$ in $C(M, s, r, y)$ iff $(a, b) \in \text{queries}_{\mathcal{S}}(M, s, r, y)$). Letting $q_{\mathcal{R}}$ denote the number of queries \mathcal{R} makes to its oracle, we define $\text{queries}_{\mathcal{R}}(M, s, r, y) \in \text{Perm}_t^{q_{\mathcal{R}}}$ similarly.

Fig. 1. \bar{S} uses the given scheme to generate commitments C_1 to M and C_2 to $M_2 = h(M)$ (simulating random permutations for $(\mathcal{S}, \mathcal{R})$, as needed). C_1 (resp., C_2) may be decommitted to any of the messages in the set $S(M, s_1, r_1, y_1)$ (resp., $S(h(M), s_2, r_2, y_2)$). But for a small number of sender oracle-queries, the sizes of these sets are small, and the probability that a random h maps a message from one to the other can be shown to be less than a constant

Say $C(M, s, r, y)$ is good for $P \in \text{Perm}_t^{qs}$ if there do not exist distinct values M', M'' along with s', s'', y', y'' such that

- $C(M', s', r, y') = C(M'', s'', r, y'') = C(M, s, r, y)$; and
- $\text{queries}_{\mathcal{S}}(M', s', r, y') = \text{queries}_{\mathcal{S}}(M'', s'', r, y'') = P$.

Say $C(M, s, r, y)$ is good if it is good for all $P \in \text{Perm}_t^{qs}$. Now, if $C(M, s, r, y)$ is not good for some P , and $M', M'', s', s'', y', y''$ are the witnesses, then it is also the case that

$$\text{queries}_{\mathcal{R}}(M', s', r, y') = \text{queries}_{\mathcal{R}}(M'', s'', r, y'') = \text{queries}_{\mathcal{R}}(M, s, r, y),$$

as queries/answers of the receiver to its oracle are explicit in the receiver’s view. Furthermore, $P \cup \text{queries}_{\mathcal{R}}(M, s, r, y)$ may be extended to a permutation in $\Pi_{t,n}$. Therefore, for any M, s, y and P , we have

$$\begin{aligned} & \Pr_r[C(M, s, r, y) \text{ is not good for } P] \\ & \leq \Pr_r \left[\begin{array}{c} \exists \pi \in \Pi_{t,n} \text{ extending } P \cup \text{queries}_{\mathcal{R}}(M, s, r, y) \\ \exists M', M'', s', s'' \text{ s.t.} \\ \langle \mathcal{S}^\pi(M'; s'), \mathcal{R}^\pi(r) \rangle = \langle \mathcal{S}^\pi(M''; s''), \mathcal{R}^\pi(r) \rangle \end{array} \right] \leq \varepsilon_b, \end{aligned}$$

following the binding property of $(\mathcal{S}, \mathcal{R})$. Applying the union bound over all $\binom{2}{qs} \cdot \prod_{i=0}^{qs-1} (2^t - i) \leq 2^{2tqs}$ permutations in Perm_t^q , we obtain, for any M, s, y :

$$\Pr_r[C(M, s, r, y) \text{ is not good}] \leq 2^{2tqs} \varepsilon_b.$$

Assume $C \stackrel{\text{def}}{=} C(M, s, r, y)$ is *good*. Then there are at most 2^{2tq_S} possible messages to which C may be decommitted. This is because for any $P \in \text{Perm}_t^{q_S}$, if $C(M', s', r, y') = C(M'', s'', r, y'') = C$ and $\text{queries}_S(M', s', r, y') = \text{queries}_S(M'', s'', r, y'') = P$, then it must be the case that $M' = M''$. Let $S(M, s, r, y)$ denote this set.

Viewed this way, we have:

$$\text{NoBind} \leq \Pr_{\substack{h \in H \\ s_1, r_1, y_1 \\ s_2, r_2, y_2}} \left[\begin{array}{l} \exists M' \neq M \text{ s.t.} \\ M' \in S(M, s_1, r_1, y_1) \\ h(M') \in S(h(M), s_2, r_2, y_2) \end{array} \left| \begin{array}{l} C(M, s_1, r_1, y_1), \\ C(h(M), s_2, r_2, y_2) \\ \text{are good} \end{array} \right. \right] + 2^{2tq_S+1} \cdot \varepsilon_b,$$

where the right term represents the probability that either of $C(M, s_1, r_1, y_1)$ or $C(h(M), s_2, r_2, y_2)$ is not good. Continuing with the left term, we have:

LeftTerm

$$\begin{aligned} &= \Pr_{\substack{h \in H \\ s_1, r_1, y_1 \\ s_2, r_2, y_2}} \left[\begin{array}{l} \exists M' \in S(M, s_1, r_1, y_1) \setminus M \\ \exists M'_2 \in S(h(M), s_2, r_2, y_2) \text{ s.t.} \\ h(M') = M'_2 \end{array} \left| \begin{array}{l} C(M, s_1, r_1, y_1), \\ C(h(M), s_2, r_2, y_2) \\ \text{are good} \end{array} \right. \right] \\ &= \sum_{M_2} \Pr_{\substack{h \in H \\ s_1, r_1, y_1 \\ s_2, r_2, y_2}} \left[\begin{array}{l} \exists M' \in S(M, s_1, r_1, y_1) \setminus M \\ \exists M'_2 \in S(M_2, s_2, r_2, y_2) \text{ s.t.} \\ h(M') = M'_2, h(M) = M_2 \end{array} \left| \begin{array}{l} C(M, s_1, r_1, y_1), \\ C(M_2, s_2, r_2, y_2) \\ \text{are good} \end{array} \right. \right] \\ &\leq \sum_{\substack{M_2 \\ \hat{s}_1, \hat{r}_1, \hat{y}_1 \text{ s.t.} \\ C(M, \hat{s}_1, \hat{r}_1, \hat{y}_1) \text{ good,} \\ \hat{s}_2, \hat{r}_2, \hat{y}_2 \text{ s.t.} \\ C(M_2, \hat{s}_2, \hat{r}_2, \hat{y}_2) \text{ good,} \\ M' \in S(M, \hat{s}_1, \hat{r}_1, \hat{y}_1) \\ M'_2 \in S(M_2, \hat{s}_2, \hat{r}_2, \hat{y}_2)}} \Pr_{\substack{h \in H \\ s_1, r_1, y_1 \\ s_2, r_2, y_2}} \left[\begin{array}{l} s_1 = \hat{s}_1, r_1 = \hat{r}_1, y_1 = \hat{y}_1 \\ s_2 = \hat{s}_2, r_2 = \hat{r}_2, y_2 = \hat{y}_2 \\ h(M') = M'_2, h(M) = M_2 \end{array} \left| \begin{array}{l} C(M, s_1, r_1, y_1), \\ C(M_2, s_2, r_2, y_2) \\ \text{are good} \end{array} \right. \right] \\ &= 2^{-2m} \cdot \sum_{\substack{M_2 \\ \hat{s}_1, \hat{r}_1, \hat{y}_1 \text{ s.t.} \\ C(M, \hat{s}_1, \hat{r}_1, \hat{y}_1) \text{ good,} \\ \hat{s}_2, \hat{r}_2, \hat{y}_2 \text{ s.t.} \\ C(M_2, \hat{s}_2, \hat{r}_2, \hat{y}_2) \text{ good,} \\ M' \in S(M, \hat{s}_1, \hat{r}_1, \hat{y}_1) \\ M'_2 \in S(M_2, \hat{s}_2, \hat{r}_2, \hat{y}_2)}} \Pr_{\substack{s_1, r_1, y_1 \\ s_2, r_2, y_2}} \left[\begin{array}{l} s_1 = \hat{s}_1, r_1 = \hat{r}_1, y_1 = \hat{y}_1 \\ s_2 = \hat{s}_2, r_2 = \hat{r}_2, y_2 = \hat{y}_2 \end{array} \left| \begin{array}{l} C(M, s_1, r_1, y_1), \\ C(M_2, s_2, r_2, y_2) \\ \text{are good} \end{array} \right. \right], \end{aligned}$$

using the pairwise independence of H . Since $|S(M, s, r, y)| \leq 2^{2tq_S}$, we obtain

$$\text{LeftTerm} \leq 2^{-2m} \cdot 2^m \cdot 2^{4tq_S} \leq 2^{4tq_S - m}.$$

Putting it together, we have

$$\text{NoBind} \leq 2^{4tq_S - m} + 2^{2tq_S+1} \cdot \varepsilon_b \leq 2^{4tq_S} \cdot (2^{-m} + 2\varepsilon_b) \leq 1/4,$$

where the last inequality is due to the assumption that $q_S \leq (m - 2 - \log(1 + 2^{m+1} \cdot \varepsilon_b))/4t$. \square

This completes the proof of the theorem. \blacksquare

On Round-Efficient Argument Systems

Hoeteck Wee*

Computer Science Division, UC Berkeley
hoeteck@cs.berkeley.edu

Abstract. We consider the problem of constructing round-efficient public-coin argument systems, that is, interactive proof systems that are only computationally sound with a constant number of rounds. We focus on argument systems for $\text{NTime}(T(n))$ where either the communication complexity or the verifier's running time is subpolynomial in $T(n)$, such as Kilian's argument system for NP [Kil92] and universal arguments [BG02, Mic00]. We begin with the observation that under standard complexity assumptions, such argument systems require at least 2 rounds. Next, we relate the existence of non-trivial 2-round argument systems to that of hard-on-average search problems in NP and that of efficient public-coin zero-knowledge arguments for NP. Finally, we show that the Fiat-Shamir paradigm [FS86] and Babai-Moran round reduction [BM88] fails to preserve computational soundness for some 3-round and 4-round argument systems.

1 Introduction

1.1 Background and Motivation

Argument systems are like interactive proof systems, except we only require computational soundness, namely that it is *computationally infeasible* (and not impossible) for a prover to convince the verifier to accept inputs not in the language. The relaxation in the soundness requirement was used to obtain protocols for NP that are perfect zero-knowledge [BCC88], or constant-round with low communication complexity [Kil92], and in both cases, seems to also be necessary [For89, GH98].

In this paper, we focus on the study of round-efficient argument systems for $\text{NTime}(T(n))$ that do not necessarily satisfy any notion of secrecy, such as witness indistinguishability (WI), or zero-knowledge (although we do indulge in the occasional digression). We will however require that either the communication complexity or the verifier's running time be subpolynomial in $T(n)$ which is necessary in some applications, and to rule out the trivial one-round proof system. Argument systems of the latter type with bounded verifier's running time are a crucial component in the use of non-black-box techniques in cryptography [CGH98, Bar01, Bar04, GK03].

* Work supported by US-Israel BSF Grant 2002246.

The study of round-efficient argument systems was initiated by Kilian [Kil92], who constructed a 4-round public-coin argument system for NP with poly-logarithmic communication complexity based on a probabilistically checkable proof (PCP) system for NP. Micali [Mic00] introduced *CS Proofs*, an argument system for NEXP satisfying a relatively efficient prover condition and wherein the verifier runs in polynomial time (much less than the time needed to verify an NEXP relation). In addition, he provided a non-interactive construction in the random oracle model, which is essentially derived from scaling up and then applying the Fiat-Shamir transformation to Kilian’s argument system. Barak and Goldreich [BG02] adapted Kilian’s construction to obtain *universal arguments (of knowledge)*, which is a single argument system for any language in NP, and in addition, satisfies a weak proof-of-knowledge property. We stress that in a universal argument, the communication complexity and the verifier’s running time is bounded by an a-priori fixed polynomial in the input length, whereas the length of the witness may be any arbitrary polynomial in the length of the input. Both of the constructions in [Kil92] and in [BG02] rely on the existence of collision-resistant function ensembles.

In this work, we initiate a systematic study of round-efficient argument systems.

- What is the minimal round complexity of argument systems with bounded communication complexity or verifier’s running time?
- What are the minimal assumptions and cryptographic primitives needed for the existence of such argument systems? Are collision-resistant function ensembles really necessary? What kind of security parameters do we require from these primitives (possibly as a function of communication complexity)?
- How useful is improving the round efficiency of argument systems for the construction of round-efficient cryptographic protocols?
- Is there an efficient function ensemble with which we could securely realize the Fiat-Shamir transformation for the 4-round argument systems in [Kil92] and [BG02] (as conjectured by Micali in [Mic00])? More generally, is there some generic round reduction technique that preserves computational soundness?

We provide partial answers for all of these questions in this paper.

1.2 Our Results

We begin with the observations (possibly known in “folklore”) that under standard complexity assumptions, the argument systems we are interested in require at least 2 rounds, and anything provable with such an argument system can be proven in 4 rounds. Refer to Sec 3 for the precise statements.

Necessity of Hardness Assumptions. We show that under standard complexity assumptions, the existence of 2-round argument systems for NP with subpolynomial communication complexity implies the existence of hard-on-average search problems in NP, that is, there is samplable distribution over

CSAT instances (circuit satisfiability, namely given a circuit, decide whether the circuit has a satisfying assignment) with the property that most instances (say a constant fraction) are satisfiable, but any nonuniform polynomial-time algorithm on input a random instance from the distribution succeeds in finding a satisfying assignment for that instance with only negligible probability. Note that the existence of hard-on-average search problems in NP is possibly weaker than that of one-way functions and collision-resistant function ensembles.

Zero-Knowledge and 2-Round Argument Systems. We note that the existence of a 2-round public-coin universal argument of knowledge secure against subexponential-sized circuits yields a 4-round public-coin zero-knowledge argument for NP with negligible soundness error; this follows readily from the work of Barak et al. [Bar01, BLV04]. Such an argument system is almost round-optimal, as there is no 2-round zero-knowledge argument system for languages outside of BPP [GO94]. We also relate the existence of non-interactive zero-knowledge arguments to that 2-round witness-indistinguishable arguments for NP where the length of the common reference string, messages and proofs are subpolynomial in the input length. This follows readily from a similar characterization in [DN00].

Insecurity of the Fiat-Shamir Transformation. We observe that the constructions of Goldwasser and Kalai [GK03] demonstrating the insecurity of the Fiat-Shamir transformation as applied to identification schemes also yield a 4-round argument system such that the instantiation of the Fiat-Shamir transformation with any efficiently computable function results in a 2-round protocol that is no longer computationally sound. Note that Barak's zero-knowledge argument system [Bar01] already yields a 6-round argument system for which the Fiat-Shamir transformation is insecure [DNRS03]. We also prove that there exists a 4-round universal argument of knowledge for which the Fiat-Shamir transformation fails to preserve the weak proof-of-knowledge property.

Insecurity of Babai-Moran Round Reduction. Babai and Moran [BM88] used a round reduction procedure to prove that any language having a constant-round public-coin interactive proof system also has a 2-round public-coin proof system. In particular, the round reduction procedure preserves soundness of proof systems. Here, we construct 3-round and 4-round argument systems for which the round reduction procedure fails to preserve computational soundness.

A Note on Presentation: We state our results for argument systems with either bounded communication complexity or bounded verifier's running time, depending on which of the two leads to a cleaner statement. In most cases, an analogous statement can be deduced for the other set-up. Note that a subpolynomial bound on verifier's running time must necessarily imply a subpolynomial bound on the communication complexity.

1.3 Additional Related Work

Dwork et al. [DLN⁺04] investigated the possibility of constructing 2-round argument systems for NP with poly-logarithmic communication complexity based on a suggestion of Aiello, Bhatt, Ostrovsky and Rajagopalan, namely, to compose a PCP system for NP with computational private information retrieval scheme; their results are mostly negative. Goldreich and Håstad [GH98] proved that NP does not have constant-round public-coin proof systems with subpolynomial communication complexity, unless NP has probabilistic subexponential time algorithms. Barak et al. [BLV04] proved that the Fiat-Shamir transformation is in fact secure for proof systems under a non-standard but very plausible and concrete assumption.

2 Definitions and Setup

Due to space limitations, we refer the reader to [Gol01] to definitions of interactive protocols, zero-knowledge and witness-indistinguishability.

2.1 Interactive Proofs and Argument Systems

For a relation $R \subseteq \{0, 1\}^* \times \{0, 1\}^*$, the *language associated with R* is $L_R = \{x : \exists y (x, y) \in R\}$.

Definition 1 (interactive proof system). *An interactive protocol (P, V) is an interactive proof system for a language L if there is a relation R such that $L = L_R$, and functions $c, s : \mathbb{N} \rightarrow [0, 1]$ such that $1 - c(n) > s(n) + 1/\text{poly}(n)$ and the following holds:*

- (efficiency): *the length of all the messages are polynomially-bounded, and V is computable in probabilistic polynomial time.*
- (completeness): *If $(x, w) \in R$, then V accepts in $(P(w), V)(x)$ with probability at least $1 - c(|x|)$,*
- (soundness): *If $x \notin L$, then for every P^* , V accepts in $(P^*, V)(x)$ with probability at most $s(|x|)$.*

We call $c(\cdot)$ the *completeness error* and $s(\cdot)$ the *soundness error*. We say that (P, V) has *negligible error* if both c and s are negligible. We say that it has *perfect completeness* if $c = 0$. P is an *efficient prover* if $P(w)$ is computable by a probabilistic polynomial-time algorithm when $w \in R_x$. The *communication complexity* of the proof system is the total length of all the messages exchanged by both parties. For a public-coin protocol (P, V) , $\text{view}(V(x))$ is the set of accepting transcripts on common input x . We also use $\text{AM}_{c,s}(m(n))$ to denote constant-round public-coin interactive proof systems with completeness error c , soundness s and communication complexity bounded by $m(n)$.

Definition 2 (argument system). *An argument system (P, V) is defined in the same way as an interactive proof system, with the following modification:*

- *The soundness condition is replaced with computational soundness: For every nonuniform PPT P^* and for all sufficiently long $x \notin L$, the verifier V accepts in $(P^*, V)(x)$ with probability at most $s(|x|)$.*

2.2 Universal Arguments

We begin with the universal language L_U : the tuple (M, x, t) (where t is specified in binary) is in L_U if M is a non-deterministic Turing machine that accepts x within t steps. We use R_U to denote the associated relation.

Definition 3 (universal argument). *A universal argument for $\text{NTime}(T(n))$ is an argument system (P, V) for $L_U \cap \text{NTime}(T(n))$ that satisfies the following properties:*

- *(completeness by a relatively-efficient prover) For every $((M, x, t), w) \in R_u$ with $(M, x, t) \in \text{NTime}(T(n))$,*

$$\Pr[V \text{ accepts } (P(w), V)(M, x, t)] = 1$$

Furthermore, there exists a polynomial p such that the total time spent by $P(w)$, on common input (M, x, t) , is at most $p(T_M(x, w)) \leq p(t)$.

- *(computational soundness) For every nonuniform PPT P^* , there exists a negligible function $\epsilon(n)$ such that for every n and every $(M, x, t) \in \{0, 1\}^n \setminus L_U$, the verifier V accepts in $(P^*, V)(M, x, t)$ with probability at most $\epsilon(n)$.*

In addition, we call (P, V) a *universal argument of knowledge* if it satisfies the weak proof-of-knowledge property [BG02]. Informally, this means that there is an efficient oracle machine (the knowledge extractor) that given oracle access to a cheating prover that convinces the verifier with inverse polynomial probability, outputs an implicit description of a witness. Both the running time and the success probability of the knowledge extractor are allowed to depend on the success probability of the cheating verifier.

Theorem 1 ([BG02]). *The existence of (standard) collision-resistant function ensembles implies the existence of a 4-round public-coin universal argument of knowledge $(P_{\text{ua}}, V_{\text{ua}})$ for $\text{NTime}(n^{\log n})$. In addition, if the collision-resistant function ensemble is secure against circuits of size 2^n for some $\epsilon > 0$, then $(P_{\text{ua}}, V_{\text{ua}})$ is a universal argument of knowledge against circuits of size $2^{O(n)}$.*

3 Simple Bounds on Round Complexity

The results in this section are probably known in “folklore”. As pointed out in [BP04], non-interactive (one-round) arguments are equivalent to non-interactive (one-round) proof systems, since if there exists a prover message that can convince the verifier of a false statement, the non-uniform prover that has this message “hard-wired into it”. This essentially rules out non-interactive argument systems for NP with subpolynomial communication complexity.

Proposition 1. *Unless $\text{NP} \subseteq \text{BPTIME}(2^{n^{(1)}})$, non-interactive argument systems with subpolynomial communication complexity for NP do not exist.*

In the context of efficient-prover argument systems, we have a collapse to 4 rounds (as pointed out to us by Salil Vadhan).

Proposition 2. *Suppose there exists collision-resistant function ensembles secure against 2^n -sized circuits for some $\epsilon > 0$ and a language in \mathbf{E} with $2^{\Omega(n)}$ circuit complexity. Then, any language L with an efficient-prover argument system has a 4-round, public-coin, efficient-prover argument system with subpolynomial (in fact, poly-logarithmic) communication complexity.*

This follows from the observation in [BLV04] that any language with an efficient-prover argument system is contained in MA , which collapses to NP under the given derandomization assumption. The proposition then follows from Kilian’s protocol [Kil92].

4 Necessity of Hardness Assumptions

We present hardness assumptions that are necessary for 2-round argument systems for NP with subpolynomial communication complexity. Under complexity assumptions, such a protocol cannot be a proof system [GH98]. Hence, there exists infinitely many NO instances that are merely “computationally sound”, from which we may construct hard-on-average search problems in NP .

Note that we may assume the 2-round argument system has negligible soundness error, which can be achieved with $\omega(\log n)$ parallel repetitions [BIN97]. Parallel repetition blows up the communication complexity by a $\omega(\log n)$ multiplicative factor, but preserves prover’s complexity, perfect completeness and public-coin property.

Lemma 1. *Suppose a promise problem $\Pi = (\Pi_Y, \Pi_N)$ has a 2-round public-coin argument system (P, V) with communication complexity $m(n)$, perfect completeness and negligible soundness error. Then, there exists a subset $I \subset \Pi_N$ such that:*

- Ignoring inputs in I , Π has a $\text{AM}_{1,1/2}(m(n))$ proof system. Formally, $(\Pi_Y, \Pi_N \setminus I) \in \text{AM}_{1,1/2}(m(n))$.
- When $x \in I$, the predicate $V(x, \cdot, \cdot)$ induces a hard-on-average search instances in NP . That is, for every $x \in I$:

$$\Pr_r[\exists y : V(x, r, y) = 1] \geq 1/2,$$

but for every n , every $x \in I \cap \{0, 1\}^n$ and every nonuniform PPT A , there exists a negligible function $\epsilon(n)$ such that ,

$$\Pr_r[V(x, r, A(r)) = 1] < \epsilon(n)$$

Remark 1. Note that we may boost the probability of generating a satisfying assignment for the hard-on-average search instance to $1 - 1/\text{poly}(n)$ while maintaining the same hardness parameters by taking the OR of $O(\log n)$ independent copies of $V(x, \cdot, \cdot)$.

Theorem 2. *Suppose NP has a 2-round public-coin argument system (P, V) with communication complexity $n^{o(1)}$, perfect completeness and negligible soundness error. Then, at least one of the following is true:*

- $\text{NP} \subseteq \text{AM}_{1,1/2}(n^{o(1)})$
- *There exists an infinite set I such that for all $x \in I$, the predicate $V(x, \cdot, \cdot)$ induces a hard-on-average search instance in NP (as formalized in Lemma 1). This yields an auxiliary-input samplable distribution over search instances in NP that is infinitely-often hard on average.*

Remark 2. The first statement is unlikely to be true as it would imply that $\text{NP} \subseteq \text{BPTIME}(2^{n^{(1)}})$ [GH98]. On the other hand, the latter is possibly weaker than the existence of (auxiliary input, i.o.) one-way functions. However, it does imply that there is no probabilistic polynomial-time algorithm for the circuit satisfiability problem where the number of variables is bounded by $n^{o(1)}$.

Remark 3. Salil Vadhan pointed out that if there exists a hard-on-average decision problem in NP where the instances and witnesses have length bounded by $m(n)$, then every language has a 2-round argument system with communication complexity $m(n)$. However, the argument system does not satisfy the efficient prover constraint, though the constraint is (trivially) satisfied if we consider the empty language. This shows that the conclusion in Theorem 2 is essentially the strongest we can hope for without making additional assumptions about the argument system, for instance, that it has an efficient prover, that it is WI, or that it is an argument of knowledge.

5 Zero-Knowledge and 2-Round Argument Systems

Barak et. al [BLV04] constructed a 2-round argument for NP that is zero-knowledge against cheating verifiers of bounded non-uniformity assuming the existence of a 2-round universal argument secure against 2^n -sized circuits. We observe that if we strengthen the soundness requirement on the universal argument to an argument of knowledge, it follows readily from [Bar01, BLV04] that there exists a 4-round zero-knowledge argument for NP. The idea is to convert the universal argument of knowledge into a WI universal argument of knowledge (with a subexponential-time knowledge extractor) without any overhead in the number of rounds. To accomplish this, we encrypt the messages of the universal argument using a weak commitment scheme and prove correctness using a WI proof for NP [DN00].

Theorem 3 ([Bar01, BLV04]). *Suppose there exist 2-round public-coin universal argument of knowledge for $\text{NTime}(f(n))$ for some super-polynomial $f : \mathbb{N} \rightarrow \mathbb{N}$, enhanced trapdoor permutations and collision-resistant function ensembles secure against 2^n -sized circuits for some constant $\epsilon > 0$. Then, there exists a 4-round public-coin (auxiliary-input) zero-knowledge argument system for NP, with perfect completeness, negligible soundness error, an efficient prover and a simulator that runs in strict polynomial time.*

Another open problem is whether there exists non-interactive zero-knowledge (NIZK) arguments or 2-round WI arguments for NP with subpolynomial communication complexity and randomness [FLS99, KP98, DLN⁺04]. We do not know how to construct either primitive starting from an argument system for NP with subpolynomial communication complexity, but it follows from the characterization of zaps (a 2-round public-coin WI proof system for NP) in [DN00] that they are almost equivalent:

Theorem 4 ([FLS99, DN00]). *Suppose there exist one-way functions secure against 2^n -sized circuits for some constant $\epsilon > 0$. Then, the following statements are equivalent:*

- *There exists a 2-round public-coin efficient-prover honest-verifier WI argument for NP with subpolynomial communication complexity.*
- *There exists an efficient-prover NIZK argument for NP where the length of the common reference string and the proof are subpolynomial in the length of the input.*

Theorem 4 is weaker than the characterization of zaps in [DN00] in that we can only deduce the existence of honest-verifier WI (but not cheating-verifier WI) arguments for NP from NIZK. This is because the construction of zaps from NIZK protocols requires that the underlying NIZK protocol be a proof system in order to preserve soundness. On the other hand, we observe that honest-verifier WI is sufficient for the construction of a NIZK argument for NP.

6 Insecurity of the Fiat-Shamir Transformation

Goldwasser and Kalai [GK03] proved the existence of a (secure) 3-round public-coin identification scheme for which any instantiation of the Fiat-Shamir transformation with an efficiently computable function ensemble yields an insecure signature scheme. As both the identification scheme and the signature scheme are defined in the public-key model, there is a fairly natural interpretation of the construction as obtaining a 2-round argument system from a 4-round argument system via the Fiat-Shamir transformation. The main (albeit minor) technical difference is in handling auxiliary inputs inherent to argument systems, as the set-up in [GK03] is inherently uniform (there, the variable is the security

parameter, and messages to be signed are thought of as having constant size¹). We also feel that viewing the constructions of [GK03] in the context of argument systems yields a clearer and simpler presentation of their constructions and results. The following result has been independently observed by the authors of [GK03] (but was not explicitly mentioned in [GK03]):

Theorem 5 ([GK03]). *Suppose there exists (standard) collision-resistant function ensembles. Then, there exists a 4-round public-coin argument system with negligible soundness error, but for which the instantiation of the Fiat-Shamir transformation with any efficiently function ensemble yields a 2-round protocol that is not computationally sound (that is, it has a polynomial-sized cheating prover that succeeds with non-negligible probability).*

Remark 4. The cheating prover in the proof of Theorem 5 succeeds with only a non-negligible probability. It is therefore conceivable while the Fiat-Shamir paradigm does not in general preserve soundness of 4-round argument systems, the Fiat-Shamir paradigm along with parallel repetition does preserve soundness of 4-round argument systems (since parallel repetition does reduce the soundness error for 2-round argument systems to a negligible quantity [BIN97]).

We also observe that the Fiat-Shamir transformation fails to preserve the weak proof-of-knowledge property. The proof goes via a case analysis similar to that in [GK03] (except a lot simpler). Suppose the statement holds for (P_{ua}, V_{ua}) ; then we are done. Otherwise, we have a 2-round public-coin universal argument of knowledge which combined with Barak's non-uniform generation protocol [Bar01] yields the desired argument system.

Theorem 6. *Suppose there exists (standard) collision-resistant function ensembles. Then, there exists a 4-round public-coin universal argument of knowledge, but for which the instantiation of the Fiat-Shamir transformation with any efficiently function ensemble yields a 2-round protocol that does not satisfy the weak proof-of-knowledge property.*

7 Insecurity of Babai-Moran Round Reduction

We start by describing Babai-Moran round reduction. For a public-coin proof system $\Pi = (P, V)$ of at most 4 rounds, this procedure has a simple description and comprises two steps, for some parameter $k = \text{poly}(n)$. First, the residual protocol after the prover's first message is repeated k times in parallel and the new verifier accepts if all k repetitions are accepting. Next, second, the order of the prover's first message and the verifier's next message are reversed. We denote the new protocol by $\Pi^{rr(k)}$. For protocols with 3 or 4 rounds, the resulting protocol has 2 rounds.

¹ Alternatively, we may consider the forger as forging a family of uniformly computable messages of length polynomial in the security parameter, infinitely often.

Intuitively, Babai-Moran round reduction fails to preserve computational soundness for the following reasons:

- Parallel repetition fails to reduce soundness error at an exponential rate beyond $1/\text{poly}(n)$ if we require a black-box proof of security [BIN97].
- A cheating prover can gain significant advantage upon round-switching, wherein the verifier reveals his coin tosses before the prover sends his next message.

We exploit the former reasoning in our construction of the 3-round argument system, as the latter does not seem to apply in this case (made precise in Prop 3) as the first message of a 3-round argument system is “unconditionally sound”. For the 4-round argument system, we exploit the latter reasoning in an essential manner so as to obtain a result that holds even with a non-black-box proof of security.

Theorem 7 (Babai-Moran round reduction).

- (i) *Suppose there exists collision-resistant function ensembles secure against $n^{\log n}$ -sized circuits. Then, there exists a 4-round public-coin argument system with negligible soundness error for which Babai-Moran round reduction yields a 2-round argument system that is not computationally sound.*
- (ii) *There exists a 3-round (relativized) public-coin argument system with negligible soundness error for which Babai-Moran round reduction yields a 2-round argument system that is not computationally sound if limited to a black-box proof of security.*

In both constructions, the cheating prover succeeds with probability $1 - \text{neg}(n)$. This means that even upon applying parallel repetition to the resulting 2-round argument systems, we would not obtain a computationally sound protocol.

Both constructions are for the empty language L_\emptyset . The 4-round protocol, specified in Fig 1, is a straight-forward simplification of the argument system in [Kil92]. For 3-round argument systems, we only rule out the case with a black-box proof of security. In this setting, it suffices to construct a relativized protocol, wherein all parties (provers, cheating provers, verifier) have oracle access to a permutation π , as shown in Fig 2. It helps to think of π as a one-way permutation, although we will require a stronger property that we only know how to prove in a relativized setting:

Lemma 2 ([GT00]). *For all sufficiently large n , there exists a permutation π on $\{0, 1\}^n$ such that for all oracle circuits A of size $n^{\log n}$,*

$$\Pr[\sigma \leftarrow \{0, 1\}^n; A^{\pi, I}(\sigma) = y; \pi(y) = \sigma] < \frac{1}{n^{\log n}}$$

where I_σ is an oracle that on input $\sigma' \neq \sigma$ returns $\pi^{-1}(\sigma')$, and \perp otherwise.

We note that overcoming the limitation to black-box proof of security for 3-round argument systems will require resolving a well-known open problem:

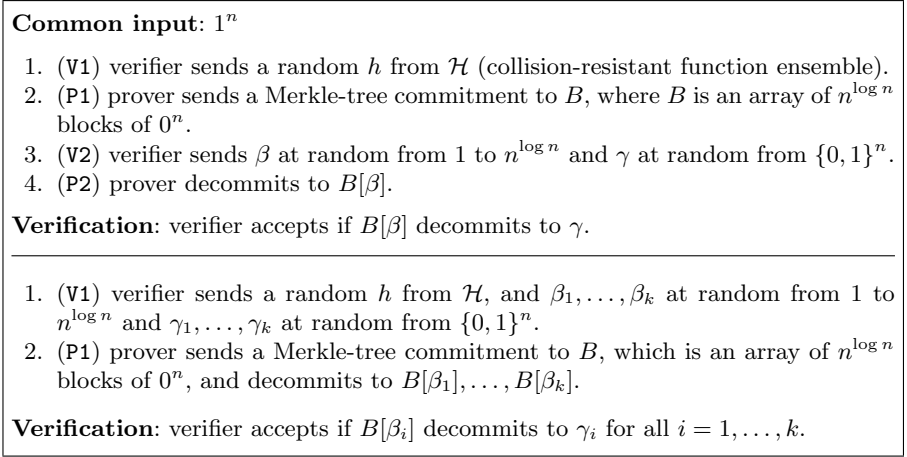

Fig. 1. 4-round protocol Π_1 and 2-round protocol $\Pi_1^{rr(k)}$ for the empty language L_\emptyset

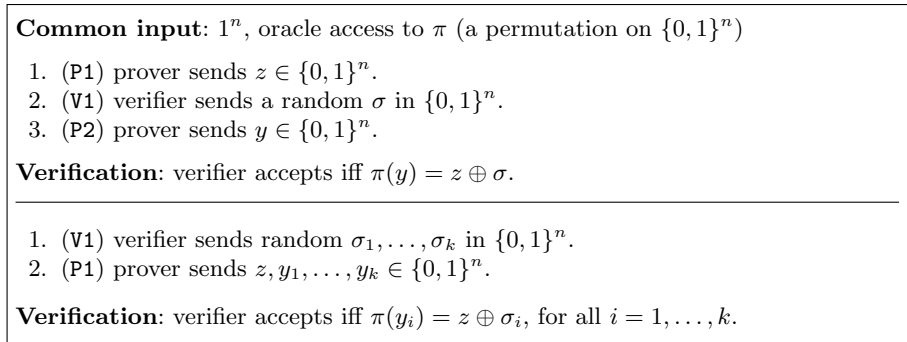

Fig. 2. 3-round relativized protocol Π_2 and 2-round protocol $\Pi_1^{rr(k)}$ for L_\emptyset

Proposition 3. *Suppose parallel repetition on 2-round argument systems can reduce the computational soundness error exponentially fast to $2^{-\text{poly}(n)}$, then Babai-Moran round reduction yields a collapse of 3-round argument systems to 2-round argument systems.*

8 Conclusion

We hope that the collection of observations, connections and results presented in this paper (one that is perhaps better regarded as a survey) clarifies our understanding of round-efficient argument systems and motivates further work in this area, and perhaps a resolution of the main open problem – determining the exact round complexity of non-trivial argument systems.

Acknowledgments

I am very grateful to Yael Tauman Kalai, Luca Trevisan and Salil Vadhan for their encouragement and insightful discussions on the subject; Salil also gave me very valuable feedback on earlier versions of this paper. I thank Kobbi Nissim for bringing [DLN⁺04] to my attention, and the anonymous referees for helpful suggestions on the write-up.

Computational Bounds on Hierarchical Data Processing with Applications to Information Security^{*}

(Extended Abstract)

Roberto Tamassia and Nikos Triandopoulos

Department of Computer Science, Brown University
{rt, nikos}@cs.brown.edu

Abstract. We introduce *hierarchical data processing (HDP)* problems, a class of computations over a collection of values associated with a set of n elements, based on a directed acyclic graph (DAG). We present an $\Omega(\log n)$ lower bound on various computational cost measures for HDP problems and we develop an efficient randomized DAG scheme for HDP problems. We apply our results to *data authentication through cryptographic hashing* and *multicast key distribution using key-graphs*. We show that both problems involve HDP and prove logarithmic lower bounds on their computational and communication costs. Using our new DAG scheme, we present a new efficient authenticated dictionary and a new skip-list version with expected search complexity $1.25 \log_2 n + O(1)$.

1 Introduction

In this paper, we present a unified analysis and design of algorithms and data structures for two important, and seemingly unrelated, information security problems: the authentication of membership queries in the presence of data replication at untrusted directories and the distribution of cryptographic keys by the controller of a dynamic multicast group. For both problems, we provide logarithmic lower bounds on various time and space cost measures, develop new efficient data structures and give an accurate analysis of their performance, taking into account constant factors in the leading asymptotic term.

Our unified approach is based on the definition of the class of *hierarchical data processing (HDP)* problems, where a directed acyclic graph (DAG) describes the computation of a collection of output values from an input set of n elements. We define structural cost measures for DAGs that express computational costs in an HDP problem and prove $\Omega(\log n)$ lower bounds for them using a reduction from the problem of searching by comparisons in an ordered set. We also design a new

efficient randomized DAG scheme for HDP problems, based on a variation of the skip-list. Our results for the two information security problems are obtained by showing that they can be modeled as an HDP problem and by appropriately applying to their domain the general lower bounds and our new DAG scheme. This extended abstract omits the details of our work. A full version is available in [14]. Our contributions are summarized as follows.

Hierarchical Data Processing. In Section 2, we introduce the class of hierarchical data processing (HDP) problems and initiate their study. This class models computations on a dynamic set of elements that share the following characteristics. Associated with the elements is a structured collection of values, organized according to a DAG. Update operations change elements and require adjusting the values. Also, queries on elements are issued, where typically the answer to a query is a subset of the associated values. The computational cost of an update or query operation depends on certain structural properties of the underlying DAG. In general, HDP provides an abstract model for problems where computations are performed sequentially and hierarchically according to a DAG and their complexity depends on the structure of the DAG.

We define various structural cost measures for DAGs and we relate them to the space and time complexity of queries and updates in an HDP problem. Using a reduction from the problem of searching by comparisons in an ordered set, we prove an $\Omega(\log n)$ lower bound on the space and time complexity of query and update operations in an HDP problem of size n . We also show that with respect to HDP problems, trees are optimal DAG structures compared with general DAGs. In Section 3, we design and analyze a new randomized DAG scheme for HDP problems, called *multi-way skip-list DAG scheme*, which is based on a variation of the skip-list data structure [12]. Our DAG scheme has better cost measures than previous DAG schemes based on the skip-list data structure.

Data Authentication. An *authenticated data structure (ADS)* is a distributed model of data authentication, where a *directory* answers queries on a data structure on behalf of a trusted *source* and provides to the *user* a cryptographic proof of the validity of the answer. In the important class of *hash-based authenticated data structures*, a digest of the data set is computed by hierarchically applying a cryptographic hash function over the data set and is digitally signed by the source.

Early work on ADSs has focused on hash-based authenticated dictionaries, where Merkle trees are used to authenticate answers to membership queries incurring logarithmic authentication cost. General techniques for hash-based query authentication are presented in [6, 7]. Beyond dictionaries, hash-based ADSs have been developed for various type of queries, including connectivity queries in graphs and range queries in two-dimensional point sets [3, 6, 7]. An alternative approach to the design of an authenticated dictionary, based on the *RSA accumulator* (e.g., [1]) is presented in [4]. Related to ADSs is also work on zero-knowledge sets and consistency proofs [8, 11]. All existing hash-based authenticated dictionaries have logarithmic authentication cost. Naor and Nissim [10] posed as an open problem the question of whether one can achieve sublogarithmic

mic authentication cost for dictionaries. We answer this question negatively for hash-based ADSs.

In Section 4, we present a detailed analysis of the cost of ADSs, focusing on dictionaries. We show how a hash-based dictionary ADS can be modeled as an HDP problem. We consider a general authentication technique where hashing is hierarchically performed over the data set according to a DAG and multiple digests can be digitally signed by the source. Applying our HDP framework to this domain, we prove the first nontrivial lower bound on the authentication cost for dictionaries: any hash-based authenticated dictionary of size n where the source signs k digests of the data set has $\Omega(\log \frac{n}{k})$ update cost, verification cost, and communication cost in the worst case. We also present a new hash-based dictionary ADS based on our new DAG scheme.

Multicast Key Distribution. *Multicast key distribution* refers to a model for realizing secrecy in multicast communications among a dynamic group of n users. Users share secret keys and a common *group-key* with which they encrypt multicast messages using secret-key encryption. When updates in the multicast group occur, in order to preserve (forward/backward) security, the group-key needs to be securely updated. A *group controller* is responsible for distributing an initial set of keys to the users and for updating the keys accordingly. Costs associated with this problem include the number of messages transmitted after an update and the time spent for key encryptions by the controller. We focus on the widely studied *key-graph* scheme (see, e.g., [15]), where possession of keys by users and key updates are modeled through a DAG. Known constructions based on key-trees achieve $O(\log n)$ communication cost for a group of size n . In [2], the first lower bounds are given for a special class of key distribution protocols. In [13], an amortized logarithmic lower bound is presented on the number of messages sent after an update. A similar amortized logarithmic lower bound is shown in [9] for a more general class of key distribution protocols, where one can additionally employ a pseudorandom generator to extract (in a one-way fashion) two new keys from one key and where multiple nested key encryptions can be used.

In Section 5, we show that the multicast key distribution problem using key-graphs is an HDP problem and we apply our results to this domain. We perform the first study of general key-graphs and show that trees are optimal structures. Our new DAG scheme for multicast key distribution achieves costs closer to the theoretical optimal. We also prove the first worst-case logarithmic lower bound on both the communication cost and the computational cost of a single update operation. We prove that for any instance of the problem of size n , there exists an update whose communication cost is at least $\lfloor \log_2 n \rfloor$. All previous lower bounds are amortized, i.e., they refer to a sequence of updates such that the average cost of an update in the sequence is logarithmic.

Skip-Lists. The skip-list [12] is an efficient randomized data structure for dictionaries. A search in a skip-list with n elements takes $1.5 \log_2 n + O(1)$ expected comparisons. As an application of our improved DAG scheme to search structures, in Section 6, we present a new version of the skip-list such that the expected number of comparisons in a search is $1.25 \log_2 n + O(1)$.

2 Hierarchical Data Processing and Its Theoretical Limits

In this section, we define structural cost measures for subgraphs of a DAG and prove lower bounds on them. These cost measures are related to the computational complexity of operations in HDP problems, as will be shown in the next sections.

DAG Scheme for HDP. We define here some graph notation. Let $G = (V, E)$ be a directed acyclic graph. For each node v of G , $indeg(v)$ denotes the in-degree of v and $outdeg(v)$ denotes the out-degree of v . We denote with $V_{so} \subset V$ the set of *source* nodes of G , i.e., nodes v such that $indeg(v) = 0$ and with $V_{si} \subset V$ the set of *sink* nodes of G , i.e., nodes v such that $outdeg(v) = 0$. A subgraph H of G is said to be *weakly connected* if it is connected when one ignores edge directions. For any node v in a DAG G , we denote with G_v the subgraph of G consisting of the nodes that can be reached from v through directed paths.

Definition 1. A DAG scheme Γ is a quadruple (G, S, n, k) , where $G = (V, E)$ is a directed acyclic graph without parallel edges, $S \subset V$ is a set of special nodes and n and k are integers such that: (i) $|V_{so}| = n$; (ii) $|V|$ is bounded by a polynomial in n ; and (iii) $|S| = k$, $S \supset V_{si}$ and $S \cap V_{so} = \emptyset$.

We define three structural cost measures for a subgraph of a DAG and based on them, we define three cost measures for a DAG scheme Γ .

Definition 2. Let $H = (V_H, E_H)$ be a weakly connected subgraph of a DAG G . With respect to G : (i) The node size $size(H)$ of H is the number of nodes in H , i.e., $size(H) = |V_H|$; (ii) the degree size $indeg(H)$ of H is the sum of the in-degrees (with respect to G) of the nodes of H , i.e., $indeg(H) = \sum_{v \in H} indeg(v)$; (iii) the combined size $comb(H)$ of H is the sum of its node and degree sizes, i.e., $comb(H) = size(H) + indeg(H)$; (iv) the boundary size $bnd(H)$ of H is the number of edges of G that enter nodes of H but are not in H .

Definition 3. Given a DAG scheme $\Gamma = (G, S, n, k)$, let s be a source node of G . Let P_s^t denote the set of directed paths connecting node s to node t in G . The associated path π_s of s is a directed path in G_s that starts at s , ends at a node of S and has the minimum combined size among all such paths, i.e., $comb(\pi_s) = \min_{u \in S, p \in P} comb(p)$. We define the following cost measures for Γ : (i) the update cost $\mathcal{U}(\Gamma)$ of Γ is $\mathcal{U}(\Gamma) = \max_{s \in V} comb(G_s)$; (ii) the query cost $\mathcal{Q}(\Gamma)$ of Γ is $\mathcal{Q}(\Gamma) = \max_{s \in V} comb(\pi_s)$ (i.e., $\max_s \min_{u \in S, p \in P} comb(p)$); and the sibling cost $\mathcal{S}(\Gamma)$ of Γ is $\mathcal{S}(\Gamma) = \max_{s \in V} bnd(\pi_s)$.

Observe that if $\Gamma = (G, S, n, k)$ is a DAG scheme, H is a subgraph of G and p is any directed path in G , then we have that (with respect to G): (i) $comb(H) = \sum_{v \in H} (1 + indeg(v))$ and $bnd(p) = 1 + indeg(p) - size(p)$; (ii) $comb(H) > indeg(H) \geq size(H)$ and $indeg(H) \geq bnd(H)$; (iii) $\mathcal{U}(\Gamma) \geq \mathcal{Q}(\Gamma) > \mathcal{S}(\Gamma)$.

Our motivation for introducing DAG schemes is that they model an abstract class of computational problem where a DAG G holds a collection of n input

elements (stored at source nodes) and a collection of output *values* (stored at non-source nodes) that are computed using the DAG. Query operations on elements return a collection of values. Update operations modify the DAG G and the input elements, causing corresponding changes to the set of values. Computations are performed sequentially and hierarchically, according to the hierarchy induced by the underlying DAG G . The computational cost (time, space, or communication complexity) of query and update operations can be expressed as the combined, degree or boundary size of a subgraph (usually G_s or π_s , for a source node s of G), where every node v in the subgraph contributes an amount proportional to $\text{indeg}(v)$ to the cost. Generally, any computational cost measure for a problem in this class is completely characterized by structural cost measures of subgraphs of DAG G . We refer to such problems (informally defined due to space limitations) as *hierarchical data processing (HDP) problems*.

We study the cost measures of general DAG schemes, derive results that explain the inherent computational limits that exist in any HDP problem and characterize optimal DAG scheme structures for these problems. We first show that the cost measures for a tree-based DAG scheme are related to the number of comparisons for searching in an ordered set, by drawing a direct analogy between the sibling cost of any tree-based DAG scheme and the number of comparisons performed in a search tree corresponding to the DAG scheme. This result forms the basis for a reduction from searching by comparisons to any computational procedure of an HDP problem, with cost that is expressed by the sibling cost of a tree-based DAG scheme. Using this reduction we get the following.

Theorem 1. *Any DAG scheme $\Delta = (T, S, n, 1)$ such that T is a directed tree has $\Omega(\log n)$ update, query and sibling costs.*

We show that among all possible DAGs, trees have optimal cost measures.

Theorem 2. *Let $\Gamma = (G, S, n, 1)$ be a DAG scheme. There exists a DAG scheme $\Delta = (T, S, n, 1)$ such that T is a directed tree and $\mathcal{U}(\Delta) \leq \mathcal{U}(\Gamma)$, $\mathcal{Q}(\Delta) \leq \mathcal{Q}(\Gamma)$, and $\mathcal{S}(\Delta) \leq \mathcal{S}(\Gamma)$.*

The above result also applies to a general DAG scheme (G, S, n, k) with k special nodes. In this case, there exists a forest of trees achieving better performance with respect to the cost measures being considered. The following theorem summarizes the results of this section with respect to the cost measures of any DAG scheme.

Theorem 3. *Any DAG scheme $\Gamma = (G, S, n, k)$ has $\Omega(\log \frac{n}{k})$ update, query and sibling costs.*

The above results establish a reduction from searching by comparisons to computations related to HDP problems (computations performed sequentially and hierarchically according to the hierarchy induced by the underlying DAG scheme) and give us lower bounds on the costs of these computations. Also, the optimality of tree-based DAG schemes over general graphs further characterizes the optimal schemes for HDP problems. The connection between HDP problems and

DAG schemes is illustrated in Sections 4 and 5, where we model two information security problems as HDP problems and translate the above results to their domain.

3 A New DAG Scheme Based on Skip-Lists

In view of the logarithmic lower bounds and the optimality of tree structures for DAG schemes, we present a new DAG scheme that is based on skip-lists. Our *multi-way skip-list DAG scheme* $\Delta = (T, S, n, 1)$ is based on the skip-list data structure and achieves cost measures close to the theoretical optimal.

Skip-Lists and Bridges. A *skip-list* [12] with *probability parameter* p is a set of lists L_1, \dots, L_h , where L_1 stores the element of a totally ordered set (X, \preceq) of size n (sorted according to \preceq) and, for each i , each of the elements of list L_i is independently chosen to be contained in L_{i+1} with probability p . Lists are viewed as *levels* and we consider all elements of the same value that are stored in different levels to form a *tower*. The *level* of a tower is the level of its top element. Each node of a tower has a forward pointer to the successor element in the corresponding list and a pointer to the element one level below it. A *header* tower that stores sentinel element $-\infty$ is included in the skip-list as the left-most tower of level one more than the maximum level of any other tower in the skip-list. A node of the skip-list is a *plateau* node if it is the top node of its tower. We introduce next the notion of a *bridge* and define related concepts.

Definition 4. *In a skip-list: (i) a bridge b is a maximal sequence of towers of the same level such that no higher tower lies between them and the plateau nodes of the towers are all reachable in a sequence using forward pointers; (ii) the size $|b|$ of bridge b is the number of towers in the bridge and the bridge size of a tower is the size of the bridge that the tower belongs to; (iii) a child bridge of b is a bridge that is contained under b and to which a tower of b connects through forward pointers; (iv) the plateau towers of a tower t are the towers whose plateau nodes can be reached by a node of t using one forward pointer.*

Directed Tree T . We now describe the multi-way skip-list DAG scheme $\Delta = (T, r, n, 1)$, where the directed tree T is defined with respect to a skip-list. By *list node* we refer to a node of the skip-list and by *DAG node* to a node of tree T . An edge (v, u) in T is directed towards node u . If v, v_1, \dots, v_l are nodes in T , then operation $New(v, v_1, \dots, v_l)$ on existing DAG nodes creates in T new nodes u_1, \dots, u_l and new edges $(v_1, u_2), \dots, (v_{l-1}, u_l), (v_l, v), (u_1, u_2), \dots, (u_{l-1}, u_l)$ and (u_l, v) , where DAG node u_1 becomes a new *source* node of T . The notion of a bridge is essential in skip-list DAG T . For each bridge b in the skip-list, a corresponding node $v(b)$ is created in T . We call $v(b)$ the DAG node of b . Node $v(b)$ is connected in T with the DAG nodes of all the child bridges of b . Thus, DAG T is defined in a recursive way with respect to a skip-list. First, all bridges in the skip-list are identified and the DAG node for the outer bridge (header tower) is created. Then, given that the DAG node $v(b)$ of a bridge b is created, using

Fig. 1. Multi-way skip-list DAG Δ , where circle nodes are DAG nodes (bridge DAG nodes are solid) and square nodes are nodes of the skip-list. DAG node $v(b)$ of bridge b is recursively connected to the DAG nodes of the child bridges depending on the following two cases: **(a)** $|b| = 1$ and **(b)** $|b| > 1$

operation $New(\cdot)$, $v(b)$ is connected with paths in T to the newly created DAG nodes of the child bridges of b , as follows (see Figure 1).

If $|b| = 1$ (Figure 1(a)), let t_1, \dots, t_l (in increasing level) be the plateau towers of the tower t of b . If plateau tower t_i belongs to bridge b_i , we perform operation $New(v(b), v(b_1), \dots, v(b_l))$ where $v(b)$ is the DAG node of b .

If $|b| > 1$ (Figure 1(b)), then let $k = |b|$ and let t_1, \dots, t_k be the towers of b . For each such tower t_i , we create a new DAG node $v(t_i)$, $1 \leq i \leq k$. For tower t_k , we consider its, say l , plateau towers t_{k1}, \dots, t_{kl} and perform operation $New(v(t_k), v(b_{k1}), \dots, v(b_{kl}))$, where b_{k1}, \dots, b_{kl} are the child bridges of b that plateau towers t_{k1}, \dots, t_{kl} belong to. Moreover, for each tower t_i , $i < k$, of, say $l + 1$, plateau towers, we consider its l lowest plateau towers t_{i1}, \dots, t_{il} , that is, for $i < k$, tower t_{i+1} is omitted from this sequence. Let b_{i1}, \dots, b_{il} be the child bridges of b that plateau towers t_{i1}, \dots, t_{il} belong in. For tower t_i , $i < k$, we perform operation $New(v(t_i), v(b_{i1}), \dots, v(b_{il}))$. Finally, we add k new edges in T : edge $(v(t_i), v(b))$ for $1 \leq i \leq k$. By this construction, T is a directed tree, the root of T is the DAG node r of the header bridge, and T has exactly n leaves.

We can show that multi-way skip-list Δ achieves cost measures that are close to the theoretical optimal value of $\lfloor \log_2 n \rfloor + 1$.

Theorem 4. *With respect to a skip-list with probability parameter p , the multi-way skip-list DAG scheme $\Delta = (T, r, n, 1)$ has the following expected cost measures for any fixed source node s of T with corresponding source to root path π_s :*

1. $E[\text{size}(\pi_s)] \leq 2(1-p) \log_{\perp} n + O(1)$;
2. $E[\text{indeg}(\pi_s)] \leq (1-p) \frac{(1+p)^2}{p} \log_{\perp} n + O(1)$;
3. $E[\text{bnd}(\pi_s)] \leq \frac{(1-p)(1+p^2)}{p} \log_{\perp} n + O(1)$; and
4. $E[\text{size}(T)] \leq (1 + pq^2 + pq + \frac{p}{q(2-pq^2)})n$, where $q = 1 - p$.

In particular, our multi-way skip-list DAG scheme Δ has better expected cost measures than the DAG scheme of [5, 12], also based on the skip-list, which we

Table 1. Comparison of three tree DAG schemes in terms of their cost measures

	$E[size(\pi_s)]$	$E[indeg(\pi_s)]$	$E[bnd(\pi_s)]$	$E[size(T)]$
red-black tree	$\log_2 n$	$2 \log_2 n$	$\log_2 n$	$2n$
standard skip-list	$1.5 \log_2 n$	$3 \log_2 n$	$1.5 \log_2 n$	$2n$
multi-way skip-list	$\log_2 n$	$2.25 \log_2 n$	$1.25 \log_2 n$	$1.9n$

call *standard skip-list DAG scheme*. Table 1 summarizes the comparison results for probability parameter $p = 1/2$. The comparison between multi-way skip-list scheme and red-black tree scheme shows an interesting trade-off on the performance with respect to the cost measures we study.

4 Data Authentication Through Hashing

We apply our results of Sections 2 and 3 to *data authentication through cryptographic hashing*. We focus on *authenticated dictionaries*, ADSs that authenticate answers to membership queries. ADSs provide a model of computation, where an untrusted *directory* answers queries issued by a *user* on a data structure on behalf of a trusted *source* and provides a proof of the validity of the answer to the user. In this model, authentication is achieved by having the data source signing some *digest* of the data, where, for data authentication through hashing, a hash function is systematically used to produce this digest. On any query, along with the answer, the signed digest and some information that relates the answer to this digest are given to the user and these are used for the answer verification.

Authenticated Dictionary. Let X be a data set owned by the source that evolves through update operations *insert* and *delete*. Membership queries contains are issued about X . A (multivariate extension of a) cryptographic hash function h is used to produce a digest of set X which is signed by the source (see [6]). In our study, we actually consider a more general model where several digests are produced and signed by the source. These digests are computed through a *hashing scheme* over a DAG that has k *signature nodes* t_1, \dots, t_k and stores the elements of X at the source nodes. Each node u of G stores a *label* (hash value) $L(u)$ such that, if u is a source of G , then $L(u) = h(e_1, \dots, e_p)$, where e_1, \dots, e_p are elements of X , else (u is not a source of G) $L(u) = h(L(w_1), \dots, L(w_l), e_1, \dots, e_q)$, where $(w_1, u), \dots, (w_l, u)$ are edges of G , e_1, \dots, e_q are elements of X and p, q and l are some non negative integers. Without loss of generality, we focus our study on the *canonical* case where $p = 1$ and $q = 0$, noting that any general hashing scheme is *equivalent* to a canonical one. We view the labels $L(t_i)$ of the signature nodes t_i of G as the digests of X , computed via the above DAG G .

The authentication technique is based on the following general approach. The source and the directory store identical copies of the data structure for X and maintain the same hashing scheme on X . The source periodically signs the digests of X together with time-stamps and sends the signed time-stamped digests to the directory. When updates occur on X , they are sent to the directory

together with the new signed time-stamped digests. When the user poses a query, the directory returns to the user some *answer authentication information*, which consists of: (i) one signed time-stamped digest of X , (ii) the answer to the query and (iii) a proof consisting of a small collection of labels from the hashing scheme (or of data elements if needed) that allows the recomputation of the digest. The user validates the answer by recomputing the digest, checking that it is equal to the signed one and verifying the signature of the digest. Security against forgery of proofs by the directory follows from the properties of the signature scheme and the hash function.

Authentication Overhead. Now we study the performance overhead of computations related to authentication in an authenticated dictionary based on a hashing scheme (the analysis is valid for any ADS). This *authentication overhead* consists of *time overhead* for the (i) maintenance of the hashing scheme after updates, (ii) generation of the answer authentication information in queries, and (iii) verification of the proof of the answer; *communication overhead*, defined as the size of the answer authentication information; *storage overhead*, given by the number of hash values used by the authentication scheme; and *signature overhead*, defined as the number of signing operations performed at the source (and thus the number of signatures sent by the source). The time for computing a hash function is a few orders of magnitude larger than the time for comparing two basic numerical types. Thus, the rehashing overhead dominates the update time and the practical performance of an ADS is characterized by the *authentication overhead*, which depends on the hash function h in use and the mechanism for realizing a multivariate hash function from h .

Cryptographic Hash Functions. A *collision-resistant hash function* $h(x)$ maps a bit string x of arbitrary length to a hash value of fixed length, such that collisions are hard to find. We refer to h simply as *hash function*. Generic constructions of hash functions are modeled by *iterative computations* based on a *compression function* $f(\cdot)$ that is applied iteratively on the input. For this class of hash functions, there exist constants c_1 and c_2 (which may depend on a security parameter) such that, given an input string x , the computation $h(x)$ takes time $T(x) = c_1|x| + c_2$. Moreover, without loss of generality, we extend h to a multivariate function using *string concatenation*. We define $h(x_1, \dots, x_d) = h(x_1||\dots||x_d)$.

Cost of Data Authentication Through Hashing. Let G be any hashing scheme used to implement a hash-based authenticated dictionary for set X of size n , where k signature nodes store hash values signed by the source. Hashing scheme G along with the signature nodes can be viewed as a DAG scheme $\Gamma = (G, S, n, k)$, where special nodes are signature nodes and there are exactly n source nodes in G storing elements in X . Each cost parameter of the authentication overhead depends *linearly* on $\text{size}(H)$ and $\text{indeg}(H)$ for some subgraph H of G . The node size corresponds to the number of performed *hash operations* and the degree size to the total number of hash values that participate as operands in these hash operations. In particular, the following holds.

Lemma 1. *Let $\Gamma = (G, S, n, k)$ be any hashing scheme used to implement a hash-based authenticated dictionary for set X , where special nodes are signature nodes. Let s be a source node of G storing element $x \in X$, G_s be the subgraph of G that is reachable from s , and π_s the associated path of s . We have: (i) an update operation on element x has update time overhead that is lower bounded by $\text{comb}(G_s)$; (ii) a query operation on element x has verification time overhead that is lower bounded by $\text{comb}(\pi_s)$ and communication overhead that is lower bounded by $\text{bnd}(\pi_s)$; (iii) the storage overhead is $\text{size}(G)$. All involved computations are performed according to the hierarchy induced by G .*

Thus, hash-based authentication of membership queries is an HDP problem, where operations insert/delete are related to the update cost and operation contains is related to the query cost of the underlying DAG scheme. Our results on DAG schemes indicate that signing multiple hash values does not help and that tree structures are optimal.

Theorem 5. *In the data authentication model through hashing, any hashing scheme with k signature nodes that implements an authenticated dictionary of size n has (i) $\Omega(\log \frac{n}{k})$ worst-case update and verification time overheads; (ii) $\Omega(\log \frac{n}{k})$ worst-case communication overhead; and (iii) $\Omega(k)$ signature overhead.*

Theorem 6. *An authenticated dictionary of size n implemented with a multi-way skip-list DAG scheme with probability parameter p achieves the following expected performance, where c_1 and c_2 are constants that depend on the hash function h in use and $q = 1 - p$:*

1. *the expected hashing overhead of an update or verification operation is at most $(1 - p) \left(2c_2 + \frac{(1+p)^2}{p} c_1 \right) \log_{\perp} n + O(1)$,*
2. *the expected communication cost is at most $(1 - p) \left(\frac{1+p^2}{p} \right) \log_{\perp} n + O(1)$ and*
3. *the expected storage overhead is at most $\left(1 + pq^2 + pq + \frac{p}{q(2-pq^2)} \right) n$.*

5 Multicast Key Distribution Using Key-Graphs

In this section, we apply our results of Section 2 and 3 to multicast key distribution.

Multicast Key Distribution. The problem refers to secure communication in multicast groups. A *group* consists of a set of n users and a *group key controller*. Secret-key cryptography is used to transmit *encrypted* multicast messages among users of the group. Messages are encrypted using a *group key* available to all the current users of the group. The security problem arises when updates on the group are performed through users addition to or deletions from the group. The goal is to achieve *confidentiality*, i.e., only group members can decrypt messages, and *forward (backward) secrecy*, i.e., users deleted from (added to) the group can not decrypt messages transmitted in the future (past). In this model, the group controller is responsible for distributing secret keys to the users and updating

them appropriately after user updates. The idea is that a set of keys, known to the controller, is distributed to the users, so that a key is possessed by multiple users and a user possesses multiple keys. In particular, any user is required to have, except from the group key, a *secret key* that no other user knows. On user updates, subsets of these keys need to be updated appropriately by the controller.

Key-Graphs. *Key-graphs* (e.g., [15]) provide a framework to implement this idea. A key-graph models the possession of keys by users and the computations (encryptions at the controller, decryptions at the users) and message transmissions that need to be performed after an update. A key-graph is a single-sink DAG G , known by the group controller and the users, that facilitates key updates. The source nodes of G correspond to users and store their individual secret keys. The non-source nodes of G correspond to keys that are shared among subsets of users. The user associated with a source node s of G possesses *all* and *only* the keys that correspond to the subgraph G_s of G (i.e., the nodes reachable from s). On any update of user s , the keys in G_s have to change to achieve forward and backward secrecy. The group controller distributes each new key by sending it encrypted with a previously distributed key.

Cost parameters. The cost parameters of a key distribution scheme using key-graphs are defined as follows: (i) the *encryption cost* is the computational cost at the controller for encrypting all new keys and thus producing the messages for transmission; (ii) the *decryption cost* is the computational cost at a user for decrypting received messages and updating her keys; (iii) the *communication cost* is the number of transmitted messages; and (iv) the *key-storage cost* is the total number of keys stored at the key controller and at the users.

We can view a key-graph G as DAG scheme $\Gamma = (G, S, n, 1)$, where S consists of the unique sink node of G , called *group* node, and the source nodes correspond to the users. Each cost parameter of the key distribution scheme depends linearly on $size(H)$ and $indeg(H)$, for some subgraph H of G . The node size corresponds to keys stored at users, decryptions and key generations and the degree size corresponds to the number of messages sent and the number of encryptions performed during the update.

Definition 5. Let $\Gamma = (G, S, n, 1)$ be a key-graph scheme and let v be a node in G . The support $Sup(v)$ of v is the set of users that possess the key stored at v , i.e., $s \in Sup(v)$ if and only if $v \in G_s$. Let $U = \{u_1, \dots, u_k\}$ be a set of nodes of G and let $T \subseteq V_{so}$ be a set of source nodes of G . We say that set U spans set T if $\bigcup_{1 \leq i \leq k} Sup(u_i) = T$. A node v is said to be safe if v is a source node or if $indeg(v) > 1$ and any node set that spans $Sup(v)$ and does not include v has size at least $indeg(v)$. Key-graph scheme Γ is said to be reduced, if all nodes in G are safe.

Lemma 2. Let $\Gamma = (G, S, n, 1)$ be a reduced key-graph scheme used for the multicast key distribution problem. Then we have: (i) an update operation on a user that corresponds to a source node s has communication cost at least $indeg(G_s)$ and encryption cost at least $comb(G_s)$; and (ii) the key-storage cost is $size(G)$.

All involved encryptions and decryptions are performed according to the hierarchy induced by G .

Multicast key distribution using reduced key-graphs is an HDP problem, where the cost of an update in the group is related to the update cost of the underlying DAG scheme. By studying more carefully reduced key-graph schemes and using Theorems 1 and 2, we can prove the main result of the section.

Theorem 7. *For a multicast key distribution problem of size n using key-graphs, in the worst case, an update operation in the group requires at least $\lfloor \log_2 n \rfloor$ communication cost and $\Omega(\log n)$ encryption cost. Also, key-tree structures are optimal over general key-graphs.*

6 A New Skip-List Version

From the relation of the sibling cost of any tree-based DAG scheme and the number of comparisons performed in a search tree corresponding to the DAG scheme and Theorem 4, we get a new version of the skip-list data structure with an expected number of comparisons closer to the theoretical optimal $\lfloor \log_2 n \rfloor + 1$, up to an additive constant term, than the one of the standard skip-list. The new skip-list version can be viewed as a *multi-way* extension of the skip-list data structure. We omit the details due to space limitations.

Theorem 8. *There is a multi-way version of a skip-list for set X of size n and probability parameter p , where the expected number of comparisons performed while searching in X for any fixed element is at most $\frac{(1-p)(1+p^2)}{p \log_2 \frac{1}{1-p}} \log_2 n + O(1)$, or $1.25 \log_2 n + O(1)$ for $p = \frac{1}{2}$.*

Abstract. We study an aspect of the balanced allocation paradigm (also known as the “two-choices paradigm”). Assume there are n balls and $m = (1 + \varepsilon)n/d$ bins of capacity d each, for a fixed $d \geq 1$. To each of the balls two possible bins are assigned at random. We show that $\varepsilon > (2/e)^{d-1}$ is sufficient to guarantee that with high probability each ball can be put into one of the two bins assigned to it, without any bin overflowing. Further, it takes constant time on average for changing the arrangement to accommodate a new ball, if $\varepsilon > \gamma \cdot \beta^d$, for some constants $\gamma > 0$, $\beta < 1$. The problem may also be described in data structure language. Generalizing cuckoo hashing (Pagh and Rodler, 2001), we consider a hash table with m positions, each representing a bucket of capacity $d \geq 1$. Key x may be stored in bucket $h_1(x)$ or $h_2(x)$, for two fully random hash functions h_1 and h_2 . For arbitrary $\varepsilon > 0$, we obtain an implementation of a dynamic dictionary that accommodates n keys in $m = (1 + \varepsilon)n/d$ buckets of size $d = O(\log(1/\varepsilon))$. For a lookup operation only two hash functions have to be evaluated and two contiguous segments of d memory cells have to be inspected. The expected time for inserting a new key is constant.

1 Introduction: Bounded Balanced Allocation, d -Orientability, and Blocked Cuckoo Hashing

In this paper, we study a data allocation problem that can be described in different terminologies. In the “**balanced allocation paradigm**” (also known as the “two-choices paradigm”) we have n balls and m bins. To each ball two bins are assigned at random. Each ball is to be placed into one of the two bins assigned to it; the aim is to keep the maximum load in the bins small. Much work has been devoted to analyzing the online version of this experiment, where the balls arrive one after the other and are put into a bin upon arrival, and this

placement can never be changed later. Not that much is known about the offline version, where all balls with their two choices are given as input. However, it has been known for quite a while that with high probability¹ for $n = O(m)$ constant bin size is enough to place all balls. Other authors have considered “dynamic” situations in which the positions of balls may change in the course of a random process.

In this paper, we ask how well we can utilize the space in the bins if we fix the capacity of the bins to some number $d \geq 1$. That means, given n , we wish to keep the space overhead $\varepsilon = \frac{dm-n}{n}$ as small as possible and still be able to place the balls w.h.p. We show that $\varepsilon > (2/e)^{d-1}$ is sufficient to guarantee this. We also consider a dynamic version of the problem. Assume that n balls are placed and a new ball arrives, with two randomly assigned bins. We show that the expected time needed to rearrange the balls so that the new ball can be accommodated as well is constant, as long as $\varepsilon > \gamma \cdot \beta^d$, for some constants $\gamma > 0$, $\beta < 1$. This implies that the expected time to place n balls is $O(n)$. No estimates for the density that can be achieved asymptotically for fixed bin size d larger than some small constant have been known before.

The allocation problem with bounded bin size d is equivalent to a version of the **d -orientability problem** [12] for random graphs. We say an undirected graph $G = (V, E)$ of m nodes and n edges is d -orientable if the edges can be directed in such a way that every node has outdegree not larger than d . Given a constant d , we ask for upper and lower bounds on the edge density $\frac{n}{m}$ so that a graph with n randomly placed edges (including loops and multiple edges) is d -orientable w.h.p. Also, we ask how long it takes to adapt a given edge orientation when a new random edge arrives.

Yet another formulation of the same problem can be given in **data structure** language. We wish to implement dynamic dictionaries so that constant lookup time is guaranteed. Dynamic dictionaries store keys from a universe U (possibly together with satellite data) and support the operations *insert*, *delete*, and *lookup*. Pagh and Rodler’s “**cuckoo hashing**” method [17] assumes that each one of n keys is assigned to two locations $h_1(x)$ and $h_2(x)$ in a hash table of size m , and can be stored in one of the two locations. Each location has capacity 1. We generalize this approach by considering buckets of capacity d , for some arbitrary constant $d \geq 1$. Our construction results in the following. Assuming that fully random hash functions are available, we obtain an implementation of a dynamic dictionary that for given $\varepsilon > 0$ stores n keys in space $(1 + \varepsilon)n$ in such a way that a lookup for x requires evaluating two hash functions and probing two contiguous blocks of d memory cells. The expected cost of inserting a new key is $(1/\varepsilon)^{O(\log \log(1/\varepsilon))}$. This compares favorably with the performance of “ *d -ary cuckoo hashing*”, a different generalization of cuckoo hashing by Fotakis, Pagh, Sanders, and Spirakis [9]. There $d = O(\log(1/\varepsilon))$ independent hash functions are used to achieve a similar space utilization. The access procedure of our scheme is more local and hence more suited for cache architectures. Experiments (see [7])

¹ abbreviated: “w.h.p.”, meaning “with probability $1 - \frac{1}{\text{poly}(n)}$ ”.

support the hope that the new scheme is competitive with d -ary cuckoo hashing [17] as far as space utilization is concerned, and allows faster accesses.

Remark 1. For reference, we describe the connection between the hashing formulation and the d -orientability formulation from [2, 12, 19] in detail. Given is a set S of n keys and two random hash functions h_1, h_2 . We consider a random (multi)graph $G_u = (V, E_u)$ with labeled edges. The node set is $V = [m] = \{0, \dots, m-1\}$, the set of labeled edges is $E_u = E_u(S, h_1, h_2) = \{\{h_1(x), h_2(x)\} \mid x \in S\}$. We say that G_u is d -orientable if the n edges in E_u can be directed in such a way that each node has outdegree at most d . Assigning such directions to edges is equivalent to storing the keys in a table with m blocks with maximal load d , as follows: the edge $\{y, y'\} = \{h_1(x), h_2(x)\}$ is directed from y to y' if and only if x is stored in block y . Below, any directed version of G_u with outdegree bounded by d will be called $G = (V, E)$.

Terminology. In this paper, the algorithms and the analysis are described in the language of a hash table with two functions. This also makes it possible to describe a new workaround for the assumption that fully random hash functions are available for free, see Section 2.3. However, all results readily translate into the terminology of the balanced allocation paradigm or the graph orientation paradigm.

1.1 Background and Related Work

Early contributions to the fixed sized bin allocation problem were made in connection with the balanced allocation paradigm. (For a survey of this area, see [14].) In the seminal paper [1] by Azar, Broder, Karlin, and Upfal it was noted [10] (also see [2]) that if a set of $n \leq 1.67m$ balls is allocated to m cells, with two choices per ball, then with high probability the keys can be placed so that no bin holds more than two balls. This immediately extends to a scheme for storing n balls in m bins with a maximum load of $d = 2 \cdot \lceil n/(1.67m) \rceil \leq 2 + 1.2 \frac{n}{m}$, which for m, n large corresponds to a space overhead of $\varepsilon = 0.2$ in our notation.

Simultaneously, observations concerning the existence of such placements were made in papers on the simulation of parallel random access machines on distributed memory machines by redundantly storing data (e.g., [3, 13]). In particular, it was shown there that a maximum load of $O(1 + n/m)$ is achievable with high probability, even if for allocating the bins hash functions from classes described in [22] are used.

Sanders et al. [20, 21] studied the static allocation problem with fixed bin sizes as the combinatorial abstraction of a scheme called “Randomized Duplicate Allocation (RDA)”, used for storing data blocks on disks. In [21] it was shown that with high probability a bin size of $d = 1 + \lceil n/m \rceil$ is sufficient (this would correspond to a bound $d \geq \frac{1}{\varepsilon}$ in our notation). In [20] the question was asked how close n/m might be to $d = \lceil n/m \rceil$ so that still block size d is sufficient. No asymptotic relation between n/m and d was derived. In the analysis of the static case we start with the condition (2) on d and ε that has been noted already in

[20]. The transformation of this condition into the general relation $d > 1 + \frac{\ln(1/\varepsilon)}{1 - \ln 2}$ by means of calculus has escaped other researchers until this date.

In [2] the online version of the case of heavily loaded bins (i.e., $\frac{n}{m} \rightarrow \infty$) was studied. In [4] it was demonstrated that perfect balance ($n = dm$, with no slack at all) is impossible w.h.p. if $d < \gamma_1 \ln n$ for a suitable constant γ_1 , while perfect balance is possible w.h.p. if $d > \gamma_2 \ln n$ for some larger constant γ_2 . Further, a randomized rebalancing procedure was described and analyzed, with running time polynomial in n .

On the data structures side, the paper by Pagh and Rodler [17] showed that $m = (2 + \varepsilon)n$ cells are enough if each cell may have load 1 and a key x may be stored in one of the locations given by two hash functions. It is easy to see that space below $2n$ is not sufficient for cuckoo hashing in the simple form. As a remedy for this situation, Fotakis et al. [9] suggested “ d -ary cuckoo hashing”. Their scheme amounts to the balanced allocation problem with bin size 1 and d random targets for each ball. They show that with n balls and $m = (1 + \varepsilon)n$ bins it is sufficient to have $d = O(\log(1/\varepsilon))$ for statically placing the balls and inserting new balls in expected constant time, w.h.p. This leads to an implementation of a dictionary for n keys in space $(1 + \varepsilon)n$, where a lookup requires evaluating $d = O(\log(1/\varepsilon))$ hash values and probing d random locations in the worst case. Inserting a key takes expected constant time. Our result leads to a comparable space utilization, but has the advantage that only two hash functions have to be evaluated and two contiguous blocks of d memory cells must be probed in a search, which has advantages in architectures with caches. The basic structure of our analysis for the dynamic case is the same as in [9]; however, quite a few extra technical obstacles have to be overcome.

Recently, Panigrahy [18] studied the dynamic version of the allocation problem (in the formulation for dynamic hash tables with insertions) for two choices and bin size $d = 2$. He established, by analyzing related branching processes, that inserting keys is possible in expected constant time as long as $n \leq 1.67m$.

For lack of space, not all details of the analysis are given in this extended abstract. They may be found in the technical report version [7].

2 The Results

2.1 The Static Case

A set S of n keys from the universe U is to be stored. We use an array $T[0..m-1]$ consisting of $m = n(1 + \varepsilon)/d$ blocks (subarrays) of d cells each. Inside each block we store up to d keys sequentially. Given two hash functions $h_1, h_2: U \rightarrow [m]$, we say that h_1, h_2 are *suitable* for S and d if it is possible to store each key x from S in one of the blocks $h_1(x), h_2(x)$ without any block receiving more than d keys. If the keys from S are stored according to h_1, h_2 , a *lookup procedure* is obvious, which involves evaluating two hash values and searching two blocks. Our first result is the following theorem, whose proof is outlined in Section 3.

Theorem 1. *Let $\varepsilon > 0$ be arbitrary. Assume that $d \geq 1 + \frac{\ln(1/\varepsilon)}{1 - \ln 2}$. Let n be sufficiently large, let $S \subseteq U$ be an arbitrary set of n keys, and let T be a table with m blocks of size d each, where $dm \geq (1 + \varepsilon)n$. Further assume that $h_1, h_2: U \rightarrow [m]$ are fully random hash functions. Then with probability $1 - O(1/m^{d-1})$ the functions h_1, h_2 are suitable for S and d .*

2.2 Updates: The Cuckoo Insertion Procedure

Assume n keys are stored in the table T according to h_1, h_2 , with blocks of size d . Inserting a new key x can best be described in terms of the directed graph G from Remark 1. In G , find a directed path y_0, y_1, \dots, y_ℓ with $y_0 \in \{h_1(x), h_2(x)\}$ and y_ℓ a node that is “free”, i.e., has outdegree smaller than d . (This means that block y_ℓ contains an empty cell.) The edges that form the path correspond to keys x_1, \dots, x_ℓ such that x_i is stored in y_{i-1} , but may be stored in y_i . After moving x_i from y_{i-1} to y_i , for $1 \leq i \leq \ell$ (this corresponds to flipping the edges on the path), node (block) y_0 is free, and hence we can store x there. We call a path y_0, y_1, \dots, y_ℓ as described an “augmenting path” for G and x .

It is very easy to see that if h_1, h_2 are suitable for $S \cup \{x\}$, then there is an augmenting path. So the problem is to find an augmenting path fast. As proposed in [9], a simple approach for this is *breadth-first-search (BFS)* in G , starting from $\{h_1(x), h_2(x)\}$. The time for this is proportional to the number of edges probed before a free node is found. Since the nodes in the part of G that is searched have outdegree d , this number is not larger than $2(d + d^2 + \dots + d^\ell) < 4d^\ell$, where ℓ is the length of a *shortest* path from $\{h_1(x), h_2(x)\}$ to a free node. Thus we will have to analyze (the distribution of) the distance between $\{h_1(x), h_2(x)\}$ and the set of free nodes. The proof of the following theorem is outlined in Section 4.

Theorem 2. *Let $\varepsilon > 0$ be arbitrary. Assume that $d \geq 90.1 \cdot \ln(1/\varepsilon)$. Let n be sufficiently large, let S an arbitrary set of n keys, let $x \in U - S$, and let T be a table with m blocks of size d each, where $dm \geq (1 + \varepsilon)n$. Assume that $h_1, h_2: U \rightarrow [m]$ are fully random hash functions, and that the keys from S have been stored in T by an algorithm that is ignorant of $h_1(x), h_2(x)$. Then the expected time to insert x by the BFS procedure is $(1/\varepsilon)^{O(\log d)}$.*

The constants in the bound are certainly not optimal. In particular, the horrendous factor 90.1 is only an artefact of our proof. Numerical estimates suggest that the approach we use could be tuned to get by with $d \geq 4 \ln(1/\varepsilon)$, for ε very small. — In this extended abstract, we do not address the issue of extra space (up to $O(n)$) needed by the BFS, for the following reason: If the technique described in Section 2.3 below is used, no more than $n^{2/3}$ keys have to be handled at any time, so the scratch space problem vanishes.

An alternative approach to insertion (also suggested in [9]) is to search an augmenting path by a certain kind of random walk in G , as follows: Assume x is to be inserted. Repeat the following, starting with $z := x$:

Calculate $h_1(z)$ and $h_2(z)$. If one of the two blocks $h_1(z)$ or $h_2(z)$ is not full, store z in one such block, and stop. Ties are broken arbitrarily. If

both blocks are full, randomly choose one of the keys stored in these blocks, call it z' , kick z' out from its block (this is the “cuckoo step”) and insert z in its place. Let $z := z'$, and start again.

Of course, some rules for stopping the loop have to be incorporated. The implementations used in our experiments [7] are based on this random walk idea, not on the BFS procedure. It is an intriguing open problem to provide an analysis of the random walk insertion procedure. (The same question is open for d -ary cuckoo hashing [9].)

2.3 Sharing Fully Random Hash Functions

For the analysis to carry through, we assume that the hash functions h_1, h_2 behave fully randomly on S . If in the course of inserting a key it turns out that h_1, h_2 are not suitable, we might want to rehash the whole set, using new hash functions h_1, h_2 . Although in the balanced allocation literature the full randomness assumption is routinely used, this is not the case in the hashing literature. Earlier work on hashing (e.g., [3, 9, 13, 17]) has, very carefully, pointed out ways of working around this problem, for example by using functions from high-performance universal classes like in [22]. (This would not be sufficient for d -ary cuckoo-hashing, though.) In [8, 16] it was demonstrated that full randomness can be simulated by universal hashing at the cost of $O(n)$ words of extra space. However, using such a construction would be unsatisfactory in our context, since we aim at getting by with εn extra space.

We propose the following workaround, which might be helpful also in other contexts. Let $\varepsilon > 0$ and n be given. Using high-performance hash classes [6, 22] we may choose a function $h: U \rightarrow [n^{1/3}]$ so that with probability $1 - n^{-c}$ (for some constant c) the set S is split into $n^{1/3}$ pieces $S_i = \{x \in S \mid h(x) = i\}$ of size $\leq (1 + \frac{\varepsilon}{2})n^{2/3}$. (There is no need that S is known or the pieces are listed.) For each of the pieces S_i we run cuckoo hashing with blocks of size d in a separate table T_i of size $(1 + \varepsilon)n^{2/3}$. It is an easy exercise, using polynomial hash functions and techniques described in [6], to provide a pair h_1, h_2 of hash functions that with high probability behaves fully randomly on a single S_i , if we are allowed to use space $n^{5/6}$ for storing h_1, h_2 . Since the data structures for the pieces S_i do not interact, we may use the *same* hash function pair h_1, h_2 for all pieces S_i , $i = 0, \dots, n^{1/3} - 1$. The overall space is $O(n^{5/6}) = o(n)$. The algorithms described in the present paper then has to be applied to each of the pieces separately. (For details see [7].)

3 Analysis for the Static Case: Proof of Theorem 1

In [20, 21] it is shown that a set S of n keys can be stored in $m = (1 + \varepsilon)n/d$ blocks of size d if and only if for every $X \subseteq S$ it holds that $|\Gamma(X)| \geq \frac{1}{d}|X|$, where $\Gamma(X) = \{h_1(x), h_2(x) \mid x \in X\}$. (This may be seen directly: It is immediate that S can be stored if and only if the bipartite graph $(S, [dm], E)$, $E = \{(x, d \cdot h_i(x) + j) \mid x \in S, i \in \{1, 2\}, 0 \leq j < d\}$ has a matching that covers all nodes in S . Hall’s

marriage theorem [5, p. 31] implies that such a matching exists if and only if $|\Gamma(X)| \geq \frac{1}{d}|X|$ for all $X \subseteq S$.) Thus, to prove Theorem 1 it is sufficient to establish an upper bound on the probability F of the event that there is some $X \subseteq S$ such that $|\Gamma(X)| < \frac{1}{d}|X|$.

Lemma 1. *If $\varepsilon \leq 0.25$ and $d > 1 + \frac{\ln(1/\varepsilon)}{1-\ln 2}$, then $F = O(m^{1-d})$.*

Proof (Outline). For $1 \leq j \leq m/(1 + \varepsilon)$, let $F(j)$ be the probability that there is a set Y of j blocks such that some set $X \subseteq S$, $|X| = dj$, satisfies $\Gamma(X) \subseteq Y$. Clearly, $F \leq \sum_{1 \leq j \leq m/(1+\varepsilon)} F(j)$. Using the Chernoff-Hoeffding bound (13) and the binomial bound (11), we get

$$\begin{aligned}
 F(j) &\leq \binom{m}{j} \left(\frac{n(j/m)^2}{jd}\right)^{jd} \left(\frac{n - n(j/m)^2}{n - jd}\right)^{n-jd} \\
 &\leq (1 + \varepsilon)^{-jd} m^{-\frac{(1+\varepsilon)}{1+\varepsilon}} j^{j(d-1)} (m - j)^{j-m} \left(\frac{m^2 - j^2}{m - j(1 + \varepsilon)}\right)^{d - \frac{(1+\varepsilon)}{1+\varepsilon}}, \tag{1}
 \end{aligned}$$

which was already observed in [20, 21]. We examine the expression on the right-hand side of (1), which we abbreviate by $f(j, \varepsilon)$, in different ranges of j . For $j = 1$ we find $f(1, \varepsilon) = O(m^{1-d})$. — For j , $2 \leq j < e^{-4}m$, we prove that $f(j, \varepsilon)$ is a decreasing function of ε ; thus, we can concentrate on the case $\varepsilon = 0$. The sequence $f(j, 0)$, $j = 2, \dots, \lfloor e^{-4}m \rfloor$ turns out to be geometrically decreasing; hence we get $\sum_{2 \leq j \leq e^{-4}m} F(j) = O(m^{2-2d})$. — The most involved calculation concerns the range $e^{-4}m \leq j \leq (1 - 2\varepsilon)m$. Here we read off from (1) by substituting $j = \alpha m$, that $f(j, \varepsilon) = O(c^m)$ for a constant $c < 1$, if

$$d > \frac{\alpha \ln \alpha + (1 - \alpha) \ln(1 - \alpha)}{\alpha(\ln \alpha - \ln(1 + \varepsilon)) + \frac{(1-\alpha(1+\varepsilon))(\ln(1-\alpha^2) - \ln(1-\alpha(1+\varepsilon)))}{1+\varepsilon}}, \tag{2}$$

for $e^{-4} \leq \alpha \leq 1 - 2\varepsilon$. We prove that the right-hand side of (2) is bounded by

$$g(\alpha) := \frac{\alpha \ln \alpha + (1 - \alpha) \ln(1 - \alpha)}{\alpha \ln \alpha + (1 - \alpha) \ln(1 + \alpha)} \tag{3}$$

By calculus we show that g is an increasing function and that $g(1 - 2\varepsilon) < 1 - \frac{\ln \varepsilon}{1 - \ln 2}$. — For the range $j > (1 - 2\varepsilon)m$, we observe that for each $\varepsilon \leq 0.25$ the right-hand side of (2) is decreasing in α , if $1 - 2\varepsilon \leq \alpha \leq 1/(1 + \varepsilon)$. \square

4 The Expected Insertion Time: Proof of Theorem 2

We want to examine the expected time of the BFS algorithm for inserting a new key x in T , as described in Section 2.2 (also recall Remark 1). Just before x is inserted, a set S of n keys is stored in T . We assume that the directed graph

G determined by this placement is independent of the hash values $h_1(x), h_2(x)$ — this is the case if x was never inserted before. We start a BFS in G from $\{h_1(x), h_2(x)\}$ with the aim of finding a shortest path to a node in $Y_0 := \{y \in V \mid y \text{ is free in } G\}$. The time for the BFS in G is $O(\min\{n, d^{\ell+1}\})$, where ℓ is the length of such a shortest path. Our aim is to see that the expectation of the number of edges we have to inspect before a free node is found is $O(1)$. For this, we analyze the distribution of the number of nodes at different distances to Y_0 . (The analysis runs along the lines of that of [9], but we are dealing with quite a different graph.) — Recursively define, for $k \geq 1$:

$$\begin{aligned} X_k &:= \{x \in S \mid h_1(x) \in Y_{k-1} \text{ or } h_2(x) \in Y_{k-1}\} \text{ and} \\ Y_k &:= \{y \in [m] \mid \exists x \in X_k: x \text{ is stored in } y\}. \end{aligned}$$

We say that the keys of X_k “hit” Y_{k-1} . It is easy to see that Y_k is the set of nodes from which Y_0 can be reached in at most k steps in G . By the definitions, $Y_{k-1} \subseteq Y_k$, for $k = 1, 2, \dots$. Inserting a new key x has cost roughly $O(d^{\ell+1})$, if ℓ is minimal with $h_1(x) \in Y_\ell$ or $h_2(x) \in Y_\ell$. The proof strategy is as follows. We show that with high probability a large constant fraction of the nodes are in $Y_{k^*+\ell^*}$ for suitable constants k^*, ℓ^* . (Lemmas 2, 3, 4, and 5). Beyond that, the complements $[m] - Y_k$ shrink at a rate of roughly $d^{-2/3}$ (Lemmas 6 and 7). If a new key x arrives, with constant probability one of the values $h_1(x), h_2(x)$ will hit $Y_{k^*+\ell^*}$ (causing constant cost). The probability that both $h_1(x)$ and $h_2(x)$ hit nodes at a distance $k^* + \ell^* + j$ from Y_0 shrinks geometrically with growing j , at a rate of $(d^{-2/3})^2 = d^{-4/3}$. This probability is small enough to compensate the high cost of $O(d^{k^*+\ell^*+j})$ for reaching Y_0 should this happen. Overall, the expected insertion cost remains a constant (Lemma 8).

Lemma 2. *Let $\varepsilon \leq 0.1$ and $d \geq 90.1 \cdot \ln(\frac{1}{\varepsilon})$. Then there is a constant $\beta < 1$ such that with probability $1 - O(m\beta^m)$ each set of blocks Y that satisfies $\frac{\varepsilon}{1+\varepsilon}m \leq r = |Y| \leq \frac{5}{13}m$ is hit by at least $\frac{4}{3}rd$ keys from S .*

Proof (Outline). A set of blocks Y , $|Y| = r$, is hit by $\frac{4}{3}rd$ keys with h_1 or h_2 if at most $n - \frac{4}{3}rd$ keys avoid Y with both hash functions h_1 and h_2 . Let $F(r)$ denote the probability that there is a set Y of size r such that there are more than $n - \frac{4}{3}rd$ keys that avoid Y with both hash functions. Employing (13):

$$F(r) \leq \binom{m}{r} \left(\frac{n(1 - \frac{r}{m})^2}{n - \frac{4}{3}rd} \right)^{n - \frac{4}{3}rd} \left(\frac{n - n(1 - \frac{r}{m})^2}{\frac{4}{3}rd} \right)^{\frac{4}{3}rd}. \quad (4)$$

By $n = dm/(1 + \varepsilon)$, the binomial bound (11), and the substitution $r = \alpha m$ we observe that $F(r) < \beta^m$ for a suitable $0 < \beta < 1$, provided that

$$d > \frac{\alpha \ln \alpha + (1 - \alpha) \ln(1 - \alpha)}{\left(\frac{1}{1+\varepsilon} - \frac{4}{3}\alpha \right) \left(2 \ln(1 - \alpha) - \ln \left(1 - \frac{4(1+\varepsilon)\alpha}{3} \right) \right) + \frac{4\alpha}{3} \ln \left(\frac{3(2-\alpha)}{4(1+\varepsilon)} \right)} \quad (5)$$

for all α between $\frac{\varepsilon}{1+\varepsilon}$ and $\frac{5}{13}$. The right-hand side of (5) can be shown to be bounded by $90.1 \ln(1/\varepsilon)$, for $0 \leq \varepsilon \leq 0.1$ and $\frac{\varepsilon}{1+\varepsilon} \leq \alpha \leq \frac{5}{13}$. \square

Lemma 3. *If the digraph G induced by S being stored meets the conclusion of Lemma 2, then there is some $k^* \leq 2 + \log_{\frac{4}{3}} \left(\frac{5(1+\varepsilon)}{13\varepsilon} \right)$ such that $|Y_{k^*}| > \frac{m}{2}$.*

Proof. Assume $k \geq 1$ and $|Y_{k-1}| \leq \frac{5}{13}m$. Consider the set X_k of keys that hit Y_{k-1} . By the assumption, $|X_k| \geq \frac{4}{3}d|Y_{k-1}|$. By definition, all keys $x \in X_k$ are stored in blocks in Y_k . Only $d|Y_{k-1}|$ of them can be stored in Y_{k-1} , so at least $\frac{1}{3}d|Y_{k-1}|$ of them must be stored in $Y_k - Y_{k-1}$, which implies that $|Y_k - Y_{k-1}| \geq \frac{1}{3}|Y_{k-1}|$; hence $|Y_k| \geq \frac{4}{3}|Y_{k-1}|$.

Now let k' be minimal with $|Y_{k'}| > \frac{5}{13}m$. By the above, it is easy to see that either $|Y_{k'}| > \frac{1}{2}m$ (then we let $k^* = k'$) or $|Y_{k'+1}| \geq \frac{4}{3} \cdot \frac{5}{13}m > \frac{1}{2}m$ (then we let $k^* = k' + 1$). (This holds even if $5m/13 < |Y_{k'}| \leq m/2$, since then we apply the conclusion of Lemma 2 to a subset of $Y_{k'}$ of size $\lfloor 5m/13 \rfloor$.)

Because there are exactly εn free cells in the table, we have $|Y_0| \geq \frac{\varepsilon n}{d} = \frac{\varepsilon}{1+\varepsilon}m$. Thus, $|Y_k| \geq \frac{\varepsilon}{1+\varepsilon}m \left(\frac{4}{3}\right)^k$ for $0 \leq k < k'$, whence we get $k^* \leq 1 + k' \leq 2 + \left\lceil \log_{\frac{4}{3}} \left(\frac{5(1+\varepsilon)}{13\varepsilon} \right) \right\rceil$. \square

Lemma 4. *Let $d \geq 8$. Then there is some $\beta < 1$ such that with probability $1 - O(\beta^m)$ we have that each set Y of blocks with $\frac{m}{2} \leq |Y| \leq m - \frac{4m}{e^4 d^3}$ is hit by at least $n - \frac{9}{10}d(m - |Y|)$ keys.*

Proof (Outline). Let $\bar{Y} = [m] - Y$ and $r = |\bar{Y}|$. By (13) and (11) we find that the probability that there is a set Y with $r = m - |Y|$ in $[\frac{4m}{e^4 d^3}, \frac{m}{2}]$ such that more than $\frac{9}{10}dr$ keys hit \bar{Y} with both hash functions is bounded by

$$\frac{m^m}{r^r(m-r)^{m-r}} \left(\frac{10r}{9(1+\varepsilon)m} \right)^{\frac{9}{10}rd} \left(\frac{10(m^2 - r^2)}{(10m - 9r(1+\varepsilon))m} \right)^{\overline{1+\varepsilon} - \frac{9}{10}rd}. \tag{6}$$

We denote the expression in (6) by $f(r, \varepsilon)$. It is not hard to see that $f(r, \varepsilon)$ is decreasing in ε , thus we can concentrate on the case $\varepsilon = 0$. After replacing ε by 0 in (6), and substituting $\alpha = r/m$, an expression for a function $g(\alpha, d)^m$ results. For each fixed α the function $g(\alpha, d)$ is decreasing in d . A look at a Maple plot reveals that $g(\alpha, 8)$ does not exceed $\max\{g(\frac{4}{e^4 d^3}, 8), g(0.5, 8)\} = g(\frac{4}{e^4 d^3}, 8) < 1$. \square

Lemma 5. *If G meets the conclusions of Lemmas 2 and 4, and k^* satisfies $|Y_{k^*}| \geq \frac{m}{2}$, then there is some ℓ^* , $\ell^* = O(\log d)$ such that $m - |Y_{k^*+\ell^*}| \leq \frac{4m}{e^4 d^3}$.*

Proof. The induction proof, which uses Lemma 4, is omitted. \square

The following lemma states a standard expansion property of bipartite random graphs, see [15, p. 109].

Lemma 6. *Let $d \geq 20$, and $\gamma = \frac{4}{e^4 d^3}$. With probability $1 - O(m^{-d/2})$ we have that each set $X \subseteq S$ of keys with $d \leq |X| \leq \gamma dm$ hits more than $\Delta|X|$ different blocks, where $\Delta = \frac{1}{d^{1/3}} + \frac{1}{d}$.*

Proof. The probability that there is a set X of j keys, $d \leq j \leq \gamma dm$, that hits no more than Δj blocks can be bounded by

$$\sum_{d \leq j \leq \gamma dm} \binom{n}{j} \binom{m}{\lfloor \Delta j \rfloor} \left(\frac{\lfloor \Delta j \rfloor}{m} \right)^{2j} \leq \sum_{d \leq j \leq \gamma dm} \left(\frac{en}{j} \right)^j \left(\frac{em}{\Delta j} \right)^{\Delta j} \left(\frac{\Delta j}{m} \right)^{2j}. \quad (7)$$

Straightforward simplifications, using that $d \geq 20$ implies that $\Delta < \frac{1}{2}$, lead to the bound $\sum_{d \leq j \leq \gamma dm} \left((e/2)^{3/2} \cdot d \cdot \sqrt{j/m} \right)^j$ for the right hand side in (7). For $j = d, d+1, \dots, \lfloor \gamma dm \rfloor$ the terms in this sum are geometrically decreasing by a factor smaller than $\frac{1}{2}$, hence the sum is bounded by $O(m^{-d/2})$. \square

We conclude that for $k \geq k^* + \ell^*$ the complements of the sets Y_k shrink fast.

Lemma 7. *Assume that $|[m] - Y_{k^* + \ell^*}| \leq \gamma m$ and that the hash functions h_1, h_2 meet the conclusion of Lemma 6. Then the cardinalities $a_j = |[m] - Y_{k^* + \ell^* + j}|$, $j = 0, 1, 2, \dots$, satisfy $a_j \leq d^{-2/3} \cdot a_{j-1}$ for $j = 1, 2, 3, \dots$. Hence,*

$$|[m] - Y_{k^* + \ell^* + j}| \leq \gamma d^{-2j/3} m, \text{ for } j = 0, 1, 2, \dots$$

(In particular, there is some L with $Y_{k^* + \ell^* + L} \neq [m] = Y_{k^* + \ell^* + L + 1}$.)

Proof. Fix $j \geq 1$. If $a_j = 0$, there is nothing to prove; thus assume $a_j \geq 1$. Then by the definitions, all a_j nodes in $[m] - Y_{k^* + \ell^* + j}$ are full. That means that the set E_j of edges in G with tails in $[m] - Y_{k^* + \ell^* + j}$ has cardinality da_j . By the assumption that the conclusion of Lemma 6 is satisfied the edges in E_j touch at least $\Delta da_j = (d^{2/3} + 1)a_j$ nodes overall. Only a_j of these nodes are in $[m] - Y_{k^* + \ell^* + j}$. By the definition of the sets Y_k , no edge in G can run from a node in $[m] - Y_{k^* + \ell^* + j}$ to a node in $Y_{k^* + \ell^* + (j-1)}$. Hence the heads of the edges in E_j hit at least $(d^{2/3} + 1)a_j - a_j = d^{2/3}a_j$ distinct nodes in $[m] - Y_{k^* + \ell^* + (j-1)}$, which implies that $a_{j-1} \geq d^{2/3}a_j$. \square

Lemma 8. *Assume $Y_0, Y_1, \dots, Y_{k^*}, \dots, Y_{k^* + \ell^*}, \dots, Y_{k^* + \ell^* + L}$ are fixed and fulfill the expansion properties from Lemmas 3, 5, and 7. Assume further that $h_1(x), h_2(x)$ are random values in $[m]$. Then the expected number of edges probed in the BFS insertion procedure for x is $(1/\varepsilon)^{O(\log d)}$.*

Proof. Let N_x be the number of edges of G probed when x is inserted. Let $\sigma_k = \sum_{0 < \kappa \leq k} d^\kappa < 2d^k$, for $k \geq 0$, and $k_x = \min\{k \mid h_1(x) \in Y_k \text{ or } h_2(x) \in Y_k\}$. Then the number of edges of G probed when inserting x is not larger than $2\sigma_{k_x}$. Thus, it is sufficient to estimate $\mathbf{E}(\sigma_{k_x})$. We have

$$\mathbf{E}(\sigma_{k_x}) = \sum_{q \geq 1} \mathbf{Prob}(\sigma_{k_x} \geq q) = \sum_{k \geq 1} \mathbf{Prob}(k_x \geq k) \cdot d^k. \quad (8)$$

The last sum in (8) is estimated in two pieces. We have

$$\sum_{1 \leq k \leq k^* + \ell^*} \mathbf{Prob}(k_x \geq k) \cdot d^k \leq (k^* + \ell^*)d^{k^* + \ell^*}. \tag{9}$$

For the rest of the sum in (8), we notice that by Lemma 7

$$\begin{aligned} \sum_{k^* + \ell^* < k \leq k^* + \ell^* + L} \mathbf{Prob}(k_x \geq k) \cdot d^k &= d^{k^* + \ell^*} \cdot \sum_{1 \leq j \leq L} \mathbf{Prob}(k_x \geq k^* + \ell^* + j) \cdot d^j \\ &\leq d^{k^* + \ell^*} \cdot \sum_{1 \leq j \leq L} \mathbf{Prob}(h_1(x), h_2(x) \in [m] - Y_{k^* + \ell^* + (j-1)}) \cdot d^j \\ &\leq d^{k^* + \ell^*} \cdot \sum_{1 \leq j \leq L} (d^{-2(j-1)/3})^2 \cdot d^j < 2d^{k^* + \ell^* + 1}. \end{aligned} \tag{10}$$

The sum of the parts in (9) and (10) is bounded by $(k^* + \ell^* + 2)d^{k^* + \ell^* + 1} = O(d)^{O(\log(1/\varepsilon))} = (1/\varepsilon)^{O(\log d)}$. This shows that the expected number of edges probed in inserting x is bounded by $(1/\varepsilon)^{O(\log d)}$. \square

To prove Theorem 2 we note that with probability $1 - O(m^{-d/2})$ the graph G satisfies the conclusions of Lemmas 2, 4, and 6. If this is the case, then the expansion properties of Lemmas 3, 5, and 7 hold, and we may apply Lemma 8 to obtain the claimed bound on the expected insertion time. If G does not have the expansion properties from Lemmas 3, 5, and 7, and Y_0 is reachable from $\{h_1(x), h_2(x)\}$, the BFS will find an augmenting path in time $O(n)$ — this gives a contribution of $O(m^{1-d/2})$ to the expected insertion time. In case Y_0 is not reachable from $\{h_1(x), h_2(x)\}$, the functions h_1, h_2 are not suitable for $S \cup \{x\}$, and we must perform a total rehashing for all these keys. By Theorem 1 this happens with probability $O(m^{1-d})$. It is easily seen that even if we simply insert the keys by the BFS procedure, and rehash again if necessary, the expected time for rebuilding the table is $O(n)$. Hence, this last case contributes $O(m^{2-d})$ to the expected insertion cost.

5 Conclusion

We obtained new results for a natural data allocation problem arising in different contexts: balanced allocation with two choices, edge orientation in random graphs, dynamic dictionaries with worst case constant access time. It is an intriguing open problem to analyze at least one variant of the random-walk insertion procedure from Section 2.2, if possible establishing a bound of $O(\ln(1/\varepsilon))$ on the expected number of blocks probed, while maintaining the bound $d = O(\log(1/\varepsilon))$.

A Some Inequalities

We will be using the following upper bounds for binomial coefficients:

$$\binom{n}{k} \leq \frac{n^n}{k^k(n-k)^{n-k}} = \left(\frac{1}{\mu^\mu(1-\mu)^{1-\mu}} \right)^n, \text{ for } 0 \leq k \leq n, \quad (11)$$

where $\mu = k/n$, and

$$\binom{n}{k} \leq \left(\frac{e \cdot n}{k} \right)^k. \quad (12)$$

Further, a standard version of the Chernoff-Hoeffding bounds is used repeatedly: If X_1, \dots, X_n are independent 0-1-valued random variables and $X = X_1 + \dots + X_n$, then for $\mathbf{E}(X) \leq a \leq n$ we have

$$\mathbf{Prob}(X \geq a) \leq \left(\frac{\mathbf{E}(X)}{a} \right)^a \left(\frac{n - \mathbf{E}(X)}{n - a} \right)^{n-a}. \quad (13)$$

(For a proof, see e.g. [11].)

Worst Case Optimal Union-Intersection Expression Evaluation

Ehsan Chiniforooshan, Arash Farzan, and Mehdi Mirzazadeh

School of Computer Science, University of Waterloo
{echinifo, afarzan, mmirzaza}@cs.uwaterloo.ca

Abstract. We consider the problem of evaluating an expression consisting of unions and intersections of some sorted sets. Given the expression and the sizes of the sets, we are interested in the worst-case complexity of evaluating the expression in terms of the sizes of the sets. We assume no set is repeated in the expression. We show a lower bound on this problem and present an algorithm that matches the lower bound asymptotically.

1 Introduction

In this paper, we study the problem of evaluating a set expression consisting of a number of union and intersection operators. Sets are known to be sorted and we also assume that no set is repeated more than once in the input. While the worst case complexity in terms of the size of the whole combined input is straightforward, we measure the running time of algorithms as a function of the sizes of the input sets; we are interested in a worst-case optimal algorithm.

The problem arises in the context of evaluating search queries in text database systems; search engines maintain a set $S(w)$ for each word w consisting of all documents that contain w [1, 7, 11]. Thus, answering to a query such as “Database OR Search AND Engine”, requires evaluation of the expression $S(\text{Database}) \cup (S(\text{Search}) \cap S(\text{Engine}))$. Note that the queries and their corresponding expressions can become very complicated if the queries are automatically generated [6].

Different variations of the problem have been studied before. The simplest case which is finding intersection or union of two sets is equivalent to the problem of merging two ordered sets of sizes m and n , which was studied by Hwang and Lin [5]. They present an algorithm that matches the information theoretic lower bound $\lceil \log \binom{m+n}{n} \rceil$. They choose sorted arrays as the format of the input and a list of cross references (pointers) between arrays as the output format. Later Brown and Tarjan [2, 3] and Pugh [9] showed how data structures such as AVL-tree, B-tree, or skip-list can be used as the format of the input and output.

Later, Demaine, López-Ortiz, and Munro [4], studied a somewhat more general case in which the number of input sets can be more than two. The expressions they looked at, though, consist of just one type of operand: they are either all unions or all intersections. Their algorithm is adaptive; they do not focus on the worst-case complexity of the problem. They define the *difficulty* of every possible

input I as a function $D(I)$, which measures how complicated a proof for the input I is; they focus on minimizing the maximum value of $\frac{f(I)}{D(I)}$ among all inputs I of size n , where $f(I)$ is the running time of the algorithm on I . The adaptive problem was generalized by Mirzazadeh [8] to general expressions consisting of both union and intersection operators.

Neither of the algorithms that we mentioned work optimally in the worst case in terms of the sizes of the input sets. In this paper, we consider the worst case complexity as mentioned. We present a lower bound and then an algorithm that matches the lower bound.

The rest of this paper is organized as follows: In Section 2 we give some definitions and preliminary observations. In Section 3, Theorem 4, we present our lower bound and finally, in Section 4, the optimal algorithm is explained.

2 Definitions and Preliminaries

We study the problem of evaluating a set expression when the inputs are ordered sets and the output is required to be an ordered set as well. We formally define an *input* as a pair (T, Γ) , where T and Γ are defined as follows. T is an *union-intersection tree* representing the expression: every internal node v is assigned a union or an intersection operator $\pi(v)$ and each leaf v of T represents an input set and is assigned an integer $\text{size}(v)$. We call T the *signature* of the input I . Also, Γ is an *assignment function* that assigns an ordered set of size $\text{size}(v)$ to each leaf v . For an internal node v with k children u_1, \dots, u_k , we denote the union or intersection of $\Gamma(u_1), \Gamma(u_2), \dots$, and $\Gamma(u_k)$, depending on the operator assigned to v , by $\Gamma(v)$. By the *result* of an input (T, Γ) we mean the set $\Gamma(\text{Root}(T))$. We denote the set of nodes of a tree T and the set of leaves of T by V_T and $\text{leaves}(T)$, respectively. Without loss of generality, we assume that every internal node has at least two children, and that the operator assigned to every internal node other than root differs from the operator assigned to its parent.

In this paper we focus on the *comparison-based algorithms* which are those that, for any input $I = (T, \Gamma)$, use only comparisons in the input sets to compute the result. In our model, the algorithm has oracle access to Γ , which means that the algorithm reads the signature of the input and can later submit queries of the form (x, y) to the oracle, where x and y are members of the input sets. Then, the oracle informs the algorithm of the relative values of x and y , that is, the algorithm is told whether x is less than, equal to, or greater than y according to Γ . In such situations we say x and y are *touched* by the algorithm. We show the interaction between the algorithm \mathcal{A} and the oracle O on the input (T, Γ) by $\langle \mathcal{A}, O(\Gamma) \rangle(T) = (q_1, r_1, \dots, q_k, r_k, R)$ where q_i is the i th query of the algorithm, r_i is the response of O to the i th query, and $R = \Gamma(\text{Root}(T))$ is the result. We expect the algorithm to specify ranges of input sets that appear in the result, rather than to write all elements of the result. This allows us to generate the output in sub-linear time if possible. More precisely, we define the output format below. We use $S[i]$ to denote the i th element of a sequence S .

Definition 1. Consider an input $I = (T, \Gamma)$ and a set S . A cross reference representation of S is a sequence of triples $(v_1, b_1, b'_1), \dots, (v_n, b_n, b'_n)$ where v_i is a leaf of T and $1 \leq b_i \leq b'_i \leq \text{size}(v_i)$, for every $1 \leq i \leq n$, $\Gamma(v_j)[b'_j] < \Gamma(v_{j+1})[b_{j+1}]$, for every $1 \leq j < n$, and $S = \cup_{i=1}^n \cup_{j=b}^{b'} \{\Gamma(v_i)[j]\}$.

A leaf v of an expression tree T is a *shallow* leaf if v is a child of $\text{Root}(T)$ and $\pi(\text{Root}(T)) = \cup$.

We define $\binom{s}{s_1, \dots, s_n}$, when $s \leq \sum_{i=1}^n s_i$ as the number of ways to select sets X_1, \dots, X_n of sizes s_1, \dots, s_n , respectively, such that X_i 's are subsets of a given set X of size s and $\cup_{i=1}^n X_i = X$. Note that this definition matches definition of the well known notation $\binom{s}{s_1, \dots, s_n}$ when $\sum_{i=1}^n s_i = s$. Also for a union-intersection tree, we define functions ψ^* and ψ over the set of nodes of T as follows: for a leaf v we define $\psi(v) = \text{size}(v)$. If v is an internal node and u_1, \dots, u_k is the list of children of v , we define $\psi(v) = \min_{i=1}^k \psi(u_i)$ when v is an intersection node, and $\psi(v) = \sum_{i=1}^k \psi(u_i)$, otherwise. In fact $\psi(v)$ is the maximum potential size of $\Gamma(v)$. Also, for every node v we define $\psi^*(v) = \min \psi(u)$, where the minimum is taken over all ancestors u of v , including v itself. Note that the values of ψ and ψ^* for all nodes of an expression tree T can be evaluated in time $O(|V_T|)$.

Observation 1. Suppose v is an internal node with k children u_1, \dots, u_k . $\sum_{i=1}^k \psi^*(u_i) \geq \psi^*(v)$ if v is a union node and $\sum_{i=1}^k \psi^*(u_i) \geq 2\psi^*(v)$, otherwise.

We present an algorithm such that for every signature T , the maximum running time of the algorithm, over all possible inputs with the signature T , is minimum.

3 Lower Bounds

In this section, fixing an arbitrary union-intersection tree T , we present a lower bound on the maximum number of comparisons performed by any algorithm when it is run on inputs with the signature T . For this purpose, we design an adversary \mathcal{B} that for any given algorithm \mathcal{A} and any signature T , as the algorithm \mathcal{A} proceeds and compares members of the input, \mathcal{B} fixes relative values of more members and responds to \mathcal{A} . In this way, an assignment function Γ is constructed gradually and we make sure that there is at least one Γ such that the responses of \mathcal{B} to \mathcal{A} are consistent with Γ . For two members x and y , if some certain conditions (which will be defined later in this section) hold, we say x and y are *similar*. We suppose that when a query (x, y) is submitted, in addition to relative values of x and y , \mathcal{A} is informed of whether x and y are similar or not. It is clear that any lower bound for algorithms working in this new model is a lower bound for algorithms working in the comparison model as well.

Considering a set O_T of size $\psi^*(\text{Root}(T))$, \mathcal{B} responds queries such that O_T becomes the result of the final input. We spread the elements of O_T down to the nodes of T such that every vertex v is *labeled* by a subset of O_T of size $\psi^*(v)$ in such a way that for every union (intersection) vertex v , the union (the intersection) of labels of its children is the label of v . As a simple observation,

suppose that S is the set of leaves having a certain member s of O_T in their “labels”. Then, if s appears in the set associated with every leaf in S , s will appear in the result. Responses of \mathcal{B} will be such that rather than appearing in sets associated with all leaves in S , s will appear in the sets associated with leaves in just a subset of S , yet still s will appear in the result of the input. This subset will be determined based on the behavior of \mathcal{A} .

Now we define the above labeling more formally. For convenience, rather than using real numbers, we will use triples of integers for representing members of our sets. Triples are compared to each other according to their lexicographic order. We define the set O_T as $\{(1, 0, 0), (2, 0, 0), \dots, (m, 0, 0)\}$ where $m = \psi^*(\text{Root}(T))$. Given a triple $x = (i, j, k)$, we call i , j , and k the first, the second, and the third coordinates of x , respectively.

Definition 2. *Given a signature T , $\Lambda : V_T \mapsto 2^O$ is a proof labeling for T if it has the following properties: First, $\Lambda(\text{Root}(T)) = O_T$. Second, for every vertex $v \in V_T$, $|\Lambda(v)| = \psi^*(v)$. Third, if $v \in V_T - \text{leaves}(T)$ and u_1, \dots, u_k are children of v , $\cup_{i=1}^k \Lambda(u_i) = \Lambda(v)$ if v is a union node; otherwise, $\Lambda(u_i) = \Lambda(v)$, for every i , $1 \leq i \leq k$.*

\mathcal{B} chooses a proof labeling Λ arbitrarily from all possible labellings. Then, \mathcal{B} divides the sequence of members of every leaf v of T into $\psi^*(v)$ regions of sizes $\left\lfloor \frac{\text{size}(v)}{\psi^*(v)} \right\rfloor$ or $\left\lceil \frac{\text{size}(v)}{\psi^*(v)} \right\rceil$. For a leaf v and integers i and a , if the i th biggest member of $\Lambda(v)$ is $(a, 0, 0)$, then the i th region of v is called an a -region. For any a and any a -region \mathcal{R} , \mathcal{B} sets the first coordinates of all members of \mathcal{R} to a at the beginning. Thus, given a member x of an a -region and a member y of a b -region such that $a \neq b$, whenever a query (x, y) is submitted, \mathcal{B} can answer the query without knowledge on the second and the third coordinates.

For any region \mathcal{R} , the second coordinate of exactly one element of \mathcal{R} , which is called the *key member of \mathcal{R}* , will be zero. The strategy is to determine the second coordinates of triples of a region \mathcal{R} in such a way that \mathcal{A} does not touch the key member of \mathcal{R} before touching $\log |\mathcal{R}|$ members of \mathcal{R} where $|\mathcal{R}|$ denotes the length of \mathcal{R} . The second coordinates of members of a region are all distinct and the third coordinates of non-key members are zero. Moreover, the third coordinates of the key members are determined in such a way that \mathcal{A} needs to touch all key members (actually we will prove a stronger fact).

Next, we explain the strategy of determining second coordinates of the triples. For every region \mathcal{R} we consider a variable \mathcal{S} storing a subsequence in \mathcal{R} , initially \mathcal{R} . At any point, the following condition will hold: The second coordinate of every member in $\mathcal{R} \setminus \mathcal{S}$ is already fixed, the second coordinate of every member of \mathcal{R} placed before members of \mathcal{S} is at most $-|\mathcal{S}|$, and the second coordinate of every member of \mathcal{R} placed after members of \mathcal{S} is at least $|\mathcal{S}|$. Now whenever a member s of \mathcal{S} is touched, if s is the only member of \mathcal{S} , \mathcal{B} sets its second coordinate to zero. Otherwise, depending on whether s is in the first half or in the second half of \mathcal{S} , \mathcal{B} considers members of \mathcal{S} placed after or before \mathcal{S} , fixes second coordinates of these members as explained in Figure 1, and deletes them from \mathcal{S} . Then, by touching each member of \mathcal{R} the length of \mathcal{S} is divided by at

most two. Since the value of 0 is not assigned to the second coordinate of any member unless $|\mathcal{S}| = 1$, $\log |\mathcal{R}|$ members of \mathcal{R} have already been touched at the time the key member of \mathcal{R} is being touched. Whenever a member is touched in which the second coordinate is not determined before, before attempting to answer the query \mathcal{B} , determines the second coordinate according to the method we described here. Therefore, we have the following theorem.

Theorem 1. *If all key members of $L \subseteq \text{leaves}(T)$ are touched by \mathcal{A} in $\langle \mathcal{A}, \mathcal{B} \rangle(T)$, \mathcal{A} has submitted at least $\sum_{v \in L} \psi^*(v) \cdot \lg \lceil \frac{\text{size}(v)}{\psi^*(v)} + 1 \rceil$ queries.*

From now on, when we talk about the strategy of \mathcal{B} for responding a given query (x, y) , we assume second coordinates of x and y are determined.

```

if  $|\mathcal{S}| = 1$  then
    - set the second coordinate of  $s$  equal to zero;
    - set  $\mathcal{S}$  equal to the empty sequence;
else
    suppose  $s$  is the  $i$ th member of  $\mathcal{R}$ ;
    if  $i < |\mathcal{S}| - i + 1$  then
        - assign values  $-(|\mathcal{S}| - 1), -(|\mathcal{S}| - 2), \dots, -(|\mathcal{S}| - i)$  to the second
          coordinates of the first  $i$  members of  $\mathcal{S}$ ;
        - Remove the first  $i$  members of  $\mathcal{S}$  from it;
    else
        - assign values  $i - 1, i, \dots, |\mathcal{S}| - 1$  to the second coordinates of the last
           $|\mathcal{S}| - i + 1$  members of  $\mathcal{S}$ ;
        - Remove the last  $|\mathcal{S}| - i + 1$  members of  $\mathcal{S}$  from it;
    
```

Fig. 1. How to determine the second coordinates of members

Given a query (x, y) if x and y are from two a -regions, for some a , and the second coordinate of one of x or y is non-zero (that is at most one of x and y is a key member), \mathcal{B} has enough information to answer the query. We define two members x and y to be *similar* if x and y are key members of two a -regions, for some a . As noted before, \mathcal{A} will be informed if x and y are similar. In Subsection 3.1 we show that \mathcal{B} can respond to queries on similar members in such a way that at the end for each member x , \mathcal{A} knows which members are similar to x .

Theorem 2. *For any signature T , and any deterministic comparison-based algorithm \mathcal{A} , if after an interaction $\langle \mathcal{A}, \mathcal{B} \rangle(T) = (q_1, r_1, \dots, q_k, r_k, R)$, \mathcal{A} knows all sets of similar members, then $k \geq \frac{1}{2}(l_1 + \log_6 l_2)$ where l_1 and l_2 are defined below, L is the set of non-shallow leaves of T , and u_1, \dots, u_k are children of v in the expressions.*

$$l_1 = \sum_{v \in L} \psi^*(v) \cdot \lg \left(\frac{\text{size}(v)}{\psi^*(v)} + 1 \right)$$

$$l_2 = \prod_{v: \pi(v) = \cup} \left(\psi^*(u_1), \dots, \psi^*(u_k) \right)$$

Proof. For any proof labeling Λ that \mathcal{B} chooses, any key member of a non-shallow leaf is similar to at least another member. Therefore, \mathcal{A} has touched all key members of non-shallow leaves of T in $\langle \mathcal{A}, \mathcal{B} \rangle(T)$. Thus, by Theorem 1, we have $k \geq l_1$.

Also, for any member of the result R , \mathcal{A} is aware of all similar members to that member to that member. This means that \mathcal{A} has enough information to figure out what proof labeling \mathcal{B} has chosen and thus Λ can be expressed as a function of the sequence of responses of \mathcal{B} , (r_1, \dots, r_k) . Hence, (r_1, \dots, r_k) is different for different Λ 's. So, since r_i can have only six different values and the number of possible proof labellings is l_2 , we have $k \geq \log_6 l_2$. Putting this upper bound for k together with the previous upper bound we conclude that $k \geq \frac{1}{2}(l_1 + \log_6 l_2)$. \square

3.1 The Game

In this part we fix an a and focus on answering queries on key members of a -regions (which are similar). Let's focus on the subtree of T consisting of leaves of T that contain a -regions and their ancestors, and ignore the rest of T . We have a two player game here between \mathcal{A} and \mathcal{B} , in which \mathcal{A} submits queries between key members of a -regions until it knows weather a key member of an a -region appears in the result; \mathcal{B} aims to prevent the game from finishing before \mathcal{A} has enough information for calculating the set of members similar to a key member of an a -regions. The configuration of the game at some specific point is a tuple $(\mathcal{T}, \mathcal{G})$ where \mathcal{T} is a union-intersection tree in which the root is not a union node or has only one child and \mathcal{G} is a graph defined on leaves of \mathcal{T} storing the history of queries submitted. Each leaf is representing only one member (the key member of its a -region, in our application) and thus we can view a query as a pair of leaves of \mathcal{T} . Moreover, each edge of \mathcal{G} is labeled with one of $<$, $=$, or $>$, demonstrating the respond to that query. \mathcal{A} is supposed to not submit a query twice during the game. $v \in \text{leaves}(\mathcal{T})$ is \mathcal{G} -identical to $u \in \text{leaves}(\mathcal{T})$ if there is a path from v to u in \mathcal{G} such that labels of all edges in the path are $=$.

The game finishes when the root in $(\mathcal{T}, \mathcal{G})$ has a *witness* where a witness of a node v is a subset of nodes recursively defined as follows. The only witness of a leaf v is $\{v\}$. A set S is a witness of a union node v if $v \in S$ and $S \setminus \{v\}$ is a witness of a child of v . For an intersection node v , S is a witness of v if $v \in S$ and every child u of v has a witness W_u such that $S = \{v\} \cup \bigcup_u W_u$ and every two leaves in S are \mathcal{G} -identical. When a game finishes, \mathcal{B} wins if G is connected and the root has a witness; otherwise \mathcal{A} is the winner. We prove that \mathcal{B} has a winning strategy.

Moreover, let $\text{component}(u)$ be the set of all leaves of \mathcal{T} that are connected to u including u itself. By " $(\mathcal{T}, \mathcal{G})$ can be reduced to $(\mathcal{T}', \mathcal{G}')$ " we mean that if \mathcal{B} has a wining strategy in $(\mathcal{T}', \mathcal{G}')$, then \mathcal{B} has a winning strategy in $(\mathcal{T}, \mathcal{G})$. In addition, we say that a vertex of T is *unfinished* if either it is an internal node or if it is the only version of its connected component in G . We define four operations which can be used to reduce a game instance to a smaller one.

Throwing away: A leaf $u \in \text{leaves}(T)$ can be thrown away if u is a child of a union node and is unfinished. By this action, we remove u from T and G . The resulted game is denoted by $\text{throw}_u(T, G)$.

Joining: A leaf $u \in \text{leaves}(T)$ can be joined to its sibling $v \in \text{leaves}(T)$ if u is a child of an intersection node and v is \mathcal{G} -identical to u . By this action, we remove u from T and G , and we denote the resulted game by $\text{join}_{u \rightarrow v}(T, G)$.

Contracting: An internal node $x \in V_T - (\text{leaves}(T) \cup \{\text{Root}(T)\})$ that is a child of $p \in V_T$ can be contracted if it has only one child, say $q \in V_T$. By this action, we remove x from T and make q a child of p . Otherwise, we remove both x and q from T and make the children of q children of p . We denote the resulted game by $\text{contract}_x(T, G)$.

Dispersing: An internal node $x \in V_T - (\text{leaves}(T) \cup \{\text{Root}(T)\})$ can be dispersed if all its children u_1, \dots, u_k are leaves, $|\text{component}(u_i)| > 1$ for $1 \leq i \leq k$, and there is at least one child u_j of x that is not \mathcal{G} -identical to any other leaf. Moreover, no vertex can be contracted or joined to another vertex. By this action we remove u_1, \dots, u_k from T and G , and also, we remove x from T . The resulted game is denoted by $\text{disperse}_x(T, G)$.

The proof of the next lemma is omitted due to the lack of space.

Lemma 1. *Consider a game $(\mathcal{T}, \mathcal{G})$ in which \mathcal{G} has an edge between every two leaves that are \mathcal{G} -identical to each other. Then, if one of the above four operations can be applied on $(\mathcal{T}, \mathcal{G})$ to obtain $(\mathcal{T}', \mathcal{G}')$, $(\mathcal{T}, \mathcal{G})$ can be reduced to $(\mathcal{T}', \mathcal{G}')$.*

Theorem 3. *Suppose that (T, G) is a game. Then, if the following three conditions hold \mathcal{B} has a winning strategy.*

1. Labels of all edges of G are $=$.
2. If x is an internal node of T with label \cup , then all its children are unfinished.
3. If x is an internal node of T with label \cap , then at least one of its children is unfinished.

Proof. Suppose we have a game $(\mathcal{T}, \mathcal{G})$ such that the number of vertices of \mathcal{T} plus the number of connected components of \mathcal{G} is n . We can assume that \mathcal{T} does not have any internal node that can be contracted and also no leaf can be joined to another leaf in \mathcal{T} . Otherwise, we can reduce $(\mathcal{T}, \mathcal{G})$ to a smaller game by either contraction or joining and because the smaller game will satisfy all three properties, \mathcal{B} has a winning strategy. In other words, \mathcal{T} does not have any internal node that has only one child. Also, no two children of an internal node can be in the same connected component of \mathcal{G} . Furthermore, without loss of generality we can assume that \mathcal{G} has an edge between every two leaves that are \mathcal{G} -identical to each other; otherwise, $(\mathcal{T}, \mathcal{G})$ can be reduced to a game that has this property by adding more edges. Because of properties 2 and 3, $(\mathcal{T}, \mathcal{G})$ has no witness, and thus, \mathcal{A} has not won yet. Therefore, \mathcal{A} must submit a query (u, v) where $u, v \in \text{leaves}(\mathcal{T})$.

The strategy that \mathcal{B} should follow to answer \mathcal{A} is summarized in Table 1. In the table, if a leaf u is labeled with “F”, “N”, or “L” it means that u is a finished

Table 1. The strategy of \mathcal{B} for answering

$F(u)$	$F(v)$	u	v	Response	Justification
\cup	\times	\mathbb{N}	\times	$\langle \rangle$	$(\mathcal{T}, \mathcal{G})$ is reduced to the smaller game $\text{throw}_u(\mathcal{T}, \mathcal{G})$.
\cap	\cap	\mathbb{F}	\mathbb{F}	$=$	The number of components of \mathcal{G} is reduced.
\cap	\cap	\mathbb{N}	\mathbb{F}	$=$	The number of components of \mathcal{G} is reduced.
\cap	\cap	\mathbb{N}	\mathbb{N}	$=$	The number of components of \mathcal{G} is reduced.
\cap	\cap	\mathbb{L}	\times	$\langle \rangle$	$(\mathcal{T}, \mathcal{G})$ is reduced to the smaller game $\text{disperse}_{F(u)}(\mathcal{T}, \mathcal{G})$.

leaf, an unfinished leaf that has another unfinished sibling, or an unfinished leaf that does not have any other unfinished sibling, respectively. Note that those cases which can be obtained from one of the cases in Table 3.1 by switching u and v are omitted due to the symmetry. \square

Having proved Theorem 3, we know the adversary can respond to queries on key members of a -regions such that the algorithm knows all members similar to the key member of each a -region, for every $1 \leq a \leq m$, and also that $(a, 0, 0)$ is in the result of the root. Thus, Theorem 2 yields the next theorem.

Theorem 4. *For any signature T and any deterministic comparison-based algorithm \mathcal{A} , there is an input with the signature G such that \mathcal{A} submits $\Omega(l_1 + \lg l_2)$ queries where l_1 and l_2 are defined as in Theorem 2.*

4 The Worst-Case Optimal Algorithm

In this section, we present our algorithm that matches the lower bound in Section 3. First we study two special cases separately; these special problems come in handy in solving the general problem.

The first special case has the form $X_1 \cup X_2 \cup \dots \cup X_k$. This problem in case when $k = 2$ has been studied before [5]; to compute $A \cup B$, tight lower and upper bounds of $\Theta\left(\lg\left(\frac{|A|+|B|}{|A|}\right)\right)$ exist. So suppose $k > 2$. Defining $s_i = |X_i|$, for $1 \leq i \leq k$ and $s = \sum_{i=1}^k s_i$, w. l. o. g., we suppose $s_1 = \max\{s_1, s_2, \dots, s_k\}$. The way we compute this union of k sets is as follows: we temporarily ignore the first set (i.e. X_1) and compute the union of $\bigcup_{i=2}^k X_i$ in time $O((s - s_1) \lg(k - 1))$ by using the well-known k -way merging algorithm [10]. Then, we take the union of X_1 with the result of the merge. The union can be found in time $O\left(\lg\binom{s}{s_1}\right)$, as described by Hwang and Lin [5], but the result is in the cross reference format. It can be proved that $(s - s_1) \lg(k - 1) \in O\left(\sum_{i=2}^k \lg\binom{s}{s_i}\right)$ which is in $O\left(\lg\binom{s}{s_1, \dots, s}\right)$ according to the following lemma (the proof is omitted).

Lemma 2. *If $s \leq \sum_{i=1}^n s_i$, then $\lg\binom{s}{s_1, \dots, s} \geq \frac{1}{2} \sum_{i=1}^n \lg\binom{s}{s_i}$.* \square

Lemma 3. *A cross reference representation of the union of sets X_1, X_2, \dots, X_k can be computed in time $O\left(\lg\binom{s}{s_1, \dots, s}\right)$ where $s_i = |X_i|$ and $s = \sum_{i=1}^k s_i$.* \square

The complete proof of Lemma 3 is omitted. In the end, we expand the ranges of the output to have the union in the sorted list format again. The time this takes is proportional to the size of the output, which is at most $O(\sum_{i=1}^k |X_k|)$. This yields the following theorem:

Theorem 5. *A sorted array representation of the union of sets X_1, X_2, \dots, X_n can be computed in time $O\left(s + \lg\binom{s}{s_1, \dots, s}\right)$ where $s_i = |X_i|$ and $s = \sum_{i=1}^k |X_i|$.* \square

The second special case has the form $Y \cap (X_1 \cup X_2 \cup \dots \cup X_k)$, given that $|Y| \geq |X_i|$ for each i . This problem for the case when $k = 1$ (i.e. computing $Y \cap X$) has been studied before [5] and tight lower and upper bounds of $\Theta\left(|X| \lg \frac{|X| + |Y|}{|X|}\right)$ already exist. To solve the problem for $k > 1$, we first create a boolean array \mathcal{B} of size $|Y|$, so that each element y in Y has an associated element in the array ($\mathcal{B}[y]$). We initialize all the elements in it to false; we, then, compute the intersection of each X_i with Y separately: $Y_i = Y \cap X_i$. According to the result just mentioned, this takes $O\left(\sum_{i=1}^k |X_i| \lg \frac{|X_i| + |Y|}{|X_i|}\right)$ time. When Y_i 's are all computed, we consider them one by one and for each Y_i , for all $y \in Y_i$, we set $\mathcal{B}[y] = \text{true}$. Then we scan array \mathcal{B} and return, as output, each element b iff $\mathcal{B}[b]$ is true. It is clear that scanning through all Y_i 's will take $\sum_{i=1}^k |Y \cap X_i|$ which is less than the time consumed for all Y_i 's. Also creating \mathcal{B} in the beginning and scanning it in the end takes time $O(|Y|)$. Therefore:

Theorem 6. *The result set of $Y \cap (X_1 \cup X_2 \cup \dots \cup X_k)$, given that $|Y| \geq |X_i|$, for every $1 \leq i \leq k$, can be computed in $O\left(|Y| + \sum_{i=1}^k |X_i| \lg \frac{|X_i| + |Y|}{|X_i|}\right)$ time.* \square

We now turn to the general case and describe the algorithm. We generalize the problem a little and define two types of problems: in the first type, we are interested in computing $\Gamma(v) \cap U$, for a given “universal set” U . In the second type, we are solely asked to compute $\Gamma(v)$. The procedures COMPUTE(v, U) and COMPUTE(v) (Figure 2) are designed to solve these two types of problems. The intuition behind the universal set U in COMPUTE(v, U) is the following: consider an intersection node v with its children u_1, \dots, u_k . Suppose we somehow have processed the subtree rooted at u_i for some i , and have obtained $\Gamma(u_i)$. It makes perfect sense to pass $\Gamma(u_i)$ as a universal set to subtrees rooted at children of v other than u_i so that in reporting back elements, they confine themselves to the universal set and ignore those that do not appear in the universal set. As for COMPUTE(v) it turns out that, for some nodes v , the size of the possible result of a node is less than any universal set we can possibly provide with in advance. In these cases we do not pass any universal set as it will not save any computation time.

Next, we investigate the correctness and the running time of the algorithm. The following theorem can be proved easily by considering different calls to procedures COMPUTE(v, U) and COMPUTE(v) in Algorithms 1 and 2.

Theorem 7. *At each invocation of the procedure COMPUTE(v, U) in Algorithm 1, the precondition $|U| \leq \psi^*(v)$ holds and the procedure computes $\Gamma(v) \cap U$.*

```

Procedure COMPUTE( $v, U$ );
1 // precondition:  $|U| \leq \psi^*(v)$ .
  begin
    switch type of node  $v$  do
2      case Leaf: return  $\Gamma(v) \cap U$  ;
      case Union:
          foreach  $u_i$  child of  $v$  do
3             if  $\psi(u_i) < |U|$  then
                 $X_i \leftarrow \text{Compute}(u_i)$ 
4             else
                 $X_i \leftarrow \text{Compute}(u_i, U)$ 
5             return  $U \cap (X_1 \cup X_2 \cup \dots \cup X_k)$ 
      case Intersection:
           $X \leftarrow U$  ;
6          foreach  $u_i$  child of  $v$  do
               $X \leftarrow \text{Compute}(U_i, X)$ 
          return  $X$ 
    end

```

Algorithm 1 Computing the intersection of U with the result set of the subtree rooted at v (i.e. $\Gamma(v) \cap U$).

```

Procedure COMPUTE( $v$ );
1 // precondition:  $\psi(v) = \psi^*(v)$ .
  begin
    switch type of node  $v$  do
2      case Leaf: return  $\Gamma(v)$  ;
      case Union:
          foreach  $u_i$  child of  $v$  do
3              $X_i \leftarrow \text{Compute}(u_i)$ 
4             return  $X_1 \cup X_2 \cup \dots \cup X_k$  ;
      case Intersection:
           $j \leftarrow \text{minindex}(\psi(u_i))$  ;
5           $X \leftarrow \text{Compute}(u_j)$  ;
          foreach  $u_i$  child of  $v$  do
              if  $i \neq j$  then
6                  $X \leftarrow \text{Compute}(U_i, X)$ 
          return  $X$ 
    end

```

Algorithm 2 Computing the result set of the subtree rooted at v (i.e. $\Gamma(v)$).

Fig. 2. The general algorithm

Also, at each invocation of that procedure $\text{COMPUTE}(v)$ in Algorithm 2, the precondition $\psi(v) = \psi^*(v)$ holds and the procedure computes $\Gamma(v)$. \square

Next, we analyze the running times of the procedures by measuring the time we spend at each node v of the tree, not taking into account the time we spend in recursive calls. The total running time of the algorithm will be, of course, the sum of such processing times in nodes of the tree. It is easy to see that no computation is involved in intersection nodes. Here, we analyze two other types of nodes (i.e. leaf and union) separately:

Processing Time in Union Nodes: Line 5 is the only one in Algorithm 1 on which we spend some computing time. Also, in Algorithm 2, only line 4 involved computation. These two are exactly the special cases we studied in the beginning of this section. We can prove the following lemma.

Lemma 4. *Processing time in a union node v takes time of $O\left(\sum_{i=1}^k \psi^*(u_i) + \lg\left(\psi^*(u_1), \dots, \psi^*(u_k)\right)\right)$ where u_1, \dots, u_k are children of v . \square*

We make a slight change in the algorithm to save time: in the case when the root of the whole tree is of type union, we use the algorithm in Lemma 3 to compute the union in the root node as opposed to the algorithm in Theorem 5. That is, we do not expand the ranges in the result and we keep it in the cross reference format. Then, in the case when v is the root and is a union node, we can get a better result than Lemma 4.

Lemma 5. *If the root is a union node, processing time in the root takes time of $O\left(\lg\left(\psi^*(\text{root})\right)\right)$ where u_1, \dots, u_k are children of the root.* \square

Here we claim that the term $\sum_{i=1}^k \psi^*(u_i)$ in Lemma 4 is negligible when it is summed over all union nodes. In the sum, ψ^* of all the children of union nodes are added together, which means the sum is over all the intersection nodes and leaves. Now we argue that if S is the set of all intersection nodes of T , we have $\sum_{v \in S} \psi^*(v) \leq \sum_{v \in L} \psi^*(v)$ where L is the set of non-shallow leaves. This can be proved by summing up together the inequalities of Observation 1 for all nodes of the tree.

Theorem 8. *Processing in union nodes and leaves takes time of $O\left(t + \sum_{v \in L} \psi^*(v) + \sum_{\substack{\text{union} \\ \text{nodes } v}} \lg\left(\psi^*(u_1), \psi^*(u_2), \dots, \psi^*(u_k)\right)\right)$ where L is the set of non-shallow leaves and t is the time we spend in non-shallow leaves.* \square

Processing Time in Leaf Nodes: If v is a leaf, in line 2 in Algorithm 1, we compute the intersection of $\Gamma(v)$ and U . As a precondition, we know that $|U| < \psi^*(v)$ and also by definition that $\psi^*(v) \leq \psi(v) = \text{size}(v)$, so $|U| < \text{size}(v)$. In the first special case, we showed how to compute the intersection in time $O(|U| \lg \frac{|U| + \text{size}(v)}{|U|})$. Since $|U| < \psi^*(v) \leq \text{size}(v)$, the processing time is in $O\left(\psi^*(v) \lg \frac{\psi^*(v) + \text{size}(v)}{\psi^*(v)}\right)$.

In line 2 of Algorithm 2, we simply return $\Gamma(v)$ which, by precondition, has size $\psi^*(v)$. In case v is a shallow leaf by the argument mentioned in Theorem 8, we use a slightly different method to take the union at the root, and therefore we do not spend any time in the shallow leaves (we do spend, however, some time in the root for computing the union, which has been accounted for in Theorem 8.) Thus the following theorem holds:

Theorem 9. *In Algorithms 1 and 2, the time spent in each non-shallow leaf is $O\left(\psi^*(v) \lg\left(\frac{\text{size}(v)}{\psi^*(v)} + 1\right)\right)$ and we spend no time in shallow leaves.* \square

We conclude from Theorems 4, 9, and 8 that our algorithm is optimum.

5 Conclusion and Extensions

We studied the problem of evaluating an expression of sorted sets with union and intersection operands. Complexity of algorithms were measured in terms of the sizes of the input sets. We proved lower bounds on the worst case complexity of algorithms that can solve this problem, and later presented an algorithm that asymptotically matches the lower bound.

An immediate extension to this work is changing its format of input/output to a more appropriate format. Our assumption for the format of the input is lists of elements of sets, and the format of the output is a list of cross-references

which specify the ranges of the elements. However, with a little effort, the format of both the input and the output can be changed to *balanced search trees*. More specifically, we choose B-trees. Adapting the lower bounds is straightforward; Theorem 4 will still hold without any modification. As for the upper bound, it is sufficient to show that we can handle the two special cases in the beginning of Section 4 with the same time complexity, since the general algorithm only uses these two for computation. These two special cases can be dealt with in the same way Demaine et al. [4] handled B-tree representations of their input sets. It is easy to see that the extra work for assembling and disassembling the B-trees in their scheme does not affect our bounds in Theorems 5 and 6.

As a future work, one can consider expressions that can have operands of type complement besides those of type union and intersection.

Abstract. Davis-Putnam-style exponential-time backtracking algorithms are the most common algorithms used for finding exact solutions of NP-hard problems. The analysis of such recursive algorithms is based on the bounded search tree technique: a measure of the size of the subproblems is defined; this measure is used to lower bound the progress made by the algorithm at each branching step.

For the last 30 years the research on exact algorithms has been mainly focused on the design of more and more sophisticated algorithms. However, measures used in the analysis of backtracking algorithms are usually very simple. In this paper we stress that a more careful choice of the measure can lead to significantly better worst case time analysis.

As an example, we consider the minimum dominating set problem. The currently fastest algorithm for this problem has running time $O(2^{0.850n})$ on n -nodes graphs. By measuring the progress of the (same) algorithm in a different way, we refine the time bound to $O(2^{0.598n})$. A good choice of the measure can provide such a (surprisingly big) improvement; this suggests that the running time of many other exponential-time recursive algorithms is largely overestimated because of a “bad” choice of the measure.

Keywords: Algorithms and data structures, exponential-time exact algorithm, NP-hard problem, dominating set.

1 Introduction

The interest in exact and fast exponential-time algorithms solving hard problems dates back to the sixties and seventies [13, 25]. The last decade has led to much re-

search in fast exponential-time algorithms. Examples of recently developed exponential algorithms are algorithms for Maximum Independent Set [15, 23], (Maximum) Satisfiability [4, 14, 17, 19, 24, 26], Coloring [2, 3, 6], Treewidth [8], and many others (see the recent survey written by Woeginger [27] for an overview).

Most of the currently fastest exact algorithms for NP-hard problems are recursive algorithms. In order to bound the total number of subproblems generated by such algorithms, the *bounded search tree* technique is often used: one defines a suitable *measure* of the size of the subproblems. This measure is used to lower bound the “progress” made by the algorithm at each branching step.

Though the algorithms considered may be rather complicated, the measures used in their analysis are usually very simple. In this paper we remark that a more careful choice of the measure can lead to much tighter time bounds.

In order to show that, we consider one of the best known NP-hard problems: the *minimum dominating set* problem. The currently fastest exact algorithm for this problem is a recursive algorithm of running time $\mathcal{O}^*(2^{0.850n})$ on n -nodes graphs [10, 11]¹. Here we present a refined analysis, based on a different measure of the size of the subproblems generated and show that the same algorithm has indeed running time $\mathcal{O}^*(2^{0.598n})$. This surprisingly big improvement suggests the possibility that the running times of many other exponential-time recursive algorithms (including possibly the one presented here) are largely overestimated because of a “bad” choice of the measure in their analysis. Despite the importance of the problem, only few works address this issue [2, 7].

Since the current tools do not seem to be strong enough to support an analysis of exponential-time recursive algorithms providing tight running time upper bounds, it is natural to ask for lower bounds (notice that we are concerned with lower bounds on the complexity of a particular algorithm and not with lower bounds on the complexity of an algorithmic problem). A lower bound may give an idea of how far the analysis is from being tight. There are several results known on lower exponential bounds for different branching algorithms for SAT (see e.g. [1, 18]) but we are not aware of lower bounds for existing exponential-time recursive graph algorithms. One of the reasons to this could be that for most of the graph problems the construction of good lower bounds is often difficult even for very simple algorithms. In this paper we prove a $\Omega(2^{0.333n})$ lower bound on the time complexity of our minimum dominating set algorithm. The large gap between the upper bound and the lower bound suggests the possibility that the analysis of the algorithm can be further refined (possibly by measuring the size of the subproblems in a smarter way).

Previous results on dominating set. The *minimum dominating set* problem (MDS) is a classic NP-hard graph optimization problem which fits into the broader class of *domination* and *covering* problems on which hundreds of papers have been written; see e.g. the survey [12] by Haynes et al. The dominating set problem

¹ Throughout this paper we use a modified big-Oh notation that suppresses all polynomially bounded factors. For functions f and g we write $f(n) = \mathcal{O}^*(g(n))$ if $f(n) = \mathcal{O}(g(n)poly(n))$, where $poly(n)$ is a polynomial.

is also one of the basic problems in parameterized complexity [5]; it is W[2]-complete and thus it is unlikely that the problem is fixed parameter tractable. What are the best time complexities for the dominating set problem in n -node graphs $G = (V, E)$ that we can possibly hope for? It has been observed in [9] that (unless some very unexpected things happen in computational complexity theory) there is no sub-exponential time (i.e. of running time $c^{o(n)}$ for some constant c) algorithm solving dominating set problem. There is the trivial $O^*(2^n)$ algorithm that simply searches through all the 2^n subsets of V . Hence, we can only hope for time complexities of the form $O^*(2^{cn})$, with some small value $c < 1$. Although MDS is a natural and very interesting problem concerning the design and analysis of exponential-time algorithms, no exact algorithm for MDS faster than the trivial one had been known until very recently. In 2004 three different sets of authors seemingly independently published algorithms breaking the trivial “ 2^n -barrier”. The algorithm of Fomin et al. [9] uses a deep graph-theoretic result due to Reed [21], providing an upper bound on the domination number of graphs of minimum degree three. The most time consuming part of their algorithm is an enumeration of all subsets of nodes of cardinality at most $3n/8$, thus the overall running time is $\mathcal{O}^*(2^{0.955n})$. The algorithm of Randerath and Schiermeyer [20] uses a very nice and cute idea (including matching techniques) to restrict the search space. The most time consuming part of their algorithm enumerates all subsets of nodes of cardinality at most $n/3$, thus the overall running time is $\mathcal{O}^*(2^{0.919n})$. Finally, the fastest algorithm known prior to our work is due to Grandoni [10, 11], who described a $\mathcal{O}^*(2^{0.850n})$ algorithm for MDS.

Our Results. We show that MDS can be solved in $\mathcal{O}^*(2^{0.610n})$ time using polynomial space. The running time of our algorithm can be reduced at the cost of exponential space to $\mathcal{O}^*(2^{0.598n})$ which is a significant improvement of all known results on MDS. To solve the problem we represent MDS as a set cover problem which allows us to use a search tree based algorithm. This idea was first used in [10, 11]. To obtain running time $\mathcal{O}^*(2^{0.610n})$ we do not add more and more sophisticated rules to existing algorithms which is a usual practice to improve on the exponential base. Instead we give a simple and easy to implement algorithm and observe how the careful choice of the measure changes the algorithm analysis dramatically. Our refined analysis leads to a multivariate recurrence. For a general treatment of this type of recurrences we refer to Eppstein’s paper [7]. Since the analysis of our search tree based algorithms is so depended on the choice of the measure, it is natural to ask for (exponential) lower bounds on the running time of the algorithm. We prove that our algorithm requires $\Omega(2^{0.333n})$ steps.

2 Definitions and Basic Algorithm

Let $G = (V, E)$ be an n -node undirected, simple graph without loops. The open neighborhood of a node v is denoted by $N(v) = \{u \in V : uv \in E\}$, and the closed neighborhood of v is denoted by $N[v] = N(v) \cup \{v\}$. A set $A \subseteq E$ of edges of

$G = (V, E)$ is an *edge cover*, if every node of G is incident to an edge of A ; the edge set A is a *matching* if no node of G is incident to two edges of A .

The minimum dominating set problem. Let $G = (V, E)$ be a graph. A set $D \subseteq V$ is called a *dominating set* for G if every node of G is either in D , or adjacent to some node in D . The *domination number* $\gamma(G)$ of a graph G is the minimum cardinality of a dominating set of G . The *Minimum Dominating Set* problem (MDS) asks to determine $\gamma(G)$.

The minimum set cover problem. In the *Minimum Set Cover* problem (MSC) we are given a universe \mathcal{U} of elements and a collection \mathcal{S} of (non-empty) subsets of \mathcal{U} . The aim is to determine the minimum cardinality of a subset $\mathcal{S}' \subseteq \mathcal{S}$ which *covers* \mathcal{U} , that is such that

$$\cup_{S \in \mathcal{S}'} S = \mathcal{U}.$$

The *frequency* of $u \in \mathcal{U}$ is the number of subsets $S \in \mathcal{S}$ in which u is contained. For the sake of simplicity, we always assume in this paper that \mathcal{S} covers \mathcal{U} :

$$\mathcal{U} = \mathcal{U}(\mathcal{S}) \triangleq \cup_{S \in \mathcal{S}} S.$$

With this assumption, an instance of MSC is univocally specified by \mathcal{S} .

We recall that, if all the subsets of \mathcal{S} are of cardinality two, MSC can be solved in polynomial time via the following standard reduction to maximum matching. Consider the graph \tilde{G} which has a node u for each $u \in \mathcal{U}$, and an edge uv for each subset $S = \{u, v\}$ in \mathcal{S} . Thus we have to compute a minimum edge cover of \tilde{G} . To compute a minimum edge cover of \tilde{G} we compute a maximum matching M in \tilde{G} . Then, for each unmatched node u , we add to M an arbitrary edge incident to u (if no such edge exists, there is no set cover at all). The subsets corresponding to M form a minimum set cover.

MDS can be naturally reduced to MSC by imposing $\mathcal{U} = V$ and $\mathcal{S} = \{N[v] \mid v \in V\}$. Note that $N[v]$ is the set of nodes dominated by v , thus D is a dominating set of G if and only if $\{N[v] \mid v \in D\}$ is a set cover of $\{N[v] \mid v \in V\}$. Thus every minimum set cover of $\{N[v] \mid v \in V\}$ corresponds to a minimum dominating set of G .

At first view such a transformation from one NP-hard problem to another seems to be completely useless: The only known exact algorithms for MSC are brute force $\mathcal{O}^*(2^{|\mathcal{S}|})$ and $\mathcal{O}^*(2^{|\mathcal{U}|})$ [9] dynamic programming algorithms. Both algorithms result in an $\mathcal{O}^*(2^n)$ algorithm for MDS and it seems that such an approach is not interesting. Not at all! On second thought the transformation from MDS to MSC becomes very helpful. It enables the use of a search tree based algorithm to solve MSC, and thus also MDS.

Basic algorithm. We consider a simple recursive algorithm `msc` for solving MSC. The algorithm is a slight modification of the algorithm from [11] and it makes use of the following observation.

Lemma 1. *For a given MSC instance \mathcal{S} :*

1. *If there are two distinct sets S and R in \mathcal{S} , $S \subseteq R$, then there is a minimum set cover which does not contain S .*

```

1  int msc(S) {
2      if(|S| = 0) return 0;
3      if(∃S, R ∈ S : S ⊆ R) return msc(S \ {S});
4      if(∃u ∈ U(S) ∃ a unique S ∈ S : u ∈ S) return 1+msc(del(S, S));
5      take S ∈ S of maximum cardinality;
6      if(|S| = 2) return poly-msc(S)
7      return min{msc(S \ {S}), 1+msc(del(S, S))};
8  }

```

Fig. 1. A recursive algorithm for minimum set cover

2. If there is an element u of U which belongs to a unique $S \in \mathcal{S}$, then S belongs to every set cover.

Note that each subset of cardinality one satisfies exactly one of the properties in Lemma 1.

A basic version of `msc` is described in Figure 1. If $|S| = 0$ (line 2), $msc(S) = 0$. Otherwise (lines 3 and 4), the algorithm *tries* to reduce the size of the problem without branching, by applying one of the Properties 1 and 2 of Lemma 1. Specifically, if there are two sets S and R , $S \subseteq R$, we have $msc(S) = msc(S \setminus S)$. If there is an element u which is contained in a unique set S , we have $msc(S) = 1 + msc(del(S, S))$, where $del(S, S) = \{Z \mid Z = R \setminus S \neq \emptyset, R \in \mathcal{S}\}$ is the instance of MSC which is obtained from \mathcal{S} by removing the elements of S from the subsets in \mathcal{S} , and by eventually removing the empty sets obtained.

If none of the two properties above applies, the algorithm takes (line 5) a set $S \in \mathcal{S}$ of maximum cardinality. If $|S| = 2$ (line 6), the algorithm directly solves the problem with the polynomial time algorithm `poly-msc` based on the reduction to maximum matching. Otherwise (line 7), it branches on the two subproblems $S_{IN} = del(S, S)$ (the case where S belongs to the minimum set cover) and $S_{OUT} = \mathcal{S} \setminus S$ (corresponding to the case S is not in the minimum set cover). Thus

$$msc(S) = \min\{msc(\mathcal{S} \setminus \{S\}), 1 + msc(del(S, S))\}.$$

Notice that with simple modifications, the algorithm can also provide one minimum set cover (besides its cardinality).

To emphasize the importance of the measure we sketch the analysis of the algorithm with a simple measure (taken from [11]). Let us choose the following *measure* $k(\mathcal{S}')$ of the size of a MSC instance \mathcal{S}' ,

$$k(\mathcal{S}') = |\mathcal{S}'| + |U(\mathcal{S}')|.$$

Let $\ell(k)$ be the number of leaves in the search tree generated by the algorithm to solve a problem of size $k = k(\mathcal{S})$. If one of the conditions of lines 3 and 4 is satisfied, $\ell(k) \leq \ell(k - 1)$. Let S be the set selected in line 5. If $|S| = 2$, the algorithm directly solves the problem in polynomial time ($\ell(k) = 1$). Otherwise ($|S| \geq 3$), the algorithm branches on the two subproblems $\mathcal{S}_{OUT} = \mathcal{S} \setminus \{S\}$

and $\mathcal{S}_{IN} = del(\mathcal{S}, \mathcal{S})$. The size of \mathcal{S}_{OUT} is $k - 1$ (one set removed from \mathcal{S}). The size of \mathcal{S}_{IN} is at most $k - 4$ (one set removed from \mathcal{S} and at least three elements removed from \mathcal{U}). This brings us to $\ell(k) \leq \ell(k - 1) + \ell(k - 4)$. We conclude that $\ell(k) \leq \alpha^k$, where $\alpha = 1.3802\dots < 1.3803$ is the (unique) positive root of the polynomial $(x^4 - x^3 - 1)$. It turns out that the total number of subproblems solved is within a polynomial factor from $\ell(k)$. Moreover, solving each subproblem takes polynomial time. Thus the complexity of the algorithm is $\mathcal{O}^*(\ell(k)) = \mathcal{O}^*(\alpha^k) = \mathcal{O}^*(1.3803^{|\mathcal{S}|+|\mathcal{U}|}) = \mathcal{O}^*(2^{0.465(|\mathcal{S}|+|\mathcal{U}|)})$.

In next section we will show how to refine the running time analysis to $\mathcal{O}^*(2^{0.305(|\mathcal{S}|+|\mathcal{U}|)})$ via a more careful choice of the measure $k(\mathcal{S}')$ (without modifying the algorithm!).

3 Refined Analysis

In this section we show that algorithm `msc` has time complexity $\mathcal{O}^*(2^{0.305(|\mathcal{S}|+|\mathcal{U}|)})$.

Our result is based on the following observation. Removing a large set has a different impact on the “progress” of the algorithm than removing a small one. In fact, when we remove a large set, we decrease the frequency of many elements. Decreasing elements frequency pays off on long term, since the elements of frequency one can be filtered out (without branching). A dual argument holds for the elements. Removing an element of high frequency is somehow preferable to removing an element of small frequency. In fact, when we remove an element occurring in many sets, we decrease the cardinality of all such sets by one. This is good on long term, since sets of cardinality one can be filtered out. Both phenomena are not taken into account in the measure used in [10]. With that measure, by removing one set (element), we decrease the size of the problem by one, no matter which is the cardinality (frequency) of the set (element) considered.

This suggests the idea to give a different “weight” to sets of different cardinality and to elements of different frequency. In particular, let n_i denote the number of subsets $S \in \mathcal{S}$ of cardinality i . Let moreover m_j denote the number of elements $u \in \mathcal{U}$ of frequency j . We will use the following measure $k = k(\mathcal{S})$ of the size of \mathcal{S} :

$$k(\mathcal{S}) = \sum_{i \geq 1} w_i n_i + \sum_{j \geq 1} v_j m_j,$$

where the weights $w_i, v_j \in (0, 1]$ will be fixed in the following. Note that $k \leq |\mathcal{S}| + |\mathcal{U}|$. The quantities

$$\Delta w_i = \begin{cases} w_i - w_{i-1} & \text{if } i \geq 3, \\ w_2 & \text{if } i = 2, \end{cases} \quad \text{and} \quad \Delta v_i = \begin{cases} v_i - v_{i-1} & \text{if } i \geq 3, \\ v_2 & \text{if } i = 2, \end{cases}$$

turn out to be useful in the analysis. Intuitively, Δw_i (Δv_i) is the reduction of the size of the problem corresponding to the reduction of the cardinality of a set (of the frequency of an element) from i to $i - 1$. Note that this holds also in the

case $i = 2$. In fact, in that case the size of the problem first increases by $1 - w_2 (1 - v_2)$, but the new set of cardinality one (the new element of frequency one) introduced is removed before the next branching, with a reduction of the size by one. Thus one has an overall reduction by $1 - (1 - w_2) = w_2 (1 - (1 - v_2) = v_2)$.

Theorem 1. *Algorithm msc solves MSC in time $\mathcal{O}^*(2^{0.305(|\mathcal{U}|+|\mathcal{S}|)})$.*

Proof. The correctness of the algorithm is trivial. In order to simplify the running time analysis, we will make the following assumptions:

- $w_1 = v_1 = 1$ and $w_i = v_i = 1$ for $i \geq 6$;
- $0 \leq \Delta w_i \leq \Delta w_{i-1}$ for $i \geq 2$.

Note that this implies $w_i \geq w_{i-1}$ for every $i \geq 3$ (excluding sets of cardinality one, larger sets have larger weights). Moreover, $\Delta w_i = \Delta v_i = 0$ for $i \geq 7$.

Let $P_h(k)$ be the number of subproblems of size h , $0 \leq h \leq k$, solved by *msc* to solve a problem of size k . Clearly, $P_k(k) = 1$. Consider the case $h < k$ (which implies $|\mathcal{S}| \neq 0$). If one of the condition of lines 3 and 4 holds, one set S is removed from \mathcal{S} . Thus the reduction of the size of the problem is at least w_2 (corresponding to the case $|\mathcal{S}| = 2$) and $P_h(k) \leq P_h(k - w_2)$. Otherwise, let S be the subset selected in line 5. If $|\mathcal{S}| = 2$, no subproblem is generated ($P_h(k) = 0$). Otherwise ($|\mathcal{S}| \geq 3$), *msc* generates two subproblems $\mathcal{S}_{IN} = del(S, \mathcal{S})$ and $\mathcal{S}_{OUT} = \mathcal{S} \setminus S$.

Consider the subproblem \mathcal{S}_{OUT} . The size of \mathcal{S}_{OUT} decreases by $w_{|S|}$ because of the removal of S . Let r_i be the number of elements of S of frequency i . Note that there cannot be elements of frequency 1. Consider an element $u \in S$ of frequency $i \geq 2$. When we remove S , the frequency of u decreases by one. As a consequence, the size of the subproblem decreases by Δv_i . Thus the overall reduction of the size of \mathcal{S}_{OUT} due to the reduction of the frequencies is at least

$$\sum_{i \geq 2} r_i \Delta v_i = \sum_{i=2}^6 r_i \Delta v_i.$$

Suppose that there is an element $u \in S$ of frequency 2. Let $R \neq S$ be the other set containing u . When we remove S , we have to include R in the set cover. Thus we reduce the size of the problem by at least w_2 (corresponding to the case $|R| = 2$). Also $R \setminus S$ is not empty (otherwise condition of line 3 of the algorithm is met) and thus all elements of $R \setminus S$ are removed when we include R in the set cover. This reduces the size by at least v_2 (corresponding to the case that the frequency of z is 2). Therefore the overall reduction of the size of \mathcal{S}_{OUT} due to the removal of the sets R is at least $r_2 w_2 + \delta(r_2) v_2$, where $\delta(r_2) = 0$ for $r_2 = 0$, and $\delta(r_2) = 1$ otherwise.

Consider now the subproblem \mathcal{S}_{IN} . The size of \mathcal{S}_{IN} decreases by $w_{|S|}$ because of the removal of S . Consider an element $u \in S$ of frequency i ($i \geq 2$). The size of \mathcal{S}_{IN} further decreases by v_i because of the removal of u . Thus the overall reduction due to the removal of the elements u of S is

$$\sum_{i \geq 2} r_i v_i = \sum_{i=2}^6 r_i v_i + r_{\geq 7},$$

where $r_{\geq i}$ is the number of elements of S of frequency at least i . Let R be a set sharing an element u with S . Note that $|R| \leq |S|$. By removing u , the cardinality of R is reduced by one. This implies a reduction of the size of \mathcal{S}_{IN} by $\Delta w_{|R|} \geq \Delta w_{|S|}$. Thus the overall reduction of \mathcal{S}_{IN} due to the reduction of the cardinalities of the sets R is at least:

$$\Delta w_{|S|} \sum_{i \geq 2} (i - 1) r_i \geq \Delta w_{|S|} \left(\sum_{i=2}^6 (i - 1) r_i + 6 \cdot r_{\geq 7} \right).$$

Note that this quantity is 0 for $|S| \geq 7$. Putting all together, for all the possible values of $|S| \geq 3$ and of the r_i such that

$$\sum_{i=2}^6 r_i + r_{\geq 7} = |S|,$$

we have the following set of recursions

$$P_h(k) \leq P_h(k - \Delta k_{OUT}) + P_h(k - \Delta k_{IN}),$$

where

- $\Delta k_{OUT} \triangleq w_{|S|} + \sum_{i=2}^6 r_i \Delta v_i + r_2 w_2 + \delta(r_2) v_2,$
- $\Delta k_{IN} \triangleq w_{|S|} + \sum_{i=2}^6 r_i v_i + r_{\geq 7} + \Delta w_{|S|} \left(\sum_{i=2}^6 (i - 1) r_i + 6 \cdot r_{\geq 7} \right).$

Since $\Delta w_{|S|} = 0$ for $|S| \geq 7$, we have that each recurrence with $|S| \geq 8$ is “dominated” by some recurrence with $|S| = 7$. For this reason, we restrict our attention only to the cases $3 \leq |S| \leq 7$. Thus we consider a large but finite number of recursences. For every fixed 8-tuple $(w_2, w_3, w_4, w_5, v_2, v_3, v_4, v_5)$ the number $P_h(k)$ is upper bounded by α^{k-h} , where α is the largest number from the set of real roots of the set of equations

$$\alpha^k = \alpha^{k-\Delta k} + \alpha^{k-\Delta k}$$

corresponding to different combinations of values $|S|$ and r_i . Thus the estimation of $P_h(k)$ boils up to choosing the weights minimizing α . This optimization problem is interesting in its own and we refer to Eppstein’s work [7] on quasi-convex programming for general treatment of such problems.

We numerically obtained the following values of the weights:

$$w_i = \begin{cases} 0.3774 & \text{if } i = 2, \\ 0.7548 & \text{if } i = 3, \\ 0.9095 & \text{if } i = 4, \\ 0.9764 & \text{if } i = 5, \end{cases} \quad \text{and} \quad v_i = \begin{cases} 0.3996 & \text{if } i = 2, \\ 0.7677 & \text{if } i = 3, \\ 0.9300 & \text{if } i = 4, \\ 0.9856 & \text{if } i = 5, \end{cases}$$

which yields $\alpha \leq 1.2352 \dots < 1.2353$. In Table 1 the values of $|S|$ and r_i of the eight worst case recursences are listed.

Table 1. The eight worst case recurrences

$ S $	$(r_2, r_3, r_4, r_5, r_6, r_{\geq 7})$
6	(0, 0, 0, 0, 0, 6)
5	(0, 0, 0, 0, 4, 1)
5	(0, 0, 0, 0, 5, 0)
4	(0, 0, 0, 0, 4, 0)
4	(0, 0, 0, 4, 0, 0)
3	(0, 0, 3, 0, 0, 0)
3	(0, 3, 0, 0, 0, 0)
3	(3, 0, 0, 0, 0, 0)

Let K denote the set of the possible sizes of the subproblems solved. Note that $|K|$ is polynomially bounded. The total number $P(k)$ of subproblems solved satisfies:

$$P(k) \leq \sum_{h \in K} P_h(k) \leq \sum_{h \in K} \alpha^{k-h} \leq |K| \alpha^k.$$

The cost of solving a problem of size $h \leq k$, excluding the cost of solving the corresponding subproblems (if any), is a polynomial $poly(k)$ of k . Thus the time complexity of the algorithm is

$$\mathcal{O}^*(poly(k)|K|\alpha^k) = \mathcal{O}^*(1.2353^{|\mathcal{U}|+|\mathcal{S}|}) = \mathcal{O}^*(2^{0.305(|\mathcal{U}|+|\mathcal{S}|)}). \quad \square$$

As already observed, MDS can be reduced to MSC by imposing $\mathcal{U} = V$ and $\mathcal{S} = \{N[v] \mid v \in V\}$. The size of the MSC instance obtained is at most $2n$. By simply combining this reduction with algorithm `msc` one obtains:

Corollary 1. *There is a $\mathcal{O}^*(2^{0.305(2n)}) = \mathcal{O}^*(2^{0.610n})$ algorithm for MDS.*

3.1 An Exponential Space Algorithm

The time complexity of `msc` can be reduced at the cost of an exponential space complexity via the *memorization* technique by Robson [22]. The general idea is the following: The algorithm keeps the solutions of all the subproblems solved. If the same subproblem turns up more than once, the algorithm is not to run a second time, but the already computed result is looked up. Note that the corresponding data structure can be implemented in such a way that the *query time* is logarithmic in the number of solutions stored [22].

Theorem 2. *Algorithm `msc`, modified as above, solves MSC in $\mathcal{O}^*(2^{0.299(|\mathcal{S}|+|\mathcal{U}|)})$ time.*

Corollary 2. *There is an algorithm which solves MDS in time $\mathcal{O}^*(2^{0.299(2n)}) = \mathcal{O}^*(2^{0.598n})$.*

Due to space restrictions, the proof of Theorem 2 is omitted here.

4 An Exponential Lower Bound

By carefully measuring the size of the subproblems, we obtained a much tighter running time bound. However the bound achieved might still be only a pessimistic estimation of the worst case running time of the algorithm. Therefore it is natural to ask for lower bounds: A lower bound may give an idea of how far is the bound computed from the real worst case running time.

Let us consider the $\mathcal{O}^*(2^{0.610n})$ polynomial-space MDS algorithm `m``d``s` based on the reduction to `M``S``C` and (the polynomial-space version of) algorithm `m``s``c`.

Theorem 3. *The worst case running time of `m``d``s` is $\Omega(2^{n/3}) = \Omega(2^{0.333n})$.*

Proof. Consider the following input graph G_n ($n \geq 1$): the node set of G_n is $\{a_i, b_i, c_i : 1 \leq i \leq n\}$. The edge set of G_n consists of two types of edges: for each $i = 1, 2, \dots, n$, the vertices a_i, b_i and c_i induce a triangle T_i ; and for each $i = 1, 2, \dots, n - 1$: $\{a_i, a_{i+1}\}$, $\{b_i, b_{i+1}\}$ and $\{c_i, c_{i+1}\}$ are edges.

Each node of the search tree corresponds to a subproblem of the `M``S``C` problem with input $(\mathcal{U}; \mathcal{S} = \{S_v : v \in V\})$ where $S_v = N[v]$.

We give a selection rule for the choice of the vertices v (respectively sets S_v) to be chosen for the branching. Clearly the goal is to choose them such that the number of nodes in the search tree obtained by the execution of algorithm `m``s``c` on graph G_n is as large as possible.

In each round i , $i \in \{2, 3, \dots, n - 1\}$, we start with a pair $P = \{x_i, y_i\}$ of nodes (belonging to triangle T_i), where $\{x, y\} \subset \{a, b, c\}$. Initially $P = \{a_2, b_2\}$. Our choice makes sure that for each branching node x the cardinality of its set S_x is five in the current subproblem \mathcal{S} , and that no other rules of the algorithm will apply to a branching node than the one of line 5. Consequently, by line 7 of `m``s``c` either the set S_v is taken into the set cover ($\mathcal{S} := \text{del}(\mathcal{S}, S_v)$), or S_v is removed ($\mathcal{S} := \mathcal{S} \setminus S_v$).

For each pair $P = \{x_i, y_i\}$ of nodes we branch in the following 3 ways

- 1) take S_x
- 2) remove S_x , and then take S_y
- 3) remove S_x , and then remove S_y

The following new pairs of nodes correspond to each of the three branches:

- 1) $P_1 = \{a_{i+2}, b_{i+2}, c_{i+2}\} \setminus x_{i+2}$
- 2) $P_2 = \{a_{i+2}, b_{i+2}, c_{i+2}\} \setminus y_{i+2}$
- 3) $P_3 = \{x_{i+1}, y_{i+1}\}$

On each pair P_j we recursively repeat the process. Thus of the three branches of T_i two are proceeded on T_{i+2} and one is proceeded on T_{i+1} .

Let $T(k)$ be the number of leaves in the search tree when all triangles up to T_k have been used for branching. Thus $T(k) = 2 \cdot T(k - 2) + T(k - 1)$, and hence $T(k) \geq 2^{k-2}$. Consequently the worst case number of leaves in the search tree of `m``s``c` for a graph on n vertices is at least $2^{n/3-2}$. \square

The lower bound above can be easily improved by considering disconnected graphs formed by several (disconnected) copies of a carefully chosen small sub-

graph. We did not consider such lower bounds, since algorithm `mds` can be easily modified in order to invalidate them (it is sufficient to solve each disconnected subproblem separately, and then combine the partial solutions).

We may notice that there is a large gap between the $\mathcal{O}^*(2^{0.610n})$ upper bound and the $\Omega(2^{0.333n})$ lower bound. This could suggest the possibility that the analysis of algorithm `mds` can be further refined (possibly via a further refined measure of the size of the MSC instances).

5 Conclusions

We investigated the impact of different measures of the size of the problem in the analysis of exponential-time recursive algorithms. In particular, we considered the minimum dominating set problem. We showed how a more careful choice of the measure leads to a much tighter running time bound on the fastest known algorithm for the problem. Specifically, we reduced the time bound from $\mathcal{O}^*(2^{0.850n})$ to $\mathcal{O}^*(2^{0.598n})$ (without modifying the algorithm).

The impressive reduction of the running time achieved for minimum dominating set, suggests the possibility that the time complexity of many other exponential-time exact algorithms is largely overestimated because of a bad choice of the measure. Indeed, this could be the case also for our refined analysis of minimum dominating set. This possibility is somehow supported by the large gap between the $\mathcal{O}^*(2^{0.598n})$ upper bound and the $\Omega(2^{0.333n})$ lower bound we managed to prove.

Another natural problem to play with measure is Independent Set. The best running time $\mathcal{O}^*(2^{n/4})$ for this problem was claimed by Robson [23]. Though Robson's algorithm is extremely technical and complicated, the measure used in its analysis is very simple (the number of nodes in the graph). Can we refine the analysis of this algorithm via a different choice of the measure? Moreover, how fast really are simple algorithms for Independent Set?

Optimistic Asynchronous Atomic Broadcast

Klaus Kursawe¹ and Victor Shoup²

¹ KU Leuven

² New York University

Abstract. This paper presents a new protocol for atomic broadcast in an *asynchronous* network with a maximal number of *Byzantine* failures. It guarantees both *safety* and *liveness* without making any timing assumptions. Under normal circumstances, the protocol runs in an extremely efficient “optimistic mode,” while in rare circumstances the protocol may briefly switch to a less efficient “pessimistic mode.”

1 Introduction

Atomic broadcast is a fundamental building block in fault tolerant distributed computing. By ordering broadcast requests in such a way that they are delivered in the same order to all honest recipients, a synchronization mechanism is provided that deals with many of the most problematic aspects of asynchronous networks. We present a new protocol for atomic broadcast in an *asynchronous* network with a maximal number of *Byzantine* failures. It guarantees both *safety* and *liveness* without making any timing assumptions or using any type of “failure detector,” and under normal circumstances is just as efficient as a simple “Bracha broadcast.”

The FLP “impossibility” result [F+85] implies that there is no deterministic protocol for Byzantine agreement (and hence, for atomic broadcast) that guarantees both safety and liveness. However, there are *randomized* protocols that terminate quickly with very high probability.

A protocol for asynchronous Byzantine agreement may be used as a building block for atomic broadcast. Canetti and Rabin’s protocol [CR93] runs in polynomial time, but is in fact, highly impractical. The protocol of Cachin *et al.* [C+00] is a practical, polynomial-time protocol that makes use of public-key cryptographic primitives that can be proven correct in the “random oracle” model [BR93], assuming a computationally bounded adversary; this protocol relies on a trusted dealer during system set-up, but after this, an arbitrary number of instances of the protocol can be executed. Building on [C+00], the paper [C+01] presents a fairly practical protocol for atomic broadcast. However, this protocol still uses a lot of fairly expensive, public-key operations, and may not be fast enough for some applications.

Our protocol is inspired by the innovative work of Castro and Liskov [CL99b, CL99a, C00]. Like their protocol, our protocol works in two phases: an *optimistic phase* and a *pessimistic phase*. The optimistic phase is very “lightweight” —

each request is processed using nothing more than a “Bracha broadcast” [B84] — in particular, no public-key cryptography is used (only message authentication codes, which are very cheap, are used). As long as the network is reasonably behaved, the protocol remains in the optimistic phase — even if some number of parties, barring a designated leader, are corrupted. If there are unexpected network delays, or the leader is corrupted, several parties may “time out,” shifting the protocol into the pessimistic phase. The pessimistic phase is somewhat more expensive than the optimistic phase — both in terms of communication and computational complexity. Nevertheless, it is still reasonably practical, although certainly not as efficient as the optimistic phase. The pessimistic phase cleans up any potential “mess” left by the current leader, re-synchronizing the protocol, after which the optimistic phase starts again with a new leader.

The optimistic phase of our protocol is essentially the same as that of Castro and Liskov. While [CL99b] relies extensively on expensive public-key cryptographic operations, the optimized versions in [CL99a, C00] do not use on public-key cryptography in the optimistic phase. Therefore, we expect that in practice, our protocol is just as efficient as theirs. However, our pessimistic phase is quite different. In the Castro/Liskov protocol, the new leader is responsible for re-synchronizing the protocol; this re-synchronization may fail, either because the new leader is corrupt or because of unexpected network delays, in which case yet another leader must take on the task of re-synchronization. In contrast, in our protocol, this re-synchronization is done using a distributed computation, based on randomized Byzantine agreement, and is guaranteed to succeed, regardless of the behavior of the corrupted parties and regardless of any network delays.

Castro and Liskov’s protocol is completely deterministic, and hence is subject to the FLP impossibility result. Indeed, although their protocol guarantees safety, it does not guarantee liveness, unless one makes additional *timing assumptions*. Our protocol guarantees both safety and liveness without making any timing assumptions *at all*, while being just as efficient in practice as the Castro/Liskov protocol. The trade-off, of course, is that our protocol is randomized and relies on more cryptographic assumptions; however, there is no practical downside to this, in terms of either security or performance, and so it seems to be a trade-off worth making.

Our work builds on the work of [C+01] in two ways: we use the same definitional framework as [C+01], and we make novel use of a protocol in [C+01] for *multivalued Byzantine agreement*.

Other Related Work. There is a rich literature on ordering broadcast channels, including several implementations and a broad theoretical basis. However, most work in the literature is done in the crash-failure model; much less work has been done in the Byzantine failure model. Rampart [R94] and SecureRing [K+98] directly transfer crash-failure protocols into the Byzantine setting by using a modified failure detector along with digital signatures. The disadvantage of this approach is that it is relatively expensive, as a large number of public-key cryptographic operations need to be performed. Furthermore, there are attacks on the failure detector [A+95] that can violate the safety of these protocols. Doudou

et al. [D+00] take a similar approach to that of Castro and Liskov. However, their protocol is described in a more abstract and modular way, leading to a protocol that is somewhat less complex and easier to analyze.

2 System Model and Problem Statement

Our formal system model and definitions of security are the same as in [C+00, C+01], which models attacks by *computationally bounded* adversaries. We refer the reader to [C+01] for complete details. We give only a brief summary here. We assume a network of n parties P_1, \dots, P_n , t of which are corrupted and fully controlled by an adversary. We shall assume that $t < n/3$. We also assume a trusted dealer that is needed only at system set-up time. Informally, the adversary also has full control over the network; the adversary may insert, duplicate, and reorder messages at will.

More formally, at the beginning of the attack, the trusted dealer is run, initializing the internal state of the honest parties; the initial state information for the corrupted parties is given to the adversary. The attack then proceeds in steps. In each step of the attack, the adversary delivers a single message to an honest party, upon receipt of which the party updates its internal state and generates one or more response messages. These response messages indicate their origin and intended destination; however, the adversary is free to do with these messages what he wishes: to deliver them when he wishes, in any order that he wishes; he may also deliver them more than once, or not all. We do assume, however, that the adversary may not modify messages or “fake” their origin. This assumption is reasonable, since this property can be effectively enforced quite cheaply using message authentication codes.

We assume that the adversary’s corruptions are *static*: the set of corrupted parties is chosen once and for all at the very beginning of the attack. However, it should be straightforward to prove that our protocol is secure in an *adaptive* corruption model, assuming all underlying cryptographic primitives are secure in this model.

Because we want to use cryptographic techniques, it does not make sense to consider “infinite runs” of protocols, but rather, we only consider attacks that terminate after some bounded amount of steps. The number of steps in the adversary’s attack, as well as the computational complexity of the adversary, are assumed to be bounded by a polynomial in some security parameter.

Our protocols are defined such that they are only guaranteed to make progress to the extent to which the adversary actually delivers messages. To ensure that such a protocol behaves well in practice, an implementation would have to re-send messages until receiving (secure) acknowledgments for them. We do not discuss any of these implementation details any further in this paper.

In our formal model, there is no notion of time. However, in making the transition from the optimistic phase to the pessimistic phase of our protocol, we need a way to test if an unexpectedly large amount of time has passed since some progress has been made by the protocol. That is, we need a “time out”

mechanism. This is a bit difficult to represent in a formal model in which there is no notion of time. Nevertheless, we can effectively implement such a “time out” as follows: to start a timer, a party simply sends a message to itself, and when this message is delivered to that party, the clock “times out.” By representing time outs in this way, we effectively give the adversary complete control of our “clock.”

We define the *message complexity* of a protocol as the number of messages generated by all honest parties. This is a random variable that depends on the adversary and the value of the security parameter, and is denoted $MC(ID)$, where ID identifies a particular protocol instance. The term *probabilistically uniformly bounded* is a technical term that we borrow from [C+01]. Let X be a random variable associated with a run of a protocol that depends on the adversary and the value of the security parameter. Informally, “ X is probabilistically uniformly bounded” means that X is distributed “very tightly” around a quantity Y , where Y is bounded by a polynomial in the security parameter that is independent of the adversary. See [C+01] for the formal definition.

Our definition of atomic broadcast comes directly from [C+01], with just some minor notational changes. As we define it, an atomic broadcast primitive offers one or several broadcast channels, each specified by some channel identifier ID . Before a party can use a channel, it must be explicitly *opened*. Formally speaking, this is done by the adversary. At any point, the adversary may deliver the message $(ID, \text{in}, \text{a-broadcast}, m)$ to some honest party, where m is an arbitrary bit string (of bounded size); we say the party *a-broadcasts the request* m at this point. At any point, an honest party may generate an output message $(ID, \text{out}, \text{a-broadcast}, m)$, which is given to the adversary; we say the party *a-delivers the request* m at this point. We adopt the following terminological convention: a “request” is something that is *a-broadcast* or *a-delivered*, while a “message” is something that is sent or delivered in the implementation of the protocol.

To give higher level protocols the option to block the atomic broadcast protocol, the delivering party waits for an acknowledgment after every *a-delivery* of a request. That is, the number of *a-delivered* requests is equal to either the number of acknowledgments or the number of acknowledgments plus one. This is necessary so that higher-level protocols may satisfy a property analogous to the *efficiency* property (see Definition 1 below). Without this ability to synchronize protocol layers, a low-level atomic broadcast protocol could generate an arbitrary amount of network traffic without a higher-level protocol ever doing anything useful.

At any point in time, for any honest party P_i , we define $\mathcal{B}^{(i)}$ to be the set of requests that P_i has *a-broadcast*, and we define $\mathcal{D}^{(i)}$ to be the set of requests that P_i has *a-delivered*. We say that one request in $\mathcal{B}^{(i)}$ is *older* than another if P_i *a-broadcast* the first request before it *a-broadcast* the second request. At any point in time, we also define $\mathcal{D}^* = \cup_{\text{honest } P} \mathcal{D}^{(i)}$.

In discussing the values of the sets $\mathcal{B}^{(i)}$, $\mathcal{D}^{(i)}$, or \mathcal{D}^* at particular points in time, we consider the sequence of events E_1, \dots, E_k during the adversary’s

attack, where each event but the last is either an *a-broadcast* or *a-delivery* by an honest party, and the last event is a special “end of attack” event. The phrase “at time τ ,” for $1 \leq \tau \leq k$, refers to the point in time just *before* event E_τ occurs.

Definition 1 (Atomic Broadcast). *A protocol for atomic broadcast satisfies the following conditions, for all channels ID and all adversaries, with all but negligible probability.*

Agreement: *If some honest party has a-delivered m on channel ID , then all honest parties a-deliver m on channel ID , provided the adversary opens channel ID for all honest parties, delivers all associated messages, and generates acknowledgments for every party that has not yet a-delivered m on channel ID .*

Total Order: *Suppose one honest party has a-delivered m_1, \dots, m_s on channel ID , and another honest party has a-delivered $m'_1, \dots, m'_{s'}$ on channel ID with $s \leq s'$. Then $m_l = m'_l$ for $1 \leq l \leq s$.*

Validity: *There are at most t honest parties P_j with $\mathcal{B}^{(j)} \setminus \mathcal{D}^* \neq \emptyset$, provided the adversary opens channel ID for all honest parties, delivers all associated messages, and generates all acknowledgments.*

Fairness: *There exist a quantity Δ , which is bounded by a fixed polynomial in the security parameter (independent of the adversary), such that the following holds. Suppose that at some time τ_1 , there is a set \mathcal{S} of $t+1$ honest parties, such that for all $P_j \in \mathcal{S}$, the set $\mathcal{B}^{(j)} \setminus \mathcal{D}^*$ is non-empty. Suppose that there is a later point in time τ_2 such that the size of \mathcal{D}^* increases by more than Δ between times τ_1 and τ_2 . Then there is some $P_j \in \mathcal{S}$, such that the oldest request in $\mathcal{B}^{(j)} \setminus \mathcal{D}^*$ at time τ_1 is in \mathcal{D}^* at τ_2 .*

Efficiency: *At any point in time, the quantity $MC(ID)/(|\mathcal{D}^*|+1)$ is probabilistically uniformly bounded.*

Integrity: *Every honest party a-delivers a request m at most once on channel ID . Moreover, if all parties follow the protocol, then m was previously a-broadcast by some party on channel ID .*

3 Protocol Conventions and Notations

At each step of an attack, the adversary delivers a message to an honest party, and activates the honest party: the party performs some computations, updates its internal state, generates messages, and then returns control to the adversary. Messages delivered to a party are appended to the rear of an *incoming message queue*. When activated, the party may examine this queue, and remove any messages it wishes.

A party consists of one or more threads of execution. When a party is activated, each thread is in a *wait state*, waiting for one of the corresponding conditions to be satisfied. If the condition upon which any thread is waiting is satisfied, the corresponding thread is activated (if several threads could be activated, one is chosen arbitrarily), and this thread runs until it reaches another

wait state. This process continues until all threads are in wait states whose conditions are not satisfied, and then control returns to the adversary.

Our protocol syntax is rather self explaining, with one exception. A *wait* condition can either *receive* messages or *detect* them. In the former case, the messages are deleted from the queue (and thus do not trigger any further conditions) while in the latter, they remain in the queue. We also define an abstract timeout mechanism, which allows a process to start or stop the timer or wait for a timeout. In our model, this is implemented by the party simply sending a message to itself. As the adversary has full control over message delivery, this gives him full control over the timer, too.

4 Our New Protocol for Atomic Broadcast

The protocol operates in epochs, each epoch $e = 0, 1, 2$, etc., consisting of an optimistic and a pessimistic phase. In the optimistic phase, a designated leader orders incoming requests by assigning sequence numbers to them and initiating a Bracha broadcast [B84]; the optimistic phase guarantees the *agreement* and *total order* properties, but not the *validity* or *fairness* properties; however, the protocol can effectively determine if *validity* or *fairness* are potentially threatened, and if so, switch to the pessimistic phase, which cleans up any “mess” left by the current leader; then the optimistic phase starts again with a new leader.

4.1 Overview and Optimistic Phase

In the optimistic phase of epoch e , when a party *a-broadcasts* a request m , it *initiates* the request by sending a message of the form $(ID, \text{initiate}, e, m)$ to the leader for epoch e . When the leader receives such a message, it *0-binds* a sequence number s to m by sending a message of the form $(ID, \text{0-bind}, e, m, s)$ to all parties. Sequence numbers start at zero in each epoch. Upon receiving a *0-binding* of s to m , an honest party *1-binds* s to m by sending a message of the form $(ID, \text{1-bind}, e, m, s)$ to all parties. Upon receiving $n - t$ such *1-bindings* of s to m , an honest party *2-binds* s to m by sending a message of the form $(ID, \text{2-bind}, e, m, s)$ to all parties. A party also *2-binds* s to m if it receives $t + 1$ *2-bindings* of s to m — this has the effect of “amplifying” *2-bindings*, which is used to ensure *agreement*. Upon receiving $n - t$ such *2-bindings* of s to m , an honest party *a-delivers* m , provided all messages with lower sequence numbers were already delivered, enough acknowledgments have been received, and m was not already *a-delivered*.

A party only sends or reacts to *0-*, *1-*, or *2-bindings* for sequence numbers s in a “sliding window” $\{w, \dots, w + \text{WinSize} - 1\}$, where w is the number of requests already *a-delivered* in this epoch, and *WinSize* is a fixed system parameter. Keeping the “action” bounded in this way is necessary to ensure *efficiency* and *fairness*.

The number of requests that any party *initiates* but has not yet *a-delivered* is bounded by a parameter *BufSize*: a party will not *initiate* any more requests

once this bound is reached. We denote by \mathcal{I} the set of requests that have been *initiated* but not *a-delivered*, and we call this the *initiation queue*. If sufficient time passes without anything leaving the initiation queue, the party “times out” and *complains* to all other parties. These *complaints* are “amplified” analogously to the *2-bindings*. Upon receiving $n - t$ *complaints*, a party enters the pessimistic phase of the protocol. This strategy will ensure *validity*. Keeping the size of \mathcal{I} bounded is necessary to ensure *efficiency* and *fairness*.

Also to ensure *fairness*, a party keeps track of the “age” of the requests in its initiation queue, and if it appears that the oldest request is being ignored, i.e., many other requests are being *a-delivered*, but not this one, then the party simply refuses to generate *1-bindings* until the problem clears up. If $t + 1$ parties block in this way, they effectively prevent the remaining parties from making any progress in the optimistic phase, and thus, the pessimistic phase will be entered, where the fairness problem will ultimately be resolved.

We say that an honest party P_i *commits* s to m in epoch e , if m is the s th request (counting from 0) that it *a-delivered* in this epoch, optimistically or pessimistically.

Now the details. The state variables for party P_i are as follows.

Epoch number e : The current epoch number, initially zero.

Delivered set \mathcal{D} : All requests that have been *a-delivered* by P_i . It is required to ensure that requests are not *a-delivered* more than once; in practice, however, other mechanisms may be employed for this purpose. Initially, \mathcal{D} is empty.

Initiation queue \mathcal{I} : The queue of requests that P_i *initiated* but not yet *a-delivered*. Its size is bounded by *BufSize*. Initially, \mathcal{I} is empty.

Window pointer w : w is the number of requests that have been *a-delivered* in this epoch. Initially, $w = 0$. The optimistic phase of the protocol only reacts to messages pertaining to requests whose sequence number lies in the “sliding window” $\{w, \dots, w + \text{WinSize} - 1\}$. Here, *WinSize* is a fixed system parameter.

Echo index sets $BIND_1$ and $BIND_2$: The sets of sequence numbers which P_i has *1-bound* or *2-bound*, respectively. Initially empty.

Acknowledgment count $acnt$: Counts the number of acknowledgments received for *a-delivered* requests. Initially zero.

Complaint flag $complained$: Set if P_i has issued a complaint. Initially *false*.

Initiation time $it(m)$: For each $m \in \mathcal{I}$, $it(m)$ is equal to the value of w at the point in time when m was added to \mathcal{I} . Reset to zero across epoch boundaries.

These variables are used in combination with a fixed parameter *Thresh* to ensure *fairness*.

Leader index l : The index of the leader in the current epoch; we simply set $l = (e \bmod n) + 1$. Initially, $l = 1$.

Scheduled request set \mathcal{SR} : Only maintained by the current leader. It contains the set of messages which have been assigned sequence numbers in this epoch. Initially, it is empty.

Next available sequence number $scnt$: Only maintained by the leader. Value of the next available sequence number. Initially, it is zero.

```

/* Initiate  $m$ . */
upon receiving a message  $(ID, \text{in}, \text{a-broadcast}, m)$  for some  $m$  such that
 $m \notin \mathcal{I} \cup \mathcal{D}$  and  $|\mathcal{I}| < \text{BufSize}$  (note that we take the oldest such message
first):
    Send the message  $(ID, \text{initiate}, e, m)$  to the leader.
    Add  $m$  to  $\mathcal{I}$ ; set  $it(m) \leftarrow w$ .
/* 0-bind  $s$  to  $m$ . */
upon receiving a message  $(ID, \text{initiate}, e, m)$  for some  $m$ , such that  $i = l$ 
and  $w \leq \text{scnt} < w + \text{WinSize}$  and  $m \notin \mathcal{D} \cup \mathcal{SR}$ :
    Send the message  $(ID, \text{0-bind}, e, m, \text{scnt})$  to all parties.
    Increment  $\text{scnt}$  and add  $m$  to  $\mathcal{SR}$ .
/* 1-bind  $s$  to  $m$ . */
upon receiving a message  $(ID, \text{0-bind}, e, m, s)$  from the current leader for
some  $m, s$  such that  $w \leq s < w + \text{WinSize}$  and  $s \notin \text{BIND}_1$  and  $(\mathcal{I} = \emptyset)$ 
or  $(w \leq \min\{it(m) : m \in \mathcal{I}\} + \text{Thresh})$ :
    Send the message  $(ID, \text{1-bind}, e, m, s)$  to all parties; add  $s$  to  $\text{BIND}_1$ .
/* 2-bind  $s$  to  $m$ . */
upon receiving  $n - t$  messages of the form  $(ID, \text{1-bind}, e, m, s)$  from distinct
parties that agree on  $s$  and  $m$ , such that  $w \leq s < w + \text{WinSize}$  and
 $s \notin \text{BIND}_2$ :
    Send the message  $(ID, \text{2-bind}, e, m, s)$  to all parties; add  $s$  to  $\text{BIND}_2$ .
/* Amplify a 2-binding of  $s$  to  $m$ . */
upon detecting  $t + 1$  messages of the form  $(ID, \text{2-bind}, e, m, s)$  from distinct
parties that agree on  $s$  and  $m$ , such that  $w \leq s < w + \text{WinSize}$  and
 $s \notin \text{BIND}_2$ :
    Send the message  $(ID, \text{2-bind}, e, m, s)$  to all parties; add  $s$  to  $\text{BIND}_2$ .
/* Commit  $s$  to  $m$ . */
upon receiving  $n - t$  messages of the form  $(ID, \text{2-bind}, e, m, s)$  from distinct
parties that agree on  $s$  and  $m$ , such that  $s = w$  and  $\text{acnt} \geq |\mathcal{D}|$  and
 $m \notin \mathcal{D}$  and  $s \in \text{BIND}_2$ :
    Output  $(ID, \text{out}, \text{a-deliver}, m)$ ; increment  $w$ ; add  $m$  to  $\mathcal{D}$ , and re-
move it from  $\mathcal{I}$  (if present); stop timer.
/* Start timer. */
upon (timer not running) and (not complained) and  $(\mathcal{I} \neq \emptyset)$  and  $(\text{acnt} \geq |\mathcal{D}|)$ :
    start timer.
/* Complain. */
upon timeout:
    if not complained: send the message  $(ID, \text{complain}, e)$  to all parties;
set complained  $\leftarrow$  true.
/* Amplify complaint. */
upon detecting  $t + 1$  messages  $(ID, \text{complain}, e)$  from distinct parties, such
that not complained:
    Send the message  $(ID, \text{complain}, e)$  to all parties; set complained  $\leftarrow$ 
true; stop timer.
/* Go pessimistic. */
upon receiving  $n - t$  messages  $(ID, \text{complain}, e)$  from distinct parties, such
that complained:
    Execute the procedure Recover below.
    
```

Fig. 1. The optimistic phase

The protocol for party P_i consists of two threads. The first is a trivial thread that simply counts acknowledgments for *a-delivered* requests; it consists of an infinite loop whose body is as follows:

wait until receiving an acknowledgment; increment $acnt$

The main thread is an infinite loop whose body is as follows:

case $MainSwitch$ **end case**

where the $MainSwitch$ is a sequence of **upon** clauses described in Figure 1.

4.2 Fully Asynchronous Recovery

The recovery protocol is invoked if the optimistic phase appears to not work properly; this happens if either the leader is faulty or the network is too slow. Its job is to synchronize the parties by *a-delivering* all broadcasts that any honest party *may* have already *a-delivered*, and to guarantee the efficiency of the overall protocol by assuring that *some* messages are *a-delivered*. Finally, it hands over to a new leader to restart a new optimistic phase.

Validated Multivalued Byzantine Agreement. Our recovery-protocol builds on top of validated multivalued Byzantine agreement (i.e., the agreement is not restricted to a binary value), as defined and implemented in [C+01]. The final agreement value must be legal according to some validation function, which guarantees that it is some “useful” value. The definition of the validation function is clear from the context as the exact form of a valid proposal is defined in the protocol description. In the atomic broadcast protocol, we use the phrase “*propose X_i for multivalued Byzantine agreement on X* ” to denote the invocation of a validated multivalued Byzantine agreement protocol, where X_i is P_i ’s initial proposal, and X the resulting agreement value.

Overview of the Recovery Procedure. We distinguish between three types of requests: (i) requests for which it can be guaranteed that they have been *a-delivered* by an honest party; (ii) requests that potentially got *a-delivered* by an honest party; (iii) requests for which it can be guaranteed that they have not been *a-delivered* by an honest party. For the first two kinds of requests, an order of delivery might already be defined, and has to be preserved. The other requests have not been *a-delivered* at all, so the recovery protocol has complete freedom on how to order them. They can not be left to the next leader, however, as an adversary can always force this leader to be thrown out as well. To guarantee efficiency, the recovery procedure has to ensure that *some* request is *a-delivered* in every epoch. This is precisely the property that Castro and Liskov’s protocol fails to achieve: in their protocol, without imposing additional timing assumptions, the adversary can cause the honest parties to generate an arbitrary amount of messages before a single request is *a-delivered*. According to the three types of requests, the recovery protocol consists of three parts.

Part 1: Requests whose sequence number is determined. A “watermark” \hat{s}_e is jointly computed, which has the property that at least one honest party opti-

mistically committed the sequence number \hat{s}_e , and no honest party optimistically committed a sequence number higher than $\hat{s}_e + 2 \cdot \text{WinSize}$. After computing the watermark, all parties “catch up” to the watermark, i.e., commit all sequence numbers up to \hat{s}_e , by simply waiting for $t + 1$ consistent 2 -bindings for each sequence number up to the watermark. The work performed in this part constant, and especially independent of the number of unfinished requests.

Part 2: Requests whose sequence number may be determined. Here, we deal with the requests that might or might not have been a -delivered by some honest party in the optimistic phase of this epoch. We have to ensure that if some honest party has optimistically a -delivered a request, then all honest parties a -deliver this request as well. The sequence numbers of requests with this property lie in the interval $\hat{s}_e + 1 \dots \hat{s}_e + 2 \cdot \text{WinSize}$. Each party makes a proposal that indicates what action should be taken for all sequence numbers in this critical interval. Again, multivalued Byzantine agreement will be used to determine which of possibly several valid proposals should be accepted. While this part is relatively expensive, we can guarantee an upper bound of the number of requests processed here, which is determined by the window-size parameter.

Part 3: Undetermined Requests. This part is the one that guarantees that some messages are a -delivered in this epoch. We use a multivalued Byzantine agreement protocol to agree on a certain set of additional requests that should be a -delivered this epoch. We need to do this to ensure fairness and efficiency.

Terminology of the Recovery Procedure. For any party P_i , and any message α , we denote by $\{\alpha\}_i$ a signed version of the message, i.e., α concatenated with a valid signature under P_i 's public key on α , along with P_i 's identity.

For any $s \geq -1$, a *strong consistent set* Σ for s is a set of $t + 1$ correctly signed messages from distinct parties, each of the form $\{(ID, \mathbf{s-2-bind}, e, s')\}_j$ for some j and $s' \geq s$.

A *valid watermark proposal* \mathcal{M} is a set of $n - t$ correctly signed messages from distinct parties, each of the form $\{(ID, \mathbf{watermark}, e, \Sigma_j, s_j)\}_j$ for some j , where Σ_j is a strong consistent set of signatures for s_j . The maximum value s_j appearing in these watermark messages is called the *maximum sequence number* of \mathcal{M} .

For any $s \geq 0$, a *weak consistent set* Σ' for s is a set of $n - t$ correctly signed messages from distinct parties — each of the form $\{(ID, \mathbf{w-2-bind}, e, s, m_j)\}_j$ for some j — such that either all $m_j = \perp$ (indicating no 2 -binding for s), or there exists a request m and all m_j are either m or \perp . In the former case, we say Σ' *defines* \perp , and in the latter case, we say Σ' *defines* m .

A *valid recover proposal* \mathcal{P} is a set of $n - t$ correctly signed messages from distinct parties each of the form $\{(ID, \mathbf{recover-request}, e, \mathcal{Q}_j)\}_j$ for some j , where \mathcal{Q}_j is a set of at most BufSize requests.

The protocol for the pessimistic phase is presented in Figure 2.

A proof of security of the complete atomic broadcast protocol, as well as a number of other details, can be found in the full version of this paper [KS01].

```

/* Part 1: Recover requests with a determined sequence-number */
Send a the signed message  $\{(ID, \mathbf{s-2-bind}, e, \max(BIND_2 \cup \{-1\}))\}_i$  to all
parties.
wait until receiving a strong consistent set  $\Sigma_i$  for  $w - 1$ .
Send the signed message  $\{(ID, \mathbf{watermark}, e, \Sigma_i, w - 1)\}_i$  to all parties.
wait until receiving a valid watermark proposal  $\mathcal{M}_i$ .
Propose  $\mathcal{M}_i$  for multivalued Byzantine agreement on a valid watermark propo-
sal  $\mathcal{M}$ .
Set  $\hat{s}_e \leftarrow \tilde{s} - WinSize$ , where  $\tilde{s}$  is the maximum sequence number of  $\mathcal{M}$ .
while  $w \leq \hat{s}_e$  do:
    wait until receiving  $t+1$  messages of the form  $(ID, \mathbf{2-bind}, e, m, w)$ 
        from distinct parties that agree on  $m$ , such that  $acnt \geq |\mathcal{D}|$ .
    Output  $(ID, \mathbf{out, a-deliver}, m)$ ; increment  $w$ .
    Add  $m$  to  $\mathcal{D}$ , and remove it from  $\mathcal{I}$  (if present).

/* Part 2: Recover requests with a potentially determined sequence-
number */
For  $s \leftarrow \hat{s}_e + 1$  to  $\hat{s}_e + (2 \cdot WinSize)$  do:
    If  $P_i$  sent the message  $(ID, \mathbf{2-bind}, e, m)$  for some  $m$ , set  $\tilde{m} \leftarrow m$ ;
        otherwise, set  $\tilde{m} \leftarrow \perp$ .
    Send the signed message  $(ID, \mathbf{w-2-bind}, e, s, \tilde{m})$  to all parties.
    wait until receiving a weak consistent set  $\Sigma'_i$  for  $s$ .
    Propose  $\Sigma'_i$  for multivalued Byzantine agreement on a weak consis-
tent set  $\Sigma'$  for  $s$ .
    Let  $\Sigma'$  define  $m$ .
    If  $(s \geq w$  and  $m \in \mathcal{D})$  or  $m = \perp$ , exit the for loop and go to Part 3.
    If  $m \notin \mathcal{D}$ : wait until  $acnt \geq |\mathcal{D}|$ ; output  $(ID, \mathbf{out, a-deliver}, m)$ ;
        increment  $w$ ; add  $m$  to  $\mathcal{D}$ , and remove it from  $\mathcal{I}$  (if present).

/* Part 3: Recover undetermined Requests */
If  $w = 0$  and  $\mathcal{I} \neq \emptyset$ : send the message  $(ID, \mathbf{recover-help}, e, \mathcal{I})$  to all parties.
If  $w = 0$  and  $\mathcal{I} = \emptyset$ : wait until receiving a message  $(ID, \mathbf{recover-help}, e, \mathcal{Q})$ ,
    such that  $\mathcal{Q}$  is a non-empty set of at most  $BufSize$  requests, and  $\mathcal{Q} \cap \mathcal{D} = \emptyset$ .
If  $w \neq 0$  or  $\mathcal{I} \neq \emptyset$ : set  $\mathcal{Q} \leftarrow \mathcal{I}$ .
Send the signed message  $\{(ID, \mathbf{recover-request}, e, \mathcal{Q})\}_i$  to all parties.
wait until receiving a valid recover proposal  $\mathcal{P}_i$ .
Propose  $\mathcal{P}_i$  for multivalued Byzantine agreement on a valid recover proposal  $\mathcal{P}$ .
Sequence through the request set of  $\mathcal{P}$  in some deterministic order, and for
each such request  $m \notin \mathcal{D}$ , do the following:
    wait until  $acnt \geq |\mathcal{D}|$ ; output  $(ID, \mathbf{out, a-deliver}, m)$ ; increment
         $w$ ; add  $m$  to  $\mathcal{D}$ , and remove it from  $\mathcal{I}$  (if present).

/* Start New Epoch */
Set  $e \leftarrow e + 1$ ;  $l \leftarrow (e \bmod n) + 1$ ;  $w \leftarrow scnt \leftarrow 0$ ;  $\mathcal{SR} \leftarrow BIND_1 \leftarrow BIND_2 \leftarrow$ 
     $\emptyset$ ;  $complained \leftarrow false$ .
For each  $m \in \mathcal{I}$ : send the message  $(ID, \mathbf{initiate}, e, m)$  to the leader; set
 $it(m) \leftarrow 0$ .

```

Abstract. The “One-Time Pad” is a fundamental cryptographic protocol as it represents the ideal in secure unidirectional communication (i.e., in cases where there is a designated sender and a designated receiver) both in terms of security (in the presence of eavesdroppers) as well as in terms of computational efficiency. Surprisingly, no modeling and investigation of this protocol has been done in important practical settings, as distributed and asynchronous ones. In this work we introduce an asynchronous model for multidirectional and multi-player One-Time Pad asynchronous communication protocols. In this model the random pad is shared by all players, and there is no designated sender and receiver; in fact any participating player can act as a receiver at any given time, players communicate in a totally asynchronous fashion and may arbitrarily go off-line.

We define the problem of designing One-Time Pad asynchronous communication protocols, where the goal is that of maximizing the amount of the shared pad used before new randomness needs to be generated, with the constraint of maintaining the security property under reasonable adversarial assumptions on the relative behavior of the players and the network. We present lower bounds and protocol solutions for this problem that significantly improve over the obvious scenario where parties use an equal fraction of the pad. Our constructions are *non-interactive* in the sense that they require no additional synchronizing communication beyond the (usual) information that accompanies each ciphertext.

1 Introduction

The “One-Time Pad” is a well-known private-key encryption scheme, originally invented by Vernam [14] in 1918. Assume Alice and Bob agree on a random key K (a random “pad”); then, they can communicate securely (that is, without the eavesdropper Eve obtaining any information about their message) as follows: On input message m , Alice computes the ciphertext $c = m \oplus [K]$ where $[K]$

^{*} Copyright Telcordia.

^{**} Research partly supported by NSF CAREER Award CNS-0447808.

denotes a substring of K of appropriate length and sends it to Bob. Given c , Bob can recover message m , by decrypting c as $m = c \oplus [K]$. Here, \oplus is the “exclusive OR” operator, and K is at least as large as m . What makes one-time pad encryption remarkable is the following two facts (i) as shown by Shannon, in [13], it holds that any provably-secure (in the information-theoretic sense) encryption scheme must satisfy $|K| \geq |m|$ and more specifically one-time pad is optimally secure in the information theoretic sense. (ii) the encryption and decryption operations are essentially optimal in terms of time-complexity (being a mere exclusive-or operation). While the length of the key is inappropriate for most practical cryptographic applications, one-time pads are widely utilized as atomic components of more elaborate encryption systems by employing pseudo-random generators to generate arbitrarily long sequences of pseudo-random bits given only a short shared random seed (see e.g. [12, 7]). In this case the resulting pseudorandom sequence is used as a pad. The employment of such pseudorandom generators allows the transmission of messages longer than the shared key and security would rely solely on the unpredictability of the pseudo-random generator (since one-time pad over a truly random pad is information theoretically secure).

Now consider the setting where Alice and Bob both wish to play the sender or receiver role engaging in a *conversation* without a predetermined schedule and in an asynchronous communication setting. In the obvious solution, both players divide the pad K in two halves and each one uses a separate portion. Nevertheless, it would be much preferable to allow players to dynamically balance the pad portion they use depending on their need as this is determined by the progress of their interaction. In this sense the protocol allowing $|K|/2$ maximum total communication by each player individually loses a lot of the one-time pad efficiency in terms of utilizing their private storage and computation power (we stress that expanding the shared pad is an expensive operation and players would wish to utilize the jointly generated pad as efficiently as possible). In the bidirectional setting, a solution with more efficient pad utilization would allow the segment that can be expended by Alice in some conversations to be expended by Bob in others. Note that in the asynchronous setting we consider we cannot rely on participants being online to execute synchronization steps (and in this case even deterministic consensus decision is unattainable, [6]), while other synchronization techniques employing e.g. randomization [2], are clearly quite expensive in terms of communication for our setting.

The Problem. The problem we consider in this paper is then, as follows: Is it possible for $m \geq 2$ players, sharing a one-time pad of a certain size, to communicate securely (that is, without re-using portions of the one-time pad) and efficiently (that is, by using as much pad material as possible before re-generating new randomness)? In particular we will seek answers to the above problem where (i) the communication model is *multidirectional* and totally *asynchronous*; (ii) players do not use additional messages to synchronize themselves; (iii) players might arbitrarily go off-line or crash. Note that in order to satisfy these constraints we will opt for *non-interactive* protocol constructions: when a player wishes to transmit a message he should make a decision based only on his local

data on which pad to use next. The adversarial action that we will consider deals with the relative behavior of the players and the possible delays/swaps that are introduced during message transmission.

Our results. To describe the class of protocols solving the above problem we introduce the notion of one-time pad asynchronous communication (OTPAC) protocols. Our formal definition of secure OTPAC protocols considers an adversary arbitrarily delaying messages and introduces an undelivery parameter d meaning that, at any time, and for each sender, at most d messages were already sent by other players but have not been delivered to him yet. Note that this adversarial behavior refers to the relative behavior of the participants rather than properties of the network that is assumed to be totally asynchronous. The adversarial behavior is formally defined by specifying some natural property of a family of communication patterns (described as graphs) among the players. As a consequence, protocols for secure communication in this model can be shown to be secure according to this family of communication patterns.

In order to compare protocols in terms of the allowed flexibility in expending the shared pad, we define a measure called the “efficiency ratio” that is associated with each OTPAC protocol. Informally, the ratio is a metric for the maximum number of random bits from the one-time pad that can be used by any player before the pad needs to be refreshed. Under this metric, the protocol of the unidirectional or the synchronous setting exhibits ratio 1 (thus, optimal), while the protocol of m players equally splitting the pad has ratio $1/m$.

We present concrete constructions of secure OTPAC protocols in the asynchronous setting whose efficiency ratio is larger than $1/m$ and is expressed as a function of the undelivery parameter d , the number of players m and the number of pads n . Our general approach for OTPAC protocol construction ensures improved expendability of the pad by having players maintaining various types of “logical clocks” [11]. We completely characterize the two party case, by exhibiting a protocol achieving efficiency ratio $1 - d/n$ for $d \leq \lfloor n/2 \rfloor$, and a lower bound that matches this protocol when $d \leq \lfloor n/2 \rfloor$ and the protocol of 2 players equally splitting the pad otherwise. In the m -party case, we exhibit a protocol with efficiency ratio $1 - 1/\text{poly}(n)$ for typical parameter values, and a lower

Protocol	Number of players	Efficiency Ratio	Proven Secure for	Other Constraints
\mathcal{A}_1	m	$\frac{1}{m}$	unconditional	
\mathcal{A}_2	m	1	undelivery 0	
\mathcal{A}_3	2	$1 - \frac{d}{n}$	undelivery d	$d < n/2$
\mathcal{A}_4	m	$1 - \frac{d}{n}(L - 2)^{\log m - 1} - \frac{\log m - 2}{L}$	undelivery d	$d < nL^{1 - \log m}$

Fig. 1. Comparison of 4 Protocols. Note that in all cases we assume $n \gg m$. \mathcal{A}_1 refers to the protocol where players use disjoint pad segments, where \mathcal{A}_2 refers to the protocol where players employ a jointly maintained counter (players are synchronized). These two protocols are listed for the sake of comparison. Our main constructions are protocols $\mathcal{A}_3, \mathcal{A}_4$. L is a parameter of \mathcal{A}_4

bound of $1 - d/n$ for $d \leq \lfloor n(m-1)/m \rfloor$ and $1/m$ otherwise, the latter matching the protocol of m players equally splitting the pad. Our upper bound results are overviewed in figure 1. We note that we know of no previous work in the literature that considered one-time pads in the asynchronous communication setting. The problem of designing OTPAC protocols relates to the Do-All (DA) problem (see, e.g., [5, 4, 10]) and Write-All (WA) problem (see, e.g., [9, 1, 3, 8]) from the Distributed Computing literature. In fact, from this literature’s viewpoint, designing OTPAC protocols can be thought of as solving a “Do/Write-Once” kind of problem; this interrelationship will be further analyzed in upcoming work.

2 One-Time Pad Asynchronous Communication

In this section we present definitions for the communication model and protocols, the security requirements as well as an efficiency metric, which we instantiate through examples of basic protocols.

OTPAC Protocols. In our setting, m players A_1, \dots, A_m wish to communicate securely taking advantage of a shared random pad. Players are assumed to communicate through a network that supports broadcast transmission and each player can be a sender or a receiver in a certain communication. There is no global clock that the players can use for synchronization and message delays are unbounded; all messages are eventually delivered but their order is not necessarily preserved by the network (such assumptions are typical in the Distributed Computing literature). Each player A_i is initialized by executing an **Initialization** procedure, and subsequently sequences of two events may happen to A_i : **Send** and **Receive**, according to the requests of sending messages that the specific application environment demands from the players in the protocol. Each player A_j is assumed to have access to the same shared private *random pad* \mathbf{p} that can be written as the concatenation of n words p_1, \dots, p_n , of k bits each, k being the length of one message-block. The communication is driven by a sequence of *send requests* for the players (that can be thought to be adversarially generated) and are ordered according to some (unknown to the players) global notion of time; the send requests form the *schedule* of the protocol denoted by $\mathbf{s} = ((s_1, t_1), \dots, (s_v, t_v))$, where $t_1 \leq t_2 \leq \dots \leq t_v$ correspond to the time of the send requests and each $s_\ell = (j, u)$ stands for the u -th request of the j -th player. To achieve the highest possible generality we will assume that each execution of the protocol takes as input a pad \mathbf{p} and follows an arbitrary schedule \mathbf{s} . Let us denote by $[n] = \{1, \dots, n\}$. We can now proceed with a formal definition.

Definition 1. Let m, n be positive integers, let $\text{Head} = [m] \times [n]$, and let Conf denote a set of possible configurations; at local time t we denote the configuration of player A_j as $\Pi_j[t] \in \text{Conf}$. We define a *One-Time-Pad Asynchronous Communication* (OTPAC) protocol as a triple of polynomial-size circuits $\langle I, S, R \rangle$, with the following functionality:

$$I : [m] \rightarrow \text{Conf} \quad S : [m] \times \text{Conf} \rightarrow \{\perp\} \cup (\text{Conf} \times [n]) \quad R : [m] \times \text{Conf} \times \text{Head} \rightarrow \text{Conf}$$

The operation of an OTPAC protocol is as follows: initially every player A_j executes $I(j) \rightarrow \Pi_j[0]$ to set its initial configuration. Then the sequence of send requests in the schedule \mathbf{s} is sequentially scanned. Given a send request at time t , player A_j generates a **Send** event, by executing $S(\Pi_j[t]) \rightarrow \langle \Pi_j[t+1], i \rangle$ and resulting in the transmission of the ciphertext $\langle j, i, p_i \oplus M \rangle$, where $M \in \{0, 1\}^k$ is the message that player A_j wishes to transmit and $\langle j, i \rangle \in [m] \times [n]$ is the ciphertext header (note that frequently we will write $S(\cdot)$ instead of $S(j, \cdot)$ if the sending player is clear from the context; similarly for $R(\cdot)$). If $S(\Pi_j[t]) = \perp$ player A_j ceases to send messages. Every ciphertext has length $\log m + \log n + k$. A **Receive** event is triggered by the arrival of a ciphertext $\langle j', i', C \rangle$ at player A_j in time t . Player A_j decrypts the message by computing $p_{i'} \oplus C$ and updates its configuration to $\Pi_j[t+1] \leftarrow R(\Pi_j[t], j', i')$. We assume that the S, R circuits satisfy the property $S(\Pi_j[t]) = \perp \Rightarrow S(R(\Pi_j[t], j, i)) = \perp$ for any $\langle j, i \rangle \in \text{Head}$. An OTPAC protocol stops when all parties A_j enter in a configuration $\Pi_j[t]$ such that $S(\Pi_j[t]) = \perp$. A particular execution of an OTPAC protocol (namely, an execution of algorithms I, S, R , for fixed random tapes of all participants) can be characterized as in the following definition.

Definition 2. A feasible *asynchronous communication pattern* (ACP) for an m -player OTPAC protocol $\langle I, S, R \rangle$ on input an n -word pad \mathbf{p} and a schedule \mathbf{s} is a finite directed acyclic graph \mathcal{P} so that the set of its nodes is a subset of $\mathbb{N} \times \mathbb{N}$ and is partitioned into m subsets. Every node $\langle j, t \rangle$ is labeled by an element of Conf , denoted by $\Pi_j[t]$. \mathcal{P} includes the nodes $\langle 1, 0 \rangle, \dots, \langle m, 0 \rangle$ labeled by $I(1), \dots, I(m)$ respectively, as well as the nodes $\langle 1, t_{1, \max} \rangle, \dots, \langle m, t_{m, \max} \rangle$ such that for any $t > t_{j, \max}$, $\langle j, t \rangle \notin \mathcal{P}$. For any $j, t < t_{j, \max}$ there is an edge from $\langle j, t \rangle$ to $\langle j, t' \rangle$ for some $t' > t$ and such that for all $t^* \in \{t+1, \dots, t'-1\}$, $\langle j, t^* \rangle \notin \mathcal{P}$; the node $\langle j, t' \rangle$ is the *subsequent* node of $\langle j, t \rangle$. The nodes of \mathcal{P} and their labels fall into either one of the following three categories:

- *Send Nodes.* It is a node $\langle j, t \rangle$ with $S(\Pi_j[t]) \neq \perp$ that has m outgoing edges to $\langle 1, t_1 \rangle, \dots, \langle m, t_m \rangle$ s.t. $t_j = t + 1$ and at most one incoming edge. The label of $\langle j, t + 1 \rangle$ is equal to Π where $\langle \Pi, i \rangle \leftarrow S(\Pi_j[t])$.
- *Receive Nodes.* It is a node $\langle j, t \rangle$ with one incoming edge coming from some Send-node $\langle j', t' \rangle$ $j' \neq j$. The label of $\langle j, t + 1 \rangle$ is equal to $R(\Pi_{j'}[t], j', i')$ where i' is such that $\langle \Pi', i' \rangle \leftarrow S(\Pi_{j'}[t'])$.
- *Idle Nodes.* It is a node $\langle j, t \rangle$ that is neither a Send or Receive node. If $t > 0$, the node has one incoming and one outgoing edge to its subsequent node $\langle j, t' \rangle$ (recall $t' > t$); if $\langle j, 0 \rangle$ is idle then it has no incoming edge. The label of $\langle j, t' \rangle$ is equal to $\Pi_j[t]$.

Any OTPAC protocol $\mathcal{A} := \langle I, S, C \rangle$ for m players using a random pad \mathbf{p} of n k -bit words and a schedule \mathbf{s} defines a family of feasible ACP's denoted by $\mathcal{F}_{\mathcal{A}, \mathbf{s}}^{m, n}$. (By $\mathcal{F}_{\mathcal{A}}^{m, n}$ we denote the union, over all schedules \mathbf{s} , of the family of feasible ACP's $\mathcal{F}_{\mathcal{A}, \mathbf{s}}^{m, n}$.)

Security and efficiency of OTPAC protocols. We define the security of OTPAC protocols by extending the security notion of the one-time pad from

the unidirectional synchronous setting (namely, that the same portion of the pad should not be used twice) to the asynchronous setting considered here.

Let \mathcal{A} be an OTPAC protocol, and $\mathcal{F}_{\mathcal{A}}^{m,n}$ be the set of feasible ACP's. While players A_1, \dots, A_m are attempting to communicate, the adversary is capable of controlling the network so to both choose a particular schedule of send requests and swap or delay messages being sent. The goal of the adversary is to force the re-use of some portion of the pad so that the “one-time” property is lost and some information can be derived from the transcript. It follows that the only mechanism available to players to protect the security of their communication is to reach the \perp output of their **Send**-event state update function S , before the adversary is capable of violating the one-time property. So given an OTPAC protocol \mathcal{A} , the adversary selects a schedule \mathbf{s} that is input to \mathcal{A} , and furthermore selects a pattern $\mathcal{P} \in \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$; the protocol is executed following the pattern \mathcal{P} ; if \mathcal{P} contains two **Send** events that use the same pad segment, then the adversary wins. In conclusion, security of an OTPAC protocol would be argued for a subfamily of $\mathcal{F}_{\mathcal{A}}^{m,n}$ for which no pad is used twice. Formally,

Definition 3. The Security Property. Let $\mathcal{A} := \langle I, S, C \rangle$ be an OTPAC protocol, let $\mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$ be the family of feasible ACP's for \mathcal{A} on input schedule \mathbf{s} and let $\mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n} = \cup_{\mathbf{s}} \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$. We say that \mathcal{A} is *insecure on* $\mathcal{P} \in \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$ if \mathcal{P} includes two **Send** nodes $\langle j, t \rangle$ and $\langle j', t' \rangle$ so that if $\langle \Pi, i \rangle \leftarrow S(\Pi_j[t])$ and $\langle \Pi', i' \rangle \leftarrow S(\Pi_{j'}[t'])$ it holds that $i = i'$. Let $\mathcal{G} = \cup_{\mathbf{s}} \mathcal{G}_{\mathbf{s}}$ be a family of ACP's, where for each \mathbf{s} , $\mathcal{G}_{\mathbf{s}} \subseteq \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$. We say that \mathcal{A} is *secure on family* \mathcal{G} , if there exists no schedule \mathbf{s} and no pattern $\mathcal{P} \in \mathcal{G}_{\mathbf{s}}$ such that \mathcal{A} is insecure on \mathcal{P} .

Naturally, for any given \mathcal{A} it would be the most desirable that it is secure for any $\mathcal{P} \in \mathcal{F}_{\mathcal{A}}^{m,n}$. Considering only such protocols though is very restrictive. Instead, as it is standard in cryptography as well as in distributed systems theory, we will opt to restrict the behavior of the adversary in meaningful ways and consider protocols that can be proven secure in such adversarial setting.

Adversarial Setting: Undelivery. A communication pattern $\mathcal{P} \in \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$ admits various total orderings \prec between the vertices of \mathcal{P} (topological sortings of the graph \mathcal{P}). One such sorting \prec corresponds to the actual “real global time” (unknown to the participants). Such total orderings can also be called “runs” of an asynchronous communication pattern \mathcal{P} , following the standard terminology in distributed systems. Note that, as it is common in distributed systems theory, we assume that no two events happen at the same time, i.e. the total ordering \prec is strict. A **Send** event $\langle j, t \rangle$ is said to have d *undelivered messages* w.r.t. a topological sorting \prec of \mathcal{P} , if there exist d **Send** events $\langle j_1, t_1 \rangle, \dots, \langle j_d, t_d \rangle$, $j \notin \{j_1, \dots, j_d\}$ for which it holds $\langle j_\ell, t_\ell \rangle \prec \langle j, t \rangle$ for $\ell = 1, \dots, d$, and if $\langle j, s_1 \rangle, \dots, \langle j, s_d \rangle$ are the corresponding **Receive** events at player A_j it holds that $s_\ell > t$ for $\ell = 1, \dots, d$. For any schedule \mathbf{s} , let $\mathcal{U}_{\mathcal{A},\mathbf{s},d}^{m,n}$ denote the subfamily of all ACP's $\mathcal{P} \in \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$ that have no **Send** events with d undelivered messages w.r.t. any possible topological sorting of \mathcal{P} . Also, let $\mathcal{U}_{\mathcal{A},d}^{m,n} = \cup_{\mathbf{s}} \mathcal{U}_{\mathcal{A},\mathbf{s},d}^{m,n}$.

Note that undelivery does not describe any fixed property of the network. More specifically, if an ACP contains a **Send** event that has d undelivered mes-

sages this does not mean that the network delays messages by a fixed upper time-bound that is proportional to d . Instead, the adversary controlled the message delivery of the network and the random coin tosses of the players' random processes in such a way that one of the players initiated a **Send**-event before having heard of d **Send** events of other players that happened concurrently. We remark that if it was possible for the players to synchronize themselves (e.g., by using a global clock) it would be easy to restrict the adversary to produce only ACP's that belong to $\mathcal{U}_{\mathcal{A},1}^{m,n}$, i.e., if a player sends a message the other players are silent until they receive it. Clearly in such a scenario designing an OTPAC protocol is a trivial matter. Tackling the asynchronous case where the parameter $d > 1$ is the motivation for our investigations.

Efficiency of OTPAC protocols. We introduce a natural metric of the efficiency of an OTPAC protocol with respect to usage of the shared pad vector.

We start with some definitions. The *message-count* of an ACP $\mathcal{P} \in \mathcal{F}_{\mathcal{A}}^{m,n}$, denoted by $\text{mc}(\mathcal{P})$, is a tuple $\langle N_1, \dots, N_m \rangle$ denoting the number of **Send** events for each of the players A_1, \dots, A_m . Let $\mathcal{G} = \cup_{\mathbf{s}} \mathcal{G}_{\mathbf{s}}$ be a family of ACP's, where for each \mathbf{s} , $\mathcal{G}_{\mathbf{s}} \subseteq \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$. Next we define the *order* of a family $\mathcal{G} \subseteq \mathcal{F}_{\mathcal{A}}^{m,n}$ as $N = \min_{\mathbf{s}} \min_{\mathcal{P} \in \mathcal{G}_{\mathbf{s}}} \sum_{i=1}^m N_i$. Intuitively, the order of \mathcal{G} is the maximum number of messages that all players can send using protocol \mathcal{A} when, on input schedule \mathbf{s} , the communication pattern is drawn from $\mathcal{G}_{\mathbf{s}}$. Using this notion, we define our main metric for OTPAC protocols, which we call the "efficiency ratio," standing for the maximum percentage of the pad all players are allowed to use.

Definition 4. The Efficiency Ratio. Let \mathcal{A} be an OTPAC protocol with corresponding ACP family $\mathcal{F}_{\mathcal{A}}^{m,n}$ and let $\mathcal{G} = \cup_{\mathbf{s}} \mathcal{G}_{\mathbf{s}}$ be an ACP family such that for each \mathbf{s} , $\mathcal{G}_{\mathbf{s}} \subseteq \mathcal{F}_{\mathcal{A},\mathbf{s}}^{m,n}$. The *efficiency ratio of algorithm \mathcal{A} on family \mathcal{G}* is defined as $\alpha := \frac{N}{n}$ where N is the order of family \mathcal{G} .

Although it does not appear explicitly in the above definition, we stress that this metric only makes sense for secure executions, as insecure executions can always have efficiency ratio 1 or even greater. To understand the above notion it is helpful to recall the two simple protocols described in figure 1: \mathcal{A}_1 will be the OTPAC protocol where all players use a disjoint segment in the pad and \mathcal{A}_2 will be the protocol that all players use the whole pad at the same time while maintaining a joint counter. It is straightforward to show that \mathcal{A}_1 has efficiency ratio $1/m$ and can be proven secure for all feasible ACP's $\mathcal{F}_{\mathcal{A}_1}^{m,n}$, whereas \mathcal{A}_2 has efficiency ratio 1, but can be proven secure only for $\mathcal{U}_{\mathcal{A}_2,1}^{m,n}$, the family of ACP's that are effectively synchronous (no **Send**-event has an undelivered message). The protocols $\mathcal{A}_1, \mathcal{A}_2$ represent the two different ends of the spectrum: \mathcal{A}_1 allows arbitrary adversarial action but has very small efficiency ratio; on the other hand \mathcal{A}_2 allows the highest efficiency ratio nevertheless it can only be proven secure if we restrict the adversary so much that players communicate in an effectively synchronous fashion. This motivates our investigations in the rest of the paper, where we construct OTPAC protocols that trade adversarial action for efficiency.

3 OTPAC Protocol Lower Bounds

In this section we prove lower bounds on the efficiency ratio of OTPAC protocols, as a function of the number n of elements in the common pad, the number m of players, and the undelivery parameter d . We start with OTPAC protocols among 2 players, and then extend the analysis to any number m of players.

The Two-Player Case. Let \mathcal{A} be an OTPAC protocol among 2 players. Recall that we consider adversaries that can choose the request schedule \mathbf{s} input to protocol \mathcal{A} and can arbitrarily delay messages, so to force any Send event to have up to d undelivered messages, where d is an unrestricted parameter (in particular, note that $d \geq n$ is equivalent to assuming $d = \infty$). We obtain the following:

Theorem 1. Any OTPAC protocol \mathcal{A} secure on $\mathcal{U}_{\mathcal{A},d}^{2,n}$ can achieve efficiency ratio α such that:

- $\alpha \leq 1 - d/n$ if $d \leq \lfloor n/2 \rfloor$,
- $\alpha \leq 1/2$ if $d > \lfloor n/2 \rfloor$.

The proof of Theorem 1 starts by assuming, towards contradiction, that there exists an OTPAC protocol \mathcal{A} that can achieve efficiency ratio larger than the claimed bound on the ACP family $\mathcal{U}_{\mathcal{A},d}^{2,n}$; finally, it reaches contradiction by showing that \mathcal{A} is not secure on this family. An intuition on how the contradiction is reached goes as follows. First, we show the existence of a schedule \mathbf{s}_1 on which the efficiency ratio larger than the claimed bound is achieved by portions of the random pad only used by party P_1 . Then we show the existence of a schedule \mathbf{s}_2 with the analogue property for P_2 . Finally, we show the existence of a schedule \mathbf{s} and of an adversary, such that in an execution of \mathcal{A} on input \mathbf{s} the following holds: at any time the adversary keeps up to d undelivered messages; the view of P_1 is as if $\mathbf{s} = \mathbf{s}_1$; and the view of P_2 is as if $\mathbf{s} = \mathbf{s}_2$. As a consequence, both parties use a large number of portions of the random pad, and at least one portion is used by both parties, thus implying that the protocol is not secure.

The m -Player Case. We now consider an OTPAC protocol \mathcal{A} among m players, for $m > 2$. We note that in this case we count one undelivered message for each player that has not received the message yet (that is, if there are 2 receivers that have not received the same message, then the undelivery parameter satisfies $d = 2$). The lower bound on the efficiency ratio of \mathcal{A} is then obtained as an appropriate generalization of the bound in the 2 player case.

Theorem 2. Let $m \leq n$. Any OTPAC protocol \mathcal{A} secure on $\mathcal{U}_{\mathcal{A},d}^{m,n}$ can achieve efficiency ratio at most $1 - d/n$ if $d \leq \lfloor n(m-1)/m \rfloor$ or at most $1/m$ otherwise.

The above theorems imply that protocol \mathcal{A}_1 (defined in figure 1) has *optimal* efficiency ratio for values of $d \geq n/2$. Note that this range of values strictly includes the range $d \geq n$, that, in turn, is equivalent to assuming $d = \infty$; that is, when no bound at all can be assumed on the undelivery parameter.

4 OTPAC Protocol Constructions: Head-on Collision Runs

In this section we present two protocol constructions that exhibit more refined trade-offs between security and efficiency. To increase the efficiency ratio we allow players to use common pad segments while at the same time maintaining safe distance between the segments that are actively used during a conversation. The manner with which players will be expending pad portions will resemble a “head-on collision run” over the pad vector. We will start with the simpler two-player case and then discuss the m -player setting.

4.1 The Two Player Setting

Informal Description of the \mathcal{A}_3 protocol. The two players initialize counters, each one at the far end of the pad vector. Players expend pads in a “head-on collision run” to each other while maintaining a “safety distance” from each other’s pad segment. The safety factor is determined by a parameter d . A formal description of the protocol will appear in the full version; a graphical representation is in figure 2. In the lemma below we characterize the ACP’s for which the security of \mathcal{A}_3 fails.

Fig. 2. A head-on collision run: protocol \mathcal{A}_3

Lemma 1. *Let $\mathcal{P} \in \mathcal{F}_{\mathcal{A}_3}^{m,n}$ for which \mathcal{A}_3 is insecure. Then, \mathcal{P} has Send-event with at least $d + 1$ undelivered messages.*

Theorem 3. *The OTPAC protocol \mathcal{A}_3 is secure for $\mathcal{U}_{\mathcal{A}_3,d}^{2,n} \subseteq \mathcal{F}_{\mathcal{A}_3}^{2,n}$. The efficiency ratio of \mathcal{A}_3 over $\mathcal{U}_{\mathcal{A}_3,d}^{2,n}$ equals $1 - d/n$.*

Because of Theorem 1, we obtain that protocol \mathcal{A}_3 has *optimal* efficiency ratio over family $\mathcal{U}_{\mathcal{A}_3,d+1}^{2,n} \subseteq \mathcal{F}_{\mathcal{A}_3}^{2,n}$ for $d \leq \lfloor n/2 \rfloor$.

4.2 The Multi-player Setting

In this section we will generalize the OTPAC protocol \mathcal{A}_3 to the multi-player setting. The protocol \mathcal{A}_4 is a multilayer recursive generalization of protocol \mathcal{A}_3 . Refer to figure 3 for a graphical depiction of the four player setting.

Below we describe the protocol \mathcal{A}_4 and we assume for simplicity that it involves $m = 2^\delta$ players. Note that to avoid cluttering of notation and due to lack of space we will only give an informal (but sufficiently detailed) description

Fig. 3. Multilayered head-on collision runs: protocol \mathcal{A}_4

of the algorithms $\langle I, R, S \rangle$. We give some notation first: every player is identified by a δ -bitstring id. For a string a we denote by $[a]_j$ the symbol in the j -th location. It holds that $a = [a]_1 \dots [a]_\delta$ if a is a δ -long string. If b is a bit, we denote by \bar{b} its complement. The neighbor set (res. native set) of degree j for a player id is a set of bitstrings a so that (i) $[a]_\ell = [\text{id}]_\ell$ for $\ell = 1, \dots, j-1$ (ii) $[a]_j = \bar{[\text{id}]_j}$, (respectively: $[a]_j = [\text{id}]_j$), and (iii) $[a]_\ell \in \{0, 1\}$ for all $\ell = j+1, \dots, \delta$. The pad vector will be divided into a number of sub-divisions using a parameter L (thought to be a small function in n). The sub-division of degree ℓ for $\ell = 1, \dots, \delta-1$ will be comprised of L^ℓ components. Finally in the sub-division of degree δ we will have actual pad segments of length $s := n/L^{\delta-1}$.

The main idea of the protocol is that at the δ -subdivision we will have individual players implementing the two-player protocol in head-on collision run fashion. Then, at the $\delta-1$ subdivision we will have groups of 2 players operating in head-on collision fashion, and so on.

A player id maintains a position variable for himself $p_{\text{id}} \in \{1, \dots, L\}^{\delta-1} \times \{1, \dots, s\}$. Note that a position maps to a specific pad inside the n -long pad-vector by specifying one of the $L^{\delta-1}$ sub-divisions of degree $\delta-1$ as well as a pad location inside this sub-division. Every player assumes an initial position in the pad vector. In particular player id assumes the initial position $p_{\text{id}}^{\text{init}}$ with $[p_{\text{id}}^{\text{init}}]_\ell = 1([\text{id}]_\ell = ? 0) + L([\text{id}]_\ell = ? 1)$ for $\ell = 1, \dots, \delta-1$ and $[p_{\text{id}}^{\text{init}}]_\delta = 1([\text{id}]_\ell = ? 0) + s([\text{id}]_\ell = ? 1)$. This $p_{\text{id}} = p_{\text{id}}^{\text{init}}$ will be the first pad used by player id if he wishes to send a message. The header of a ciphertext will be of the form $\langle \text{id}, p_{\text{id}} \rangle$.

Every player will maintain information about the movements of his neighboring subsets of users. In particular, player id will maintain δ counters v_1, \dots, v_δ for the neighboring subsets of users. These counters are initialized as follows: $v_\ell = 1([\text{id}]_\ell = ? 0) + L([\text{id}]_\ell = ? 1)$ and $v_\delta = 1([\text{id}]_\delta = ? 0) + s([\text{id}]_\delta = ? 1)$ If a message is received that has header $\langle \text{id}^*, p^* \rangle$, player id will compute the function $\alpha := \alpha(\text{id}, \text{id}^*) = j \in \{1, \dots, \delta\}$ such that $[\text{id}]_\ell = [\text{id}^*]_\ell$ for all $\ell < j$; this α is called the nativity degree between two players. Conceptually, for two players id and id^* the nativity degree specifies the highest level at which the two players are facing each other in a head-on collision run (either by themselves, or as members of larger groups).

Upon receiving a message with header $\langle id^*, p^* \rangle$, player id takes the following actions: (i) it computes the nativity degree α . (ii) for all the sub-divisions for which player id moves together with id^* as members of the same group, player id must make sure that he advances together with his group. Player id belongs to the same group of players with id^* for all the subdivisions of degree $\ell \in \{1, \dots, \alpha - 1\}$ (note: if $\alpha = 1$ this set is empty). If id is not “trailing” behind then it should hold that $[p_{id}]_\ell = [p^*]_\ell$ for all $\ell = 1, \dots, \alpha - 1$. In this case no further action would be required. On the other hand, let $j \in \{1, \dots, \alpha - 1\}$ be the smallest integer such that $[p_{id}]_j \neq [p^*]_j$. Player id determines his movement direction within the group at the subdivision of degree j , which is “to the right” if $[id]_j = 0$ or “to the left” if $[id]_j = 1$. Then, in case the direction is to the right, the player performs the operation: if $[p_{id}]_j < [p^*]_j$ set $[p_{id}]_j = [p^*]_j$. In case the direction is to the left, the player does instead: if $[p_{id}]_j > [p^*]_j$ set $[p_{id}]_j = [p^*]_j$. If one of the above two modifications takes place and the value $[p_{id}]_j$ is updated, then id resets the remaining values of p_{id} as follows $[p_{id}]_\ell = [p_{id}^{init}]_\ell$ for $\ell = j + 1, \dots, \delta$. The above update allows to a player that is trailing behind on a certain level to “catch up” with his native players; it follows that a player may change his position in the pad vector because of the movement of his native players. (iii) Regarding the neighboring players, one neighboring counter needs to be updated: v_α ; to update counter v_α player id determines the movement direction of the neighboring set of players at the α -level (to the right if $[id^*]_\alpha = 0$, or to the left if $[id^*]_\alpha = 1$) and performs the update: if $v_\alpha < [p^*]_\alpha$ and $[id^*]_\alpha = 0$ then $v_\alpha = [p^*]_\alpha$; if $v_\alpha > [p^*]_\alpha$ and $[id^*]_\alpha = 1$ then $v_\alpha = [p^*]_\alpha$. Note that player id will ignore any information provided by p^* and refers to a level greater to the nativity degree.

Having described the semantics of the counters we proceed now to see how a player id having just used the pad at position p_{id} , advances to the next pad that he can use. The player needs to determine the status of every level $\ell \in \{1, \dots, \delta\}$ among two possible states: **stay** and **jump**. The state computation for level $\ell = 1, \dots, \delta - 1$ is as follows: the player checks whether $|[p_{id}]_\ell - v_\ell| \geq 2$ and in this case assigns to level ℓ the state **stay**; for the δ -th level the state **stay** is assigned if $|[p_{id}]_\delta - v_\delta| > d$ where d is a given fixed parameter. If all levels are assigned state **stay** then player id will use the adjacent pad, i.e., if $p_{id} = l_1 l_2 \dots l_{\delta-1} l_\delta$ the next pad will be at $p_{id}^{new} = l_1 l_2 \dots l_{\delta-1} (l_\delta + 1)$ if $[id]_\delta = 0$ (movement to the right) or $p_{id}^{new} = l_1 l_2 \dots l_{\delta-1} (l_\delta - 1)$ if $[id]_\delta = 1$ (movement to the left). If all levels are assigned the state **jump** then player id terminates. Now let j be the highest level that is assigned a **stay** state (and it holds that the $(j + 1)$ -th state is at the **jump** state). Then, player id will assume the position p_{id}^{new} defined as (i) $[p_{id}^{new}]_\ell = [p_{id}]_\ell$ for $\ell = 1, \dots, j$, (ii) $[p_{id}^{new}]_{j+1} = [p_{id}^{init}]_{j+1} + 1$ if $[id]_{j+1} = 0$, or $[p_{id}^{new}]_{j+1} = [p_{id}^{init}]_{j+1} - 1$ if $[id]_{j+1} = 1$; finally (iii) $[p_{id}^{new}]_\ell = [p_{id}^{init}]_\ell$ for $\ell = j + 2, \dots, \delta$ (recall that p_{id}^{init} is the initial position of player id). In addition to the above, player id must update all its neighbor counters v_ℓ for the levels $\ell = j + 1, \dots, \delta$ to their initial position, as in the beginning of the protocol, $v_\ell = 1(\overline{[id]_\ell} = ? 0) + L(\overline{[id]_\ell} = ? 1)$ and $v_\delta = 1(\overline{[id]_\delta} = ? 0) + s(\overline{[id]_\delta} = ? 1)$.

A formal description of the protocol will appear in the full version.

Lemma 2. Assume parameters $L, d, \delta = \log m$ such that $n/L^{\delta-1} > d$. Let $\mathcal{P} \in \mathcal{F}_{\mathcal{A}_4}^{m,n}$ be an asynchronous communication pattern for which protocol \mathcal{A}_4 is insecure. Then, \mathcal{P} has Send-event with at least $d + 1$ undelivered messages.

Theorem 4. The OTPAC protocol \mathcal{A}_4 is secure for $\mathcal{U}_{\mathcal{A}_4,d}^{m,n} \subseteq \mathcal{F}_{\mathcal{A}_4}^{2,n}$. The efficiency ratio of \mathcal{A}_4 over $\mathcal{U}_{\mathcal{A}_4,d}^{m,n}$ equals $1 - 2(\delta - 2)/L - (L - 2)^{\delta-1}d/n$.

We note that in the typical case $m = O(1), d = O(n^\epsilon), \epsilon < 1$, it is possible to select the parameter L so that the efficiency ratio becomes $1 - 1/\text{poly}(n)$, i.e., arbitrarily close to 1 for sufficiently large n .

Single-Prover Concurrent Zero Knowledge in Almost Constant Rounds^{*}

Giuseppe Persiano and Ivan Visconti

Abstract. In this paper we study the round complexity of *concurrent zero-knowledge* arguments and show that, for any function $\beta(n) = \omega(1)$, there exists an *unbounded* concurrent zero-knowledge argument system with $\beta(n)$ rounds. Our result assumes that the *same* prover is engaged in several concurrent sessions and that the prover has a counter whose value is shared across concurrent executions of the argument. Previous constructions for concurrent zero knowledge required a (almost) logarithmic number of rounds [Prabhakaran et al. - FOCS 2002] in the plain model or seemingly stronger set-up assumptions.

Moreover, we construct two $\beta(n)$ -round unbounded concurrent zero-knowledge arguments that are mutually concurrent simulation sound for any $\beta(n) = \omega(1)$. Here we assume that each party has access to a counter and that the two protocols are used by the *same* two parties to play several concurrent sessions of the two protocols.

1 Introduction

Since its introduction, the concept of a zero-knowledge proof system and the simulation paradigm have been widely used to prove the security of many protocols. The notion of *concurrent zero knowledge* [2] formalizes security in a scenario in which several verifiers access concurrently a prover and maliciously coordinate their actions so to extract information from the prover. In [3] it has been showed that in the black-box model $\tilde{\Omega}(\log n)$ round are necessary for concurrent zero knowledge for non-trivial languages. The first concurrent zero-knowledge proof system for \mathcal{NP} has been given by [4] that showed that $O(n^\epsilon)$ are sufficient for any $\epsilon > 0$. Poly-logarithmic round-complexity was achieved in [5] and, finally, in [1] it is shown that $\tilde{O}(\log n)$ rounds are sufficient. The proof systems presented in [4, 5, 1] are black-box zero knowledge and the round-complexity of the proof system of [1] is almost optimal in view of the lower bound proved in [3]. Thus unlike the stand-alone case, black-box concurrent zero knowledge cannot be achieved in a constant number of rounds.

^{*} Work supported by Network of Excellence ECRYPT under contract IST-2002-507932.

Different models have been presented in which round-efficient black-box concurrent zero knowledge is possible. In [2, 6, 7] constant-round concurrent zero-knowledge proof systems have been presented by relaxing the asynchrony of the model or the zero-knowledge property. In [8, 9], constant-round concurrent zero-knowledge proof systems have been presented assuming the existence of a common reference string or a shared random string (i.e., a trusted third party) while in [10] a constant-round concurrent zero-knowledge with concurrent soundness argument system is shown by assuming that there exists a public repository that contains the public keys of the verifiers. Furthermore, Pass [12] gave a constant-round concurrent zero-knowledge argument with a super-polynomial-time simulator. In [13], Barak presented a *non-black-box* constant-round *bounded-concurrent* zero-knowledge argument system. The construction of [13] assumes that the maximum number of concurrent sessions is known in advance.

Simulation-sound zero knowledge. Simulation-sound zero knowledge has been introduced in [14] for the purpose of constructing cryptosystems secure against adaptive chosen-ciphertext attacks. This concept is related to the concept of non-malleability introduced in [15]. Indeed, both notions deal with an adversary (called the *man-in-the-middle*) that simultaneously participates to many executions of two proof systems and acts as a prover in the former and as a verifier in the latter. The adversary has complete control over the scheduling of the messages in the executions of the protocols. Informally, two zero-knowledge proof systems are said mutually concurrent *simulation sound* if the information that the man-in-the-middle adversary collects as a verifier from concurrent sessions played with a *simulated* prover of the former proof system does not help him to prove a *false* statement in the latter proof system and vice versa. Here the man-in-the-middle can choose to see *simulated* proofs of true and false statements.

Simulation-sound zero knowledge plays an important role for proving the security of protocols. Indeed, when the simulation paradigm is used to prove the security of a protocol, the simulator could, in some cases, need to simulate the proof of a false statement. Here simulation soundness is crucial since the adversary could gain knowledge from such a proof in order to prove a false statement in another protocol.

Our results. In this paper we show that, for any function β such that $\beta = \omega(1)$, there exists a $\beta(n)$ -round concurrent zero-knowledge argument system for any language in \mathcal{NP} . Our argument system assumes that: 1) the prover is equipped with a counter that counts the total number of bits he has sent so far in all sessions; 2) the argument system remains zero knowledge provided that one *single* prover is engaged by the adversarial verifier in any polynomial number of (unbounded) concurrent sessions.

We stress that our set-up assumptions seem no-stronger than the ones made in [2, 6, 7, 8, 10]. Comparing our result with the bounded-concurrent result of [13], we stress that our construction does not assume knowledge of an *a-priori* bound on the number of concurrent sessions. On the other hand, our construction requires a super-constant number of rounds. Finally, we remark that the

concurrent zero-knowledge property of our construction is obtained by means of an efficient simulator.

Relying upon our construction of concurrent zero knowledge we present two $\beta(n)$ -round argument systems that are concurrent zero knowledge and mutually concurrent simulation sound for any $\beta = \omega(1)$. Here we require set-up assumptions inherited from the concurrent zero-knowledge argument on which they are based: 1) each party is equipped with a counter that is used to keep track of the total length of some of the messages sent; 2) the two protocols are played by the *same* two players with roles inverted.

Comparison with known assumptions. In the past, round-efficient concurrent zero knowledge has been achieved by making assumptions that decrease the power of an adversarial concurrent verifier. For example timing assumptions (used in [2, 6, 7]) limit the power of adversarially scheduling the communication between prover and verifier (by imposing a bound on the delays experienced by the messages), bounded concurrency (used in [13]) upper bounds the number of concurrent sessions. When concurrent zero knowledge is obtained in presence of a common reference string [8, 9], the adversarial concurrent verifier is assumed not to corrupt the party that generated a common reference string and that this party securely preserves (or erases) any secret information about the string.

In contrast, our assumptions are quite different in nature. Let us discuss the case of concurrent zero knowledge (the same discussion can be used for the two arguments that are mutually concurrent simulation-sound and concurrent zero-knowledge). First of all, we claim that the need of a counter for a prover is a very weak assumption. Indeed, we only require that the adversarial concurrent verifier cannot modify the value of the counter of the prover. Our results continue to hold if the adversary is allowed to read the value of the counter.

Our second requirement forbids an adversarial concurrent verifier the execution of concurrent sessions with different provers. In comparison with the assumptions made in the literature, in our case the adversarial verifier can still open any polynomial number of concurrent sessions with complete control on the scheduling of the messages. There is no bound on the delay of the messages and no trusted party is assumed. Instead, the zero-knowledge property concerns an attack of an adversarial verifier that tries to gain knowledge from a *given* prover. It is interesting that such a restriction allows the design of round-efficient and concurrent-secure protocols.

Constant-round arguments. Our construction leaves as an open problem the construction (even under our set-up assumptions) of a constant-round concurrent zero-knowledge argument for all \mathcal{NP} and of constant-round mutually concurrent simulation-sound and concurrent zero-knowledge arguments. Indeed for the case of zero knowledge one would like to prove the following informal statement.

Statement 1 (Open problem.) *There exist a constant c and an argument system (P, V) such that for all constants k and all adversaries V^* that open at most n^k concurrent sessions, (P, V) takes at most c rounds and the view of V^* can be simulated in polynomial time.*

Instead we prove the following weaker statement which can be seen as an intermediate result towards the proof of Statement 1.

Statement 2. *There exists an argument system (P, V) such that for all constants k and all adversaries V^* that open at most n^k concurrent sessions, there exists a constant c such that (P, V) takes at most c rounds and the view of V^* can be simulated in polynomial time.*

Indeed, in our construction the number of rounds depends on the degree of concurrency. However, we show that a super-polynomial number of sessions are needed in order to force a super-constant number of rounds. Statement 2 should be contrasted with the following statement proved in [13] (corresponding to bounded-concurrent zero knowledge).

Statement 3 ([13]). *There exists a constant c such that for all constants k there exists an argument system (P, V) such that for all adversaries V^* that open at most n^k of concurrent sessions, (P, V) takes at most c rounds and the view of V^* can be simulated in polynomial time.*

2 Concurrent Zero Knowledge

We now define the zero knowledge requirement that is of interest for this paper: concurrent zero knowledge.

Definition 1. *Let $\langle P, V \rangle$ be an interactive or argument system for a language L . We say that a probabilistic polynomial-time adversarial verifier V^* is a concurrent adversary if it concurrently runs a polynomial number of interaction with a prover P , without any restrictions over the scheduling of the messages in the different interactions with P . Moreover we say that the transcript of such a concurrent interaction consists of the common inputs and the sequence of prover and verifier messages exchanged during the interaction. We refer to $\text{view}_V^P(x)$ as the random variable describing the content of the random tape of V^* and the transcript of the concurrent interactions between P and V^* .*

Definition 2. *Let $\langle P, V \rangle$ be an interactive argument system for a language L . We say that $\langle P, V \rangle$ is concurrent zero knowledge if, for each probabilistic polynomial-time concurrent adversary V^* there exists a probabilistic polynomial-time algorithm S_V such that the ensembles $\{\text{view}_V^P(x)\}_{x \in L}$ and $\{S_V(x)\}_{x \in L}$ are computationally indistinguishable.*

The above definition (and our construction of a concurrent zero-knowledge argument system) considers the case of a single prover that potentially runs several sessions with the adversarial verifier. Such a definition can be extended to a multi-prover setting in which the adversarial verifier concurrently runs a polynomial number of sessions with possibly different provers. In the standard model when a concurrent adversary is considered, the multi-prover setting and

the single-prover setting coincide since a single-prover in each interaction is oblivious of the existence of each other interaction. Instead in our settings, we rely on the fact that the prover knows an upper bound on the length of the view of the verifier he is interacting with and this is possible if there is only one prover.

We now present our construction of a concurrent zero-knowledge argument system for any language in \mathcal{NP} . We start by describing the model in Section 2.1, we give a high-level description of the protocol in Section 2.2, we describe its main components in Section 2.3 and 2.4, and, finally, the protocol and the proofs of its properties are presented in Section 2.5.

2.1 The Model

Our (unbounded) concurrent zero-knowledge argument system requires a model richer than the standard plain model for concurrent zero knowledge used by the previous unbounded-concurrent black-box zero-knowledge argument systems of [4, 1, 5] and the bounded-concurrent non-black-box zero-knowledge argument system of [13]. Indeed, our argument system is based on the following two set-up assumptions.

1. The prover is equipped with a counter that counts the total number of bits that he has sent in all the sessions. The counter can not be modified by the adversarial verifier.
2. The argument system is zero knowledge provided that the *same* prover is engaged by the adversarial verifier in any polynomial number of concurrent sessions.

The first assumption requires that the prover is stateful as the counter is shared by all concurrent sessions. Moreover, the adversarial verifier cannot modify this value. The fact that the adversarial verifier can run many concurrent sessions against only one prover is a consequence of the first assumption since in general a stateful prover behaves differently from another stateful prover when their states are different. Obviously, this does not constitute an issue in the plain model for concurrent zero knowledge where the prover is stateless.

2.2 A High Level Description

Our protocol follows the FLS paradigm [16] that has been used for the bounded-concurrent zero-knowledge argument system of Barak [13]. An FLS-type protocol is composed of two subprotocols: a *preamble* subprotocol and a *witness-indistinguishable argument* subprotocol. In an FLS-type protocol, the goal of the preamble subprotocol is to allow prover and verifier that are interacting on input a statement “ $x \in L$ ”, to create an augmented statement “ $(x \in L) \vee (\tau \in A)$ ” to be proved later in the witness-indistinguishable argument subprotocol. In [13], the auxiliary statement “ $\tau \in A$ ” informally stands for “com is the commitment of $h(A)$ where A is a program that on input a sufficiently short string tr outputs r in time bounded by a slightly super-polynomial function”. The simulator of [13]

sets A equal to the description of the adversary and \mathbf{tr} to its view. To guarantee soundness it is enough that r is sufficiently longer than \mathbf{tr} .

Since we want *unbounded-concurrent* zero knowledge, we cannot give a bound on the length of the string \mathbf{tr} . Instead, our preamble consists of several iterations (corresponding to increasing values for the length of \mathbf{tr}) in which the prover asks the verifier for increasingly long strings r . The prover stops when he receives a string r whose length is at least twice the length of the transcript of all the concurrent sessions¹. The prover maintains a counter to count the length of the transcript of the concurrent sessions. Notice that since the number of rounds of the preamble is not known at the beginning of the protocol, the randomness owned by the verifier could be not sufficient to complete the protocol. Therefore, we assume that the verifier has at least an n -bit random string that he stretches round by round of the preamble by means of a pseudorandom generator.

A non-black-box simulator S , interacting with a concurrent adversary V^* and given access to the code of V^* , commits to its code and randomness by setting $A = V^*$. Then in the argument subprotocol S proves that there exists a string \mathbf{tr} (the transcript of the interaction between the simulator and V^*) for which the machine whose code has been committed (that is V^*) would give as output r when receiving \mathbf{tr} as input.

The statement is obviously true and S has a witness for it (i.e., the decommitment, the description of the adversary and the sufficiently short transcript). S finishes by running the prover's program for the witness indistinguishable argument. Notice that the simulator runs the same number of sub-preambles played by the prover.

For the round complexity of the protocol, it can be seen that for each constant k there exists a constant c_k such that, if the adversary starts at most n^k concurrent sessions, the protocols will take at most c_k rounds. Thus, for any function $\beta(n) = \omega(1)$, we can conclude that, for any polynomial number of concurrent sessions, our protocol takes (for sufficiently large n) at most $\beta(n)$ rounds.

2.3 The Preamble Subprotocol

Auxiliary inputs. On input x of length n , prover P has a witness w for $x \in L$ and a counter c that is shared by all concurrent executions of P .

The preamble step by step. Let $\mathcal{H} = \{h_\alpha\}$ be an ensemble of collision-resistant hash functions secure against $n^{O(\log n)}$ -time adversaries. Each function of $h_\alpha \in \mathcal{H}$ maps any string to a string of length $3|\alpha|$. V randomly picks a hash function h by randomly picking an n -bit string α and sends (a description of) $h = h_\alpha$ to P . Moreover V picks a random seed s for the pseudorandom generator \mathcal{G} and will use the output of \mathcal{G} on input s as a random tape.

¹ The transcript of a session that we consider here consists of all the messages sent by the prover.

Then the prover uses a statistically binding commitment scheme $(\mathcal{G}, \text{Com}, \text{Dec})$ to compute $(\text{com}, \text{dec}) = \text{Com}(h(0^n))$, sends com to the verifier and increments c by $|\text{com}|$.

Now the prover and the verifier repeat the following iteration, starting with $i = 1$, until the preamble is declared completed:

1. at the i -th iteration, V randomly picks a $2n^i$ -bit string r_i and sends it to the prover;
2. if $c \leq n^i$ then the preamble is declared completed and P sends the bit “1” to V to mark the end of the preamble; otherwise, P sends the bit “0” to ask V to perform iteration $i = i + 1$. In both cases, P increments the counter c by 1.

2.4 The Argument Subprotocol

The argument subprotocol consists in the execution of a witness-indistinguishable universal argument for proving statement “ $(x \in L) \vee (\tau \in A)$.” We stress that during the execution of the argument subprotocol the prover increments c to keep track of the number of bits he has sent. Let us now describe the language A and the string τ .

We say that $(h, \text{com}, r) \in A$ if $(\text{com}, \text{dec}) = \text{Com}(h(A))$ and there exists tr of length $|\text{tr}| < |r|/2$ such that A , on input tr , outputs r in at most $n^{\log \log n/2}$ steps.

The triple $\tau = (h, \text{com}, r)$ used by the prover in the argument subprotocol consists of the (description of the) collision-resistant hash function h picked by the verifier, the commitment com sent by the prover and the last string r sent by the verifier during the preamble protocol. Obviously, the prover runs the witness indistinguishable universal argument subprotocol for $\text{Ntime}(n^{\log \log n})$ for proving statement “ $(x \in L) \vee (\tau \in A)$ ” using w such that $(x, w) \in R_L$ as witness. The simulator instead uses his knowledge of the code of the verifier to compute $(\text{com}, \text{dec}) = \text{Com}(h(V^*))$ in the preamble. Therefore, if V^* in the i -th iteration of the loop of the preamble subprotocol, on input a transcript tr of the messages sent by the simulator such that $|\text{tr}| \leq n^i$, outputs a $2n^i$ -bit message r , the triple $(\text{dec}, V^*, \text{tr})$ is a witness for $(h, \text{com}, r) \in A$ and therefore for “ $(x \in L) \vee (\tau \in A)$ ”. Thus the simulator runs the code of the prover of the witness-indistinguishable universal argument subprotocol using $(\text{dec}, V^*, \text{tr})$ as witness.

2.5 The Concurrent Zero-Knowledge Argument System

Our concurrent zero-knowledge argument system for all languages in \mathcal{NP} combines the preamble subprotocol from Section 2.3 and the witness-indistinguishable universal argument for $\text{Ntime}(n^{\log \log n})$ from Section 2.4. By using the techniques introduced in [17] our construction only needs the existence of collision-resistant hash function ensembles that are secure with respect to polynomial-time algorithms.

Theorem 1. *Assuming the existence of collision-resistant hash function ensembles that are secure against polynomial-time algorithms, then there exists (constructively) a $\beta(n)$ -round concurrent zero-knowledge argument system for \mathcal{NP} for any $\beta(n) = \omega(1)$.*

The proof of Theorem 1, is omitted from this extended abstract.

3 Concurrent Simulation Soundness

In this section we show that the concurrent zero-knowledge argument system presented in Section 2 can be used to construct two mutually concurrent simulation-sound and concurrent zero-knowledge argument systems. More precisely, in this section we show that, under set-up assumptions similar to those used to construct the concurrent zero-knowledge argument of Section 2, there exists (constructively) a pair of $\beta(n)$ -round concurrent zero-knowledge argument systems that are mutually concurrent simulation sound for any $\beta = \omega(1)$.

Man-in-the-middle adversary. The strong notion of *simulation-sound zero knowledge* deals with an adversary \mathcal{A} that mounts a man-in-the-middle attack at two arguments $SSP_0 = \langle P_0, V_0 \rangle$ and $SSP_1 = \langle P_1, V_1 \rangle$. The adversary \mathcal{A} acts as a verifier in an instance of protocol SSP_0 and as a prover in a (concurrently played) instance of protocol SSP_1 . \mathcal{A} has complete control of the communication channel and can decide the scheduling of the messages. Informally, SSP_0 is *simulation sound with respect to SSP_1* if the “simulated” proof of a (possibly false) statement seen by \mathcal{A} as a verifier of SSP_0 does not help him to prove a false statement in SSP_1 . If $SSP_0 = SSP_1$ then we say that SSP_0 is *self simulation sound*. If SSP_0 is simulation sound with respect to SSP_1 and SSP_1 is simulation sound with respect to SSP_0 then we say that SSP_0 and SSP_1 are *mutually simulation sound*.

A *concurrent man-in-the-middle* adversary \mathcal{A} is allowed to play several concurrent instances of SSP_0 and SSP_1 (instead of just one for each protocol). In this case, if the “simulated” proofs of both true and false statements in SSP_0 do not help \mathcal{A} to prove a false statement in SSP_1 we say that SSP_0 is *concurrently simulation sound* with respect to SSP_1 . We will consider this stronger notion of simulation soundness.

We denote by $\{\text{out}_{\mathcal{A}, V_1}^{S_0, \mathcal{A}}(x_1, \dots, x_{\text{poly}(n)}, x'_1, \dots, x'_{\text{poly}(n)})\}$ the distribution of the output of V_1 after a concurrent man-in-the-middle attack of \mathcal{A} . We assume that in SSP_0 , S_0 simulates the proofs for both true and false statements $(x_1, \dots, x_{\text{poly}(n)})$ and in SSP_1 \mathcal{A} tries to prove statements $(x'_1, \dots, x'_{\text{poly}(n)})$. The output of V_1 in such an experiment is therefore a vector of bits $(b_1, \dots, b_{\text{poly}(n)})$ where $b_i = 1$ means that V_1 accepted the proof for x'_i while $b_i = 0$ means that V_1 rejected the proof for x'_i , for $i = 1, \dots, \text{poly}(n)$.

We now give a formal definition of concurrent simulation soundness that we use in our construction.

Definition 3. Let $SSP_0 = \langle P_0, V_0 \rangle$ and $SSP_1 = \langle P_1, V_1 \rangle$ be two argument systems for a language L . We say that SSP_0 is concurrently simulation-sound with respect to SSP_1 if, for any concurrent man-in-the-middle adversary \mathcal{A} , there exists a probabilistic polynomial-time algorithm $S_{\mathcal{A}}$ such that the probability that the i -th bit of $\{\text{out}_{\mathcal{A}, V_1}^{S_{\mathcal{A}}, \mathcal{A}}(x_1, \dots, x_{\text{poly}(n)}, x'_1, \dots, x'_{\text{poly}(n)})\}$ is 1 and $x'_i \notin L$ for $i \in \{1, \dots, \text{poly}(n)\}$ is negligible.

3.1 The Additional Assumptions of Our Model

We show in the next section a pair of mutually (unbounded) concurrent simulation-sound and concurrent zero-knowledge arguments. For our constructions we will need set-up assumptions very similar to the ones used for concurrent zero knowledge. As for the case of concurrent zero knowledge, we do not assume the existence of any trusted third party nor of trusted sources of shared randomness. Our protocol is based on the following two set-up assumptions.

1. Each party is equipped with a counter that gives at each step the total number of bits he has sent so far in all sessions in which he acts as a prover in both protocols and as a verifier in only one of the two protocols.
2. SSP_0 and SSP_1 are played by the *same* two players with roles inverted.

As in the previous construction, the first assumption makes the parties stateful since they need to propagate the value of the counter across concurrent sessions. The fact that we need to restrict the adversary to mount an attack against only one player (although this single player is allowed to play both as a prover and as a verifier in several concurrent sessions) is a consequence of our first set-up assumption. Indeed for stateless parties, it does not make a difference whether the prover and verifier that are interacting with the man-in-the-middle adversary are the same or not.

We stress that in this model, the argument system of Section 2 is also concurrent non-malleable (we stress that non-malleability requires that proofs of *true* statements do not help the adversary for proving a different statement) and concurrent zero-knowledge. Indeed, the fact that we only have to deal with two parties implies that the simulator controls both the prover and the verifier played by the honest parties (in particular the simulator has access to the randomness used by these algorithms) which makes things much easier. This approach does not work for obtaining simulation soundness; in this case the adversary can request to see the (simulated) proofs of polynomially many true and false statements which makes the design of concurrent simulation-sound argument systems more difficult. Let us now concentrate on simulation soundness.

3.2 The Mutually Concurrent Simulation-Sound Argument Systems

In this section we describe the two argument systems that are mutually concurrent simulation-sound and concurrent zero knowledge, that is both are concurrent zero knowledge and each one is concurrently simulation sound with respect to the other one.

For our construction, we use some techniques introduced in [11], and therefore we need cryptographic primitives that are secure with respect to super-polynomial-time adversaries.

Using an ensemble of collision resistant hash functions that is secure against $T(n)^{O(1)}$ -adversaries, the universal argument presented in [17, 13] is sound with respect to adversaries running in time $T(n)$. By plugging such a strengthened universal argument in the concurrent zero-knowledge argument system of Section 2, and assuming that even in the preamble such stronger hash functions are used, we have that the resulting concurrent zero-knowledge argument systems is sound against adversaries running in time $T(n)$.

In order to obtain two mutually concurrent simulation-sound and concurrent zero-knowledge argument systems, we use the following approach. We show a concurrent zero-knowledge argument system SSP_1 that has also a straight-line simulator that by running in time $n^{O(\log n)}$ inverts a one-way permutation (here we use the recent techniques of [12, 11]). We then show a concurrent zero-knowledge argument system SSP_0 that is sound with respect to $n^{O(\log^2 n)}$ adversaries. Informally, concurrent simulation soundness of SSP_1 with respect to SSP_0 is proved in the following way. An adversarial prover P_0^* for SSP_0 that proves a false statement while concurrently interacting in any polynomial number of sessions as a prover of SSP_0 and as a verifier of SSP_1 can be used to break the stand-alone soundness of SSP_0 . We use here the existence of an $n^{O(\log n)}$ -time straight-line simulator for SSP_1 , since it can be easily extended to play also the role of verifier in SSP_0^2 , therefore a relay strategy for the session in which P_0^* proves a false statement can be used to break in time $n^{O(\log n)}$ the stand-alone soundness of SSP_0 that is assumed to work against $n^{O(\log^2 n)}$ adversaries.

For proving the concurrent simulation soundness of SSP_0 with respect to SSP_1 we use a different technique since the previous approach can not work in both directions at the same time. The idea is that for proving the simulation soundness of SSP_0 with respect to SSP_1 , it is necessary to consider an adversary P_1^* that plays both the role of prover in concurrent sessions of SSP_1 and the role of verifier in concurrent sessions of SSP_0 . The zero-knowledge simulator of SSP_0 suffices here for simulation soundness but it has to consider the view of the adversary P_1^* that also includes the messages that he receives in SSP_1 . In case P_1^* has proved a false statement for SSP_1 , we get a contradiction with respect to the stand-alone soundness of SSP_1 . This can be achieved by performing a relay strategy with a real verifier V_1 . The original parameter (i.e., the counter) of the concurrent zero-knowledge argument system of Section 2 includes in SSP_0 the messages of the sessions of SSP_0 received by P_1^* when playing the role of verifier and the messages of SSP_1 received by P_1^* when playing the role of prover. Since the same does not hold for SSP_1 (where the prover only counts the bits sent as

² This additional work does not damage the simulation of SSP_1 since such simulation is not based on the knowledge of the code of the adversary and its input. Instead, the simulation is based on the power of breaking a primitive that is assumed to be hard for $n^{o(\log n)}$ -time algorithms.

a prover of SSP_1), the communication complexity of SSP_1 is short enough to allow the desired round complexity in SSP_0 .

We now give the details of the two protocols while the formal proofs are omitted from this extended abstract.

The first protocol. The first of the two mutually concurrent simulation-sound and concurrent zero-knowledge arguments is referred to as SSP_0 and is the concurrent zero-knowledge protocol of Section 2 with the following modification. First of all, SSP_0 is the strengthened concurrent zero-knowledge argument system (as discussed above) that is sound against $n^{O(\log^2 n)}$ -adversaries (i.e., we set $T(n) = n^{O(\log^2 n)}$). For this reason, we assume the existence of an ensemble of hash functions that are collision resistant with respect to algorithms running in time $n^{O(\log^2 n)}$. Moreover, the counter is incremented also by $|m|$ when a message m is sent as a verifier in some concurrent execution of SSP_1 . Obviously, when only concurrent zero knowledge is considered, this last case never occurs. During the universal argument phase the prover proves the statement “ $x \in L \vee \tau = (h, \text{com}, r) \in A$ ” where h is the collision resistant hash function selected by the verifier, com is the commitment sent by the prover and r is the last message sent by the verifier during the preamble. It is easy to see that the modified protocol is still concurrent zero knowledge and has the same round complexity as the one discussed in Section 2. For proving (stand-alone) soundness, notice that by the soundness and the weak proof of knowledge properties of the witness indistinguishable universal argument, an extractor algorithm obtains in time $n^{O(\log \log n)}$ the witness used by the adversarial prover for proving a false statement. Therefore, in this case he obtains a triple $(\text{dec}, \mathcal{M}, \text{tr})$ such that $\mathcal{M}(\text{tr}) = r$ where $|\text{tr}| \leq |r|/2$, and \mathcal{M} outputs r in at most $n^{\log \log n/2}$ steps.

The second protocol. The second of the two mutually concurrent simulation-sound arguments is referred to as SSP_1 and is the concurrent zero-knowledge protocol of Section 2 with the following modifications. First of all, SSP_1 is the strengthened concurrent zero-knowledge argument system (as discussed above) that is witness indistinguishable with respect to $n^{O(\log n)}$ -adversaries (i.e., we set $T(n) = n^{O(\log n)}$). Then we assume the existence of a one-way permutation f such that f is hard to invert with respect to algorithms running in time $n^{O(\log \log n)}$ but can be inverted in time $n^{O(\log n)}$. In the first round the verifier still chooses an hash function. In addition, V picks a random string u in the domain of f and sends $v = f(u)$ to the prover. The language A is the same used for the concurrent zero-knowledge argument system of Section 2: $\tau = (h, \text{com}, r) \in A$ if com is a commitment of $h(A)$ and there exists a string tr such that $|\text{tr}| \leq |r|/2$, and $\mathcal{M}(\text{tr})$ outputs r in at most $n^{\log \log n/2}$ steps.

During the witness indistinguishable universal argument of knowledge the prover proves knowledge of a witness y for either $(x, y) \in L$ or $\tau = (h, \text{com}, r) \in A$ or such that $f(y) = v$.

It is easy to see that the modified protocol is still concurrent zero knowledge and has the same round complexity as the original one. Only the (stand-alone) soundness property is affected by this update. However, notice that the only

difference with respect to soundness of the argument system of Theorem 1 is that the extractor of the universal argument could also extract a witness y such that $f(y) = v$. However, since the extractor runs in time $n^{O(\log \log n)}$, we have that the one-way permutation is inverted in time $n^{o(\log n)}$ that contradicts the assumed hardness of f .

Protocol SSP_1 admits also a quasi-polynomial-time simulator that by running in time $n^{O(\log n)}$ inverts any polynomial number of one-way permutations and therefore can simulate in a straight-line fashion any polynomial number of session of SSP_1 without using knowledge of the description of the adversarial verifier. Notice that such a simulator still has to run the algorithm of the prover during the preamble, in order to maintain the same round complexity of the real prover.

Abstract. We present two methods for finding a lowest common ancestor (LCA) for each pair of vertices of a directed acyclic graph (dag) on n vertices and m edges.

The first method is surprisingly natural and solves the all-pairs LCA problem for the input dag on n vertices and m edges in time $O(nm)$. As a corollary, we obtain an $O(n^2)$ -time algorithm for finding genealogical distances considerably improving the previously known $O(n^{2.575})$ time-bound for this problem.

The second method relies on a novel reduction of the all-pairs LCA problem to the problem of finding maximum witnesses for Boolean matrix product. We solve the latter problem and hence also the all-pairs LCA problem in time $O(n^{2+\frac{1}{\omega}})$, where $\omega = 2.376$ is the exponent of the fastest known matrix multiplication algorithm. This improves the previously known $O(n^{\frac{3}{2}})$ time-bound for the general all-pairs LCA problem in dags.

1 Introduction

The problem of finding a *lowest common ancestor* (LCA) in a tree, or more generally, in a *directed acyclic graph* (dag) is one of the basic algorithmic problems. An LCA of vertices u and v in a dag is an ancestor of both u and v which has no descendant that is an ancestor of u and v , see Fig. 1 for example. We consider the problem of preprocessing a dag such that LCA queries can be answered quickly for any pair of vertices. It has a variety of important applications, e.g., in object inheritance in programming languages, analysis of genealogical data and lattice operations for complex systems (see [2] for details and further references).

For trees, linear-time preprocessing is sufficient to answer LCA queries in constant time [7]. For general dags, after an $O(n^{\frac{3}{2}})$ -time preprocessing, LCA queries can be answered in constant time [2] (where n is the number of vertices and $\omega = 2.376$ is the exponent of the fastest known matrix multiplication algo-

rithm). A lower bound $\Omega(n^w)$ by reduction of the transitive closure problem to all-pairs LCA in dags is also given in [2].

We present two methods of efficiently preprocessing a directed graph on n vertices and m edges in order to answer an LCA query for any pair of vertices in constant time, subsuming the previously known best results from [2].

The first method is surprisingly natural and solves the all-pairs LCA problem for the input dag on n vertices and m edges in time $O(nm)$. For sparse dags, this method is optimal and substantially faster than the known $O(n^{\frac{w+3}{2}})$ -time general method from [2]. As a corollary, we obtain an $O(n^2)$ -time algorithm for finding genealogical distances considerably improving the previously known $O(n^{2.575})$ time-bound for this problem [2].

The second method efficiently reduces the all-pairs LCA problem to the problem of finding maximum (index) witnesses for Boolean matrix product. We solve the latter problem and hence also the all-pairs LCA problem in time $O(n^{2+\frac{1}{4-\omega}})$. Since $2 + \frac{1}{4-\omega} \approx 2.616$ and $\frac{w+3}{2} \approx 2.688$, our result subsumes the previously known $O(n^{\frac{w+3}{2}})$ time-bound for the general all-pairs LCA problem in dags [2].

The first and second methods are respectively described in Sections 2 and 3 whereas Section 4 presents the algorithm for finding genealogical distances. Our paper concludes with final remarks.

2 Optimal Method for Sparse Dags

First, we shall describe preprocessing for answering queries about existence of a common ancestor for arbitrary pair of vertices in constant time.

For the input dag, we shall denote by n and m its number of vertices and edges, respectively. Also for a vertex v in the dag, $indeg(v)$ and $outdeg(v)$ stand respectively for the in-degree and out-degree of v . If $outdeg(v) = 0$ then v is called a *terminal vertex* and if $indeg(v) = 0$ then v is called a *source vertex*.

We may assume without loss of generality that the input dag is connected since otherwise we can decompose it into connected components and solve the

problem for each component separately. For technical reasons, we shall also assume that every vertex is its own ancestor.

The following lemma immediately follows from the definition of a dag.

Lemma 1. *If two vertices have a common ancestor then there is a source vertex that is their common ancestor.*

In the first stage of the preprocessing, for each vertex of the input dag we form a table containing its descendants. In other words, we create the transitive closure of the dag which obviously can be done in time $O(nm)$. For the sake of Section 4, we describe this stage in more details below.

We initialize the tables in time $O(n^2)$ and start from the terminal vertices, filling their tables with single vertices in time $O(n)$. Next we iterate the following step: remove the vertices of out-degree 0 with incident edges and fill the tables for the new vertices v of out-degree 0 by merging the information from the tables associated with the removed direct descendants of v , and taking into account the set of direct descendants of v . We also add v to its table. For each vertex v such an operation takes time $O(n) \times outdeg(v)$. Thus, for the whole graph it takes $O(nm)$ time.

Lemma 2. *The tables of descendants for all vertices can be formed in time $O(nm)$.*

In the second stage of the preprocessing, we determine for each vertex v the set of vertices which have a common ancestor with v . We proceed similarly as in the first stage of preprocessing starting from source vertices instead of the terminal ones. For the source vertices s , the sets are already computed, they are just the sets of descendants of s . Next, we iterate the following step: remove the vertices of in-degree 0 with incident edges and fill the tables for the new vertices v of in-degree 0 by merging the information from the tables associated with the removed direct ancestors of v . For each vertex v such an operation takes time $O(n) \times indeg(v)$. Thus, for the whole graph it takes $O(nm)$ time.

By the *height* of a vertex v in a dag, we shall mean the length of the longest path from a source vertex to v in the dag.

Note that the set of vertices having a common ancestor with a vertex v is the union of the sets of vertices having common ancestors with the ancestors of v (recall that v is also an ancestor of itself). Hence, we obtain the following lemma by induction on the height of v .

Lemma 3. *For all vertices v , the tables of vertices having a common ancestor with v can be computed in time $O(nm)$.*

In order to answer LCA queries we need to refine the preprocessing slightly. During the second descending phase of the preprocessing we additionally enumerate the vertices in their visiting order. Since an ancestor is always visited before its descendant, we obtain the following lemma.

Lemma 4. *A vertex of a higher number cannot be an ancestor of a vertex of a lower number.*

For all vertices v , in the table keeping vertices w having a common ancestor with v , we keep also the maximum of the numbers assigned to the common ancestors of v and w . To achieve this, when we merge the information from the tables of direct ancestors of v , we pick the maximum number of a common ancestor of a direct ancestor of v and w . Clearly, the refinement can be accomplished within the same asymptotic time $O(mn)$. By induction, we obtain the following lemma.

Lemma 5. *For all vertices v , the tables of vertices w having a common ancestor with v with a pointer to a lowest common ancestor of v and w can be computed in time $O(nm)$.*

Hence, we obtain immediately the following theorem.

Theorem 1. *A dag on n vertices and m edges can be preprocessed for constant-time LCA queries in time $O(nm)$.*

If $m = O(n)$ then the preprocessing is optimal.

Corollary 1. *The all-pairs LCA problem for a dag on n vertices and m edges can be solved in time $O(n(n + m))$.*

3 $O(n^{2+\frac{1}{4-\omega}})$ -Time Method for General Dags

If an entry $C[i, j]$ of the Boolean product of two Boolean matrices A and B is equal to 1 then any index k such that $A[i, k]$ and $B[k, j]$ are equal to 1 is a *witness* for $C[i, j]$. If k is the largest possible witness for $C[i, j]$ then it is called the *maximum witness* for $C[i, j]$.

In [3], Galil and Margalit presented an $O(n^{\omega+\epsilon})$ -time method for the problem of computing witnesses for all positive entries of the Boolean product of two $n \times n$ Boolean matrices. Their method (too involved to describe shortly) can be viewed as a sequence of algorithms for a generalization of the problem. The first algorithm corresponds to the straightforward cubic method testing all the n witness possibilities for each positive entry of the product. The consecutive algorithms partition the input into blocks. Next, they use the fast algorithm for Boolean matrix product to compute the product of the blocks pairwise, and use the resulting products to partition the problem into subproblems. In the subproblems, for a row of the first input matrix and a column of the second input matrix, only an unique index fragment induced by the block partition and containing a witness is considered. The subproblems are solved recursively by permuting rows and columns and using the previous algorithms from the sequence.

Only the first two algorithms in the sequence of algorithms constructed by their recursive method do not rely on row and column permutations. Therefore, the method does not seem adaptable to produce the maximum witnesses without altering its asymptotic time.

Fig. 2. The relationship between A'_{rp} s, B'_{pq} s and C'_{rq} s

Our method for maximum witnesses of the Boolean product C of two $n \times n$ Boolean matrices A and B can be viewed as a modification of the second of the algorithms for witnesses of C in the aforementioned sequence of algorithms from [3].

Let l be a positive integer smaller than n . Partition the matrices A and B into $l \times l$ sub-matrices A_{rq}, B_{rq} , where $1 \leq r, q \leq n/l$, such that for $1 \leq r \leq n/l$, the sub-matrices $A_{rq}, 1 \leq q \leq n/l$, cover the rows $(r - 1)l + 1$ through rl of A whereas for $1 \leq q \leq n/l$, the sub-matrices $B_{rq}, 1 \leq r \leq n/l$, cover the columns $(q - 1)l + 1$ through ql of B .

For $1 \leq r, q \leq n/l, p = 1, \dots, n/l$, compute the Boolean product C^p_{rq} of A_{rp} and B_{pq} using the fast algorithm. The following remark is straightforward.

Remark. Suppose that the (i, j) entry of the product matrix C is positive and $(r - 1)l < i \leq rl$ and $(q - 1)l < j \leq ql$. Let p' be the maximum value of p such that the entry of C^p_{rq} which is the dot product of the row of A_{rp} corresponding to the i -th row of A and the column of B_{pq} corresponding to the j -th column of B is 1. The maximum witness of the (i, j) entry of the Boolean product of A and B belongs to the interval $[(p' - 1)l + 1, p'l]$.

By this remark, after computing all the products $C^p_{rq}, 1 \leq p, r, q \leq n/l$, we need $O(l)$ time per positive entry of C to find the maximum witness. Thus, the total time taken by our method for maximum witnesses is $O((\frac{n}{l})^3 l^\omega + n^2 l)$.

By solving the equation $(\frac{n}{l})^3 l^\omega = n^2 l$, we conclude that for $l = n^{\frac{1}{4-\frac{1}{\omega}}}$ our method achieves minimum worst-case time complexity at $O(n^{2+\frac{1}{4-\frac{1}{\omega}}})$. Hence, we obtain the following theorem.

Theorem 2. *The maximum witnesses for all positive entries of the Boolean product of two $n \times n$ Boolean matrices can be computed in time $O(n^{2+\frac{1}{4-\frac{1}{\omega}}})$.*

The following obvious lemma leads to an efficient reduction of the problem of all pairs LCA in a dag to that of determining maximum witnesses of the Boolean product of two Boolean matrices.

Lemma 6. *Let G be a dag and let G^* be its transitive closure. For vertices u, v in G , let w be its common ancestor of highest rank among all common ancestors*

of u and v in the ordering resulting from a topological sort of G^* . The vertex w is a lowest common ancestor of u and v .

Our algorithm for all pairs LCA in a dag is as follows.

Algorithm 1

1. Compute the transitive closure of the input dag G .
2. Topologically sort the vertices of G and number them by their ranks in the resulting sorting order.
3. Form two Boolean $n \times n$ matrices A and B such that for $i, k \in \{1, \dots, n\}$ the k -th coordinate of the i -th row of A and the i -th column of B is set to 1 if the k -th vertex is an ancestor of the i -th vertex, or $k = i$, otherwise these two coordinates are set to 0.
4. Find maximum witnesses for the Boolean product C of A and B and for each non-zero entry $C[i, j]$ output the vertex whose number is the index of maximum witness of $C[i, j]$ as the lowest common ancestor of the i -th and j -th vertices.

The correctness of the algorithm follows from Lemma 6. Step 1 can be implemented in time $O(n^\omega)$. Steps 2 and 3 take $O(n^2)$ time. Finally, Step 4 requires $O(n^{2+\frac{1}{4-\epsilon}})$ time by Theorem 2. Hence, we obtain our second main result.

Theorem 3. *For a dag on n vertices, we can determine for each pair of vertices having a common ancestor their lowest common ancestor in time $O(n^{2+\frac{1}{4-\epsilon}})$.*

4 Shortest Genealogical Distances

The authors of [2] discuss the so called *pedigree graphs* which are sparse dags used to model human ancestor relations. Since each human has at most two parents, a pedigree graph has maximum in-degree bounded by two. For the fundamental applications of pedigree graphs in the identification of genes associated with genetic diseases the reader is referred to [4, 6]. In these applications, computing the so called *shortest ancestral distance* between a pair of vertices in a pedigree graph is important [2]. The shortest ancestral distance between two vertices u and v in a dag is defined as the length of a shortest path between u and v which passes through a common ancestor of u and v (observe that the common ancestor is not necessarily the lowest one ¹). Bender et al. showed that the all-pairs shortest ancestral distances can be computed in time $O(n^{2.575})$ [2]. In this section, we show that the all-pairs shortest ancestral distances can be optimally computed for sparse dags, in particular, pedigree graphs.

¹ One can also consider the so called shortest ancestral lca distance where the common ancestor is required to be lowest [2].

We can modify our first method to obtain an $O(mn)$ -time algorithm to compute the all-pairs shortest ancestral distances as follows. In the ascending phase, for each vertex v , and for each descendent u of v , we additionally compute the shortest directed distance between u and v . This can be easily accomplished within the same asymptotic time $O(mn)$. At the beginning of the descending phase, the previously computed shortest directed distances yield the shortest ancestral distances between sources and their descendents. While descending the shortest ancestral distances between the parents of the current vertex v and each other vertex u are increased by one. Next, the minimum of them and the shortest directed distance between v and u (it can be infinite) is taken as the shortest ancestral distance between v and u . In this way for all pairs of vertices v and u the shortest ancestral distance is computed.

Similarly, the so modified descending phase can be also implemented in time $O(mn)$. We conclude with the following theorem.

Theorem 4. *For a dag on n vertices and m edges, the all-pairs shortest ancestral distances can be computed in time $O(nm)$.*

Corollary 2. *For a pedigree graph on n vertices, the all-pairs shortest ancestral distances can be computed in time $O(n^2)$.*

5 Final Remarks

The problems of finding LCA are classical and central in the area of algorithms and data structures [2, 5, 7]. In spite of the long history of studies devoted to LCA problems, we have succeeded to design two quite natural methods for finding LCA in dags considerably subsuming the previously known best results [2].

The problem of finding maximum witnesses of Boolean matrix product seems to be of interest in its own rights. At first glance it seems that the recursive $O(n^{\omega+\epsilon})$ -time method of Galil and Margalit [3] could be adapted to produce the maximum witnesses by considering the fragments containing maximum witnesses in the subproblems without substantially altering its asymptotic time. However, the aforementioned method may permute rows or columns in recursive steps which may disturb the search for maximum witnesses. Thus, the problem of whether or not our $O(n^{2+\frac{1}{4}-})$ -time method is optimal is open.

It is also an interesting question whether or not the instances of the problem of finding maximum witnesses of Boolean matrix product occurring in our reduction from the LCA problem in dags are computationally easier than the general ones.

Replacement Paths and k Simple Shortest Paths in Unweighted Directed Graphs

Liam Roditty and Uri Zwick

School of Computer Science,
Tel Aviv University, Tel Aviv 69978, Israel

Abstract. Let $G = (V, E)$ be a *directed* graph and let P be a shortest path from s to t in G . In the *replacement paths* problem we are required to find, for every edge e on P , a shortest path from s to t in G that avoids e . We present the first non-trivial algorithm for computing replacement paths in unweighted directed graphs (and in graphs with small integer weights). Our algorithm is Monte-Carlo and its running time is $\tilde{O}(m\sqrt{n})$. Using the improved algorithm for the replacement paths problem we get an improved algorithm for finding the k *simple* shortest paths between two given vertices.

1 Introduction

Let $G = (V, E)$ be a graph, let $s, t \in V$ be two vertices in G , and let P be a shortest path from s to t in G . In certain scenarios, edges in the graph G may occasionally fail, and we are thus interested in finding, for every edge e on the path P , the shortest path from s to t in G that avoids e . This problem is referred to as the *replacement paths* problem.

The replacement paths problem for *undirected* graphs is a well studied problem. An $O(m + n \log n)$ time algorithm for the problem was given by Malik *et al.* [13]. A similar algorithm was independently discovered, much later, by Hershberger and Suri [7]. Hershberger and Suri [7] claimed that their algorithm also works for directed graphs, but this claim turned out to be false (see Hershberger and Suri [8]). Nardelli *et al.* [14] gave an $O(m\alpha(m, n))$ time algorithm for the undirected version of the problem using the linear time single source shortest paths algorithm of Thorup [18].

All the results mentioned above for the replacement paths problem work only for undirected graphs. This situation is partially explained by an $\Omega(m\sqrt{n})$ lower bound for the replacement paths problem for directed graphs in the *path-comparison* model of Karger *et al.* [10] given by Hershberger *et al.* [9].

The replacement paths problem in directed graphs can be trivially solved in $O(|P|(m + n \log n)) = O(mn + n^2 \log n)$ time by removing each edge on P from the graph and finding a shortest path from s to t . No faster algorithm for the problem was previously known.

The replacement paths problem in directed graphs is strongly motivated by the following applications:

The fastest algorithm to compute a set of k simple shortest paths in a directed graph uses in each iteration a replacement paths algorithm. This algorithm which was given independently by Yen [20] and Lawler [12], has a running time of $O(kn(m + n \log n))$. An $o(mn)$ algorithm for the replacement paths problem implies immediately on $o(mn)$ algorithm for the k simple shortest paths problem.

The second motivation for studying replacement paths is the *Vickrey pricing* of edges. Suppose we like to find the shortest path from s to t in a directed graph G in which edges are owned by selfish agents. As noted by Nisan and Ronen [15], a mechanism that offers to pay $d_{G|e=\infty}(s, t) - d_{G|e=0}(s, t)$ to the owner of edge e , for any edge e on the shortest path from s to t , and zero otherwise, forces the edge owners to reveal their true cost. This kind of pricing is called *Vickrey pricing*. Computing the first quantity for every edge in the graph is equivalent to computing the replacement paths between s and t . (For further details see Hershberger and Suri [7] and Demetrescu *et al.* [4]).

We present here the first non-trivial algorithm for the replacement paths problem in directed graphs. It improves immediately the running time of the two applications mentioned above. Our algorithm is randomized and its running time is $\tilde{O}(m\sqrt{n})$ time. This seemingly matches the lower bound of Hershberger *et al.* [9]. Unfortunately, our algorithm works only for unweighted directed graphs, or directed graphs with small integer weights, while the lower bound of [9] is for generally weighted directed graphs.

One of the ingredients used in our algorithm for the replacement paths problem is a simple sampling technique used before to develop parallel algorithms (Ullman and Yannakakis [19]), static algorithms (Zwick [21]) and dynamic algorithms (Henzinger and King [6], Baswana *et al.* [1, 2] Roditty and Zwick [17, 16]) for paths problems. This technique on its own, however, does not supply an improved algorithm for the replacement paths problems and other ideas are needed.

Demetrescu and Thorup [3] considered the more general problem of finding, for every pair of vertices $u, v \in V$ and every edge $e \in E$, a shortest path from u to v that avoids e . They devise a data structure of size $O(n^2 \log n)$ capable of answering each such query in $O(\log n)$ time. The preprocessing time needed for constructing this data structure is, however, $\tilde{O}(mn^2)$. The preprocessing time can be reduced to $\tilde{O}(mn^{1.5})$ at the price of increasing the size of the data structure to $O(n^{2.5})$. (For a recent improvement, see Demetrescu *et al.* [4].)

We also consider two variants of the replacement paths problem. Assume again that $G = (V, E)$ is a directed graph and that P is a shortest path from s to t in G . In the *restricted replacement paths* problem, we are required to find, for every edge $e = (u, v)$ on the path P , a shortest path from u to t in G that avoids e . This corresponds to a scenario in which the failure of the edge $e = (u, v)$ is only detected at u (see Figure 1(b) for example). In the *edge replacement paths* problem we are required to find, for every edge $e = (u, v)$ on the path P , a shortest path from u to v in G that avoids e , (see Figure 1(c) for example). Our $\tilde{O}(mn^{1/2})$ time algorithm for the replacement paths problem can be adapted to solve these two versions of the problem.

Fig. 1. Three detours and the auxiliary graph used to find short detours

We next turn our attention to the k shortest paths problem. Given a graph $G = (V, E)$, two vertices $s, t \in V$ and an integer k , we are required to find the k shortest paths from s to t in G . Eppstein [5], gave an $O(m + n \log n + k)$ time algorithm for the directed version of the problem. However, the paths returned by Eppstein’s algorithm are not necessarily simple. i.e., they may visit certain vertices more than once. In the k simple shortest paths problem, the paths returned should all be simple. Katoh *et al.* [11] gave an $O(k(m + n \log n))$ time algorithm for solving the k simple shortest paths problem for undirected graphs. Yen [20] and Lawler [12] gave an $O(kn(m + n \log n))$ time algorithms for solving the problem for directed graphs. It is interesting to note that, as for the replacement paths problem, the directed version of the problem seems to be much harder than the undirected version. Using our $\tilde{O}(m\sqrt{n})$ time algorithm for the replacement paths problem we obtain a randomized $\tilde{O}(km\sqrt{n})$ time algorithm for the k simple shortest paths problem for unweighted directed graphs and for directed graphs with small integer weights.

We also show that computing the k simple shortest paths can be reduced to $O(k)$ computations of a *second* simple shortest path between s and t , each time in a different subgraph of G . Thus, to obtain an $o(kmn)$ time algorithm for the k simple shortest paths problem it is enough to obtain an $o(mn)$ time algorithm for the second shortest path problem.

The rest of this extended abstract is organized as follows. In the next section we describe our replacement paths algorithm and its adaption to the different variants of the replacement paths problem mentioned above. In Section 3 we show that the k simple shortest paths between two given vertices can be found by at most $2k$ invocations of an algorithm for finding the second shortest path between a given pair of vertices. As the second simple shortest path can be trivially found by solving the replacement paths problem, we obtain an $\tilde{O}(km\sqrt{n})$ time algorithm for the k simple shortest paths problem for unweighted graphs. We end in Section 4 with some concluding remarks and open problems.

2 Replacements Paths

In this section we describe an algorithm for solving the replacement paths problem for unweighted directed graphs and directed graphs with small integer weights. Let $G = (V, E)$ be a directed graph and let s and t be two vertices in the graph. Let $P(s, t) = \langle u_0, u_1, \dots, u_\ell \rangle$ be a shortest path from $s = u_0$ to $t = u_\ell$. Let $P^E(s, t) = \langle (u_0, u_1), (u_1, u_2), \dots, (u_{\ell-1}, u_\ell) \rangle$ be the set of edges of

this path. The objective of a replacement path algorithm is to find for every edge $e \in P^E(s, t)$ a shortest path $P'(s, t)$ in the graph $G_e = (V, E \setminus \{e\})$.

We start by defining detours:

Definition 1 (Detours). Let $P(s, t)$ be a simple path from s to t . A simple path $D(u, v)$ is a detour of $P(s, t)$ if $D(u, v) \cap P(s, t) = \{u, v\}$ and u precedes v on $P(s, t)$.

Three detours of a shortest path from s to t are depicted in Figure 1. A shortest path from s to t that avoids the edge (u_i, u_{i+1}) of the shortest path $P(s, t) = \langle u_0, u_1, \dots, u_\ell \rangle$ is composed of an initial portion $\langle u_0, u_1, \dots, u_j \rangle$ of P , where $0 \leq j \leq i$, a detour $D(u_j, u_{j'})$, where $i + 1 \leq j' \leq \ell$, and then the final portion $\langle u_{j'}, \dots, u_\ell \rangle$ of P .

Let L be a parameter to be chosen later. A detour is said to be *short* if its length is at most L . Otherwise, it is said to be *long*. (Note that we are considering here only the length of the detour, not the total length of the resulting path from s to t . For example, the detour in Figure 1(a) is longer than the one in Figure 1(b), but the resulting paths may have the same length.)

We find separately the best short detours and the best long detours. The short detours are found in Section 2.1 in $\tilde{O}(mL)$ time. The long ones are found in Section 2.2 in $\tilde{O}(mn/L)$ time. Setting $L = \sqrt{n}$, we get that the running time of both algorithms is $\tilde{O}(m\sqrt{n})$. By choosing for every edge the best short or long detour, we obtain all the optimal replacement paths.

2.1 Finding Short Detours

We now describe an $\tilde{O}(mL)$ time algorithm for finding the best detours of length at most L . We can easily find the best detours that start in a given vertex u on the shortest path $P(s, t)$ by running the BFS algorithm from u in the graph $G - P^E$. However, doing so from each vertex on P may require n BFS computation which is too time consuming. The main observation made in this Section is that if v_0, v_1, \dots, v_k are vertices on $P(s, t)$ that are at a distance of at least $2L$ apart from each other, then the best short detours from all these vertices can be found by one run of Dijkstra’s algorithm on a suitably modified graph. Thus, $O(L)$ runs suffice to find all short detours.

More specifically, to find the best detours from the vertices $u_0, u_{2L}, \dots, u_{2kL}$, where $k = \lfloor \frac{\ell}{2L} \rfloor$, we consider the graph $G - P^E$ to which we add a new source vertex r and an edge (r, u_{2iL}) of weight iL , for every $0 \leq i \leq k$. The weight of all the edges of $E - P^E$ is set to 1. We denote the weight function of the auxiliary graph with w_t . Note that the weight assigned to the edge (r, u_{2iL}) is iL , and not $2iL$ as might have been expected. Also, note that even though we are interested in detours that are of length at most L , the distance between every two selected vertices should be at least $2L$. The reason to that will become clear in the proof of Theorem 1. The resulting auxiliary graph, which we denote by G^A , is depicted in Figure 1.

We claim that by running Dijkstra’s algorithm, from r , on G^A we find all the best short detours that start in one of the selected vertices. We then run this

<pre> algorithm ShortDet(P, b, L) $\langle u_0, u_1, \dots, u_\ell \rangle \leftarrow P$ $V' \leftarrow V \cup \{r\}$ $E' \leftarrow E \setminus P^E$ for each $e \in E'$ do $wt(e) \leftarrow 1$ for $i \leftarrow 0$ to $\lfloor (\ell - b)/(2L) \rfloor$ $E' \leftarrow E' \cup \{(r, u_{2iL+b})\}$ $wt(r, u_{2iL+b}) \leftarrow iL$ $\delta' \leftarrow \text{Dijkstra}(r, (V', E', wt))$ for $i \leftarrow 0$ to $\lfloor (\ell - b)/(2L) \rfloor$ $g \leftarrow 2iL + b$ for $j \leftarrow 1$ to L if $\delta'(r, u_{g+j}) \leq (i+1)L$ then $RD[g, j] \leftarrow \delta'(r, u_{g+j}) - iL$ else $RD[g, j] \leftarrow \infty$ </pre>	<pre> algorithm ShortRepPath(P, L) $\langle u_0, u_1, \dots, u_\ell \rangle \leftarrow P$ for $b \leftarrow 0$ to $2L - 1$ ShortDet(P, b, L) $Q \leftarrow \phi$ for $i \leftarrow 0$ to $\ell - 1$ for $j \leftarrow i + 1$ to $\min\{i + L, \ell\}$ $\text{Insert}(Q, (i, j), RD[i, j - i] + i + \ell - j)$ for $j \leftarrow \max\{i - L, 0\}$ to $i - 1$ $\text{Delete}(Q, (j, i))$ $(a, b) \leftarrow \text{findmin}(Q)$ $len \leftarrow RD[a, b - a] + a + \ell - b$ $RP[i] \leftarrow \langle len, a, b \rangle$ </pre>
--	---

Fig. 2. The algorithm for finding short detours and short replacement paths

algorithm $2L - 1$ more times to find short detours emanating from the other vertices of $P(s, t)$. In the i -th run we find the short detours emanating from one of the vertices $u_i, u_{2L+i}, \dots, u_{2kL+i}$.

We let $\delta(u, v)$ denote the distance from u to v in the graph G . We let $\delta^-(u, v)$ denote the distance from u to v in the graph $G - P^E$, i.e., the graph G with the edges of the path P removed. (The minus sign is supposed to remind us that the edges of P are removed from the graph.) We let $\delta^A(u, v)$ denote the distance from u to v in the auxiliary graph G^A . We now claim:

Theorem 1. *If $\delta^A(r, u_{2iL+j}) \leq (i+1)L$, where $0 \leq i \leq k$ and $1 \leq j \leq L$, then $\delta^-(u_{2iL}, u_{2iL+j}) = \delta^A(r, u_{2iL+j}) - iL$. Otherwise, $\delta^-(u_{2iL}, u_{2iL+j}) > L$.*

Proof. For brevity, let $v_i = u_{2iL}$ and $v_{ij} = u_{2iL+j}$. Assume at first that $\delta^A(r, v_{ij}) \leq (i+1)L$. Consider a shortest path from r to v_{ij} in G^A . Let (r, v_q) be the first edge on the path. If $q < i$, then we have

$$\begin{aligned} \delta^A(r, v_{ij}) &= qL + \delta^-(v_q, v_{ij}) \geq qL + 2(i-q)L + j \\ &= (2i-q)L + j \geq (i+1)L + j > (i+1)L, \end{aligned}$$

a contradiction. Note that if the distance between any v_i and v_{i+1} was L instead of $2L$ then for $q < i$ we do have $\delta^A(r, v_{ij}) \leq (i+1)L$.

Similarly, if $q > i$ then we again have $\delta^A(r, v_{ij}) = qL + \delta^-(v_q, v_{ij}) > (i+1)L$. Thus, we must have $q = i$ and $\delta^A(r, v_{ij}) = iL + \delta^-(v_i, v_{ij})$, as required.

On the other hand, if $\delta^-(v_i, v_{ij}) \leq L$, then clearly

$$\delta^A(r, v_{ij}) \leq wt(r, v_i) + \delta^-(v_i, v_{ij}) \leq iL + L = (i + 1)L,$$

as required. □

A description of the resulting algorithm, which we call **ShortDet** is given in Figure 2. By running the algorithm with the parameter b ranging from 0 to $2L - 1$ we find, for every vertex on the path, the best short detours starting at it. This information is gathered in the table RD .

The entry $RD[i, j]$ gives us the length of the shortest detour starting at u_i and ending at u_{i+j} , if that length is at most L . To find the shortest path from s to t that avoids the edge (u_i, u_{i+1}) and uses a short detour, we need to find indices $i - L \leq a \leq i$ and $i < b \leq i + L$ for which the expression

$$\delta(s, u_a) + \delta^-(u_a, u_b) + \delta(u_b, t) = a + RD[a, b - a] + (\ell - b)$$

is minimized. An algorithm, called **ShortRepPath**, for finding such replacement paths is given in Figure 2. Algorithm **ShortRepPath** uses a priority queue Q . When looking for the shortest replacement path for the edge (u_i, u_{i+1}) , the priority queue Q contains all pairs (a, b) such that $i - L \leq a \leq i$ and $i < b \leq i + L$. The key associated with a pair (a, b) is naturally $a + RD[a, b - a] + (\ell - b)$. In the start of the iteration corresponding to the edge (u_i, u_{i+1}) , we insert the pairs (i, j) , for $i + 1 \leq j \leq i + L$ into Q , and remove from it the pairs (j, i) , for $i - L \leq j \leq i$. A *findmin* operation on Q then returns the minimal pair (a, b) . It is easy to see that the complexity of this process is only $\tilde{O}(nL)$. Thus, the total running time of the algorithm is $\tilde{O}(mL)$, as required. We have thus proved:

Theorem 2. *Algorithm ShortRepPath finds all the shortest replacement paths that use short detours. Its running time is $\tilde{O}(mL)$.*

2.2 Finding Long Detours

To find long detours, i.e., detours that are of length at least L , we use the following simple sampling lemma. (To the best of our knowledge, it was not used before in the context of finding replacement paths).

Lemma 1. *Let $D_1, D_2, \dots, D_q \subseteq V$ such that $|D_i| \geq L$ for $1 \leq i \leq q$ and $|V| = n$. If $R \subseteq V$ is a random subset obtained by selecting each vertex, independently, with probability $(c \ln n)/L$, for some constant c , then with probability of at least $1 - q \cdot n^{-c}$ we have $D_i \cap R \neq \emptyset$ for every $1 \leq i \leq q$.*

For every pair of vertices u and v on the path P for which the shortest detour from u to v is of length at least L , let $D(u, v)$ be such a shortest detour. By the lemma, if R is a random set as above, then with a probability of at least $1 - n^{2-c}$ we have $D(u, v) \cap R \neq \emptyset$, for every such pair u and v . The choice of the random set R is the only randomization used by our algorithm.

Our algorithm for finding the best replacement paths that use long detours starts by calling $sample(V, (4 \ln n)/L)$ which selects a random set R in which each vertex $v \in V$ is placed, independently, with probability $(4 \ln n)/L$. The expected size of R is clearly $\tilde{O}(\frac{n}{L})$. We assume, throughout the section, that $D(u, v) \cap R \neq \emptyset$, whenever $|D(u, v)| \geq L$.

For every sampled vertex $r \in R$, the algorithm maintains two priority queues $Q_{in}[r]$ and $Q_{out}[r]$ containing indices of vertices on P . When looking for a replacement path for the edge (u_i, u_{i+1}) we have $Q_{in}[r] = \{0, 1, \dots, i\}$ and $Q_{out}[r] = \{i+1, \dots, \ell\}$. The key associated with an element $j \in Q_{in}[r]$ is $j + \delta^-(u_j, r)$. The key associated with an element $j \in Q_{out}[r]$ is $\delta^-(r, u_j) + (\ell - j)$.

Recall that $\delta^-(u, v)$ is the distance from u to v in $G - P^E$. The algorithm computes $\delta^-(r, v)$ and $\delta^-(v, r)$, for every $r \in R$ and $v \in V$, by running two BFS's from r , for each $r \in R$, one in $G - P^E$ and one in the graph obtained from $G - P^E$ by reversing all the edges. (Only one of these BFS's is explicitly mentioned in **LongRepPath**.) The total running time of computing these distances is $\tilde{O}(mn/L)$.

To find the shortest replacement path for the edge (u_i, u_{i+1}) that passes through a given vertex $r \in R$, the algorithm needs to find an index $0 \leq a \leq i$ which minimizes the expression $a + \delta^-(u_a, r)$, and an index $i < b \leq \ell$ which minimizes the expression $\delta^-(r, u_b) + (\ell - b)$. The minimizing index a is found by a *findmin* operation on $Q_{in}[r]$ and the minimizing index b is found by a *findmin* operation on $Q_{out}[r]$.

It is not difficult to check that the total running time of the algorithm is $\tilde{O}(mn/L)$, as required. We have thus proved:

Theorem 3. *Algorithm LongRepPath finds, with very high probability, all the shortest replacement paths that use long detours. Its running time is $\tilde{O}(mn/L)$.*

2.3 The Replacement Paths Algorithm and Its Variants

The algorithms **ShortRepPath** and **LongRepPath** find the best short and long replacement paths available to bypass every edge on a given shortest path. By passing on their output and picking the minimal path found for every edge we obtain the solution for the replacement paths problem as promised.

There are another two natural variants of replacement paths that can be solved by our short and long detours detection.

Let $G = (V, E)$ be a directed graph and let P be a shortest path from s to t in G . In the *restricted replacement paths* problem, we are required to find, for every edge $e = (u, v)$ on the path P , a shortest path from u to t in G that avoids e . This corresponds to a scenario in which the failure of the edge $e = (u, v)$ is only detected at u . In the *edge replacement paths* problem we are required to find, for every edge $e = (u, v)$ on the path P , a shortest path from u to v in G that avoids e .

To solve the above two problems the main idea of short and long detours remains unchanged. The only change is in the set from which we choose the best

detour to be used to bypass a given edge. This set is now updated according to the structural restrictions given by the problem definition.

For the restricted replacement paths after finding the short detours by the algorithm **ShortDet** we maintain the heap subject to the following constraint: If we currently searching for a restricted replacement path to bypass the edge (u_i, u_{i+1}) the heap contains only detours that emanate from u_i .

In a similar manner, when searching for a restricted replacement path composed from a long detour to bypass the edge (u_i, u_{i+1}) we use only detours that emanate from u_i . Thus, we only need one heap for this process. A pseudo-code of the algorithm will be given in the full version of this paper. We claim:

Theorem 4. *Algorithm ResRepPath, with $L = \sqrt{n}$, finds, with very high probability, all the restricted shortest replacement paths. Its running time is $\tilde{O}(m\sqrt{n})$.*

Using similar constraints on the set from which paths are picked we can adapt our ideas to solve also the edge replacement paths problem.

3 The k Simple Shortest Paths Problem

The k simple shortest paths problem (also known as the k shortest loopless paths) is a fundamental graph theoretic problem. Let $G = (V, E)$ be a directed graph and let s and t be two vertices of the graph. Let k be an integer. The target is to find the k simple shortest paths from s to t . This version of the problem is considered to be much harder than the general version in which non-simple paths (i.e. paths that may contain a loop) are allowed to be among the k shortest paths. The k shortest non-simple paths can be computed in time of $O(m + n \log n + k)$ using an algorithm of Eppstein [5]. In cases that a shortest paths tree can be computed in $O(m + n)$, Eppstein's algorithm has a running time of $O(m + n + k)$. However, the running time of the restricted problem is much worse. The best algorithm is due to Yen [20] and Lawler [12]. It has a running time of $O(kn(m + n \log n))$.

In this section we show that for unweighted directed graphs (and for graphs with small integer weights) the running time of $O(kn(m + n \log n))$ can be significantly improved using our new replacement paths algorithm. We obtain a randomized algorithm with running time of $O(km\sqrt{n} \log n)$.

We also reduce the problem of computing k simple shortest paths to $O(k)$ computations of a second shortest path each time in a different subgraph of G . This reduction works in weighted graphs. Both Yen [20] and Lawler [12] use $O(k)$ computations of replacement paths. Our reduction implies that we can focus our efforts in improving the second shortest path algorithm, which may turn out to be an easier problem than the replacement paths problem. We only deal in this section with simple paths thus we refer to a simple path simply by saying a path.

The algorithm for computing k shortest paths works as follow. It maintains a priority queue Q of paths from s to t . The key attached with each path is its length. The algorithm preforms k iterations. The priority queue is initialized

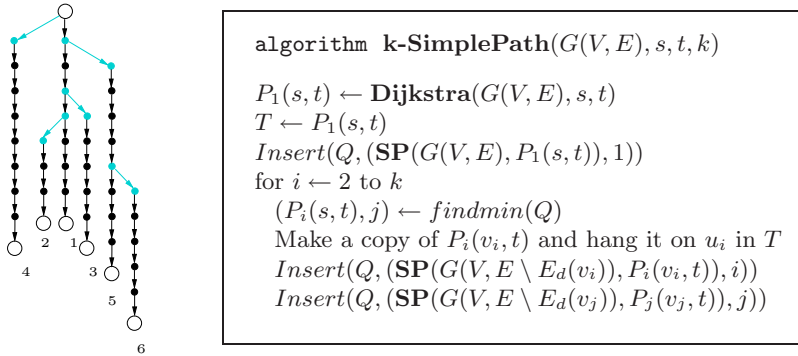

Fig. 3. A deviations tree and our k -simple shortest paths algorithm

with a second shortest path of a shortest path from s to t . In the i -th iteration the algorithm picks from Q the path with the minimal length and remove it. Let $P_i(s, t) = \langle s, u_1, \dots, u_{\ell-1}, t \rangle$ be the i -th path picked by the algorithm. This path is added to the output as the i -th shortest path. To describe the output structure we need the following definition:

Definition 2 (Deviation edge and Deviations tree). For $k = 1$ the deviations tree is simply a copy of a shortest path from s to t . Suppose that the tree already exists for $i - 1$ paths. Let $P_i(s, t) = \langle s, u_1, \dots, u_\ell \rangle$ be the i -th shortest path to be output. Let $P_i(s, u_j)$ be the longest subpath of $P_i(s, t)$ that was already part of the output and thus part of the tree. We make a copy only from $P_i(u_{j+1}, t)$ and hang it on the copy of u_j in the tree. We say that the edge (u_j, u_{j+1}) is the deviation edge of $P_i(s, t)$.

Note that by this definition a vertex may have more than one occurrence in the deviations tree. However, there are at most k copies of each vertex in the deviations tree, thus, the size of the tree is $O(kn)$. An example of a deviations tree is given in Figure 3. The deviation edges are in light color.

The main challenge is to quickly obtain the paths to be added to Q in each iteration. Suppose we have extracted the i -th shortest path $P_i(s, t)$ from Q . After having $P_i(s, t)$ in the deviations tree we need to find the new paths to be added to Q . Let (u_i, v_i) be the deviation edge of $P_i(s, t)$. In Yen’s algorithm the path $P_i(u_i, t) = \langle w_1, w_2, \dots, w_l \rangle$, where $w_1 = u_i$ and $w_l = t$, is scanned. For each vertex $w_j \in P_i(u_i, t)$, the algorithm finds a shortest path $P'(w_j, t)$ from w_j to t which does not use the edge (w_j, w_{j+1}) . In the special case of w_1 the path $P'(w_1, t)$ is obtained when all the edges emanate from the copy of w_1 in the tree are forbidden to use. Each such a path is concatenated to $P_i(s, w_j)$ and added to Q . This is essentially a restricted replacement paths problem for the path $P_i(u_i, t)$. Thus, we can claim the following:

Theorem 5. The algorithm of Yen combined with our restricted shortest paths algorithm computes k simple shortest paths in $\tilde{O}(km\sqrt{n})$ time.

However, this process generates many paths and most of them are not needed. Many of these paths can be ruled out without being actually computed by making just two computations of second shortest paths in the i -th iteration.

Recall that $P_i(s, t)$ is the i -th shortest path extracted from Q and (u_i, v_i) is its deviation edge. Let $E_d(v_i)$ be the set of deviation edges emanate from $P_i(v_i, t)$. We compute a second shortest path for the path $P_i(v_i, t)$ in the graph $G(V, E \setminus E_d(v_i))$, concatenate it to $P_i(s, v_i)$ and add it to Q . This path is associated to $P_i(s, t)$. Note that in the first computation of a second shortest path for $P_i(v_i, t)$ the set $E_d(v_i)$ is empty by its definition. However, we are not done yet. The extracted path $P_i(s, t)$ is associated to some other path $P_j(s, t)$, where $j < i$. Since we have extracted the path associated to $P_j(s, t)$ we need to find a new path, other than $P_i(s, t)$, to associate to $P_j(s, t)$. Let (u_j, v_j) be the deviation edge of $P_j(s, t)$. We compute a second shortest path for the path $P_j(v_j, t)$ in the graph $G(V, E \setminus E_d(v_j))$. By its definition the set $E_d(v_j)$ contains in this stage the deviation edge of $P_i(s, t)$, thus, the resulting second shortest path will be other than $P_i(s, t)$. We concatenate this path to $P_j(s, v_j)$ and add it to Q . The algorithm is given in Figure 3. We assume that the deviation edge of the path $P_i(s, t)$ if exists is (u_i, v_i) . For the path $P_1(s, t)$ we treat s as the head of a deviation edge. We use the algorithm of *Dijkstra* to compute a shortest path from s to t and the algorithm *SP* to compute a second shortest path given a shortest path.

Next, we justify why the extracted path is only associated to one other path or more precisely why a path cannot be added to Q as a second shortest path of two different paths.

Lemma 2. *In any stage all paths in Q are distinct.*

Proof. To the purpose of the proof only we divide the paths of the graph into disjoint sets. Each set is associated with a path which already was picked from Q . The set C_i is associated with the path $P_i(s, t)$. We prove that these sets exist and any second shortest path in Q is associated to a different set. This implies that all paths in Q are distinct.

We set C_1 to be all the paths in the graph. After finding a second shortest path for the first time we divide C_1 into two sets. Let (u_2, v_2) be the deviation edge of $P_2(s, t)$ then C_2 is set to be all the paths from C_1 that have the prefix $P_2(s, v_2)$ and C_1 is set to $C_1 \setminus C_2$. Obviously, C_1 and C_2 are disjoint. Now computing a second shortest path for $P_2(v_2, t)$ and concatenating it with $P_2(s, v_2)$ results in a path from C_2 and computing a second shortest path for the path $P_1(s, t)$ in $G(V, E \setminus E_d(s))$ results in a second shortest path in C_1 . (Note that $E_d(s)$ contains the edge (u_2, v_2) .) Thus, the paths added to Q are from two disjoint sets. We prove by induction that in general it also holds.

Suppose that right before the i -th extraction we have $i - 1$ disjoint sets, such that for any $j \leq i - 1$ the set C_j is associated to $P_j(s, t)$ and a path composed from the concatenation of $P_j(s, v_j)$ and a second shortest path of $P_j(v_j, t)$ in the graph $G(V, E \setminus E_d(v_j))$ is the path in Q from C_j . We show that right before the $i + 1$ -th extraction this invariant still holds. Let $P_i(s, t)$ be the path picked from Q in the i -th extraction. By the induction hypothesis we know that there is a set

C_j , disjoint from all the others, such that $P_i(s, t) \in C_j$ and $P_j(s, t)$ is associated with C_j . Let (u_i, v_i) be the deviation edge of $P_i(s, t)$. We divide C_j into two sets as follow, C_i will have the paths from C_j with the prefix $P_i(s, v_i)$ and C_j is set to $C_j \setminus C_i$. The resulted sets are disjoint. Now computing a second shortest path for $P_i(v_i, t)$ and concatenating it with $P_i(s, v_i)$ results in a path from C_i and computing a second shortest path for the path $P_j(v_j, t)$ in $G(V, E \setminus E_d(v_j))$ and concatenating it with $P_j(s, v_j)$ results in a second shortest path in C_j . In this process the two paths added to Q are from different disjoint sets and the above invariant still holds. \square

It follows that once a path is out of Q only two second shortest path computations have to be done. We now claim the correctness of the algorithm.

Lemma 3. *The algorithm computes k simple shortest paths.*

Proof. The proof is by induction. For $i = 1$ the claim trivially holds. Suppose that the $i - 1$ first paths are found by our algorithm. We prove that the i -th path is found also. Let W be the weight of the i -th shortest path. Let $P_i(s, t)$ be an i -th shortest path. Let (u_i, v_i) be its deviation edge and let $P_j(s, t)$ be the path $P_i(s, t)$ deviates from. We will show that the path $P_i(s, t)$ or other path of the same length must be associated to $P_j(s, t)$.

Let (u', v') be the closest deviation edge to (u_i, v_i) on the path $P_j(s, u_i)$, if exists, or let $v' = s$ otherwise. Consider the last time a second shortest path computation was done for the path $P_j(v', t)$ before the i -th extraction. The weight of the path P obtained in this computation is at most W since all the edges of $P_i(u_i, t)$ are eligible to use. Suppose that the length of P is strictly less than W then by the induction hypothesis the path P is extracted before the i -th extraction. By our algorithm when P is extracted we recompute a second shortest path for $P_j(v', t)$, the path that P was associated to. However, the second shortest path computation that have added P was the last computation done for $P_j(v', t)$ before the i -th extraction, a contradiction. \square

The following Theorem stems from Lemma 2 and Lemma 3.

Theorem 6. *The algorithm described above computes correctly the k simple shortest paths of a directed graph by $O(k)$ computation of second shortest paths.*

4 Concluding Remarks and Open Problems

We presented a randomized $O(m\sqrt{n})$ time algorithm for the replacement paths problem in unweighted graphs and in graphs with small integer weights. Many problems are still open, however. In particular, is it possible to obtain an $o(mn)$ time algorithm for the replacement paths problem in weighted directed graphs? Is it possible to obtain an $o(mn)$ time algorithm for the second simple shortest path in weighted directed graphs. A positive answer to one of these questions will yield an $o(kmn)$ time algorithm for finding the k simple shortest paths problem in weighted directed graphs.

Deterministic Constructions of Approximate Distance Oracles and Spanners

Liam Roditty¹, Mikkel Thorup², and Uri Zwick¹

¹ School of Computer Science, Tel Aviv University, Israel

² AT&T Research Labs, USA

Abstract. Thorup and Zwick showed that for any integer $k \geq 1$, it is possible to preprocess any positively weighted undirected graph $G = (V, E)$, with $|E| = m$ and $|V| = n$, in $\tilde{O}(kmn^{1/k})$ expected time and construct a data structure (a $(2k - 1)$ -approximate distance oracle) of size $O(kn^{1+1/k})$ capable of returning in $O(k)$ time an approximation $\hat{\delta}(u, v)$ of the distance $\delta(u, v)$ from u to v in G that satisfies $\delta(u, v) \leq \hat{\delta}(u, v) \leq (2k - 1) \cdot \delta(u, v)$, for any two vertices $u, v \in V$. They also presented a much slower $\tilde{O}(kmn)$ time deterministic algorithm for constructing approximate distance oracle with the slightly larger size of $O(kn^{1+1/k} \log n)$. We present here a deterministic $\tilde{O}(kmn^{1/k})$ time algorithm for constructing oracles of size $O(kn^{1+1/k})$. Our deterministic algorithm is slower than the randomized one by only a logarithmic factor.

Using our derandomization technique we also obtain the first deterministic linear time algorithm for constructing optimal spanners of weighted graphs. We do that by derandomizing the $O(km)$ expected time algorithm of Baswana and Sen (ICALP'03) for constructing $(2k - 1)$ -spanners of size $O(kn^{1+1/k})$ of weighted undirected graphs without incurring any asymptotic loss in the running time or in the size of the spanners produced.

1 Introduction

Thorup and Zwick [16] showed that for any integer $k \geq 1$, any graph $G = (V, E)$, with $|V| = n$ and $|E| = m$, can be preprocessed in $\tilde{O}(kmn^{1/k})$ expected time, producing an approximate distance oracle of size $O(kn^{1+1/k})$ capable of returning, in $O(k)$ time, a stretch $2k - 1$ approximation of $\delta(u, v)$, for any $u, v \in V$. As discussed in [16], the stretch-size tradeoff presented by this construction is believed to be optimal. The approximate distance oracles of [16] improve previous results of [4] and [7]. For other results dealing with approximate distances, see, [1],[6],[8],[10],[11] [12].

We present here two independent extensions of the result of [16]. The first extension deals with situations in which we are only interested in approximate distances from a specified set $S \subseteq V$ of sources. We show that both the construction time and the space requirements of the appropriate data structure can be reduced in this case. More specifically, we show that if $|S| = s$, then the expected preprocessing time can be reduced from $\tilde{O}(mn^{1/k})$ to $\tilde{O}(ms^{1/k})$ and the space required can be reduced from $O(kn^{1+1/k})$ to $O(ks^{1/k})$. This is significant when $s \ll n$. We call the obtained data structures *source-restricted approximate distance oracles*.

We then move on to solve a major open problem raised in [16], namely the development of *deterministic* algorithms for constructing approximate distance oracles that are almost as efficient as the randomized ones. The deterministic construction in [16] first computes exact APSP in $\tilde{O}(mn)$ time, and then uses the complete distance matrix to derandomize the randomized construction algorithm. In addition to being much slower, the space used by the constructed stretch $2k - 1$ oracles is increased to $O(kn^{1+1/k} \log n)$. Our new derandomization loses only a logarithmic factor in running time and suffers no asymptotic loss in space. Thus we get a deterministic $\tilde{O}(mn^{1/k})$ time algorithm for constructing stretch $2k - 1$ approximate distance oracles of size $O(kn^{1+1/k})$, solving the problem from [16]. For the source-restricted distance oracles with s sources, the deterministic construction time and space is $\tilde{O}(ms^{1/k})$ and $O(kns^{1/k})$, respectively.

The techniques we use to obtain the new deterministic algorithm can also be used to derandomize the expected linear time algorithm of Baswana and Sen [5] for constructing $(2k - 1)$ -spanners of size $O(kn^{1+1/k})$, retaining the linear running time and the $O(kn^{1+1/k})$ size of the spanners. Similarly, they can be used to improve the deterministic algorithm of Dor et al. [10] for the construction of 2-emulators (surplus 2 additive spanners) of unweighted graphs. The size of the emulators produced is reduced by a factor of $O(\sqrt{\log n})$ to the optimal $O(n^{3/2})$, with a similar improvement is obtained in the running time. Furthermore, our techniques can be used to improve the algorithm of Baswana and Sen [6] for the construction of approximate distance oracles for unweighted graphs and make it run, deterministically, in $O(n^2)$ time, which is optimal in terms on n . (Due to lack of space we will not elaborate on this result here.)

The new deterministic algorithm uses two new ingredients that are of interest in their own right and may find additional applications. They are both simple and implementable. The first ingredient is an $\tilde{O}(qm)$ time algorithm that given a weighted directed graph $G = (V, E)$, a subset $U \subseteq V$ of sources, and an integer q , finds for every vertex $v \in V$ the set of the q vertices of U that are closest to v .

The second ingredient is a linear time deterministic algorithm for constructing *close dominating sets*. For a definition of this concept, see Section 4.

The rest of this extended abstract is organized as follows. In the next Section we present the construction of source-restricted approximate distance oracles. In Section 3 we present the algorithm for finding the nearest neighbors. In Section 4 we describe the linear time algorithm for constructing close dominating sets. In Section 5 we then present the main result of this paper, an efficient deterministic algorithm for constructing approximate distance oracles. Due to lack of space we cannot describe here the deterministic version of the linear time spanner construction algorithm of Baswana and Sen [5]. This algorithm will appear in the full version of the paper.

2 Source-Restricted Approximate Distance Oracles

We present here an extension of the approximate distance oracle construction of [16].

Theorem 1. *Let $G = (V, E)$ be an undirected graph with positive weights attached to its edges. Let $k \geq 1$ be an integer, and let $S \subseteq V$ be a specified set of sources. Then, it is*

Fig. 1. The randomized preprocessing algorithm

possible to preprocess G in $\tilde{O}(km|S|^{1/k})$ expected time, and produce a data structure of size $O(kn|S|^{1/k})$, such that for any $u \in S$ and $v \in V$ it is possible to produce, in $O(k)$ time, an estimate $\hat{\delta}(u, v)$ of the distance $\delta(u, v)$ from u to v in G that satisfies $\delta(u, v) \leq \hat{\delta}(u, v) \leq (2k - 1) \cdot \delta(u, v)$.

Thorup and Zwick [16] prove Theorem 1 for the case $S = V$. The proof of Theorem 1 is obtained by slightly modifying the construction of [16]. For the sake of completeness, we give the full details. This also allows us to review the randomized construction of [16] before presenting a deterministic version of it later in this paper.

Proof. A high level description of the preprocessing algorithm is given in Figure 1. The algorithm starts by defining a hierarchy $A_0 \supseteq A_1 \supseteq A_2 \supseteq \dots \supseteq A_k$ of subsets of S in the following way: We begin with $A_0 = S$. For every $1 \leq i < k$, we let A_i be random subset of A_{i-1} obtained by selecting each element of A_{i-1} , independently, with probability $|S|^{-1/k}$. Finally, we let $A_k = \phi$. The elements of A_i are referred to as i -centers. A similar hierarchy is used in [16]. There, however, we have $A_0 = V$, and A_i , for $1 \leq i < k$, is obtained by selecting each element of A_{i-1} with probability $n^{-1/k}$. Interestingly, this is the *only* change needed with respect to the construction of [16].

Next, the algorithm finds, for each vertex $v \in V$, and each $1 \leq i < k$, the distance $\delta(A_i, v) = \min\{\delta(w, v) \mid w \in A_i\}$ and an i -center $p_i(v) \in A_i$ that is closest to v . (We assume $A_{k-1} \neq \phi$.) For every vertex $v \in V$ it then defines the *bunch* $B(v)$ as follows:

$$B(v) = \cup_{i=0}^{k-1} B_i(v) \quad , \quad B_i(v) = \{w \in A_i \mid \delta(w, v) < \delta(A_{i+1}, v)\} .$$

Note that $B_i(v) \subseteq A_i - A_{i+1}$ as if $w \in A_{i+1}$ then $\delta(A_{i+1}, v) \leq \delta(w, v)$. We show later that the centers $p_i(v)$ can be found in $\tilde{O}(km)$ time and that the bunches $B(v)$, and the distances $\delta(w, v)$, for every $w \in B(v)$, can be found in $\tilde{O}(km|S|^{1/k})$ expected time.

Finally, for every vertex $v \in V$ the preprocessing algorithm constructs a hash table $H(v)$ of size $O(|B(v)|)$ that stores for each $w \in B(v)$ the distance $\delta(w, v)$. The hash table is constructed in $O(|B(v)|)$ expected time using the algorithm of Fredman *et al.*

[13]. (For a deterministic version, see Alon and Naor [2].) For every $w \in V$ we can then check, in $O(1)$ time, whether $w \in B(v)$ and if so obtain $\delta(w, v)$.

The total size of the data structure produced is $O(kn + \sum_{v \in V} |B(v)|)$. We next show that for every $v \in V$ we have $E[|B(v)|] \leq k|S|^{1/k}$, and thus the expected size of the whole data structure is $O(kn|S|^{1/k})$.

Lemma 1. *For every vertex $v \in V$ we have $E[|B(v)|] \leq k|S|^{1/k}$.*

Proof. We show that $E[|B_i(v)|] \leq |S|^{1/k}$, for $0 \leq i < k$. For $i = k - 1$ the claim is obvious as $B_{k-1}(v) \subseteq A_{k-1}$, and $E[|A_{k-1}|] = |S|^{1/k}$. Suppose, therefore, that $0 \leq i < k - 1$, and suppose that A_i was already chosen, while A_{i+1} is now about to be chosen. Let w_1, w_2, \dots, w_ℓ be the vertices of A_i arranged in non-decreasing order of distance from v . If $w_j \in A_{i+1}$, then $B_i(v) \subseteq \{w_1, w_2, \dots, w_{j-1}\}$. Thus $\Pr[w_j \in B_i(v)] \leq \Pr[w_1, w_2, \dots, w_{j-1} \notin A_{i+1}]$. As each vertex of A_i is placed in A_{i+1} , independently, with probability $p = |S|^{-1/k}$, we get that $\Pr[w_j \in B_i(v)] \leq (1-p)^{j-1}$ and thus $E[|B_i(v)|] \leq \sum_{j \geq 1} (1-p)^{j-1} = p^{-1} = |S|^{1/k}$, as required. \square

The algorithm used to answer approximate distance queries is given in Figure 2.

Lemma 2. *For every $u \in S$ and $v \in V$, algorithm $\mathbf{dist}_k(u, v)$ runs in $O(k)$ time and returns an approximate distance $\hat{\delta}(u, v)$ satisfying $\delta(u, v) \leq \hat{\delta}(u, v) \leq (2k-1)\delta(u, v)$.*

Proof. Let $\Delta = \delta(u, v)$. We begin by proving, by induction, that at the start of each iteration of the while loop we have $w \in A_i$ and $\delta(w, u) \leq i\Delta$. This clearly holds at the start of the first iteration, when $i = 0$, as $w = u \in S = A_0$ and $\delta(w, u) = 0$. (Here is where we use the assumption that $u \in S$.) Suppose, therefore that the claim holds at the start of some iteration, i.e., $w \in A_i$ and $\delta(w, u) \leq i\Delta$, and that the while condition, i.e., $w \notin B(v)$, is satisfied. Let $w' = p_{i+1}(v) \in A_{i+1}$. As $w \notin B(v)$, we get, by the definition of $B(v)$, that $\delta(w', v) = \delta(A_{i+1}, v) \leq \delta(w, v)$. We therefore have

$$\delta(w', v) \leq \delta(w, v) \leq \delta(w, u) + \delta(u, v) \leq i\Delta + \Delta = (i+1)\Delta.$$

Thus, by incrementing i , swapping u and v and letting $w \leftarrow w'$ we reestablish the invariant condition. (The algorithm performs these operations in a slightly different order.)

In each iteration of the while loop the algorithm performs only a constant number of operations. (To check whether $w \in B(v)$ it uses the hash table $H(v)$.) As $B(v) \supseteq A_{k-1}$ and $w \in A_i$, the algorithm performs at most $k-1$ iterations and hence the running time is $O(k)$.

When the while loop terminates, we have $\delta(w, u) \leq i\Delta$, $w \in B(v)$ and $i \leq k-1$. The algorithm then returns the estimate $\hat{\delta}(u, v) = \delta(w, u) + \delta(w, v)$ which satisfies

$$\begin{aligned} \delta(w, u) + \delta(w, v) &\leq \delta(w, u) + (\delta(w, u) + \delta(u, v)) \\ &= 2\delta(w, u) + \Delta \leq 2(k-1)\Delta + \Delta \leq (2k-1)\Delta, \end{aligned}$$

as required. \square

All that remain, therefore, is to explain how the preprocessing algorithm can be implemented to run in $\tilde{O}(km|S|^{1/k})$ time. Finding for each vertex $v \in V$ and every $0 \leq i < k$ the vertex $p_i(v) \in A_i$ closest to v is fairly easy. For every $0 \leq i < k$ we add a new source vertex s_i to the graph and connect it with zero weight edges to all the vertices of A_i . By running Dijkstra’s algorithm (see [9]) we compute the distances from s_i to all other vertices and construct a shortest paths tree rooted at s_i . The distances thus computed are exactly $\delta(A_i, v)$, for every $v \in V$. Using the shortest paths tree it is easy to identify for every $v \in V$ a vertex $p_i(v) \in A_i$ for which $\delta(p_i(v), v) = \delta(A_i, v)$. The whole process requires only $\tilde{O}(km)$ time.

We next describe an $\tilde{O}(km|S|^{1/k})$ algorithm for constructing the bunches $B(v)$, for every $v \in V$. Instead of computing the bunches directly, we compute their ‘duals’. For every i -center $w \in A_i - A_{i+1}$ we define the *cluster* $C(w)$ as follows:

$$C(w) = \{v \in V \mid \delta(w, v) < \delta(A_{i+1}, v)\} \quad , \quad \text{for } w \in A_i - A_{i+1} .$$

It is easy to see that $v \in C(w)$ if and only if $w \in B(v)$. We now claim:

Lemma 3. *If $v \in C(w)$, and u is on a shortest path from w to v in G , then $u \in C(w)$.*

Proof. Suppose that $w \in A_i - A_{i+1}$. If $u \notin C(w)$, then $\delta(A_{i+1}, u) \leq \delta(w, u)$. But then $\delta(A_{i+1}, v) \leq \delta(A_{i+1}, u) + \delta(u, v) \leq \delta(w, u) + \delta(u, v) = \delta(w, v)$, contradicting the assumption that $v \in C(w)$. \square

It follows that the cluster $C(w)$ can be constructed using the modified version of Dijkstra’s algorithm given in Figure 3. For the straightforward correctness proof, the reader is referred to [16]. The running time of the algorithm, when Fibonacci heaps [14]

```

algorithm distk( $u, v$ )
(Assumption:  $u \in S$ )
 $w \leftarrow u ; i \leftarrow 0$ 
while  $w \notin B(v)$ 
     $i \leftarrow i + 1$ 
     $(u, v) \leftarrow (v, u)$ 
     $w \leftarrow p_i(u)$ 
return  $\delta(w, u) + \delta(w, v)$ 
    
```

Fig. 3. Constructing a cluster

(see also [9]) are used to implement the priority queue Q , is $O(m_w + n_w \log n_w) = O(m_w + n_w \log n)$, where $n_w = |C(w)|$ and m_w is the total number of edges touching the vertices of $C(w)$. This is $O(\log n)$ time per vertex v in $C(w)$ and constant time per edge touching such a vertex v . However, $v \in C(w) \iff w \in B(v)$ and $E[|B(v)|] \leq ks^{1/k}$, so the total expected running time needed for constructing all clusters is $O((m + n \log n)ks^{1/k})$, as required. The running time can be reduced to $O(kms^{1/k})$ using the techniques of Thorup [15]. This completes the proof of Theorem 1. \square

3 A Deterministic Algorithm for Finding the q Nearest Centers

Let $G = (V, E)$ be a weighted directed graph and let $U \subseteq V$ be an arbitrary set of sources, or centers. We start with a formal definition of the set $U_q(v)$ of the q nearest centers from U of a vertex $v \in V$. We assume that all edge weights are positive. We also assume, without loss of generality, that $V = \{1, 2, \dots, n\}$.

Definition 1 (Nearest centers from U). *Let $G = (V, E)$ be a directed graph with positive edge weights assigned to its edges. Let $U \subseteq V$ be an arbitrary set of sources, and let $1 \leq q \leq |U|$ be an integer. For every $v \in V$, the set $U_q(v)$ is defined to be the set of the q vertices of U that are closest to v . Ties are broken in favor of vertices with smaller indices. More precisely, for every $v \in V$ we have $U_q(v) \subseteq U$, $|U_q(v)| = q$ and if $w_1 \in U_q(v)$ while $w_2 \notin U_q(v)$ then either $\delta(w_1, v) < \delta(w_2, v)$ or $\delta(w_1, v) = \delta(w_2, v)$ and $w_1 < w_2$.*

The following lemma, which is reminiscent of Lemma 1, is easily verified.

Lemma 4. *If $u \in U_q(v)$ and w lies on a shortest path from u to v in G , then $u \in U_q(w)$.*

We now claim:

Theorem 2. *Let $G = (V, E)$ be a directed graph with positive weights assigned to its edges. Let $U \subseteq V$ be an arbitrary set of sources, and let $1 \leq q \leq |U|$ be an integer. Then, the sets $U_q(v)$, for every $v \in V$, can be computed by performing q single-source shortest paths computations on graphs with at most $O(n)$ vertices and $O(m)$ edges.*

Proof. We begin by finding for every vertex $v \in V$ its nearest neighbor in U . This is easily done by adding a new source vertex s to the graph, connecting it with 0 length edges to all the vertices of U , and computing a tree of shortest paths in the resulting graph. This gives us $U_1(v)$, for every $v \in V$.

Suppose now that we have already computed $U_{i-1}(v)$, for every $v \in V$. We show that $U_i(v)$, for every $v \in V$ can be obtained by finding a tree of shortest paths in an auxiliary graph with $O(n)$ vertices and $O(m + n)$ edges. This auxiliary graph is constructed as follows:

1. Add to G a new source vertex s and copies of all vertices of U . If $u \in U$, we let \bar{u} denote the copy of u . Add a 0 length edges from s to \bar{u} , for every $u \in U$.
2. For every edge $(v, w) \in E$:
 - (a) If $U_{i-1}(v) = U_{i-1}(w)$, keep the edge (v, w) .

- (b) Otherwise, if $U_{i-1}(v) \neq U_{i-1}(w)$ and u is the first vertex in $U_{i-1}(v) - U_{i-1}(w)$, replace the edge (v, w) by an edge (\bar{u}, w) of length $\delta(u, v) + \ell(v, w)$.

The auxiliary graph thus contains $n + |U| + 1$ vertices and $m + |U|$ edges. It is not difficult to check that u is the i -th nearest neighbor from U of all the vertices in the subtree of \bar{u} in the tree of shortest paths from s in this auxiliary graph. The proof is fairly straightforward and is omitted due to lack of space. \square

4 A Deterministic Construction of Close Dominating Sets

Instead of dealing directly with the close dominating sets from the introduction, it is convenient first to consider a simpler case phrased in terms of a matrix. In that context, we will talk about *early hitting sets*: Let M be an $n \times k$ matrix whose elements are taken from a finite set S of size $|S| = s$. We assume that the elements in each row of M are distinct. A set A is said to be a *hitting set* of M if and only if every row of M contains an element of A . A standard calculation shows that if each element of S is placed in A , independently, with probability $(c \ln n)/k$, for some $c > 1$, then with a probability of at least $1 - n^{1-c}$ the resulting set A is a hitting set of M . The expected size of A is then $(c s \ln n)/k$. We are interested in hitting sets of small size that hit the rows of M close to their beginnings, at least on average.

Definition 2 (Hitting sums). Let M be an $n \times k$ matrix, let A be a set, and let $P \geq 0$ be a penalty. Let $hit(M_i, A)$ be the index of the first element of M_i , the i -th row of M , that belongs to A , or $k + P$, if no element of M_i belongs to A . Let $hit(M, A) = \sum_{i=1}^n hit(M_i, A)$ be the hitting sum of A with respect to M .

Note that a set A need not be a hitting set of M for the hitting sum $hit(M, A)$ to be defined. A penalty of P , plus the length of the row, is paid, however, for each row that is not hit. Typically, the goal is to hit all rows avoiding all penalties. A set A with a small hitting sum $hit(M, A)$ is informally referred to as an *early hitting set*. The following simple probabilistic lemma proves the existence of small early hitting sets.

Lemma 5. Let M be an $n \times k$ matrix whose elements are taken from a finite set S of size $|S| = s$ and let $P \geq 0$ be a penalty. Then, for every $0 < p < 1$ there exists a set $A \subseteq S$ for which $\frac{n}{p^2 s} |A| + hit(M, A) \leq 2n/p + (1 - p)^k P n$. In particular, if $pP \geq 3n$ and $pP(1 - p)^k \leq 1$ then all rows are hit with $|A| < 3ps$ and $hit(M, A) < 3n/p$.

Proof. Let A be a random subset of S obtained by selecting each element of S , independently, with probability p . It is easy to see that

$$E[|A|] = ps,$$

$$E[hit(M_i, A)] = \sum_{j=1}^k (1 - p)^{j-1} + (1 - p)^k P < p^{-1} + (1 - p)^k P,$$

and thus $E[\frac{n}{p^2 s} |A| + hit(M, A)] \leq \frac{2n}{p} + (1 - p)^k P n$. This proves the existence of the required set.

Concerning the last statement, the condition $pP(1 - p)^{-k} < 1$ implies that the right hand side is at most $3n/p$. By the first condition, this corresponds to at most a single penalty, but since we have other costs, we conclude that we pay no penalties. The bounds on $|A|$ and $hit(M, A)$ follow because each term on the left hand size is non-zero and strictly smaller than the right hand side. \square

The main result of this section is a deterministic *linear time* algorithm for constructing early hitting sets that almost match the bounds of Lemma 5. Quite naturally, the algorithm is based on the *method of conditional expectations* (see, e.g., Alon and Spencer [3]). The challenge is to get a running time linear in the size of the matrix M .

Theorem 3. *Let M be an $n \times k$ matrix whose elements are taken from a finite set S of size $|S| = s$ and let $P \geq 0$ be a penalty. Let $0 < p < 1$. Then, there is a deterministic $O(nk)$ time algorithm that finds a set $A \subseteq S$ for which $\frac{n}{p^2s}|A| + hit(M, A) \leq 3n/p + (1 - p)^k Pn$. In particular, if $pP \geq 4n$ and $pP(1 - p)^k \leq 1$ then all rows are hit with $|A| < 3ps$ and $hit(M, A) < 3n/p$.*

Proof. Let $A_0, A_1 \subseteq S$ be two disjoint sets. Define

$$hit(M \mid A_0, A_1) = E\left[\frac{n}{p^2s}|A| + hit(M, A) \mid A_1 \subseteq A \subseteq A_0^c\right].$$

In other words, $hit(M \mid A_0, A_1)$ is the (conditional) expectation of the random variable $\frac{n}{p^2s}|A| + hit(M, A)$ where the set A is chosen in the following way: Each element of A_1 is placed in A . Each element of A_0 is *not* placed in A . Each other element is placed in A , independently, with probability p .

Lemma 5 states that $hit(M, A) = hit(M \mid \phi, \phi) \leq \mu = 2n/p + (1 - p)^k Pn$. Our goal it to deterministically find a set $A \subseteq S$ such that $hit(M \mid A^c, A) \leq \mu$. Suppose that we have already found two disjoint sets $A_0, A_1 \subseteq S$ such that $hit(M \mid A_0, A_1) \leq \mu$ and that $e \in S - (A_0 \cup A_1)$. We then have

$$hit(M \mid A_0, A_1) = p \cdot hit(M \mid A_0, A_1 \cup \{e\}) + (1 - p) \cdot hit(M \mid A_0 \cup \{e\}, A_1).$$

Thus, at least one of the two conditional expectations appearing above is at least μ . We choose it and then consider another element that was not yet placed in either A_0 and A_1 . Continuing in this way, we get two disjoint sets $A_0, A_1 \subseteq S$ such that $A_0 \cup A_1 = S$ and $hit(M \mid A_0, A_1) \leq \mu$, as required. This is precisely the method of conditional expectations.

The remaining question is the following: Given $hit(M \mid A_0, A_1)$ and an element $e \in S - (A_0 \cup A_1)$, how fast can we compute $hit(M \mid A_0, A_1 \cup \{e\})$ and $hit(M \mid A_0 \cup \{e\}, A_1)$? Let us focus on the computation of the conditional expectations $hit(M_i \mid A_0, A_1 \cup \{e\})$ and $hit(M_i \mid A_0 \cup \{e\}, A_1)$ corresponding to the i -th row of M .

Let $n_i = n_i(A_1)$ be the index of the first element in M_i that belongs to A_1 . If none of the elements of M_i belongs to A_1 , we let $n_i = \infty$. Let $n_{i,j} = n_{i,j}(A_0)$ be the number of elements among the first j elements of M_i that do *not* belong to A_0 . (We let $n_{i,0} = 0$.) It is easy to see that

$$hit(M_i \mid A_0, A_1) = \sum_{j=1}^{\min\{n_i, k\}} (1 - p)^{n_i - j} + \begin{cases} (1 - p)^{n_i} \cdot P & \text{if } n_i = \infty \\ 0 & \text{otherwise} \end{cases}.$$

Maintaining the penalty term $(1 - p)^n \cdot P$ is easy. To simplify the presentation we therefore ignore this term. (In other words we assume that $P = 0$. The changes needed when $P > 0$ are minimal.) Let

$$x_{i,j} = \begin{cases} (1 - p)^{n_i - j} & \text{if } j \leq n_i, \\ 0 & \text{otherwise.} \end{cases}$$

With this notation, and with the assumption $P = 0$, we clearly have $hit(M_i | A_0, A_1) = \sum_{j=1}^k x_{i,j}$. We now consider the changes that should be made to the $x_{i,j}$'s when an element e is added to A_0 or to A_1 . If e does not appear in M_i , then no changes are required. Assume, therefore, that $M_{i,r} = e$, i.e., the e is the r -th element in M_i . If $r > n_i$, then again no changes are required. Assume, therefore, that $r < n_i$.

If e is added to A_1 , then the required operations are $n_i \leftarrow r$ and $x_{i,j} \leftarrow 0$, for $r < j \leq k$. If e is added to A_0 , then the required operations are $n_{i,j} \leftarrow n_{i,j} - 1$, for $r \leq j \leq k$, and therefore $x_{i,j} \leftarrow x_{i,j}/(1 - p)$, again for $r \leq j \leq k$. In both cases, the new conditional expectation is the new sum $\sum_{j=1}^k x_{i,j}$.

These operations can be implemented fairly efficiently using a data structure that maintains an array $x = [x_1, x_2, \dots, x_q]$ of q real numbers under the following update operations: *init*(x) – initialize the array x ; *scale*(i, j, a) – multiply the elements in the sub-array $[x_i, \dots, x_j]$ by the constant a ; *sum* – return the sum $\sum_{i=1}^k x_i$; and *undo* – undo the last update operation. (The *undo* operation is required for tentatively placing new elements in A_0 and then in A_1 .) Using standard techniques it is not difficult to implement such a data structure that can be initialized in $O(k)$ time and that can support each update operation in $O(\log k)$ time. However, the description of such a data structure is not short, and the resulting algorithm would have an over all non-linear running time of $O(nk \log k)$. Luckily, there is a simpler to implement, and a more efficient, solution. Let us define the following variant of hitting sums:

Definition 3 (Dyadic hitting sums). Let M be an $n \times k$ matrix, let A be a set, and let $P \geq 0$ be a penalty. Let $\overline{hit}(M_i, A) = 2^{\lceil \log_2 hit(M_i, A) \rceil}$ be the smallest power of 2 greater or equal to the index of the first element of M_i that belongs to A , or $q + P$, if no element of M_i belongs to A . Let $\overline{hit}(M, A) = \sum_{i=1}^n \overline{hit}(M_i, A)$ be the dyadic hitting sum of A with respect to M .

Clearly $hit(M, A) \leq \overline{hit}(M, A) < 2 \cdot hit(M, A)$. Thus, as in the proof of Lemma 5, we get that $E[\frac{n}{p^2 s} |A| + \overline{hit}(M, A)] \leq 3n/p + (1 - p)^k Pn$. The conditional expectation $\overline{hit}(M | A_0, A_1)$ is defined in the obvious analogous way. Now define

$$\bar{k} = \lceil \log_2 k \rceil, \quad \bar{n}_i = \lceil \log_2 n_i \rceil, \quad \bar{n}_{i,j} = n_{i,2^j},$$

$$\bar{x}_{i,j} = \begin{cases} (1 - p)^{\bar{n}_i - j} & \text{if } j \leq \bar{n}_i, \\ 0 & \text{otherwise.} \end{cases}, \quad \bar{y}_{i,r} = 1 + \sum_{j=1}^r \bar{x}_{i,j} 2^{j-1}$$

With these definitions we have $\overline{hit}(M_i | A_0, A_1) = \bar{y}_{i, \bar{k} - 1}$.

Each update now trivially takes $O(\bar{k}) = O(\log k)$ worst-case time, even if we implement the updates naively. Furthermore, we argue that the *amortized* cost of each update is only $O(1)$!

<pre> procedure <i>init</i>(<i>i</i>) $\bar{x}_{i,1} \leftarrow 1 - p$ $\bar{y}_{i,1} \leftarrow 1 + \bar{x}_{i,1}$ for $j \leftarrow 2$ to $\bar{k} - 1$ $\bar{x}_{i,j} \leftarrow \bar{x}_{i,j-1}^2$ $\bar{y}_{i,j} \leftarrow \bar{y}_{i,j-1} + \bar{x}_{i,j} \cdot 2^{j-1}$ </pre>	<pre> procedure <i>update</i>₀(<i>i</i>, <i>r</i>) $\bar{r} \leftarrow \lceil \log_2 r \rceil$ for $j \leftarrow \bar{r}$ to $\bar{k} - 1$ $\bar{x}_{i,j} \leftarrow \bar{x}_{i,j} / (1 - p)$ $\bar{y}_{i,j} \leftarrow \bar{y}_{i,j-1} + \bar{x}_{i,j} \cdot 2^{j-1}$ return $\bar{y}_{i,\bar{k}-1}$ </pre>	<pre> procedure <i>update</i>₁(<i>i</i>, <i>r</i>) $\bar{r} \leftarrow \lceil \log_2 r \rceil$ for $j \leftarrow \bar{r} + 1$ to $\bar{k} - 1$ $\bar{x}_{i,j} \leftarrow 0$ $\bar{y}_{i,j} \leftarrow y_{i,j-1}$ return $\bar{y}_{i,\bar{k}-1}$ </pre>
--	---	---

Fig. 4. Updating the conditional expectations

A complete description of procedures used to initialize and update the conditional expectations is given in Figure 4. A call to $init(i)$ initializes $\bar{x}_{i,j} = (1 - p)^{2^{j-1}}$ and $\bar{y}_{i,r} = 1 + \sum_{j=1}^r \bar{x}_{i,j} \cdot 2^{j-1}$, for $1 \leq r \leq \bar{k} - 1$. Calls to $update_0(i, j)$ and $update_1(i, j)$, respectively, perform the necessary updates to the i -rows of the arrays $x[i, j]$ and $y[i, j]$ as a result of adding the element $e = M_{ir}$ to A_0 , or to A_1 , and return the new value of $\overline{hit}(M_i | A_0, A_1)$. The difference between the old and the new value of $\overline{hit}(M_i | A_0, A_1)$ should also be applied to the global sum $\overline{hit}(M | A_0, A_1) = \sum_{i=1}^n \overline{hit}(M_i | A_0, A_1)$. It is easy to implement an $undo(i)$ procedure that undos the last update performed on the i -th row. We simply need to record the operations made and undo them in reverse order. To obtain $\overline{hit}(M, A_0, A_1)$, we simply sum $\overline{hit}(M_i | A_0, A_1)$ up, for $1 \leq i \leq n$. The correctness of the computation follows from the long discussion above.

All that remains is to analyze the complexity of the proposed algorithm. Each element $e \in S$ is considered once by the algorithm. For each appearance of $e = M_{ir}$ in M we need to call $update_0(i, r)$ and $update_1(i, r)$. The complexity of these calls is $O(\bar{k} - \bar{r} + 1) = O(\lceil \log_2 k \rceil - \lceil \log_2 r \rceil + 1)$. For every $2^{\bar{k}-j} \leq r \leq 2^{\bar{k}-j+1}$, where $1 \leq j \leq \bar{k}$, the cost is $O(j)$. Thus, the total cost of handling all the elements of the i -th row is $O(k \sum_{j \geq 1} j 2^{-j}) = O(k)$. The total cost is therefore $O(kn)$, as required. The last statement of the theorem is derived like the last statement of Lemma 5. \square

Theorem 4. *A close dominating set of any given size can be found in linear time.*

Proof. We now consider the closest dominating set problem from the introduction, modifying our early hitting set algorithm to solve this problem. The first change is to let each row M_i to have an individual length $k_i \leq k$. The total number of elements is then $m = \sum_{i=1}^n k_i$. We also make the change that there is only a penalty P for not hitting a full row M_i with $k_i = k$. It is straightforward to modify the previous early hitting set algorithm for these variable length rows. Essentially, we just replace k and \bar{k} by k_i and \bar{k}_i , and drop the penalty for the partial rows. We then get a deterministic algorithm that in $O(m)$ time finds a hitting set A with the same properties as those stated in Theorem 3. In particular, if $pP \geq 4n$ and $pP(1 - p)^k \leq 1$ then all full rows are hit with $|A| < 3ps$ and $\overline{hit}(M, A) < 3n/p$.

We now need to transform our bipartite graph $G = (U, V, E)$ to the matrix form. The set S of elements that are placed in the matrix is simply the set U . The matrix constructed has a row for each vertex $v \in V$. Ideally, the row M_v would contain the

neighboring centers u ordered according to the edge weights $\ell(u, v)$. The list should be truncated to only contain the $k = (s/h)(2 + \ln n)$ nearest centers. The lists with k centers are the full rows with a penalty P for not being hit. We use $p = h/(3s)$ and $P = 12ns/h$. Then $pP = 4n$ and

$$pP(1-p)^k < 4n \exp(-(h/s)(s/h(2 + \ln n))) < 4/e^2 < 1.$$

Since the conditions are satisfied, we get a set A hitting all full rows with $|A| < 3ps = h$, and $\text{hit}(M, A) < 3n/p = 9ns/h$. This also means that A is a close dominating set.

Our only remaining problem is that we cannot sort neighboring centers according to distance. However, thanks to the dyadic solution, it suffices to apply a linear time selection algorithm (see, e.g., [9]). First, if a vertex v has more the k neighboring centers, we apply selection to find the k nearest centers. Next, for r decreasing from $\lceil \log_2 k_i \rceil$ down to 0, we identify the 2^r nearest centers. The total running time is linear, and this provides a sufficient sorting for the diadic hitting sum algorithm. \square

5 A Deterministic Construction of Approximate Distance Oracles

In this section we present a *deterministic* algorithm for constructing (source-restricted) approximate distance oracles. The algorithm is slower than the randomized algorithm of Theorem 1 by only a logarithmic factor. Obtaining such a deterministic algorithm is one of the open problems mentioned in [16].

Theorem 5. *Let $G = (V, E)$ be an undirected graph with positive weights attached to its edges. Let $k \geq 1$ be an integer, and let $S \subseteq V$ be a specified set of sources. Then, it is possible to preprocess G , deterministically, in $\tilde{O}(km|S|^{1/k})$ time, and produce a data structure of size $O(kn|S|^{1/k})$, such that for any $u \in S$ and $v \in V$ it is possible to produce, in $O(k)$ time, an estimate $\hat{\delta}(u, v)$ of the distance $\delta(u, v)$ from u to v in G that satisfies $\delta(u, v) \leq \hat{\delta}(u, v) \leq (2k - 1) \cdot \delta(u, v)$.*

```

algorithm detprek( $G, S$ )
 $A_0 \leftarrow S; A_k \leftarrow \emptyset$ 
 $p \leftarrow \frac{1}{4}|S|^{-1/k}; \ell \leftarrow 3|S|^{1/k} \ln n; P \leftarrow n^2$ 
for  $i \leftarrow 1$  to  $k - 1$ 
     $N_{i-1} \leftarrow \text{near}(G, A_{i-1}, \ell)$ 
    Create bipartite graph  $B$  from  $A_{i-1}$  to  $V$  with
    an edge  $(u, v)$  of length  $\delta_G(u, v)$  if  $u \in N_{i-1}[v]$ .
     $A_i \leftarrow \text{domset}(B, s^{1-i/k})$ 
for every  $v \in V$ 
     $B(v) \leftarrow A_{k-1}$ 
    for  $i \leftarrow 0$  to  $k - 2$ 
         $B(v) \leftarrow B(v) \cup \{w \in N_i[v] \mid \delta(w, v) < \delta(A_{i+1}, v)\}$ 
    
```

Fig. 5. The deterministic preprocessing algorithm

Proof. The deterministic preprocessing algorithm is given in Figure 5. It is composed of $k - 1$ iteration. The i -th iteration constructs the set A_i . We let $s = |S|$ and $\ell = \lceil s^{1/k}(2 + \ln n) \rceil$, the iteration begins by finding for each vertex $v \in V$ the set $N_i[v]$ of the ℓ vertices of A_{i-1} that are nearest v , using algorithm **near** of Section 3. The running time of the algorithm is $\tilde{O}(ms^{1/k})$. Next we create a bipartite graph B from A_{i-1} to V with an edge (u, v) of length $\delta_G(u, v)$ if $u \in N_{i-1}[v]$. Using the algorithm of Theorem 4, which we here call **domset**, we now find a close dominating subset A_i of size $h_i = s^{1-i/k} = |A_{i-1}|/s^{1/k}$. Since each vertex have at least $s^{1/k}(2 + \ln n) = |A_{i-1}|/h_i(2 + \ln n)$ neighboring centers, we know that A_i hits all these neighborhoods. The result is that in the original graph G , the sum of the number of centers in from A_{i-1} nearer than then nearest center in A_i is at most $9|A_{i-1}|/h_i = O(ns^{1/k})$. It follows that the total size of the bunches returned by the algorithm is in $O(kns^{1/k})$, as required. \square

An $\tilde{O}(m^2n)$ Randomized Algorithm to Compute a Minimum Cycle Basis of a Directed Graph

Telikepalli Kavitha*

Indian Institute of Science, Bangalore, India

kavitha@csa.iisc.ernet.in

Abstract. We consider the problem of computing a minimum cycle basis in a directed graph G . The input to this problem is a directed graph whose arcs have positive weights. In this problem a $\{-1, 0, 1\}$ incidence vector is associated with each cycle and the vector space over \mathbb{Q} generated by these vectors is the cycle space of G . A set of cycles is called a cycle basis of G if it forms a basis for its cycle space. A cycle basis where the sum of weights of the cycles is minimum is called a minimum cycle basis of G . The current fastest algorithm for computing a minimum cycle basis in a directed graph with m arcs and n vertices runs in $\tilde{O}(m^{\omega+1}n)$ time (where $\omega < 2.376$ is the exponent of matrix multiplication). If one allows randomization, then an $\tilde{O}(m^3n)$ algorithm is known for this problem. In this paper we present a simple $\tilde{O}(m^2n)$ randomized algorithm for this problem.

The problem of computing a minimum cycle basis in an *undirected* graph has been well-studied. In this problem a $\{0, 1\}$ incidence vector is associated with each cycle and the vector space over \mathbb{F}_2 generated by these vectors is the cycle space of the graph. The fastest known algorithm for computing a minimum cycle basis in an undirected graph runs in $O(m^2n + mn^2 \log n)$ time and our randomized algorithm for directed graphs almost matches this running time.

1 Introduction

Let $G = (V, A)$ be a directed graph with m arcs and n vertices. A *cycle* C in G consists of *forward arcs* C^+ and *backward arcs* C^- such that $C = C^+ \dot{\cup} C^-$ and reorienting all arcs in C^- results in a closed path. Associated with each cycle is a $\{-1, 0, 1\}$ vector, indexed on the arc set A . This vector, also called C , is defined as follows. For each arc $a \in A$

$$C(a) = \begin{cases} 1 & \text{if } a \text{ is a forward arc of } C \\ -1 & \text{if } a \text{ is a backward arc of } C \\ 0 & \text{if } a \notin C \end{cases}$$

* This research was partially supported by a “Max Planck-India Fellowship” provided by the Max Planck Society.

The *cycle space* of G is the vector space over \mathbb{Q} that is generated by the incidence vectors of cycles in G . When G is connected, the cycle space has dimension $d = m - n + 1$. A *cycle basis* of G is a basis of the cycle space of G .

The arcs of G have positive weights assigned to them. A cycle basis where the sum of the weights of the cycles is minimum is called a *minimum cycle basis* of G . In this paper we consider the problem of computing a minimum cycle basis in a given digraph.

Background. The problem of computing a minimum cycle basis in a graph is well-studied. Apart from its interest as a natural question, it is motivated by its use as a preprocessing step in several algorithms. That is, a cycle basis is used as an input for a later algorithm, and using a minimum cycle basis instead of any arbitrary cycle basis usually reduces the amount of work that has to be done by this later algorithm. Such algorithms include algorithms for diverse applications like structural engineering [4], cycle analysis of electrical networks [5], and chemical ring perception [7]. And in many cases the network graphs of interest are directed graphs.

Undirected graphs. In an undirected graph $U = (N, E)$, with each cycle C we associate a $\{0, 1\}$ incidence vector x , indexed on E , where $x_e = 1$ if e is an edge of C , $x_e = 0$ otherwise. The vector space over \mathbb{F}_2 generated by these vectors is called the *cycle space* of U . A minimum cycle basis of U is a set of linearly independent (over \mathbb{F}_2) cycles that span the cycle space of U and whose sum of weights is minimum.

For a directed graph G , we obtain the underlying undirected graph of G by removing the directions from the arcs. A set of cycles C_1, \dots, C_d of G projects onto an undirected cycle basis, if by removing the orientations of the arcs in the cycles, we obtain a cycle basis for the underlying undirected graph. If $\mathcal{C} = \{C_1, \dots, C_d\}$ is a set of cycles in a directed graph G that projects onto an undirected cycle basis, then \mathcal{C} is a cycle basis of G . But the converse is not true. Similarly, a minimum cycle basis of a digraph need not project onto a cycle basis of the underlying undirected graph. Such examples are given in [13, 14]. In particular, [14] contains an example of a directed graph, which is a generalized Petersen graph, whose *unique* minimum cycle basis does not project onto a cycle basis of the underlying undirected graph. The books by Deo [6] and Bollobás [3] have an in-depth coverage of the subject of cycle bases.

Previous Results. Algorithms for computing a minimum cycle basis in an undirected graph have been well-studied [2, 5, 8, 9, 11] and the current fastest algorithm for this problem runs in $O(m^2n + mn^2 \log n)$ time [11], where m is the number of edges and n is the number of vertices. The first polynomial time algorithm for computing a minimum cycle basis in a directed graph had a running time of $\tilde{O}(m^4n)$ [10]. Liebchen and Rizzi [14] gave an $\tilde{O}(m^{\omega+1}n)$ algorithm for this problem, where $\omega < 2.376$ is the exponent of matrix multiplication. This is the current fastest deterministic algorithm known for this problem. But faster

randomized algorithms are known. Kavitha and Mehlhorn [10] gave an $\tilde{O}(m^3n)$ Monte Carlo algorithm for this problem.

New Results. In this paper we present a simple $O(m^2n \log n)$ randomized algorithm to compute a minimum cycle basis in a directed graph G with m arcs and n vertices. This algorithm always returns a cycle basis and we show that with high probability this cycle basis is a minimum cycle basis. We obtain this algorithm through an effective use of randomization, which enables us to work entirely over the finite field \mathbb{F}_p for a randomly chosen prime p instead of working over \mathbb{Q} .

We recall here that the $\tilde{O}(m^3n)$ randomized algorithm given in [10] works by sampling $\log^2 m$ random primes independently in each iteration of the algorithm. Then the algorithm either uses at least $\log m$ suitable primes from this sample to compute cycles in that iteration or it quits if there is no large enough subset of suitable primes in this sample.

In Section 2.1 we first present a deterministic algorithm, whose correctness is simple to show. But the numbers used in this algorithm grow very large and so this algorithm is not interesting from an implementation point of view. However, the analysis of this algorithm leads to our efficient randomized algorithm. Section 2.2 contains our randomized algorithm and its analysis.

A key step in our algorithm is a subroutine to compute a shortest cycle whose inner product with a given vector is non-zero modulo p . Such a subroutine was also used in [10] and we first review that method in Section 3.1. However that subroutine is not good enough for us since using it would make the running time of our algorithm $\tilde{O}(m^4n)$. Here we modify Dijkstra's algorithm for this particular problem and improve this subroutine. Section 3.2 contains this implementation. This leads to an $O(m^3 + m^2n \log n)$ randomized algorithm for computing a minimum cycle basis in a directed graph.

We can improve the running time even further. As mentioned earlier, the current fastest algorithm for computing a minimum cycle basis in an undirected graph has a running time of $O(m^2n + mn^2 \log n)$. This running time is achieved through the use of fast matrix multiplication to speed up certain operations on vectors. In Section 4 we use the same technique to get rid of the m^3 term in our running time and we thus get an $O(m^2n \log n)$ algorithm.

2 An $\tilde{O}(m^3)$ Randomized Algorithm

Our algorithm is broadly based on the approach used in [5, 2, 11, 10] for computing a minimum cycle basis. We are given a digraph $G = (V, A)$, where $|V| = n$ and $|A| = m$. There is no loss of generality in assuming that the underlying undirected graph of G is connected. Then $d = m - n + 1$ is the dimension of the cycle space of G . The notation $\langle v_1, v_2 \rangle$ denotes the standard inner product or dot product of the vectors v_1 and v_2 . First we will assume that we have ordered the arcs in the arc set A so that the arcs a_{d+1}, \dots, a_m form the edges of a spanning tree T of the underlying undirected graph. This

means that in the incidence vector representation of cycles, the first d coordinates correspond to arcs outside the tree T and the last $n - 1$ coordinates are the arcs of T .

Before we present our randomized algorithm, let us first consider the following deterministic algorithm.

2.1 Deterministic-MCB

1. Initialize the vectors S_1, \dots, S_d of \mathbb{Q}^m to the first d vectors e_1, \dots, e_d of the standard basis of \mathbb{Q}^m .
2. For $i = 1$ to d do
 - compute a shortest cycle C_i such that $\langle C_i, S_i \rangle \neq 0$.
 - for $j = i + 1$ to d do

$$\text{update } S_j \text{ as: } S_j = S_j - S_i \frac{\langle C_i, S_j \rangle}{\langle C_i, S_i \rangle}$$

It can be easily shown that the set $\{C_1, \dots, C_d\}$ is a minimum cycle basis. We can also show the following lemma using induction.

Lemma 1. *For $1 \leq i \leq d - 1$ the above algorithm maintains the following invariant: at the end of the i -th iteration the vectors S_{i+1}, \dots, S_d are orthogonal to the cycles C_1, \dots, C_i .*

Let us now understand the structure of the vectors S_j in Deterministic-MCB. The vector S_j gets updated in each iteration till iteration j . Call the version of S_j at the beginning of iteration i as S_j^i . And S_j^j is finally used in iteration j to compute the cycle C_j . (Let us denote the final version S_j^j by S_j itself.) S_j^i has the form $(r_1, r_2, \dots, r_{i-1}, 0, \dots, 0, 1, 0, \dots, 0)$, where r_1, \dots, r_{i-1} are some rational numbers and the 1 occurs in the j -th coordinate. Since S_j^i is orthogonal to C_1, \dots, C_{i-1} , we have $C_k \cdot (r_1, \dots, r_{i-1}, 0, \dots, 1, 0, \dots)^T = 0$ for $k = 1, \dots, i - 1$.

Let the incidence vector of C_k be (c_{k1}, \dots, c_{km}) and let \tilde{C}_k be the restriction of this vector to its first $i - 1$ coordinates. Then (r_1, \dots, r_{i-1}) is a solution to

$$\tilde{C}_k \cdot (x_1, \dots, x_{i-1})^T = -c_{kj} \text{ for } k = 1, \dots, i - 1. \tag{1}$$

We will show that this set of equations has a unique solution. Suppose the linear combination

$$\sum_{j=1}^{i-1} \alpha_j \tilde{C}_j = \mathbf{0} \tag{2}$$

and not all α_j are 0. Then consider the largest t such that $\alpha_t \neq 0$ and take the inner product of both sides of Equation (2) with \tilde{S}_t , where \tilde{S}_t is the restriction of the vector S_t to its first $i - 1$ coordinates.

Then the left hand side is $\sum_{k=1}^t \alpha_k \langle \tilde{C}_k, \tilde{S}_t \rangle = \sum_{k=1}^t \alpha_k \langle C_k, S_t \rangle$ since \tilde{S}_t has all the non-zero entries of S_t for each $1 \leq t \leq i - 1$. This is equal to $\alpha_t \langle C_t, S_t \rangle$ since $\langle C_k, S_t \rangle = 0$ for $k < t$. Since $\langle C_t, S_t \rangle \neq 0$ and the right hand side is 0 we get $\alpha_t = 0$ - a contradiction. Hence each α_k has to be 0 for $1 \leq k \leq i - 1$. So the \tilde{C}_k 's are linearly independent. So we can conclude the following lemma.

Lemma 2. For any i , the $(i - 1) \times (i - 1)$ matrix \mathcal{M}_i whose k -th row is the vector \tilde{C}_k for $1 \leq k \leq i - 1$ is nonsingular.

Thus Equation (1) has a unique solution, which is (r_1, \dots, r_{i-1}) . By Cramer’s rule, each r_l is of the form $r_l = y_l/k_i$, where k_i is the determinant of \mathcal{M}_i and y_l is the determinant of the matrix obtained by replacing the l -th column of \mathcal{M}_i by the vector on the right hand side of Equation (1). So multiplying S_j^i with k_i gives us an integral vector $N_j^i = (y_1, \dots, y_{i-1}, 0, \dots, k_i, 0, \dots)$. Since k_i is the determinant of an $(i - 1) \times (i - 1)$ matrix whose entries are $-1, 0, 1$, it follows from Hadamard’s inequality that $|k_i| \leq (i - 1)^{\frac{-1}{2}}$. Similarly, the absolute value of each y_l is bounded from above by $(i - 1)^{\frac{-1}{2}}$. So we have $\|N_j^i\|_1 \leq i(i - 1)^{\frac{-1}{2}} \leq d^{\frac{-1}{2}}$ since $i \leq d$. Let us denote each N_j^i by N_j , respectively.

Definition 1. Call a prime p good if for each $i = 1, \dots, d$: $\langle C_i, N_i \rangle \not\equiv 0 \pmod{p}$. Call a prime p bad if it is not good.

Lemma 3. Let P be a set of d^2 primes, each of which is at least d^2 . Then at least $3/4$ -th of the set P is good.

Proof. For any i , $\langle C_i, S_i \rangle \neq 0$ is equivalent to $\langle C_i, N_i \rangle \neq 0$ since $N_i = k_i S_i$ and $k_i = \det(\mathcal{M}_i) \neq 0$ by Lemma 2. So for each $1 \leq i \leq d$, it holds that $\langle C_i, N_i \rangle \neq 0$. Since C_i is a $\{-1, 0, 1\}$ vector we also get that $|\langle C_i, N_i \rangle| \leq \|N_i\|_1$. So $|\langle C_i, N_i \rangle| \leq d^{\frac{-1}{2}}$.

Since $N_1 = S_1 = (1, 0, \dots, 0)$, the number $\langle C_1, N_1 \rangle$ is always ± 1 . So no prime can divide it. For $i \geq 2$, we will use $0 \neq |\langle C_i, N_i \rangle| \leq d^{\frac{-1}{2}}$. Since each prime in P is at least d^2 , at most $(d+1)/4$ elements in P can be divisors of $\langle C_i, N_i \rangle$. So the number of primes in P that can divide at least one of $\langle C_2, N_2 \rangle, \langle C_3, N_3 \rangle, \dots, \langle C_d, N_d \rangle$ is at most $(d - 1)(d + 1)/4$. Hence the fraction of bad primes in P is at most $(d - 1)(d + 1)/4d^2 < 1/4$. \square

Now we present the algorithm Randomized-MCB. This is similar to the algorithm Deterministic-MCB. But here we work over the field \mathbb{F}_p for a randomly chosen prime p from the set P , instead of working over \mathbb{Q} .

2.2 Randomized-MCB

1. Compute a set P of d^2 primes p_0, p_1, \dots where each $p_j \geq d^2$. Choose a prime p uniformly at random from this set.
2. Initialize the vectors X_1, \dots, X_d of \mathbb{F}_p^m to the first d vectors of the standard basis e_1, \dots, e_d .
3. For $i = 1$ to d do
 - compute a shortest cycle B_i such that $\langle B_i, X_i \rangle \not\equiv 0 \pmod{p}$.
 - for $j = i + 1$ to d do

$$\text{update } X_j \text{ (over the finite field } \mathbb{F}_p) \text{ as: } X_j = X_j - X_i \frac{\langle B_i, X_j \rangle}{\langle B_i, X_i \rangle}$$

(An analogue of Lemma 1 shows that X_{i+1}, \dots, X_d are now orthogonal to B_1, \dots, B_i over \mathbb{F}_p .)

We will now show that $\{B_1, \dots, B_d\}$ is always a cycle basis.

Lemma 4. *The cycles B_1, \dots, B_d are linearly independent.*

Proof. We know that $\langle B_j, X_i \rangle = 0 \pmod p$ for all $j < i$. It is now easy to see that B_i is linearly independent of B_1, \dots, B_{i-1} over \mathbb{F}_p . X_i is a witness of this linear independence since $\langle B_j, X_i \rangle = 0 \pmod p$ for each $j < i$, so the inner product of X_i with any linear combination of B_1, \dots, B_{i-1} has to be zero modulo p but $\langle B_i, X_i \rangle \neq 0 \pmod p$. Hence the whole set $\{B_1, \dots, B_d\}$ is linearly independent over \mathbb{F}_p , which means that it is linearly independent over \mathbb{Q} . \square

We will next show that the set $\{B_1, \dots, B_d\}$ is a minimum cycle basis with probability at least $3/4$. In the rest of this section, we will prove the following theorem.

Theorem 1. *When p is good, Randomized-MCB computes a minimum cycle basis.*

We will assume that the algorithm Deterministic-MCB breaks ties for the shortest cycle in the same way as Randomized-MCB breaks them. That is, both the algorithms use the same rule to determine the *shorter* cycle between two cycles of equal weight. Then we can show the following.

Lemma 5. *When p is good, $B_i = C_i$, for each $1 \leq i \leq d$.*

We will show this by induction. The vector $X_1 = S_1 = (1, 0, \dots, 0)$. The inner product of any cycle with $(1, 0, \dots, 0)$ is ± 1 or 0 . The inner product will be ± 1 if and only if the cycle contains the arc a_1 . Also, looking at the inner product modulo p does not change a 1 or a -1 to 0 . So B_1 is a shortest cycle that contains the arc a_1 . C_1 is also a shortest cycle that contains the arc a_1 and so by our assumption that both these algorithms break ties identically, we have that $B_1 = C_1$.

Let us now assume that $B_j = C_j$ for $j \leq i-1$. Recall that N_i is a vector in \mathbb{Z}^m of the form $(y_1, \dots, y_{i-1}, k_i, 0, \dots, 0)$, where (y_1, \dots, y_{i-1}) is the unique solution to

$$\begin{pmatrix} \tilde{C}_1 \\ \vdots \\ \tilde{C}_{i-1} \end{pmatrix} \mathbf{x} = \begin{pmatrix} -k_i c_{1i} \\ \vdots \\ -k_i c_{(i-1)i} \end{pmatrix}. \tag{3}$$

Recall that \tilde{C}_j is the incidence vector of cycle C_j restricted to its first $i-1$ coordinates and $k_i = \det(\mathcal{M}_i)$, where \mathcal{M}_i is the $(i-1) \times (i-1)$ matrix above whose rows are \tilde{C} 's. Note that $(y_1, \dots, y_{i-1}) \pmod p$ is a solution to this set of equations in \mathbb{F}_p .

X_i is a vector in \mathbb{F}_p^m of the form $(t_1, \dots, t_{i-1}, 1, 0, \dots)$ for some t_1, \dots, t_{i-1} in \mathbb{F}_p and X_i is orthogonal to B_1, \dots, B_{i-1} in \mathbb{F}_p . Since $B_j = C_j$ for $j \leq i-1$, this means that X_i is orthogonal to C_1, \dots, C_{i-1} in \mathbb{F}_p . So in \mathbb{F}_p , (t_1, \dots, t_{i-1}) is a solution to

$$\begin{pmatrix} \tilde{C}_1 \\ \vdots \\ \tilde{C}_{i-1} \end{pmatrix} \mathbf{x} = \begin{pmatrix} -c_{1i} \\ \vdots \\ -c_{(i-1)i} \end{pmatrix}.$$

So $k_i(t_1, \dots, t_{i-1}) \bmod p$ is a solution to Equation (3) in \mathbb{F}_p . We would like to prove that Equation (3) has a unique solution in \mathbb{F}_p .

Lemma 6. *If $\langle C_j, N_j \rangle \neq 0 \pmod{p}$ for $1 \leq j \leq i-1$, then $k_i \neq 0 \pmod{p}$.*

Let us assume the above Lemma and complete the argument. Then we will prove Lemma 6. Since $\det(\mathcal{M}_i) = k_i \neq 0 \pmod{p}$, Equation (3) should have a unique solution in \mathbb{F}_p . So $k_i(t_1, \dots, t_{i-1}) \bmod p = (y_1, \dots, y_{i-1}) \bmod p$. In other words, $k_i(t_1, \dots, t_{i-1}, 1, 0, \dots, 0) \bmod p = (y_1, \dots, y_{i-1}, k_i, 0, \dots, 0) \bmod p$. That is,

$$k_i \cdot X_i \pmod{p} = N_i \pmod{p}.$$

So N_i is just a scalar multiple of X_i when these vectors are viewed as elements of \mathbb{F}_p^m . Hence for any cycle D , $\langle D, N_i \rangle \neq 0 \pmod{p}$ if and only if $\langle D, X_i \rangle \neq 0 \pmod{p}$. Since p is a good prime, $\langle C_i, N_i \rangle \neq 0 \pmod{p}$. So $\langle C_i, X_i \rangle \neq 0 \pmod{p}$. This proves that C_i is a candidate for a shortest cycle whose inner product with X_i is non-zero modulo p . And every cycle that has non-zero inner product with X_i modulo p is also a candidate cycle of Deterministic-MCB in its i -th iteration. Since C_i was the shortest among all these candidate cycles for Deterministic-MCB, we get that C_i also has to be the shortest cycle for Randomized-MCB in its i -th iteration. That is, $B_i = C_i$. This proves the induction step.

Proof of Lemma 6. We know that $\langle C_k, N_l \rangle = 0$ for $k < l$, so when we multiply the $(i-1) \times m$ matrix whose rows are C 's with the $m \times (i-1)$ matrix whose columns are N 's we get:

$$\begin{pmatrix} C_1 \\ \vdots \\ C_{i-1} \end{pmatrix} \cdot (N_1^T \dots N_{i-1}^T) = \begin{pmatrix} \langle C_1, N_1 \rangle & 0 & 0 & \dots & 0 \\ * & \langle C_2, N_2 \rangle & 0 & \dots & 0 \\ * & * & \langle C_3, N_3 \rangle & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ * & * & * & \dots & \langle C_{i-1}, N_{i-1} \rangle \end{pmatrix}$$

which is a lower triangular $(i-1) \times (i-1)$ matrix. Since each N_j has only 0's after its j -th coordinate, we can restrict the matrix of N 's to its first $i-1$ rows and the matrix of C 's to its first $i-1$ columns and we still have:

$$\begin{pmatrix} \tilde{C}_1 \\ \vdots \\ \tilde{C}_{i-1} \end{pmatrix} \cdot (\tilde{N}_1^T \dots \tilde{N}_{i-1}^T) = \begin{pmatrix} \langle C_1, N_1 \rangle & 0 & 0 & \dots & 0 \\ * & \langle C_2, N_2 \rangle & 0 & \dots & 0 \\ * & * & \langle C_3, N_3 \rangle & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ * & * & * & \dots & \langle C_{i-1}, N_{i-1} \rangle \end{pmatrix}$$

where \tilde{N}_j is the restriction of N_j to its first $i-1$ coordinates. Now all the matrices are square matrices. The determinant of the matrix of \tilde{C} 's is k_i and the determinant of the matrix of \tilde{N}_j 's is an integer. So k_i divides the determinant on the right hand side, which is $\langle C_1, N_1 \rangle \dots \langle C_{i-1}, N_{i-1} \rangle$. Since none of $\langle C_j, N_j \rangle$

is 0 modulo p for $1 \leq j \leq i - 1$, the prime p does not divide this product. So p cannot divide k_i . Hence $k_i \not\equiv 0 \pmod{p}$. \square

This also completes the proof of Lemma 5 which says that when p is good, $B_i = C_i$, for $1 \leq i \leq d$. This immediately implies Theorem 1 since $\{C_1, \dots, C_d\}$ is a minimum cycle basis. So the cycle basis computed by Randomized-MCB is a minimum cycle basis with probability at least $3/4$ (from Lemma 3).

3 Running Time of Randomized-MCB

The value of $\pi(r)$, the number of primes less than r , is given by $r/6 \log r \leq \pi(r) \leq 8r/\log r$ [1]. So the elements in P can be bounded by $100d^2 \log d$. Using sieving, we can compute the set of primes in the first $100d^2 \log d$ numbers in $O(d^2 \log^2 d)$ time. So the set P can be determined in $O(d^2 \log^2 d)$ time.

3.1 Computing B_i

Now we consider the problem of computing a shortest cycle in G whose inner product with X_i is non-zero modulo p . Let us first review the technique in [10] and then we describe our improved algorithm for this problem. Using the digraph $G = (V, A)$ and the vector X_i , an undirected graph $U_{i,p}$ can be constructed. The graph $U_{i,p}$ can be visualized as a graph with p layers. Call these layers as layer $0, \dots$, layer $(p - 1)$. Each layer has a copy of every vertex $v \in V$. Let v_j be the copy of vertex v in layer j . The edge set of $U_{i,p}$ also consists of p copies of each arc $a \in A$. The edges corresponding to arc $a = (u, v)$ are (u_j, v_k) where $k = (j + X_i(a)) \pmod{p}$ for each $j = 0, 1, \dots, p - 1$. For example, let $a = (u, v)$, $X_i(a) = 3$ and $p = 5$. Then $U_{i,p}$ has 5 copies of a which are $(u_0, v_3), (u_1, v_4), (u_2, v_0), (u_3, v_1), (u_4, v_2)$. Each edge (u_j, v_k) in $U_{i,p}$ inherits the weight of its corresponding arc (u, v) of G .

The above construction gives us a well-defined map from the vertex set of $U_{i,p}$ to the vertex set of G and from the edge set of $U_{i,p}$ to the arc set of G . We can extend this map to paths of $U_{i,p}$. Any path in $U_{i,p}$ maps to a *chain*¹ in G by mapping the vertices and edges in $U_{i,p}$ to their images in G . We say that path (e_0, \dots, e_r) in the graph $U_{i,p}$ has *repeated* edges if e_i and e_j for some $i \neq j$, map to the same arc of G .

The following properties of $U_{i,p}$ capture the essence of this graph.

- any (v_0, v_ℓ) path in $U_{i,p}$ maps to a closed chain in G .
- a (v_0, v_ℓ) path in $U_{i,p}$ with no repeated edges maps to a cycle in G .
- the inner product of such a cycle with X_i is ℓ (in \mathbb{F}_p).

The following lemma from [10] is what we need. Its proof follows easily from the above properties.

¹ a chain is an alternating sequence of vertices and arcs $(x_0, a_1, x_1, a_2, \dots, a_r, x_r)$ such that either $a_k = (x_{k-1}, x_k)$ or $a_k = (x_k, x_{k-1})$.

Lemma 7. *Let $q = \min_v \min_{\ell \neq 0}$ shortest (v_0, v_ℓ) path in the graph $U_{i,p}$. Then q corresponds to a shortest cycle in G whose inner product with X_i is non-zero modulo p .*

So B_i can be computed by running Dijkstra's algorithm from v_0 for each v in V and taking the minimum over v , of these shortest $(v_0, v_\ell), \ell \neq 0$ paths. Since $U_{i,p}$ has pn nodes and pm edges, Dijkstra's algorithm takes $O(pm + pn \log n)$ time for each v_0 . Hence the total time taken to compute the cycle B_i is $O(n \cdot (pm + pn \log n))$.

Now we will show that we can modify Dijkstra's algorithm for this application so that we take $O(m \log n)$ time for each v_0 instead of $O(pm + pn \log n)$ time.

3.2 Improved Implementation of Computing a Shortest $(v_0, v_\ell), \ell \neq 0$ Path

We will not build the graph $U_{i,p}$ explicitly. Whenever we are at a vertex u_j , we know its neighborhood as follows. If there is an arc a between u and a vertex w in G , then in $U_{i,p}$, w_k is a neighbor of u_j where $k = (j + X_i(a)) \bmod p$ if $a = (u, w)$ (directed from u to w), and $k = (j - X_i(a)) \bmod p$ if $a = (w, u)$ (directed from w to u).

The key observation here is that to compute $\min_{\ell \neq 0}$ shortest (v_0, v_ℓ) path, it is enough to look at those intermediate vertices which are the closest or second closest of their "type" to v_0 . That is, if u_j is a vertex in $\min_{\ell \neq 0}$ shortest (v_0, v_ℓ) path, then u_j is closest or second closest to v_0 among all of $\{u_0, u_1, \dots, u_{p-1}\}$. So while running Dijkstra's algorithm to determine $\min_{\ell \neq 0}$ shortest (v_0, v_ℓ) path, we only explore neighborhoods of such vertices in the priority queue.

More formally, we will have $\text{dist}[u] = \infty$ for each vertex u in $U_{i,p}$ and the priority queue Q contains all the nodes of $U_{i,p}$, keyed by their dist values. Then we start computing single-source shortest paths for each vertex in layer 0. Call one such vertex as v_0 . This procedure runs as follows:

- set $\text{dist}[v_0] = 0$.
- Maintain an array **marked** for the n vertices of G and initially $\text{marked}[u] = 0$ for each $u \in V$.
- Repeat
 - Extract the vertex x with the smallest dist value from Q .
 - If x is v_ℓ for some $\ell \neq 0$, then store $\text{dist}[v_\ell]$ and the path computed to v_ℓ and quit the Repeat loop.
 - Else let $x = u_k$.
 - if $\text{marked}[u] < 2$, then increment $\text{marked}[u]$ and for each neighbor w do

$$\text{dist}[w] = \min(\text{dist}[w], \text{dist}[x] + \text{weight}(x, w))$$
 and update predecessor of w to x if necessary.
 - else do nothing.
- For each vertex whose distance was made finite in our loop, set its dist back to ∞ and insert back to Q the deleted vertices. (so that we can now run this procedure for another vertex w_0 of layer 0)

Remark. There is always a (v_0, v_ℓ) path for some $\ell \neq 0$ in the graph $U_{i,p}$ for each $v \in G$. This is because X_i on its last $n - 1$ coordinates (which are the arcs of the spanning tree T) is 0 and $X_i \neq \mathbf{0}$. So each layer of the graph $U_{i,p}$ is connected and there is at least one edge from layer 0 to some non-zero layer.

Running Time of the Above Algorithm. We look at neighborhoods of only those vertices which are of the type u_j such that u_j is the first or second among all the vertices in $\{u_0, \dots, u_{p-1}\}$ to be extracted from the priority queue. For such vertices we make the `dist` value of their neighbors to be finite. The total number of vertices whose distance is ever made finite in our loop is bounded by $\sum_{u \in G} \deg(u_j)$ for all u_j which are closest or second closest to v_0 among the “ u ” vertices. Since $\deg(u_j) = \deg(u)$, we get the bound of $2 \sum_u \deg(u) = O(m)$. Let us implement the priority queue as a binary heap so that each of the operations needed above can be implemented in $O(\log(pn)) = O(\log n)$ amount of time. In the Repeat loop we charge the cost of extracting a vertex x to x 's predecessor in `shortest-path`(v_0, u). So for each vertex u_j which is closest or second closest among “ u ” vertices to v_0 , we do $O(\deg(u) \cdot \log n)$ amount of work. For the other vertices we do no work. We take $O(pn)$ time to build the binary heap. But we do this just once in the entire algorithm, at the beginning of our first iteration. Thereafter, we simply reset to infinity the `dist` value of only those vertices which were made finite while running our procedure for the previous vertex. Also, we insert the deleted vertices back into the heap. This takes $O(m \log n)$ work.

In iteration i , once we compute $\min_{\ell \neq 0} \text{shortest}(v_0, v_\ell)$ path for all $v \in V$, we have determined B_i . This takes time $O(n \cdot m \log n)$ given the priority queue Q containing all the vertices with their `dist` values. So the total amount of time to compute all the cycles B_1, \dots, B_d given the vectors X_1, \dots, X_d is $O(pn + d(n \cdot m \log n))$ which is $O(m^2 n \log n)$. All we need to show now is the following lemma. The proof will be given in the full version of the paper.

Lemma 8. *In order to compute $\min_{\ell \neq 0} \text{shortest}(v_0, v_\ell)$ path in $U_{i,p}$, it is enough to look at vertices which are of the form: closest or second closest of their “type” to v_0 .*

The Overall Running Time of Randomized-MCB. Under the assumption that arithmetic on $O(\log m)$ bits takes unit time, it follows that addition, subtraction and multiplication in \mathbb{F}_p can be implemented in unit time since p is $O(d^2 \log d)$. However we also need to implement division efficiently since the update step of X_j involves division. Once p is chosen, we will compute the multiplicative inverses of all elements in \mathbb{Z}_p^* by the extended Euclid’s gcd algorithm by solving $ax = 1 \pmod{p}$ for each $a \in \mathbb{Z}_p^*$. This takes time $O(\log p)$ for each element and hence $O(p \log p)$ for all the elements. Thereafter, division in \mathbb{F}_p gets implemented as multiplication with the inverse of the divisor.

We need to account for the time taken to update the vectors X_{i+1}, \dots, X_d in iteration i . Adding a scalar multiple of X_i to a vector X_j takes $\Theta(i)$ time. So the time taken by the update step in iteration i to update $d - i$ vectors is $\Theta(i(d - i))$. So the entire time taken by the update steps of all the iterations is

$\Theta(d^3)$. So the total time taken by the algorithm Randomized-MCB is $O(m^3 + m^2n \log n)$.

4 Faster Implementation

Instead of spending $\Theta(m^3)$ time for the update step, using the technique in [11] we can implement the update step in $O(m^\omega)$ time, where $\omega < 2.376$ is the exponent of matrix multiplication. This then gives us an $O(m^2n \log n)$ randomized algorithm for computing a minimum cycle basis. The algorithm FAST-Randomized-MCB is described below.

- Compute a set P of d^2 primes p_0, p_1, \dots where each $p_j \geq d^2$. Choose a prime p uniformly at random from this set.
- Call the procedure *extend_cycle_basis*($\{\}, \{e_1, \dots, e_d\}, d$), where e_1, \dots, e_d are the first d vectors of the standard basis.

The procedure *extend_cycle_basis* takes as input a partial cycle basis, say, $\{D_1, \dots, D_i\}$ (denoted by \mathcal{D}), a parameter k , and k vectors v_{i+1}, \dots, v_{i+k} of \mathbb{F}_p^m which are orthogonal to $\{D_1, \dots, D_i\}$ over \mathbb{F}_p and computes k new cycles D_{i+1}, \dots, D_{i+k} to extend the cycle basis. The role of v_{i+1}, \dots, v_{i+k} is identical to the role played by the vectors X_{i+1}, X_{i+2}, \dots at the beginning of iteration $i + 1$ in the algorithm Randomized-MCB (Section 2.2). Just as the vectors X_j got updated in Randomized-MCB, the vectors v_j get updated during the course of *extend_cycle_basis*. But the difference is that we will update *many* v_j 's with respect to *many* cycles in one bulk update step called *update*. We describe below the recursive procedure *extend_cycle_basis*. Note that all the arithmetic that we do here is over the field \mathbb{F}_p . (For clarity we will sometimes use the notation v_j^ℓ to denote the version of v_j that is orthogonal to the cycles $D_1, \dots, D_{\ell-1}$.)

The procedure *extend_cycle_basis*($\mathcal{D}, \{v_{i+1}, \dots, v_{i+k}\}, k$):

- if $k = 1$, compute a shortest cycle D_{i+1} such that $\langle D_{i+1}, v_{i+1} \rangle \neq 0 \pmod{p}$.
- if $k > 1$, use recursion. Let $t = \lfloor k/2 \rfloor$.
 1. call *extend_cycle_basis*($\mathcal{D}, \{v_{i+1}, \dots, v_{i+t}\}, t$) to extend the current cycle basis by t elements. That is, the cycles D_{i+1}, \dots, D_{i+t} are computed in a recursive manner.
 2. call *update*($\{v_{i+1}, \dots, v_{i+t}\}, \{v_{i+t+1}, \dots, v_{i+k}\}$). This updates $\{v_{i+t+1}^{i+1}, \dots, v_{i+k}^{i+1}\}$ *en masse* into the desired versions $\{v_{i+t+1}^{i+t+1}, \dots, v_{i+k}^{i+t+1}\}$ that are orthogonal to D_1, \dots, D_{i+t} .
 3. call *extend_cycle_basis*($\mathcal{D} \cup \{D_{i+1}, \dots, D_{i+t}\}, \{v_{i+t+1}, \dots, v_{i+k}\}, k - t$) to extend the current cycle basis by $k - t$ cycles. That is, the cycles $D_{i+t+1}, \dots, D_{i+k}$ will be computed recursively.

The key subroutine *update* can be implemented efficiently using fast matrix multiplication. Then the running time of FAST-Randomized-MCB becomes

$O(m^\omega + m^2n \log n)$. We can assume that G is a simple graph, so $m \leq n^2$. Then $m^\omega < m^2n$ and so the running time is $O(m^2n \log n)$. The running time analysis and the analysis that the cycle basis computed here is the same as the cycle basis computed by the algorithm Randomized-MCB follow directly from similar analysis given in [11]. They will be presented in the full version of the paper. We conclude with the following theorem.

Theorem 2. *A minimum cycle basis of a directed graph, with positive weights on its arcs, can be computed with high probability in time $O(m^2n \log n)$.*

Acknowledgments. I am grateful to Kurt Mehlhorn for useful discussions and his help in improving the presentation of the paper. I also wish to thank Jaikumar Radhakrishnan for his helpful comments and the referee for bringing the example in [14] to my attention.

Basing Cryptographic Protocols on Tamper-Evident Seals*

Tal Moran and Moni Naor**

Department of Computer Science and Applied Mathematics,
Weizmann Institute of Science, Rehovot, Israel

Abstract. In this paper we attempt to formally study two very intuitive physical models: sealed envelopes and locked boxes, often used as illustrations for common cryptographic operations. We relax the security properties usually required from locked boxes (such as in bit-commitment protocols) and require only that a broken lock or torn envelope be identifiable to the original sender. Unlike the completely impregnable locked box, this functionality may be achievable in real life, where containers having this property are called “tamper-evident seals”. Another physical object with this property is the “scratch-off card”, often used in lottery tickets. We show that scratch-off cards can be used to implement bit-commitment and coin flipping, but not oblivious transfer. Of particular interest, we give a strongly-fair coin flipping protocol with bias bounded by $O(1/r)$ (where r is the number of rounds), beating the best known bias in the standard model even with cryptographic assumptions.

1 Introduction

In this paper we consider the use of “tamper-evident seals” in cryptographic protocols. A tamper-evident seal is a primitive based on very intuitive physical models: the sealed envelope and the locked box. These are often used as illustrations for a number of basic cryptographic primitives: For example, encryption is often depicted as placing a message in a locked box (that cannot be opened without a key), while bit commitment is usually illustrated as a sealed envelope.

In a bit-commitment protocol one party, Alice, commits to a bit b to Bob in such a way that Bob cannot tell what b is. At a later time Alice can reveal b , and Bob can verify that this is indeed the bit to which she committed. The standard illustration used for a bit-commitment protocol is Alice putting b in a sealed envelope, which she gives to Bob. Bob cannot see through the envelope (so cannot learn b). When Alice reveals her bit, she lets Bob open the envelope so he can verify that she didn’t cheat.

The problem with the above illustration is that a physical “sealed envelope” is insufficient for bit-commitment: Bob can always tear open the envelope before

* This work was partially supported by the Minerva Foundation.

** Incumbent of the Judith Kleeman Professorial Chair.

Alice officially allows him to do so. Even a locked box is unlikely to suffice; many protocols based on bit-commitment remain secure only if no adversary can *ever* open the box without a key. A more modest security guarantee seems to be more easily obtained: an adversary may be able to tear open the envelope but Alice will be able to recognize this when she sees the envelope again.

“Real” closures with this property are commonly known as “tamper evident seals”. These are used widely, from containers for food and medicines to high-security government applications. Another common application that embodies these properties is the “scratch-off card”, often used as a lottery ticket. This is usually a printed cardboard card which has some areas coated by an opaque layer (e.g., the possible prizes to be won are covered). The text under the opaque coating cannot be read without scratching off the coating, but it is immediately evident that this has been done.

In this paper we attempt to clarify what it means to use sealed envelopes in a cryptographic protocol. In particular, we study their applicability to coin flipping (CF), zero-knowledge protocols, bit commitment (BC) and oblivious transfer (OT), some of the most fundamental primitives in modern cryptography.

Our Results. In this paper we show that the sealed envelopes we consider can be used to implement standard cryptographic protocols. We construct protocols for “weakly fair” CF (in which the result is 0, 1 or *invalid*) and BC.

The existence of BC immediately implies the existence of a zero-knowledge proof system for any NP language [16]. In the full version, we also show a non-interactive zero knowledge proof system (with a preprocessing stage) for any NP language that can be implemented using pre-printed scratch-off cards.

A possibly practical application of our model is the “cryptographic randomized response technique” (CRRT), defined by Ambainis et al. [2]. “Randomized response” is a polling technique used when some of the answers to the poll may be stigmatizing (e.g., “do you use drugs?”). The respondent lies with some known probability, allowing statistical analysis of the results while letting the respondent disavow a stigmatizing response. In a CRRT, there is the additional requirement that a malicious respondent cannot bias the results more than by choosing a different answer. The techniques described by Ambainis et al. achieve this, but require “heavy” cryptographic machinery (such as OT), or quantum cryptography. In the full version of the paper we give a simple protocol for CRRT using scratch-off cards.

One of the most interesting results is a protocol for “strongly fair” CF (where the result for an honest player must be either 0 or 1 even if the other player quits before finishing the protocol) with bias bounded by $O(\frac{1}{r})$, where r is the number of rounds. In the standard model, even with cryptographic assumptions, the best known bias for a protocol with r rounds is $O(\frac{1}{\sqrt{r}})$ (due to Cleve [8]). For a large class of protocols (including any that rely on bit-commitment or weakly fair coin flipping as a black-box), an unpublished result of Cleve and Impagliazzo [9] shows this is the best possible bias.

An important contribution of this paper is the *formal* analysis for the models and protocols we construct. We show that the protocols are *Universally Com-*

posable in the sense of Canetti [7]. This allows us to use them securely as “black-boxes” in larger constructions.

On the negative side, we show that our protocol for strongly fair CF using scratch-off cards is optimal: it is impossible to do better than $O(\frac{1}{r})$ bias (this follows from a careful reading of the proof in [8]; the proof appears in the full version). We show that OT cannot be implemented using scratch-off cards without additional assumptions (note that we show the impossibility of *any* type of OT, not just universally composable realizations).

Seals in Different Flavors. In the full version of the paper, we consider some additional variants of tamper-evident seals. Roughly speaking, the difference arises from whether or not a party can distinguish their own containers from those of the other party without opening the seal, and whether or not an honest player can “break” the seal. Scratch-off cards correspond to the distinguishable case in which the honest party *can* break the seal. We show that in a distinguishable “weak-lock” model, where the honest party cannot break the seal, even BC cannot be implemented (the proof is similar to the impossibility of OT, while in the indistinguishable case it is possible to implement both BC and OT. Due to space constraints, this paper will concentrate solely on the “distinguishable envelope” (scratch-off card) model. Note that in the standard model of cryptography, where the parties exchange messages and there is no access to outside physical resources, we do not know how to implement any of these closures.

Related Work. To the best of our knowledge, this is the first attempt at using tamper evident seals for cryptographic protocols. Ross Anderson discusses “packaging and seals” in the context of security engineering [3], however the use of tamper-evidence does not extend to more complex protocols. Blaze gives some examples of the reverse side of the problem: cryptanalysis of physical security systems using techniques from computer science [4, 5]. Using scratch-off cards in the lottery setting can be described as a very weak form of CF, however we do not believe this has ever been formally analyzed (or used in more complex protocols).

On the other hand, basing cryptographic protocols on physical models is a common practice. Perhaps the most striking example is the field of quantum cryptography. One of the inspirations for this work was the idea of “Quantum Bit Escrow” (QBE) [1], a primitive that is very similar to a tamper-evident seal and that can be implemented in a quantum setting. There are, however, significant differences between our definitions of tamper-evident seals and QBE. In particular, in QBE the adversary may “entangle” separate escrowed bits and “partially open” commitments. Thus, while unconditionally secure bit-commitment is impossible in the pure quantum setting [19, 18], it is possible in ours.

Much work has been done on basing BC and OT on the physical properties of communication channels, using the random noise in a communication channel as the basis for security. Both BC and OT were shown to be realizable in the *Binary Symmetric Channel* model [11, 10], in which random noise is added to the channel in both directions with some known, constant, probability. Later work shows that they can also be implemented, under certain conditions, in the

weaker (but more convincing) *Unfair Noisy Channel* model [13, 12], where the error probability is not known exactly to the honest parties, and furthermore can be influenced by the adversary. Our construction for 1-2 OT uses some of the techniques and results from [13].

One of the motivations for this work was the attempt to construct cryptographic protocols that are implementable by humans without the aid of computers. This property is useful, for example, in situations where computers cannot be trusted to be running the protocol they claim, or where “transparency” to humans is a requirement (such as in voting protocols). Many other examples exist of using simple physical objects as a basis for cryptographic protocols that can be performed by humans, some are even folklore: Sarah Flannery [15] recounts a childhood riddle that uses a doubly-locked box to transfer a diamond between two parties, overcoming the corrupt postal system (which opens any unlocked boxes) despite the fact that the two parties have never met (and can only communicate through the mail). Fagin, Naor and Winkler [14] assembled a number of solutions to the problem of comparing secret information without revealing anything but the result of the comparison using a variety of different physical methods. Schneier devised a cipher [21] that can be implemented by a human using a pack of cards. In a lighter vein, Naor, Naor and Reingold [20] give a protocol that provides a “zero knowledge proof of knowledge” of the correct answer to the children’s puzzle “Where’s Waldo” using only a large newspaper and scissors. A common thread in these works is that they lack a formal specification of the model they use, and a formal proof of security.

Organization of the Paper. In Section 2, we give a formal definition for tamper-evident envelopes and the functionalities we attempt to realize using them. In Section 3 we discuss the capabilities of this model, showing that OT is impossible and giving protocols for BC and strongly-fair CF with bias $1/r$. Section 4 contains the discussion and some open problems.

2 The Model: Ideal Functionalities

Many two-party functionalities are easy to implement using a trusted third party that follows pre-agreed rules. In proving that a two-party protocol is secure, we often want to say that it behaves “as if it were performed using the trusted third party”. A formalization of this idea is the “Universally Composable” model defined by Canetti [7]. In the UC model, the trusted third party is called the *ideal functionality*. The point of the model is that protocols that are secure in the UC have very strong security properties, such as security under composition and security that is retained when the protocol is used as a sub-protocol to replace an ideal functionality. This security guarantee allows us to simplify many of our proofs, by showing separately the security of their component sub-protocols.

Note that our impossibility results are not specific to the UC model: the impossibility results for BC (in the full version of the paper), OT (Section 3)

and the lower bound for strongly fair CF (also in the full version) hold even for the much weaker “standard” notions of these functionalities¹.

In this section we formally define tamper-evident envelopes in terms of their ideal functionalities. For completeness, we also give the definitions of the primitives we are trying to implement (CF, BC, and OT). We restrict ourselves to the two-party case, and to adversaries that decide at the beginning of the protocol whether to corrupt one of the parties or neither.

Distinguishable Envelopes. This functionality models an opaque envelope (or scratch-off card). Without opening the envelope it is impossible to determine its contents. Any party can decide to rip open the envelope (breaking the seal), but this will be evident to the envelope’s creator if the envelope is returned.

In succeeding sections, we assume we are given a realization of this functionality and attempt to construct a protocol for a “target” functionality (these are described below)

Functionality \mathcal{F}_{DE} contains an internal table that consists of tuples of the form $(id, value, creator, holder, state)$. The table represents the state and location of the tamper-evident envelopes, and contains one entry for each existing envelope, indexed by the envelope’s id. We denote $value_{id}$, $creator_{id}$, $holder_{id}$ and $state_{id}$ the corresponding values in the table in row id (assuming the row exists). The table is initially empty. The functionality is as follows, running with parties P_1, \dots, P_n and adversary S :

Seal $(id, value)$. On receiving this command from party P_i , if this is the first message with id id store the tuple $(id, value, P_i, P_i, sealed)$ in the table (if this is not the first message with id id , do nothing).

Send (id, P_j) . On receiving this command from party P_i , the functionality checks if an entry for envelope id appears in the table and that $holder_{id} = P_i$. If so, it outputs $(Receipt, id, P_i, P_j)$ to P_j and S and replaces the entry in the table with $(id, value_{id}, creator_{id}, P_j, state_{id})$. Otherwise, it does nothing.

Open id . On receiving this command from P_i , the functionality checks that an entry for envelope id appears in the table, that $holder_{id} = P_i$. If not, the message is ignored. Otherwise, it sends $(Opened, id, value_{id}, creator_{id})$ to P_i and S . It then replaces the entry in the table with $(id, value_{id}, creator_{id}, holder_{id}, broken)$.

Verify id . On receiving this command from P_i , the functionality checks that an entry for envelope id appears in the table and that $holder_{id} = P_i$. If not, the message is ignored. If so, it considers $state_{id}$. If $state_{id} = broken$ it sends $(Verified, id, broken)$ to P_i and S . Otherwise, it sends $(Verified, id, ok)$ to P_i and S .

A Note about Notation. In the interests of readability, we will often refer to parties “preparing”, “verifying” and “opening” envelopes, instead of specifying that

¹ We *do* assume the “interface” supplied by the envelope primitives is the one defined by the ideal functionality (e.g., we do not allow putting one envelope inside another).

they send the corresponding messages (**Seal**, **Verify**, **Open**) to the functionality and wait for the appropriate response.

Weakly Fair Coin Flipping. This functionality models coin flipping in which the result of the coin flip can be 0, 1 or \perp . The result of the flip c should satisfy: $\Pr[c = 0] \leq \frac{1}{2}$ and $\Pr[c = 1] \leq \frac{1}{2}$. This is usually what is meant when talking about “coin flipping” (for instance, in Blum’s protocol [6]). The \perp result corresponds to the case where one of the parties deviated from (or prematurely aborted) the protocol. Under standard cryptographic assumptions (such as the existence of one-way functions), weakly fair coin flipping is possible. Conversely, in the standard model the existence of weakly fair coin flipping implies one-way functions [17].

Functionality \mathcal{F}_{WCF} is as follows, with parties Alice and Bob (in this definition we only allow Bob to trigger an invalid output):

Value. The sender of this command is called the *initiator*. The other party is the *receiver*. When this command is received, the functionality chooses a uniform value $d \in \{0, 1\}$. If the receiver is corrupted, the functionality then outputs “approve d ” to the receiver. In that case, the functionality ignores all input until it receives either a **Continue** command or a **Stop** command from the receiver. If the receiver is not corrupted, the functionality proceeds as if he had sent a **Continue** command.

Stop. When this command is received from a corrupt receiver (in response to an “approve d ” message) the functionality outputs \perp to all parties and halts.

Continue. When this command is received from the receiver (in response to an “approve d ” message), the functionality outputs “coin is d ” to all parties and halts.

Strongly Fair Coin Flipping with Bias p (Adapted from [7]). This functionality models a coin flip between two parties with a bounded bias. If both parties follow the protocol, they output an identical uniformly chosen bit. Even if one party does not follow the protocol², the other party outputs a random bit whose bias towards 0 or 1 is at most p .

Functionality \mathcal{F}_{SCF} is as follows:

Value. When this command is received for the first time from any party, the functionality chooses a value $d \in \{0, 1\}$. It then outputs “accept d ?” to the adversary. If the adversary responds with **no**, with probability p the functionality outputs “value $1 - d$ ” to all parties and with probability $1 - p$ outputs “value d ” to all parties. If the adversary responds with **yes** (or does not respond), the functionality outputs “value d ” to all parties.

² In “not following the protocol” we include halting (failing to respond). The UC model does not explicitly handle this behaviour, however we can treat it as a special “halt” command that can be sent by the adversary.

Bit Commitment (Adapted from [7]). Functionality \mathcal{F}_{BC} :

Commit b . The issuer of this command is called the sender, the other party is the receiver. On receiving this command the functionality records b and outputs “committed” to the receiver. It then ignores any other commands until it receives the **Open** command from the sender.

Open. On receiving this command from the sender, the functionality outputs “opened b ” to the receiver.

2.1 Intermediate Functionalities

In order to simplify the presentation, in the following sections we will present protocols that realize functionalities that are slightly weaker than the ones we want. We then use standard amplification techniques to construct the “full” functionalities from their weak version. In this section we define these intermediate functionalities and give the amplification lemmas we use to construct the stronger versions of these primitives. These definitions are in the spirit of [13].

(p, q) -Weak Bit-Commitment. This functionality models bit commitment where a corrupt sender can cheat with probability q while a corrupt receiver can cheat with probability p . The result of failing to cheat is asymmetric. In the case of a corrupt receiver, an unsuccessful attempt to cheat causes the sender to be notified, while a corrupt sender risks nothing in attempting to cheat. Note that an (ϵ, ϵ) -WBC protocol is a regular bit-commitment protocol when ϵ is negligible. Formally, functionality $\mathcal{F}_{(p,q)\text{-WBC}}$ proceeds as follows:

Commit b . The issuer of this command is called the sender, the other party is the receiver. On receiving this command the functionality records b and outputs “committed” to the receiver. It then ignores any other commands until it receives an **Open** command from the sender, an **OpenFlip** command from a corrupt sender or a **Break** command from a corrupt receiver.

Open b . On receiving this command from the sender, the functionality checks that the sender previously sent a **Commit b** command. If so, or if the sender is corrupt and previously sent a **CanEquivocate** command whose response was “Can Equivocate”, the functionality outputs “opened b ” to the receiver. Otherwise the command is ignored.

CanEquivocate On receiving this command from a corrupt sender, choose a value r uniformly in $[0, 1]$. If $r \geq q$ send “No Equivocation” to the sender and ignore further **CanEquivocate** messages. If $r < q$ send “Can Equivocate” to the sender.

Break On receiving this command from a corrupt receiver, choose a value r uniformly in $[0, 1]$. If $r \geq p$ send “cheating receiver” to the sender and receiver and then halt. Otherwise, send b to the receiver.

We can amplify any (p, q) -WBC protocol when $p, q < 1$, meaning that the existence of such a protocol implies the existence of regular BC.

Theorem 1. *Let P be a (p, q) -WBC protocol and $p, q < 1$. Then there exists an (ϵ, ϵ) -WBC for any $\epsilon > 0$ using $O(\log^2(\frac{1}{\epsilon}))$ invocations of P .*

The proof for this theorem is straightforward, and will be given in the full version.

(p, q) -Remotely Inspectable Seal (RIS). This functionality is used in our protocol for strongly fair CF. It is a strengthened version of a tamper-evident seal. With a tamper-evident seal, only its holder can interact with it. Thus, either the sender can check if it was opened, or the receiver can verify that the sealed contents were not changed, but not both at the same time. A remotely inspectable seal is one that can be tested “remotely” (without returning it to the sender). Unfortunately, we cannot realize the ideal version, and therefore relax it somewhat: we allow a corrupt receiver to learn the committed bit during the verification process, and only then decide (assuming he did not previously break the seal) whether or not the verification should succeed. Our definition is actually a further relaxation³: both sender and receiver may cheat with some probability. A corrupt sender can cause the result of the **Open** command to be a uniformly random value (instead of a specific value determined in the commit stage). The receiver will catch the sender with probability at least $1 - q$. A corrupt receiver who opens the commitment before the verify stage will be caught with probability $1 - p$.

Formally, the functionality maintains an internal state variable $v = (v_b, v_s)$ consisting of the committed bit v_b and a “seal” flag v_s . It accepts the commands:

Commit b . The issuer of this command is called the sender, the other party is the receiver. b can be either 0, 1 or (if the sender is corrupt) \perp . If $b \in \{0, 1\}$ (the sender did not try to cheat), the functionality sets $v \leftarrow (b, \text{sealed})$. If $b = \perp$ (the sender tried to cheat) with probability q (the sender cheated successfully) $v \leftarrow (r, \text{sealed})$ (where r is randomly chosen from $\{0, 1\}$) and with probability $1 - q$ it sets $v \leftarrow (\perp, \text{sealed})$. In any case the functionality concludes by outputting “committed” to the receiver, and ignoring any subsequent **Commit** commands.

Open. This command is sent by the receiver. If $v_b \in \{0, 1\}$ the functionality outputs “opened b ” to the receiver. Otherwise it outputs “invalid” to the receiver. If $v_s = \text{sealed}$, with probability $1 - p$ the functionality sets $v_s \leftarrow \text{open}$.

Verify. If $v_s \neq \text{sealed}$, the functionality outputs “invalid” to the sender. Otherwise (no opening was detected), the functionality outputs “verifying value b ” to the adversary and waits for a response. If the adversary responds with **ok**, the functionality outputs “sealed” to the sender, otherwise it outputs “invalid” to the sender. After receiving this command from the sender (and responding appropriately), the functionality ignores any subsequent **Verify** commands.

³ This second relaxation is only for convenience; we can remove it using amplification as noted in Theorem 2.

A (p, q) -Remotely Inspectable Seal can be amplified for any $p < 1$ and $q \leq 1$:

Theorem 2. *Let P be a (p, q) -RIS protocol $p < 1$ and $q \leq 1$. Then there exists an (ϵ, ϵ) -RIS for any $\epsilon > 0$ using $O(\log^2(\frac{1}{\epsilon}))$ invocations of P*

Note that the amplification works even if $q = 1$: this is because the adversary doesn't have full control over the revealed bit but can only cause it to be a random bit. The proof of this theorem will appear in the full version.

3 Capabilities of the Distinguishable Envelope Model

Oblivious Transfer is Impossible. Let Alice be the sender and Bob the receiver. Consider Alice's bits a_0 and a_1 , as well as Bob's input c , to be random variables taken from some arbitrary distribution. Alice's view of a protocol execution can also be considered a random variable $V_A = (a_0, a_1, r_A, N_1, \dots, N_n)$, consisting of Alice's bits, random coins (r_A) and the sequence of messages that comprise the transcript as seen by Alice. In the same way we denote Bob's view with $V_B = (c, r_B, M_1, \dots, M_n)$, consisting of Bob's input and random coins and the sequence of messages seen by Bob.

The essence of oblivious transfer (whether universally composable or not) is that Bob gains information about one of Alice's bits, but Alice does not know which one. We can describe the information Bob has about Alice's bits using Shannon entropy, a basic tool of information theory. The Shannon entropy of a random variable X , denoted $H(X)$ is a measure of the "uncertainty" that resides in X . When X has finite support: $H(X) = -\sum_x \Pr[X = x] \log \Pr[X = x]$.

Suppose Bob's view of a specific protocol transcript is v_B . What Bob learns about a_i ($i \in \{0, 1\}$) can be described by the conditional entropy of a_i given Bob's view of the protocol. We write this $H(a_i | V_B = v_B)$. If Bob knows a_i at the end of the protocol then $H(a_i | V_B = v_B) = 0$ since there is no uncertainty left about the value of a_i given Bob's view. If Bob has no information at all about a_i then $H(a_i | V_B = v_B) = 1$, since there are two equally likely values of a_i given Bob's view.

We show that in any protocol in the DE Model, Alice can calculate the amount of information Bob has about each of her bits:

Theorem 3. *For any protocol transcript where $V_A = v_A$ and $V_B = v_B$, both $H(a_0 | V_B = v_B)$ and $H(a_1 | V_B = v_B)$ are completely determined by v_A .*

In any OT protocol, Bob must have full information about a_c (c is Bob's "choice" bit): $H(a_c | V_B = v_B) = 0$, and no information at all about a_{1-c} : $H(a_c | V_B = v_B) = 1$. The theorem states that in this case Alice can determine c , violating the "obliviousness" requirement of the protocol.

Due to space considerations, we do not give the proof of Theorem 3 here. The basic idea is that for any injection f and any random variable Y , the event $Y = y$ is identical to the event $f(Y) = f(y)$. Therefore, for any two random variables X and Y , it holds that $H(X | Y = y) = H(X | f(Y) = f(y))$. We show an

injection from V_B to V_A, r_B, c . Since r_B and c must be independent of (a_0, a_1) , we can conclude that Alice can compute $H(a_0 | V_B = v_B)$ and $H(a_1 | V_B = v_B)$ for any transcript. A similar argument holds for Bob.

A $(\frac{3}{4}, \frac{1}{2})$ -Weak Bit Commitment Protocol. We will show a weak bit commitment protocol, and apply Theorem 1 to amplify the protocol and construct a “standard” bit commitment protocol.

To implement **Commit** b :

1. Bob prepares four sealed envelopes, two containing a 0 and two a 1 in random order. Bob sends the envelopes to Alice
2. Alice opens three envelopes (chosen randomly), and verifies that they are not all the same. Let r be the value in the remaining (sealed) envelope. Alice sends $d = b \oplus r$ to Bob.

To implement **Open**:

1. Alice sends b and the sealed envelope to Bob.
2. Bob verifies that it is sealed, then opens it. He checks that $d = b \oplus r$.

Intuitively, Bob can cheat only by sending three envelopes with the same bit in the commit phase. However, Alice will catch him with probability $\frac{1}{4}$. Alice can cheat by opening less than three envelopes (and guessing d). She will then be caught in the open phase with probability at least $\frac{1}{2}$. A proof of security will appear in the full version.

A Strongly Fair Coin Flipping Protocol with Bias $O(\frac{1}{r})$. The construction uses remotely inspectable seals (defined in Sec. 2.1), which we then show how to implement in the DE model. The idea is similar to the “standard” CF protocol using BC: Alice commits to a random bit a . Bob sends Alice a random bit b , after which Alice opens her commitment. The result is $a \oplus b$.

The reason that this is not a strongly fair CF protocol is that Alice learns the result of the toss before Bob, and can decide to quit before opening her commitment. Using RIS instead of BC solves this problem, because Bob can open the commitment without Alice’s help.

Ideally, we would like to replace BC with RIS (and have Alice verify that Bob didn’t break the seal before sending b). This seems to work; If Bob quits before verification, or if the verification fails, Alice can use a as her bit, because Bob had to have decided to quit before seeing a . If Bob quits after verification (and the verification passed), Alice can use $a \oplus b$, since Bob sent b before learning a . This idea fails, however. The reason is that RIS allows Bob to see the committed bit *during* verification. If he doesn’t like it, he can cause the verification to fail.

We can overcome the problem with probability $1 - \frac{1}{r}$ by doing the verification in r rounds. The trick is that Alice secretly decides on a “threshold round”: after this round a failure in verification won’t matter. Bob doesn’t know which is the threshold round (he can guess with probability at most $1/r$). If Bob decides to stop before the threshold round, either he did not attempt to illegally open a

commitment (in which case his decision to stop cannot depend on the result of the coin flip), or he illegally opened all the remaining commitments (opening less than that gives no information about the result). In this case all subsequent verifications will fail, so he may as well have simply stopped at this round (note that the decision to open is made before knowing the result of the coin flip). Clearly, anything Bob does after the threshold round has no effect on the result. Only if he chooses to illegally open commitments during the threshold round can this have an effect on the outcome (since in this case, whether or not the verification fails determines whether Alice outputs a or $a \oplus b$). The full protocol is as follows:

1. Alice chooses r random bits a_1, \dots, a_r and commits to each bit using the RIS scheme (this is done in parallel). Denote $a = a_1 \oplus \dots \oplus a_r$,
2. Bob chooses a random bit b . If Alice quits before finishing the commit stage, Bob outputs b . Otherwise, he sends b to Alice.
3. If Bob quits before sending b , Alice outputs a . Otherwise, Alice chooses a secret index $j \in \{1, \dots, r\}$.
4. The protocol now proceeds in r rounds. Round i has the following form:
 - (a) Alice verifies that Bob did not open the commitment for a_i .
 - (b) Bob opens the commitment for a_i .
5. If the verification is successful up to round j (and Bob didn't quit up to round j), Alice outputs $a \oplus b$. Otherwise, Alice outputs a .
6. Bob always outputs $a \oplus b$ (If Alice quits before completing the verification rounds, Bob opens the commitments without verification).

Implementation of Remotely Inspectable Seals. We start by giving a $(\frac{1}{2}, 1)$ -RIS protocol. We can then apply Theorem 2 to amplify it to (ϵ, ϵ) -RIS for some negligible ϵ . To implement **Commit** b :

1. Alice sends two envelopes to Bob, each containing the bit b .

To implement **Verify**:

1. Alice initiates a (weakly fair) coin flip with Bob.
2. Denote the result of the coin flip r . Bob returns envelope r to Alice.
3. Alice waits for the result of the coin flip and the envelope from Bob. If the result is \perp , or if Bob does not return an envelope, Alice outputs “opened”. Otherwise, Alice verifies that Bob returned the correct envelope, and that it is still sealed. If both of these conditions are not satisfied, she outputs “sealed”, otherwise she outputs “opened”.

To implement **Open**:

1. Bob randomly chooses one of the envelopes in his possession (if he already returned one to Alice during the **Verify** stage then he opens the one he has left). He outputs the contents of the envelope.

4 Discussion and Open Problems

The protocols we describe in this paper can be performed by unaided humans, however they require too many “envelopes” to be practical for most uses. It would be useful to construct protocols that can be performed with a smaller number of envelopes or with a smaller number of rounds.

Another point worth mentioning is that the protocols we construct only require one of the parties to seal and verify envelopes. Thus, the binding property is only used in one direction, and the tamper-evidence and hiding properties in the other. This property is useful when we want to implement the protocols in a setting where one of the parties may be powerful enough to open the seal undetectably. (for instance, in the context of voting, where one of the parties could be “the government” while the other is a private citizen)

In both the weakly and strongly fair CF protocols, only the first round requires envelopes to be created, and their contents do not depend on communication with the other party. This allows the protocols to be implemented using scratch-off cards (which must be printed in advance). In particular, the weakly fair CF protocol can be implemented with a scratch-off card using only a small number of areas to be scratched (this protocol is given in the full version).

In the case of BC, our protocol requires the powerful party to be the receiver. It would be interesting to construct a BC protocol for which the powerful party is the sender (i.e., only the sender is required to seal and verify envelopes).

Abstract. We introduce the notion of hybrid trapdoor commitment schemes. Intuitively an hybrid trapdoor commitment scheme is a primitive which can be either an unconditionally binding commitment scheme or a trapdoor commitment scheme depending on the distribution of commitment parameters. Moreover, such two distributions are computationally indistinguishable. Hybrid trapdoor commitments are related but different with respect to *mixed* commitments (introduced by Damgård and Nielsen at Crypto 2002). In particular hybrid trapdoor commitments can either be polynomially trapdoor commitments or unconditionally binding commitments, while mixed commitment can be either trapdoor commitments or extractable commitments. In this paper we show that strong notions (e.g., simulation sound, multi-trapdoor) of hybrid trapdoor commitments admit constructions based on the sole assumption that one-way functions exist as well as efficient constructions based on standard number-theoretic assumptions. To further stress the difference between hybrid and mixed commitments, we remark here that mixed commitments seems to require stronger theoretical assumptions (and the known number-theoretic constructions are less efficient). The main application of our results is that we show how to construct concurrent and simulation-sound zero-knowledge proof (in contrast to the arguments recently presented in [1, 2, 3]) systems in the common reference string model. We crucially use hybrid commitment since we present general constructions based on the sole assumption that one-way functions exists and very efficient constructions based on number-theoretic assumptions.

* Extended abstract. The full version of this paper can be found at <http://www.di.ens.fr/~catalano>.

1 Introduction

Commitment schemes are arguably among the most important and useful primitives in cryptography. Intuitively a commitment scheme can be seen as the digital equivalent of a sealed envelope. If a party A wants to commit to some message m she just puts it into the sealed envelope, so that whenever A wants to reveal the message, she opens the envelope. Clearly, such a mechanism can be useful only if it meets some basic requirements. First of all the digital envelope should *hide* the message: no party other than A should be able to learn m from the commitment (this is often referred in the literature as the hiding property). Second, the digital envelope should be *binding*, meaning with this that A cannot change her mind about m , and by checking the opening of the commitment one can verify that the obtained value is actually the one A had in mind originally (this is often referred as the binding property). These two properties make commitments very useful in a wide range of cryptographic applications such as zero-knowledge protocols, multi-party computation, digital auctions and electronic commerce.

A *commitment scheme* is a primitive to generate and open commitments. More precisely a commitment scheme is a two-phase interactive protocol between two probabilistic polynomial time algorithms **sender** and **receiver**. In a first stage (called the *commitment* phase) **sender** commits to a bit b using some appropriate function Com which takes as input b and some auxiliary value r and produces as output a value y . The value y is sent to **receiver** as a commitment on b . In the second stage (called the *decommitment* phase) **sender** “convinces” **receiver** that y is actually a valid commitment on b by revealing b and the auxiliary input r (if **receiver** is not convinced, it just outputs some special string). The requirements that we make on a commitment scheme are the following ones. First, if both **sender** and **receiver** behave honestly, then at the end of the decommitment phase **receiver** is convinced that **sender** had committed to bit b with probability 1. This is often referred as the *correctness* requirement. Second a cheating **receiver** cannot guess b with probability significantly better than $1/2$. This is the so-called *hiding* property. Finally, a cheating **sender** should be able to open a commitment (i.e., to decommit) with both b and $1 - b$ only with very small (i.e., negligible) probability (this is the *binding* property). Each of the last two properties (i.e., hiding and binding) can be satisfied unconditionally or relatively to a computational assumption. In our context (i.e., where only two parties are involved) this immediately implies that one cannot hope to build a commitment scheme where both the hiding and the binding properties hold unconditionally. Unconditionally binding commitment schemes have been constructed under the sole assumption that one-way functions exist [4] and in such a construction an initial message of the receiver is required. It is known how to construct non-interactive unconditionally binding commitment schemes by using any one-way permutation [5]. Constant-round (actually 2-round) unconditionally hiding commitment schemes have been constructed under the assumption that collections of claw-free functions exist [5].

Since commitment schemes are very useful primitives they are often used as building blocks to construct larger protocols. In this sense it is often the case

that the two basic requirements described above turn out to be insufficient. For this reason commitment schemes with additional properties have been proposed.

A *trapdoor commitment scheme* (sometimes also called *chameleon* commitment), is a commitment scheme with associated a pair of public and private keys (the latter also called the *trapdoor*). Knowledge of the trapdoor allows the sender to open the commitment in more than one way (this is often referred as the *equivocality* property). On the other hand, without knowledge of the trapdoor, equivocality remains computationally infeasible. When the commitments computed by means of a trapdoor are distributed exactly as real commitments then the trapdoor commitment scheme is unconditionally hiding. Instead, the equivocality property allows only computationally binding trapdoor commitment schemes.

1.1 Our Contributions

In this paper we introduce the notion of hybrid trapdoor commitment schemes. Informally an hybrid trapdoor commitment scheme is a general commitment primitive that allows for two commitment parameters generation algorithms **HGen** and **HTGen**. If the commitment parameters are obtained as the output of **HGen** then the resulting scheme is an unconditionally binding commitment scheme, while if the parameters are generated by **HTGen** the produced scheme is actually a trapdoor commitment scheme. Moreover, as for mixed commitments, no polynomially bounded adversary, taking as input only the (public) commitment parameters, should be able to tell the difference between keys generated from **HGen** and keys produced by **HTGen**.

Comparison with Mixed Commitments. Notice that the notion of hybrid trapdoor commitment may look very similar to that of mixed commitment introduced in [6]. There is a crucial difference however. Depending on the way the parameters are generated a mixed commitment can be either an extractable commitment or a trapdoor commitment. In our case, on the other hand, we require only that the commitment is either unconditionally binding or a trapdoor commitment scheme. As mentioned before, mixed commitments have been introduced to construct universally composable commitments and indeed Damgård and Nielsen proved that it is possible to construct a universally composable commitment from a mixed commitment where the number of E -keys (over the total number of keys) is negligible and that the number of X -keys (over the total number of keys) is only negligibly less than 1. Interestingly, a recent result by Damgård and Groth [7] shows that universally composable commitments imply key exchange and, when implemented in the shared random string model, they imply oblivious transfer. Therefore it seems unlikely that universally composable commitments (in the sense of [6]) can be implemented from one-way functions only. In this paper, on the other hand, we show that hybrid trapdoor commitments can be constructed from any one-way function.

Efficient Implementations. To improve on efficiency we then turn our attention to specific number-theoretic constructions and in particular we propose

a very efficient implementations that relies on the Decisional Diffie-Hellmann assumption (other constructions based on Paillier’s [8] Decisional Composite Residuosity Assumption can be found in the full version of this paper).

Stronger Extensions. As a second major contribution of this paper, we study some stronger extensions of hybrid trapdoor commitments. In particular we show how to build hybrid simulation-sound trapdoor commitments (hybrid SSTC, for short) and hybrid multi-trapdoor commitments from the sole assumption that one-way functions exist. Note that for the case of multi-trapdoor commitments their equivalence to one-way functions was not known. In this paper we show that multi-trapdoor commitment schemes are actually equivalent to digital signatures which are secure with respect to *generic* chosen message attack. Informally in a generic chosen message attack the adversary can obtain signatures only on a list of messages chosen *before* the public key of the signer is published. This is clearly a weaker notion with respect to the standard one where the adversary is allowed to choose the messages adaptively. Since SSTC’s are actually equivalent to standard secure signatures, from a practical point of view, our result further clarifies why the known (practical) implementations of multi-trapdoor commitments are more efficient than the corresponding implementations of SSTC.

Applications. We use the different variants of hybrid trapdoor commitments for achieving the following applications. Using hybrid trapdoor commitments we show how to construct 3-round concurrent zero-knowledge proof systems, in the common reference string model, for all \mathcal{NP} languages. We give a construction based on the existence of any one-way function and an efficient construction that is based on the DDH assumption. These results improves the computational soundness achieved in a previous result by Damgård [1] in the sense that ours are actually zero-knowledge proofs rather than zero-knowledge arguments. Using either hybrid SSTC or hybrid multi-trapdoor commitments we show how to construct an unbounded simulation-sound zero-knowledge proof system in the common reference string model. This improves the recent results of [3, 2] where similar results were presented for unbounded simulation-sound zero-knowledge arguments (rather than proofs).

Proofs vs Arguments. A proof system has the following property: any adversarial prover (regardless of his computing power) has negligible probability of making a honest verifier accept a false statement. This strong notion of soundness differs from the corresponding notion of soundness of an argument system, where security for honest verifiers holds only against polynomial-time adversarial provers. The notions of argument and proof differ dramatically when zero knowledge is considered. For example, while it is known that any \mathcal{NP} language has a perfect zero-knowledge argument [9], if an \mathcal{NP} -complete language has a perfect zero-knowledge proof then the polynomial hierarchy collapses to its second level [10, 11]. With respect to constant-round zero knowledge, the current state of knowledge gives us a constant-round (computational) zero-knowledge proof for \mathcal{NP} under the assumption that collections of claw-free functions ex-

ist [5], while constant-round zero-knowledge arguments for \mathcal{NP} are known to exist under the assumption that one-way functions exist [12].

As discussed above, in this paper we show that our new notion of commitment scheme can be used to obtain some strong variants of zero-knowledge proof systems improving the current state-of-the art in which only arguments have been shown.

2 Definitions

We now give some basic definitions that we will use in this paper. We use the notation $\{\beta_1, \dots, \beta_k : \alpha\}$ to specify the probability distribution of α after the sequential executions of events β_1, \dots, β_k . In general, we assume that an algorithm \mathcal{A} has access to some random (auxiliary) input even though this is not explicitly specified. Moreover, if A is a probabilistic algorithm we denote with $A(x)$ the random variable describing the output of A on input x . We say that a function ν is *negligible* iff for all constants c there exists n_0 such that for all $n > n_0$ it holds that $0 < \nu(n) < \frac{1}{n^c}$. A binary relation R is polynomially bounded if it is decidable in polynomial time and there exists a polynomial p such that for all pairs $(x, y) \in R$ it holds that $|y| \leq p(|x|)$. We denote by $L_R = \{x \mid \exists y : (x, y) \in R\}$ the \mathcal{NP} -language associated with R . For an \mathcal{NP} -language L we denote by R_L the *witness relation* associate with L defined as $x \in L \Leftrightarrow \exists y : (x, y) \in R_L$. We now give definitions for several notions of commitment schemes. For readability we will use “for all x ” to mean any possible string x of length polynomial in the security parameter. We start with the standard notion of commitment scheme with its two main variants (i.e., unconditionally binding and unconditionally hiding). Note that all definitions will use a commitment generator function that outputs the commitment parameters. Therefore, such commitments have a straightforward implementation in the common reference string model where a trusted third party generates a reference string that is later received as common input by all parties. In some cases the commitment parameters generated by the commitment generator function will be strings with uniform distribution; in such cases the corresponding commitments can be implemented in the shared random string model which is a set-up assumption weaker than the common reference string model. For the sole sake of simplicity, in the following definitions, we consider the case in which the commitment parameters are used for computing a single commitment. However all the definitions can be extended so that the same commitment parameters can be used for any polynomial number of commitments (and actually all our results hold in this stronger setting).

Definition 1. ($\text{Gen}, \text{Com}, \text{Ver}$) is a commitment scheme if:

- **efficiency:** Gen , Com and Ver are polynomial-time algorithms;
- **completeness:** for all v it holds that

$$\text{Prob}(\text{crs} \leftarrow \text{Gen}(1^k); (\text{com}, \text{dec}) \leftarrow \text{Com}(\text{crs}, v) : \text{Ver}(\text{crs}, \text{com}, \text{dec}, v) = 1) = 1;$$

- **binding:** *there is a negligible function ν such that for any polynomial-time algorithm sender it holds that*

$$\begin{aligned} & \text{Prob}(\text{crs} \leftarrow \text{Gen}(1^k); (\text{com}, v_0, v_1, \text{dec}_0, \text{dec}_1) \leftarrow \text{sender}(\text{crs}) : \\ & \quad \text{Ver}(\text{crs}, \text{com}, \text{dec}_0, v_0) = \text{Ver}(\text{crs}, \text{com}, \text{dec}_1, v_1) = 1) \leq \nu(k); \end{aligned}$$

- **hiding:** *for all crs generated with non-zero probability by $\text{Gen}(1^k)$, for all v_0, v_1 where $|v_0| = |v_1|$ the probability distributions:*

$$\{(\text{com}_0, \text{dec}_0) \leftarrow \text{Com}(\text{crs}, v_0) : \text{com}_0\} \quad \text{and} \quad \{(\text{com}_1, \text{dec}_1) \leftarrow \text{Com}(\text{crs}, v_1) : \text{com}_1\}$$

are computationally indistinguishable.

If the binding property holds with respect to a computationally unbounded algorithm sender , the commitment scheme is said unconditionally binding; if instead, the hiding property holds with respect to a computationally unbounded algorithm receiver , the commitment scheme is said unconditionally hiding.

We now give the definition of a trapdoor commitment scheme.

Definition 2. $(\text{Gen}, \text{Com}, \text{TCom}, \text{TDec}, \text{Ver})$ *is a trapdoor commitment scheme (TCS, for short) if $\text{Gen}(1^k)$ outputs a pair (crs, aux) , Gen_{crs} is the related algorithm that restricts the output of Gen to the first element crs , $(\text{Gen}_{\text{crs}}, \text{Com}, \text{Ver})$ is a commitment scheme and TCom and TDec are polynomial-time algorithms such that:*

- **trapdooriness:** *for all v the probability distributions:*

$$\{(\text{crs}, \text{aux}) \leftarrow \text{Gen}(1^k); (\text{com}, \text{dec}) \leftarrow \text{Com}(\text{crs}, v) : (\text{crs}, \text{com}, \text{dec}, v)\} \quad \text{and}$$

$$\{(\text{crs}, \text{aux}) \leftarrow \text{Gen}(1^k); (\text{com}', \text{aux}_{\text{com}'}) \leftarrow \text{TCom}(\text{crs}, \text{aux}); \text{dec}' \leftarrow \text{TDec}(\text{aux}_{\text{com}'}, v') : (\text{crs}, \text{com}', \text{dec}', v')\}$$

are computationally indistinguishable.

The definitions of commitment and trapdoor commitment schemes presented above can be extended by adding one more input to algorithms Com, Ver and TCom that is, a label referred to as “tag”. In this case, algorithm Ver has an additional constraint, it outputs 1 only if the same tag has been used as input by algorithms Com or TCom . In particular, we will use such a tag-based definition of commitment when we will consider the notion of simulation-sound trapdoor commitment.

The definitions of multi-trapdoor commitment schemes and simulation-sound trapdoor commitment schemes are deferred to the full version of this paper. Now we are ready to introduce the notion of hybrid trapdoor commitment. As sketched in the introduction, such a notion consider the existence of two commitment generation functions whose outputs are computationally indistinguishable. Still the properties of the two resulting commitment schemes are very different. We start with the basic notion of hybrid trapdoor commitment scheme.

Definition 3. $(\text{HGen}, \text{HTGen}, \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is an hybrid trapdoor commitment scheme (HTCS, for short) if:

- **binding:** $(\text{HGen}, \text{HCom}, \text{HVer})$ is an unconditionally binding commitment scheme;
- **trapdooriness:** $(\text{HTGen}, \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is a trapdoor commitment scheme.
- **hybridness:** let HTGen' be an algorithm that restricts the output (crs, aux) of $\text{HTGen}(1^k)$ to crs , then the following probability distribution are computationally indistinguishable: $\{\text{crs}_0 \leftarrow \text{HGen}(1^k) : \text{crs}_0\}$ and $\{\text{crs}_1 \leftarrow \text{HTGen}'(1^k) : \text{crs}_1\}$.

The notion given above can be extended to be a tag-based commitment scheme (as for the case of standard trapdoor commitment schemes).

We now define the notions of hybrid multi-trapdoor and hybrid simulation-sound trapdoor commitment schemes. We stress that for the latter we focus on tag-based commitments (obtained by adding a label - the tag - as input to the algorithms that compute and verify commitments).

Intuitively, since multi-trapdoor and simulation-sound trapdoor commitment schemes define families of trapdoor commitment schemes, for the *hybrid* variant of such primitives, we require that each scheme in the family is an *hybrid* trapdoor commitment scheme.

Definition 4. $(\text{HGen}, \text{HTGen}, \text{HSel}, \text{HTkg}, \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is an hybrid multi-trapdoor commitment scheme (HMTCS, for short) if:

- **multi trapdooriness:** $(\text{HTGen}, \text{HSel}, \text{HTkg}, \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is a multi-trapdoor commitment scheme;
- **hybridness:** let $\text{HGen}'(1^k)$ (resp., HTGen') be an algorithm that outputs pk (resp., (pk, tk)) if and only if (crs, aux) (resp., crs', aux') is the output of $\text{HGen}(1^k)$ (resp., $\text{HTGen}(1^k)$) and pk (resp., (pk, tk)) is the output of $\text{HSel}(\text{crs})$ (resp., $\text{HSel}(\text{crs}')$ and $\text{HTkg}(\text{aux}', \text{HSel}(\text{crs}'))$); then it holds that the following tuple of algorithms $(\text{HGen}', \text{HTGen}', \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is an hybrid trapdoor commitment scheme.

Definition 5. $(\text{HGen}, \text{HTGen}, \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is an hybrid simulation-sound trapdoor commitment scheme (HSSTCS, for short) if:

- **simulation soundness:** $(\text{HTGen}, \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is a simulation-sound trapdoor commitment scheme;
- **hybridness:** $(\text{HGen}, \text{HTGen}, \text{HCom}, \text{HTCom}, \text{HTDec}, \text{HVer})$ is an hybrid trapdoor commitment scheme.

3 Hybrid Trapdoor Commitments: Constructions

We now show that hybrid trapdoor commitment schemes exist under standard assumptions. In particular, for each definition, we show both a construction based

on general primitives and a practical construction based on number-theoretic assumptions. The constructions and therefore the proofs that we give under complexity-based assumptions are modular, thus we only briefly discuss the efficient implementations. We start with a construction for an hybrid trapdoor commitment scheme. The main idea of the proof is the following. The algorithm that generates the reference string uses Naor's commitment scheme (which is based on the existence of one-way functions) to write in the reference string a commitment com of the string 0^k . The commitment computed by the prover is the first message a of the Σ -protocol for proving that com is a commitment of 1^k . Since this is a false statement, there exists only one challenge m and a third message z such that (a, m, z) is an accepting transcript. Therefore a is an unconditionally binding commitment of message m . The sender can compute a commitment a of m by running on input m the simulator of the honest-verifier zero knowledge property, and obtains the pair (a, z) as output. The algorithm that generates the fake reference string, instead, computes com as a commitment of 1^k . In this case, for each valid first message a , and any possible challenge m , it is always possible to compute z such that (a, m, z) is an accepting transcript.

Theorem 1. *Under the assumption that one-way functions exist, there exists an hybrid trapdoor commitment scheme.*

Next, we – constructively – show how to construct an efficient scheme based on the decisional Diffie-Hellman assumption. More details can be found in the full version of this paper, here we only describe the basic idea underlying our construction. The common reference string contains a quadruple (g, h, g^{r_1}, h^{r_2}) which is either a Diffie-Hellman quadruple or a random one. Consider a Σ protocol ∇ to prove equality of two discrete logarithms. We use ∇ to prove that $g_1 = g^{r_1}$ and $h_1 = h^{r_2}$ have the same discrete logarithm with respect to bases g and h , respectively. If the quadruple is a random one the instance for the Σ -protocol is false. Consequently a commitment to a message m can be computed only using the simulator of the Σ protocol for obtaining an accepting transcript (a, m, z) where a is the commitment key and (m, z) is the decommitment key. On the other hand when the quadruple in the shared random string is a Diffie-Hellman one, then knowledge of $r_1 = r_2$ (the trapdoor) allows to send a commitment key a that can later be opened as any possible message m . This is because, by running the prover algorithm of the Σ -protocol on input $r_1 = r_2$ (as witness) and m (as challenge), it is always possible to find a z such that (a, m, z) is an accepting transcript. The efficiency of this commitment scheme directly follows from the efficiency of the considered Σ -protocol. This informal discussion leads to the following theorem.

Theorem 2. *Under the assumption that the Decisional Diffie-Hellman problem is hard, there exists an efficient hybrid trapdoor commitment scheme.*

A construction for hybrid multi-trapdoor (resp., simulation-sound trapdoor) commitment schemes may seem, at first, much harder to achieve. After all, multi-trapdoor commitments need more parameters (with respect to basic trapdoor

ones) and, to have an hybrid version of them, we need to make sure that these parameters remain distributed in a way such that it should be hard to say which of the two commitment generation algorithms was used to produce them.

Informally, we solve this problem by composing a multi-trapdoor (resp, simulation-sound trapdoor) commitment scheme with an hybrid trapdoor commitment scheme as the one described so far. The composition is made by considering the concatenation of *both* commitment parameters. Moreover all the operations made by the committing and decommitting algorithms are performed twice, once for each *subscheme*. Intuitively, using this technique, when a multi-trapdoor (resp., simulation-sound trapdoor) commitment scheme is composed with the hybrid trapdoor commitment scheme instantiated as a trapdoor commitment scheme, the resulting scheme is still a multi-trapdoor (resp., simulation-sound trapdoor) commitment scheme. On the other hand, if the hybrid trapdoor commitment scheme is instantiated as an unconditionally binding commitment scheme, then then resulting scheme is unconditionally binding. By the indistinguishability of the commitment parameters of the two instantiations we obtain the desired result.

Theorem 3. *Under the assumption that multi-trapdoor commitment scheme exist there exists an hybrid multi-trapdoor commitment scheme.*

Note that, with the theorem above, we show how to construct hybrid multi-trapdoor commitments from the hypothesis that multi-trapdoor commitments exist. It is quite natural then to ask if is it possible to base the existence of multi-trapdoor commitments on some weaker' assumption. Here we give a positive answer to this question and in particular we show that multi-trapdoor commitments exist if and only if secure signature against *generic* chosen message attack exist. Notice that one-way functions are equivalent to secure signatures [13] in the sense of [14], which, in turn, imply secure signature against *generic* chosen message attack exist. This means that theorem 3 can be restated as follows.

Theorem 4. *Under the assumption that one-way functions exist, there exists an hybrid multi-trapdoor commitment scheme.*

As for the case of hybrid trapdoor commitments we give an efficient implementation.

Theorem 5. *Under the assumption that the strong RSA and DDH problems are hard, (or under the assumption that the strong Diffie Hellman [15] and DDH problems are hard), there exists an efficient hybrid multi-trapdoor commitment scheme.*

Similar results can be proved for the case of hybrid Simulation Sound trapdoor commitments.

Theorem 6. *Under the assumption that one-way functions exist, there exists an hybrid simulation-sound trapdoor commitment scheme.*

Theorem 7. *Under the assumption that the DSA signature scheme is secure and the DDH problem is hard, (or under the assumption that the Cramer-Shoup signature scheme [16] is secure and the DDH problem is hard), there exists an efficient hybrid simulation-sound trapdoor commitment scheme.*

4 Hybrid Trapdoor Commitments: Applications

In this Section we describe some important applications of our primitive. In particular we show that hybrid trapdoor commitments can be used to construct interactive protocols that achieve strong notions of zero knowledge [17]. More precisely we improve the concurrent zero-knowledge arguments of [1] and both the simulation-sound and the left-concurrent non-malleable zero-knowledge arguments of [2, 3] by showing how to achieve zero-knowledge *proofs* (rather than *arguments*). Therefore the security of our constructions holds even against computationally unbounded provers. Moreover, our zero-knowledge proofs can be based on the same complexity-theoretic assumptions used in [1, 2, 3]. The efficient constructions also require the hardness of the *DDH* problem.

CONCURRENT ZERO-KNOWLEDGE PROOFS. In [1], 3-round concurrent zero-knowledge arguments in the common reference string model are presented. More precisely Damgård [1] presents a general protocol based on the existence of one-way functions only and an efficient implementation based on number-theoretic assumptions. In this section we improve on this result by showing the existence of 3-round concurrent zero-knowledge proof (in contrast to argument) systems in the common reference string model. The first construction needs the sole assumption that one-way functions exist, while the second, more efficient, construction relies on the decisional Diffie-Hellman assumption. Interestingly the first construction holds in the shared random string model as well. In our construction we consider unbounded black-box zero-knowledge proofs with a non-rewinding simulator (which, consequently, is also concurrent zero knowledge).

Theorem 8. *If one-way functions exist, there exists a 3-round concurrent zero-knowledge proof system in the common reference string model for any \mathcal{NP} language.*

We remark here that, going through the details of the proof of Theorem 8 one can easily verify that reference string used in the proof of Theorem 8 is uniformly distributed. Thus we have the following corollary.

Corollary 1. *If one-way functions exist, there exists a 3-round concurrent zero-knowledge proof system in the shared random string model for any \mathcal{NP} language.*

Theorem 9. *Given an \mathcal{NP} -language L that admits an efficient Σ -protocol, then under the DDH assumption there exists a 3-round concurrent zero-knowledge proof system in the common reference string model for L .*

SIMULATION-SOUND ZERO KNOWLEDGE. The notion of *simulation soundness* has been used for the design of many secure cryptographic primitives (see for instance [18]). Informally, a proof system is simulation sound if an adversary that plays the role of verifier when the proofs are simulated for both true and false instances, is not able to play as a prover another session of the protocol in which he convinces an honest verifier of a false statement. In [3], MacKenzie and Yang proposed 3-round unbounded simulation-sound zero-knowledge argument systems in the common reference string model, in particular their arguments use simulation-sound trapdoor commitment schemes, therefore they obtain efficient argument systems based on the security of DSA [19] or the Cramer-Shoup [16] signature schemes and argument systems based on the existence of one-way functions. The multi-trapdoor commitments presented in [2] allow for more efficient constructions of unbounded simulation-sound zero-knowledge argument systems. In this section we extend their results by showing the existence of 3-round unbounded simulation-sound zero-knowledge proof (in contrast to argument) systems in the common reference string model. We can achieve this result either by using hybrid simulation-sound trapdoor commitments instead of non-hybrid simulation-sound trapdoor commitments in the construction of [3] or by using hybrid multi-trapdoor commitments instead of non-hybrid multi-trapdoor commitments in the construction of [2]. For each of this two results we give a first construction that needs the sole assumption that one-way functions exist. Then we give a more efficient second construction that requires (on top of the assumptions described for the efficient constructions of [3] and [2]) the decisional Diffie-Hellman assumption.

Theorem 10. *If one-way functions exist, there exists a 3-round unbounded simulation-sound zero-knowledge proof system in the common reference string model for any \mathcal{NP} language.*

Theorem 11. *Given an \mathcal{NP} -language L that admits an efficient Σ -protocol, then under the assumption that DSA is a secure signature scheme and that the DDH assumption hold (or that the Cramer-Shoup signature scheme is secure and that the DDH assumption holds) there exists an efficient 3-round unbounded simulation-sound zero-knowledge proof system in the common reference string model for L .*

We stress that the approach used to achieve simulation-sound zero-knowledge proofs from hybrid simulation-sound trapdoor commitments (using the construction of [3]) is quite general and can be used to build simulation-sound zero-knowledge proofs from hybrid multi-trapdoor commitments (using the construction of [2]). In the proof of Theorem 10 we show that, by replacing a (non-hybrid) simulation-sound trapdoor commitment scheme with an hybrid one, an unbounded simulation-sound zero-knowledge argument can be transformed into an unbounded simulation-sound zero-knowledge proof. This same approach can be used for the case of (non-hybrid) multi-trapdoor commitment schemes and their application to unbounded simulation-sound zero-knowledge arguments [2]

(we stress that in [2] such a notion is referred to as left-concurrent non-malleable zero-knowledge arguments).

Theorem 12. *Given an \mathcal{NP} -language L that admits an efficient Σ -protocol, if collision-resistant hash functions exist then under the $s\text{RSA}$ and the DDH assumption or the $s\text{DH}$ and the DDH assumptions there exists an efficient 3-round unbounded simulation-sound zero-knowledge proof system in the common reference string model for L .*

Acknowledgments

The authors would like to thank Pino Persiano for many useful discussions on zero knowledge proofs in the shared random string model.

On Steganographic Chosen Covertext Security

Nicholas Hopper

University of Minnesota, 4-192 EECS,
200 Union St SE, Minneapolis MN 55455
hopper@cs.umn.edu

Abstract. At TCC 2005, Backes and Cachin proposed a new and very strong notion of security for public key steganography: secrecy against adaptive chosen covertext attack (SS-CCA); and posed the question of whether SS-CCA security was achievable for *any* covertext channel. We resolve this question in the affirmative: SS-CCA security is possible for any channel that admits a secure stegosystem against the standard and weaker “chosen hiddentext attack” in the standard model of computation. Our construction requires a public-key encryption scheme with ciphertexts that remain indistinguishable from random bits under adaptive chosen-ciphertext attack. We show that a scheme with this property can be constructed under the Decisional Diffie-Hellman assumption. This encryption scheme, which modifies a scheme proposed by Kurosawa and Desmedt, also resolves an open question posed by von Ahn and Hopper at Eurocrypt 2004.

1 Introduction

Suppose that Alice and Bob are prisoners, and that their prison warden has foolishly allowed them to send “harmless messages” between their cells, so long as he may listen to everything they say. *Steganography* is the study of techniques that allow Alice and Bob to hide arbitrary messages – *hiddentexts* – in their apparently harmless communications (normally, *coverttexts*) so that the warden cannot detect the presence of these messages. The case where the prisoners share a secret key has been studied extensively in both information-theoretically [5] and computationally secure settings [13, 9]. Several recent papers have also addressed the case in which one or both of the prisoners has a public key [1, 3, 17]. *In this paper, we are only concerned with the bare public key scenario, considered in [3], in which only Bob publishes a public key, and any prisoner can send hidden information to Bob.*

A recent paper by Backes and Cachin [3] considers the scenario where the warden may also inject messages into the channel between Alice and Bob, and observe Bob’s reaction to these messages. Roughly, [3] gives a formal model of this scenario and defines a strong sense of security against this adversary: a stegosystem is said to be *steganographically secure against adaptive chosen covertext attacks (SS-CCA)* if, even in this case, the warden cannot tell whether Alice’s messages contain hiddentexts. Analogously to the standard cryptographic

notion of a chosen ciphertext attack, this seems to be the most general type of attack possible on a system for steganography.

Backes and Cachin leave open the problem of constructing a stegosystem satisfying SS-CCA, and instead address a relaxed notion of security, against adaptive *replayable* chosen-coverttext attacks (SS-PDR-CCA). Roughly, in this notion, the warden is still allowed to inject messages into the channel between Alice and Bob, *except* that he is now restricted from sending messages which are, in some sense, *replays* of previous messages sent by Alice. Intuitively, two coverttexts are replays of each other with respect to a public key if they decode to the same hiddentext. Backes and Cachin construct public-key stegosystems which satisfy SS-PDR-CCA under a variety of assumptions.

While it is an important advancement to limit the adversary to replay attacks, these attacks still constitute a serious threat against steganography. Imagine that Alice sends Bob some message which prompts an “unusual” reaction; in a replay attack, the warden can construct an apparently harmless coverttext which corresponds to the same hiddentext as Alice’s message, and send it to Bob. If Bob has the same “unusual” reaction, in response to a *different message*, it suggests to the warden that Alice’s coverttext contained a hidden message.

In this paper, we show how the previously known schemes fail in defending against replay attacks, and modify them to demonstrate the feasibility of the SS-CCA security condition, for any *efficiently sampleable* channel. This is a stronger assumption on the channel than in many previous works on steganography [1, 18, 9, 3], which assume only oracle access to the channel distribution. However, [14] shows that any channel which admits a secure stegosystem at all (in the standard model of computation) must be efficiently sampleable. Thus this construction serves as a demonstration that the SS-CCA notion is *feasible*, even though our particular construction may not always be practical to implement.

Our construction relies on the existence of public-key encryption schemes which are pseudorandom against chosen-ciphertext attack, a nonstandard security notion for encryption schemes. We also show that such encryption schemes exist, *without need of the random oracle assumption*,¹ under the Decisional Diffie-Hellman assumption. The existence of an encryption scheme satisfying this notion was an open question posed by von Ahn and Hopper [1].

Related Work. In addition to the work of Backes and Cachin [3], which we build on, Le and Kurosawa [17] and von Ahn and Hopper [1] have both proposed notions of security against “chosen stegotext attack.” The notion proposed in [17] seems to be equivalent to SS-CCA; however the construction proposed there requires that the receiver know the sender’s public key in order to decode. Similarly, the SS-CSA notion of [1] explicitly includes the public key of the sender; it can be thought of as an “attacker-specific” notion of security. However, the security model of [1] is also intended to prevent forgery by the warden, which is not a concern in the present model.

¹ We note that several constructions in the random oracle model are known [4, 19].

Both of these schemes require the sender to publish a public key. While this may not be a concern for ordinary communication, it is undesirable for steganography. This is because the aim of the sender in steganography is to *avoid suspicion* – yet publishing a public key for a stegosystem may be inherently suspicious.

On the other hand, it is frequently the case, as [1] argue, that the receiver of steganography need not avoid suspicion. This could be the case when, for example, the receiver is a newspaper or government agency wishing to receive whistle-blowing reports. Or when the receiver is a human-rights organization that would like to receive reports from its volunteers in the field. Thus it is important to have a construction which is secure in the bare public key model.

Other recent papers on foundations of steganography have focused on the private key setting. Cachin [5] formulated a model for steganography in an information-theoretic setting. Hopper *et al* [13] gave the first rigorous formulation of steganography with computational security, and demonstrated the feasibility of the notion with provably secure constructions. They also proposed the model of communication which subsequent work has followed. Independently, Katzenbeisser and Petitcolas [15] proposed a similar security condition. Dedić *et al* [9] address bounds on communication rate for a generic stegosystem. Lysyanskaya and Meyerovich [18] consider the possibility of an imperfect coverttext oracle.

Anderson and Petitcolas [2] first proposed the possibility of public-key steganography and gave a heuristic construction. Craver [8] proposed a notion of public-key steganography with heuristic security against removal of the hiddentext. von Ahn and Hopper [1] were the first to formulate rigorous security definitions for the public-key case and demonstrate that public-key steganography was feasible.

Notation. A function $\mu : \mathbb{N} \rightarrow [0, 1]$ is said to be *negligible* if for every $c > 0$, for all sufficiently large n , $\mu(n) < 1/n^c$. We denote the length (in bits) of a string or integer s by $|s|$. The concatenation of string s_1 and string s_2 will be denoted by $s_1||s_2$. The assignment $a||_l b = c$ means that a is the first l bits of c and b is the remaining $|c| - l$ bits of c . We assume the existence of efficient, unambiguous *pairing* and *un-pairing* operations, so (s_1, s_2) is not the same as $s_1||s_2$.

We let U_k denote the uniform distribution on k bit strings. If \mathbb{V} denotes an event in some probability space, we denote its complement by $\bar{\mathbb{V}}$. If \mathcal{D} is a probability distribution with finite support X , we define the *minimum entropy* of \mathcal{D} , by $H_\infty(\mathcal{D}) = \min_{x \in X} \{\log_2(1/\Pr_{\mathcal{D}}[x])\}$. For a probability distribution \mathcal{D} , we denote by $x \leftarrow \mathcal{D}$ the action of drawing a sample x according to \mathcal{D} . We denote the statistical difference between distributions \mathcal{D} and \mathcal{E} , with finite support X , by $\|\mathcal{D} - \mathcal{E}\| = \frac{1}{2} \sum_{x \in X} |\Pr_{\mathcal{D}}[x] - \Pr_{\mathcal{E}}[x]|$.

2 Pseudorandomness Against Chosen-Ciphertext Attack

We will need to construct a public-key encryption scheme which satisfies a non-standard security notion: indistinguishability from random bits under chosen-ciphertext attack. A scheme satisfying this notion is also non-malleable [10] and has pseudorandom cipherttexts [1]; the existence of a scheme simultaneously

satisfying these latter notions *without random oracles* was an open question posed by von Ahn and Hopper at Eurocrypt 2004 [1].

Let \mathcal{E} be a public-key encryption scheme with message expansion function ℓ . We define a chosen-ciphertext attack against \mathcal{E} as a game played by an oracle adversary A :

1. A^D (PK) outputs *challenge message* $m^* \in \{0, 1\}^{l^*}$.
2. A is given a *challenge ciphertext* c^* , where either $c \leftarrow E_{PK}(m^*)$ or $c \leftarrow U_{\ell(l^*)}$.
3. A continues to query D_{SK} subject to the restriction that A may not query $D_{SK}(c^*)$. A outputs a bit.

We define A 's CCA advantage against \mathcal{E} by

$$\mathbf{Adv}_{\mathcal{E},A}^{\text{cca}}(k) = |\Pr[A^D(PK, E_{PK}(m^*)) = 1] - \Pr[A^D(PK, U_{\ell}) = 1]| ,$$

where $m^* \leftarrow A^D(PK)$ and $(PK, SK) \leftarrow G(1^k)$, and define the CCA insecurity of \mathcal{E} by $\mathbf{InSec}_{\mathcal{E}}^{\text{cca}}(t, q, \mu, l^*, k) = \max_{A \in \mathcal{A}(t, q, \mu, l^*)} \{ \mathbf{Adv}_{\mathcal{E},A}^{\text{cca}}(k) \}$, where $\mathcal{A}(t, q, \mu, l^*)$ denotes the set of adversaries running in time t , that make q queries of total length μ , and issue a challenge message m^* of length l^* . Then \mathcal{E} is $(t, q, \mu, l^*, k, \epsilon)$ -*indistinguishable from random bits under chosen ciphertext attack* if $\mathbf{InSec}_{\mathcal{E}}^{\text{cca}}(t, q, \mu, l^*, k) \leq \epsilon$. \mathcal{E} is called *indistinguishable from random bits under chosen ciphertext attack (IND\\$-CCA)* if for every probabilistic polynomial time (PPT) A , $\mathbf{Adv}_{A,\mathcal{E}}^{\text{cca}}(k)$ is negligible in k .

We show a simple modification of an encryption scheme of Kurosawa and Desmedt [16] (which itself is a modification of the original Cramer-Shoup encryption scheme [7]) which satisfies IND\\$-CCA. The main modification to the scheme is to use a dense encoding of the DDH subgroup and rejection sampling to produce uniform k -bit strings.

Setup. We let p_k, Q_k be large primes such that $p = 2Q + 1$ and $2^{k+1} > Q > 2^k$. We let $g \in \mathbb{Z}_p^*$ have order Q , and define the maps $lr : \langle g \rangle \rightarrow \mathbb{Z}_Q, qr : \mathbb{Z}_Q \rightarrow \langle g \rangle$ such that $lr(v) = v$ if $v \leq Q$ and $lr(v) = -v \pmod p$ otherwise; and $qr(u) = u$ if u is a quadratic residue modulo p and $qr(u) = p - u$ otherwise. Notice that $qr \circ lr$ is the identity map on the quadratic residues and $lr \circ qr$ is the identity map on \mathbb{Z}_Q . We assume the Decisional Diffie Hellman (DDH) assumption: for any PPT A , $\mathbf{Adv}_{A,g,p,Q}^{\text{ddh}}(k) = |\Pr_{x,y \leftarrow \mathbb{Z}} [A(g^x, g^y, g^{xy}) = 1] - \Pr_{x,y,z \leftarrow \mathbb{Z}} [A(g^x, g^y, g^z) = 1]|$ is negligible.

We assume the existence of a family of target collision-resistant hash functions $H : \{0, 1\}^{2k} \rightarrow \mathbb{Z}_Q$,² A universal family of hash functions $A : \mathbb{Z}_Q \rightarrow \{0, 1\}^{2k'}$, an IND\\$-CPA symmetric-key encryption scheme E, D with k' -bit keys,³ and a

² So for any PPT A , $\mathbf{Adv}_{A,H}^{\text{tr}}(k) = \Pr_{h \leftarrow H} [h(A(h(x))) = x : x \leftarrow \mathbb{Z}_Q]$ is negligible.

³ So for any PPT A , $\mathbf{Adv}_{A,E}^{\text{cpa}}(k) = |\Pr_{K \leftarrow U} [A^E(1^{k'}) = 1] - \Pr[A^{U_{1 \cdot 1}}(1^{k'}) = 1]|$ is negligible.

pseudorandom function family $F : \{0, 1\}^{k'} \times \{0, 1\}^* \rightarrow \{0, 1\}^\tau$.⁴ Note that the existence of all of these primitives is implied by the DDH assumption.

Key Generation. Choose random $g_1, g_2 \in \langle g \rangle$, and choose random $x_1, x_2, y_1, y_2 \in \mathbb{Z}_Q$. Compute the group elements $c = g_1^{x_1} g_2^{x_2}, d = g_1^{y_1} g_2^{y_2}$. Choose hash functions H, Λ . The public key is $(g_1, g_2, c, d, H, \Lambda)$ and the private key is (x_1, x_2, y_1, y_2) .

Encryption. Given a message $m \in \{0, 1\}^*$, repeat the following steps:

- Choose $r \leftarrow \mathbb{Z}_q$.
- Compute $u_1 = lr(g_1^r), u_2 = lr(g_2^r)$

Until u_1, u_2 are both at most 2^k . Then compute $\alpha = H(u_1 \| u_2), v = c^r d^{r\alpha}, (K, \kappa) = \Lambda(v), e = E_K(m), T = F_\kappa(e)$. The ciphertext is $u_1 \| u_2 \| e \| T$.

Decryption. To decrypt the ciphertext $u_1 \| u_2 \| e \| T$, first compute $\alpha = H(u_1 \| u_2)$ and compute $v = qr(u_1)^{x_1+y_1\alpha} qr(u_2)^{x_2+y_2\alpha}, K \| \kappa = \Lambda(v)$. Test whether $T = F_\kappa(e)$; if not output \perp , otherwise output $D_K(e)$.

Theorem 1. *If $k \geq 4k'$, then*

$$\text{InSec}_E^{\text{cca}}(t, q, \mu, l, k) \leq 8\text{InSec}_H^{\text{tcr}}(t, k) + 12\text{InSec}_{g,p,Q}^{\text{ddh}}(t) + 4\text{InSec}_E^{\text{cpa}}(t, 1, l, k') + (16q + 4)\text{InSec}_F^{\text{prf}}(t, q, \mu, k') + 8q(2^{-\tau} + 2^{-k'+1}) + 2^{-k'+4}$$

The security proof appears in the full version and closely follows the security proof for Kurosawa and Desmedt’s scheme given by Gennaro and Shoup [11].

3 Definitions

Channels. We follow previous work [13, 17, 1, 9] in modeling the communication between two parties by a *channel*. We define a channel \mathcal{C} as a family of probability distributions on documents from a set D , indexed by sequences $h \in D^*$. A channel implicitly defines an indexed distribution on sequences of ℓ documents — given index h , draw $d_1 \leftarrow \mathcal{C}_h, d_2 \leftarrow \mathcal{C}_{(h,d_1)}, \dots, d_\ell \leftarrow \mathcal{C}_{(h,d_1,\dots,d_{\ell-1})}$. We call the index h the *history* and label this distribution on sequences by \mathcal{C}_h^ℓ . A history $h = (d_1, d_2, \dots, d_\ell)$ is called *legal* (denoted $h \in \mathcal{H}$) if for all $i, \Pr_{\mathcal{C}_{(d_1, \dots, d_{i-1})}}[d_i] > 0$. A channel is *always informative* if for every legal history $h, H_\infty(\mathcal{C}_h^\ell) = \Omega(\ell)$.

We will require that a channel be *efficiently sampleable*: there is an efficiently computable algorithm channel such that $\text{channel}(h, U_k)$ and \mathcal{C}_h are computationally indistinguishable.⁵ This is in contrast to the models of [13, 9, 1, 3], where the

⁴ So for any PPT $A, \text{Adv}_{A,F}^{\text{prf}}(k) = |\Pr_{K \leftarrow U} [A^F(1^{k'}) = 1] - \Pr_{f: \{0,1\}^* \rightarrow \{0,1\}} [A^f(1^{k'}) = 1]|$ is negligible.

⁵ Some examples of widely used channels satisfying this notion include: scientific simulations, cryptography and security protocols, computer games, financial modeling, weather forecasts, etc.

channel is assumed to be accessible only via a probabilistic oracle. While results in that model are in some sense more general, we refer the reader to [14] for a proof that in the standard model of computation, sampleability is necessary for secure steganography.

Since it is widely believed that all natural processes can be computed in probabilistic polynomial time [12], we do not *in theory* rule out steganography for any realistic channels by requiring the channel to be sampleable. On the other hand, it is conceivable that there are channels which we can currently sample physically but not computationally, and thus in practice it is still an open problem to design a stegosystem which is SS-CCA secure for such channels.

Public-Key Stegosystem. A public-key stegosystem \mathcal{S} is a triple of probabilistic algorithms:

- \mathcal{S} .Generate (abbreviated SG) takes as input a security parameter 1^k and generates a key pair $(\rho, \sigma) \in \mathcal{PK} \times \mathcal{SK}$.
- \mathcal{S} .Encode (abbreviated SE) takes as input a public key $\rho \in \mathcal{PK}$, a string $m \in \{0, 1\}^*$ (the *hiddentext*), and a channel history h . $SE(\rho, m, h)$ returns a sequence of documents s_1, s_2, \dots, s_l (the *stegotext*) from the support of \mathcal{C}_h^l .
- \mathcal{S} .Decode (abbreviated SD) takes as input a secret key $\sigma \in \mathcal{SK}$, a sequence of documents s_1, s_2, \dots, s_l , and a channel history h . $SD(\sigma, s, h)$ returns a hiddentext $m \in \{0, 1\}^*$.

We require that a stegosystem is *correct*: for every polynomial $p(k)$ there exists a negligible $\nu(k)$ such that for every $m \in \{0, 1\}^{p(k)}$, legal history h , and $(\rho, \sigma) \in [SG(1^k)]$, $\Pr[SD(\sigma, SE(\rho, m, h), h) = m] \geq 1 - \nu(k)$.

Chosen-Coverttext Attack. In an adaptive chosen-coverttext attack against a public-key stegosystem \mathcal{S} , a challenger draws a key pair $(\rho, \sigma) \leftarrow SG(1^k)$, and an adversary W is given PK and allowed oracle access to SD_σ . The attacker produces a *challenge hiddentext* m^* and history h^* and is given as a response a sequence of documents $s^* \in D^{\ell(|m^*|)}$. After this, the attacker continues to query SD with the restriction that he may not query $SD(s^*)$. (As always, W may depend on the channel distribution \mathcal{C}) At the conclusion of the attack, W must guess whether $s^* \leftarrow SE(\rho, m^*, h^*)$ or $s^* \leftarrow \mathcal{C}_{h^*}^{\ell^*}$. We define the (steganographic) *Chosen-Coverttext Advantage* of W against \mathcal{S} with respect to \mathcal{C} by

$$\text{Adv}_{\mathcal{S}, \mathcal{C}, \mathcal{W}}^{\text{scca}}(k) = \left| \Pr[W^{SD}(PK, SE(\rho, m^*, h^*)) = 1] - \Pr[W^{SD}(\rho, \mathcal{C}_{h^*}^{\ell^*}) = 1] \right| ,$$

where $(m^*, h^*) \leftarrow W^{SD}(\rho)$ and $(\rho, \sigma) \leftarrow SG(1^k)$. We define the sCCA insecurity of \mathcal{S} with respect to \mathcal{C} by

$$\text{InSec}_{\mathcal{S}, \mathcal{C}}^{\text{scca}}(t, q, \mu, l^*, k) = \max_{W \in \mathcal{W}(t, q, \mu, l^*)} \{ \text{Adv}_{\mathcal{S}, \mathcal{C}, \mathcal{W}}^{\text{scca}}(k) \} ,$$

where $\mathcal{W}(t, q, \mu, l^*)$ denotes the class of all W running in time t which make at most q oracle queries of μ bits and submit a challenge hiddentext of length at most l^* .

We say that \mathcal{S} is $(t, q, \mu, l, k, \epsilon)$ secure against chosen-covertext attack with respect to \mathcal{C} if $\text{InSec}_{\mathcal{S}, \mathcal{C}}^{\text{scca}}(t, q, \mu, l, k) \leq \epsilon$, and that \mathcal{S} is secure against chosen-covertext attack with respect to \mathcal{C} (SS-CCA) if $\text{Adv}_{\mathcal{S}, \mathcal{C}, \mathcal{W}}^{\text{scca}}(k)$ is negligible for all PPT W .

4 Previous Constructions

Both previously known constructions of (bare) public-key steganography [1, 3] have a common structure. Let \mathcal{F} denote a strongly universal family of hash functions $f : D \rightarrow \{0, 1\}$. Let $f \leftarrow \mathcal{F}$ be chosen as part of a public key, or fixed as a “common reference string.” Then both constructions use the routine shown in figure 1 to hide uniformly chosen bits in \mathcal{C} .

Proposition 1. *Let \mathcal{C} be always informative and $f \leftarrow \mathcal{F}$. Then for any $h \in \mathcal{H}$,*

$$\| (f, \text{sample}(h, U_1, k)) - (f, \mathcal{C}_h) \| \leq 2^{-H_\infty(\mathcal{C})/2} .$$

The proposition is a direct consequence of the leftover hash lemma. If the channel is always-informative, **sample** can operate on samples from \mathcal{C}_h^k and induce only a negligible statistical difference in its output distribution. The basic construction of a stegosystem, HashRS, is shown in figure 2, where (G, E, D) is a public-key cryptosystem which has pseudorandom ciphertexts.

Informally, the scheme works by transforming the hiddentext into a uniform-looking ciphertext $c = E_{PK}(m)$. The ciphertext bits are then used one at a time (or w at a time, with sampling costs and statistical difference increased by a factor of 2^w) to select covertexts that hash (via f) to the bits of the ciphertext,

Procedure sample:
Input: target $c \in \{0, 1\}$, history h , bound k
 Let $j = 0$
 repeat:
 sample $s \leftarrow \mathcal{C}_h$, increment j
 until $f(s) = c$ OR $(j > k)$
Output: s

Fig. 1. Sampling routine

<p>Procedure Encode: Input: $m \in \{0, 1\}^l, h, PK$ Draw $c_1 \cdots c_\ell \leftarrow E(PK, m)$ for $i = 1 \dots \ell$ do set $s_i = \text{sample}(c_i, (h, s_{1, \dots, i-1}), k)$. Output: s_1, s_2, \dots, s_ℓ</p>	<p>Procedure Decode: Input: $s_1, s_2, \dots, s_\ell, SK$ for $i = 1 \dots \ell$ do set $c_i = f(s_i)$ set $c = c_1 c_2 \dots c_\ell$. Output: $D(K, c)$</p>
--	--

Fig. 2. HashRS Stegosystem

using `sample`. Since the ciphertext looks uniform, the coverttexts thus selected will be indistinguishable from samples from \mathcal{C}_h . Decoding applies f to each coverttext document to recover the ciphertext c , and then decrypts this ciphertext using SK to compute the hiddentext $m = D_{SK}(c)$.

The Backes-Cachin construction instantiates `HashRS` with a public-key encryption scheme which satisfies two properties. First, it must be PDR-CCA secure, as defined by Canetti *et al* [6]. Second, the encryption scheme should have *pseudorandom* ciphertexts: given the public key it was encrypted under, a ciphertext should be computationally indistinguishable from a random string of the same length. When instantiated with a public-key cryptosystem satisfying these properties, we call the resulting stegosystem \mathcal{BC} .

Intuitively, the SS-PDR-CCA security of the \mathcal{BC} scheme arises from the fact that W is disallowed from submitting coverttexts that decode to the same hiddentext. Thus an attack W against \mathcal{BC} can easily be turned into a PDR-CCA attack A against the underlying encryption scheme. The main technical step is in simulating decryption queries: whenever W queries the decoding oracle on a coverttext $s = s_1, \dots, s_\ell$, the PDR-CCA attacker computes a ciphertext $c = c_1, \dots, c_\ell$ by setting $c_i = f(s_i)$. If the ciphertext c is a replay of the challenge ciphertext c^* , then the stegotext s is also a replay, so A responds to W with \perp . Otherwise A queries his decryption oracle at c and returns the result to W .

This standard simulation technique also hints at a CCA attack against the \mathcal{BC} stegosystem. We now formally describe the attack W . On input PK , W uniformly picks a challenge message $m^* \leftarrow U_{l^*}$. On receiving the challenge coverttext s^* , W computes c^* by setting $c_i^* = f(s_i^*)$. W computes a “replay” coverttext $s' \leftarrow \text{sample}((h^*, s^*), c^*, k)$. Finally, W queries the decryption oracle on s' . If $SD_{SK}(s') = m^*$, W outputs 1 and otherwise W outputs 0. It is obvious that when $s^* \in SE(PK, m^*, h^*)$, then we will have that $SD(SK, s', h^*) = m^*$ except when encoding fails, since otherwise unique decryption requires that $D_{SK}(c^*) = D_{SK}(E_{PK}(m^*)) = m^*$. On the other hand, when $s^* \leftarrow \mathcal{C}_h^\ell$, then m^* and s^* are chosen independently of each other, so $\Pr[D_{SK}(c^*) = m^*] \leq 2^{-l^*}$.

Proposition 2. *For every l^* , there exists a negligible function $\nu(k)$ such that*

$$\text{Adv}_{W, \mathcal{BC}}^{\text{scca}}(k) \geq 1 - 2^{-l^*} - \nu(k)$$

Note that the “replay” coverttext will be indistinguishable from a sample from the channel, so the decoder would have no reason not to decode it and act on any information contained in the hiddentext. Thus this attack is reasonable, in that it could be applied in a realistic scenario, rather than being merely an artifact of the model. Of course the adversary might further attempt to replay the exact stegotext; this latter attack is, however, impossible to defeat.

5 Our Construction

Intuitively, the reason the attack in the previous section succeeds is that even though the underlying *ciphertext* is non-malleable, there are many possible en-

Procedure DEncode:

Input: bits c_1, \dots, c_l , history h , bound k , randomness $r_1, \dots, r_{lk} \in \{0, 1\}^k$
 Let $\iota = 0$; for $i = 1 \dots l$ do
 Let $j = 0$; repeat:
 compute $s_i = \text{channel}((h, s_{1..i-1}), r_\iota)$; increment j, ι
 until $f(s_i) = c_i$ OR $(j > k)$
Output: s_1, s_2, \dots, s_l

Fig. 3. Deterministic Encode

Procedure Encode:

Input: $m \in \{0, 1\}^\ell, h, PK$
 Choose $r \leftarrow U_k$
 Let $c = E_{PK}(r||m)$
 Let $\mathbf{r} = G(r)$
Output: $\text{DEncode}(c, h, k, \mathbf{r})$

Procedure Decode:

Input: s_1, \dots, s_l, h, SK
 Let $c = f(s_1)|| \dots || f(s_l)$
 Let $r||_k m = D_{SK}(c)$.
 Set $\mathbf{r} = G(r)$.
 If $s \neq \text{DEncode}(c, h, k, \mathbf{r})$ return \perp .
Output: m

Fig. 4. SCCA Stegosystem

codings of the ciphertext. This observation immediately suggests a possible improvement: design a sampling method such that each ciphertext corresponds to exactly one stegotext. Indeed, the construction of [17] seems to have this property, but this construction inherently requires a shared secret between the encoder and the decoder. Likewise, the “attacker-specific” construction of [1] seems to achieve a similar property, but validity of a stegotext is determined by the sender’s public key. Our construction modifies this latter approach to remove this dependence on the sender, and also removes the reliance on the random oracle model from that construction.

We make use of the fact that we have an efficiently sampleable channel \mathcal{C} , and will make use of the “deterministic encoding” routine shown in figure 3. This algorithm works in a similar manner to the `HashRS.Encode` algorithm, with the exception that the randomness for sampling is an explicit argument. Thus for a given sequence of lk random inputs, this routine has exactly one possible encoding for any message $c \in \{0, 1\}^l$. Thus if an l -bit, non-malleable, ciphertext can determine the lk bits of sampling randomness to be used in its encoding, we can prevent replay attacks. One way to do this is to apply a random oracle to the randomness used in producing the ciphertext; this approach was used by [1]. We instead use a pseudorandom generator to expand an k -bit seed into an lk -bit sequence and then include this seed in the plaintext. Proving the security of this approach requires some additional care, because now it is conceivable that the sampling algorithm could leak information about the plaintext.

We now formally describe our construction. We will assume that \mathcal{E} is a public-key IND $\$$ -CCA secure encryption scheme, and $(PK, SK) \leftarrow \mathcal{E}.G(1^k)$. Furthermore, we assume that for any l , $\Pr[D_{SK}(U_l) \neq \perp] \leq \nu(k)$ for some negligible ν . Thus, *valid* ciphertexts, which do not decrypt to \perp , have negligible density. For convenience, we assume that for all m , $|E_{PK}(m)| = \ell(|m|)$, for some poly-

nomial ℓ . We will also assume that $G : \{0, 1\}^k \rightarrow \{0, 1\}^{k \times lk}$ is a pseudorandom generator. The final scheme SCCA is shown in Figure 4.

Theorem 2. *Let $f \leftarrow \mathcal{F}$ and let $\epsilon = \max_{h \in \mathcal{H}} \left\{ 2^{-H_\infty(C_h)/2} \right\} = 2^{-\Omega(k)}$. Then*

$$\mathbf{InSec}_{\text{SCCA}, \mathcal{C}}^{\text{scca}}(t, q, \mu, l, k) \leq \mathbf{InSec}_{\mathcal{E}}^{\text{cca}}(t', q, \mu, l, k) + \nu(k) + \ell(l+k)\epsilon + \mathbf{InSec}_G^{\text{prg}}(t', k),$$

where $t' \leq t + O(lk)$.

Proof. Choose an arbitrary $W \in \mathcal{W}(t, q, \mu, l)$; let $(PK, SK) \leftarrow G(1^k)$ and let $(m^*, h^*) \leftarrow W^{SD}(PK)$. We will bound $\mathbf{Adv}_{W, \text{SCCA}, \mathcal{C}}^{\text{scca}}(k)$ by considering the following sequence of hybrid distributions:

- D_1 : $\mathcal{C}_{h^*}^{\ell(l+k)}$
- D_2 : $\text{DEncode}(U_{\ell(l+k)}, h^*, k, U_{k \times lk})$
- D_3 : $\text{DEncode}(U_{\ell(l+k)}, h^*, k, G(U_k))$
- D_4 : $\text{DEncode}(E_{PK}(r \| m^*), h^*, k, G(r))$, where $r \leftarrow U_k$

Clearly D_4 perfectly simulates the stegotext distribution, and likewise D_1 perfectly simulates the covertext distribution. For convenience, we will define the quantity $\mathbf{Adv}_W^i(k) = |\Pr[W^{SD}(PK, D_{i+1}) = 1] - \Pr[W^{SD}(PK, D_i) = 1]|$, and note that

$$\begin{aligned} \mathbf{Adv}_{W, \text{SCCA}, \mathcal{C}}^{\text{scca}}(k) &= |\Pr[W^{SD}(PK, D_4) = 1] - \Pr[W^{SD}(PK, D_1) = 1]| \\ &\leq \mathbf{Adv}_W^1(k) + \mathbf{Adv}_W^2(k) + \mathbf{Adv}_W^3(k). \end{aligned}$$

Thus we proceed to bound $\mathbf{Adv}_W^i(k)$ for $i \in \{1, 2, 3\}$.

Lemma 1. $\mathbf{Adv}_W^1(k) \leq \ell(l+k)\epsilon$

Proof. This follows because $\|f(C_h) - U_1\| \leq \epsilon$, and no (nonuniform) efficient process can increase statistical distance.

Lemma 2. $\mathbf{Adv}_W^2(k) \leq \mathbf{InSec}_G^{\text{prg}}(t', k)$

Proof. We will construct a PRG adversary A for G such that $\mathbf{Adv}_{A, G}^{\text{prg}}(k) = \mathbf{Adv}_W^2(k)$. A works as follows: first, A picks a key pair $(PK, SK) \leftarrow G(1^k)$ to use in responding to the queries W makes to SD . A is given as input a string $r \in \{0, 1\}^{k \times lk}$ and asked to decide whether $r \leftarrow U_{k \times lk}$ or $r \leftarrow G(U_k)$. Then A can achieve advantage precisely $\mathbf{Adv}_W^2(k)$ by emulating W , responding to its decoding queries using SK , and responding to the challenge hidtext (m^*, h^*) by drawing $c \leftarrow U_{\ell(l+k)}$ and giving the response $s = \text{DEncode}(c, h, k, r)$. If $r \leftarrow U_{k \times lk}$, then $s \leftarrow D_1$, and if $r \leftarrow G(U_k)$, then $s \leftarrow D_2$. Thus A 's advantage in distinguishing $G(U_k)$ and $U_{k \times lk}$ is exactly:

$$\begin{aligned} \mathbf{Adv}_{A, G}^{\text{prg}}(k) &= |\Pr[A(G(U_k)) = 1] - \Pr[A(U_{k \times lk}) = 1]| \\ &= |\Pr[W^{SD}(D_2) = 1] - \Pr[W^{SD}(D_1) = 1]| \\ &= \mathbf{Adv}_W^2(k) \end{aligned}$$

Lemma 3. $\text{Adv}_W^3(k) \leq \text{InSec}_{\mathcal{E}}^{\text{cca}}(t', \mathbf{q}, \boldsymbol{\mu}, k) + \nu(k)$

Proof. We will construct an adversary A that plays the chosen-ciphertext attack game against \mathcal{E} with advantage $\text{Adv}_{A, \mathcal{E}}^{\text{cca}}(k) \geq \text{Adv}_W^3(k)$.

A starts by emulating W to get a challenge hiddentext, responding to decoding queries as follows: on query (s_1, \dots, s_l, h) , A computes $c = f(s_1) \parallel \dots \parallel f(s_l)$; A then uses its decryption oracle to compute $r \parallel_k m = D_{SK}(c)$. If $c \neq \perp$ and $s = \text{DEncode}(c, h, k, G(r))$, A returns m , otherwise A returns \perp .

When W generates challenge (m^*, h^*) , A chooses $r^* \leftarrow U_k$ and outputs the challenge $r^* \parallel m^*$. A is given the challenge ciphertext c^* and returns $s^* = \text{DEncode}(c^*, h^*, k, G(r^*))$ to W .

A continues to emulate W , responding to queries as before, except that on decoding query (s_1, \dots, s_l, h) , A first checks whether $f(s_1) \parallel \dots \parallel f(s_l) = c^*$; if so, A returns \perp rather than querying $D_{SK}(c^*)$.

In other words, A simulates running SCCA.Decode with its D_{SK} oracle, except that because A is playing the $\text{IND\$-CCA}$ game, he is not allowed to query D_{SK} on the challenge value c^* : thus a decoding query that has the same underlying ciphertext c^* must be dealt with specially.

Notice that when A is given an encryption of $r^* \parallel m^*$, he perfectly simulates D_4 to W , so that $\Pr[A^D(PK, E_{PK}(r^* \parallel m^*)) = 1] = \Pr[W^{SD}(PK, D_4) = 1]$. This is because when $c^* = E_K(r^* \parallel m^*)$ then the test $s = \text{DEncode}(c, h, k, G(r))$ would fail anyways. Likewise, when A is given a random string, he perfectly simulates D_3 to W , given that c^* is not a valid ciphertext. Let us denote the event that c^* is a valid ciphertext by V , and the event that a sample from D_3 encodes a valid ciphertext by U ; notice that by construction $\Pr[U] = \Pr[V]$. We then have that

$$\begin{aligned} \Pr[A^D(PK, U_\ell) = 1] &= \Pr[A^D(PK, U_\ell) = 1 | \bar{V}] \Pr[\bar{V}] + \Pr[A^D(PK, U_\ell) = 1 | V] \Pr[V] \\ &\leq \Pr[W^{SD}(PK, D_3) = 1 | \bar{U}] \Pr[\bar{U}] + \Pr[V] \\ &\leq \Pr[W^{SD}(PK, D_3) = 1] + \Pr[V] \\ &\leq \Pr[W^{SD}(PK, D_3) = 1] + \nu(k), \end{aligned}$$

since $\Pr[V] \leq \nu(k)$ by assumption on \mathcal{E} . Combining the cases, we find that

$$\begin{aligned} \text{Adv}_{A, \mathcal{E}}^{\text{cca}}(k) &= \Pr[A^D(PK, E_{PK}(r^* \parallel m^*)) = 1] - \Pr[A^D(PK, U_\ell) = 1] \\ &= \Pr[W^{SD}(PK, D_4) = 1] - \Pr[A^D(PK, U_\ell) = 1] \\ &\geq \Pr[W^{SD}(PK, D_4) = 1] - \Pr[W^{SD}(PK, D_3) = 1] - \nu(k) \\ &= \text{Adv}_W^3(k) - \nu(k) \end{aligned}$$

Remark. As described, the stegosystem SCCA requires the decoder to know the algorithm channel used by the encoder to sample from \mathcal{C} . This can be avoided by changing the encoder to append a canonical encoding of this algorithm to the hiddentext before encrypting; the decoder then recovers this algorithm before running the final DEncode check. Since the length of the algorithm is constant, the security bounds for the resulting scheme are essentially unchanged.

6 Conclusion and Open Problems

We have argued for the importance of a SS-CCA-secure stegosystem in the bare public key model, and given the first construction which meets this criterion. This resolves an open question posed by Backes and Cachin [3]. Furthermore, our construction relies on a public-key cryptosystem which is pseudorandom against chosen-ciphertext attack in the standard model. The existence of a cryptosystem satisfying this notion was an open problem posed by von Ahn and Hopper [1]. Because replay attacks are a realistic possibility, this represents an important advance over previous work.

One interesting direction for future work is to investigate the relationship between efficiently sampleable channels and the probabilistic channel oracle notion of earlier work. Designing a SS-CCA stegosystem in this setting seems to be a challenging problem. Another important notion of security against active attacks is *robustness* — the property that an attacker is unable to “remove” the hiddentext from a message. Hopper *et al* [13] define a weak notion of robustness and give a robust construction in the private key case. To our knowledge, there is no provably secure construction satisfying this definition in the public-key case. It is interesting to note that SS-CCA and robustness are inherently contradictory, since robustness *requires* that a replay attack is possible. Thus it is also an interesting question whether some notion of robustness with decoding oracles can be achieved, even in the private key case.

Abstract. This paper presents an efficient approach to the classification of the affine equivalence classes of cosets of the first order Reed-Muller code with respect to cryptographic properties such as correlation-immunity, resiliency and propagation characteristics. First, we apply the method to completely classify with this respect all the 48 classes into which the general affine group $AGL(2, 5)$ partitions the cosets of $RM(1, 5)$. Second, after distinguishing the 34 affine equivalence classes of cosets of $RM(1, 6)$ in $RM(3, 6)$ we perform the same classification for these classes.

1 Introduction

Many constructions of Boolean functions with properties relevant to cryptography are recursive. The efficiency of the constructions relies heavily on the use of appropriate functions of small dimensions. Another important method for construction is the random and heuristic search approach. As equivalence classes are used to provide restricted input of such optimization algorithms, it is very important to identify which equivalence classes obtain functions with desired properties.

In this paper, we present an efficient approach (based on some group-theoretical considerations) for the classification of affine equivalence classes of cosets of the first order Reed-Muller code with respect to cryptographic properties such as correlation-immunity, resiliency, propagation characteristics and

their combinations. We apply this method to perform a complete classification of all the 48 orbits of affine equivalent cosets of $RM(1, 5)$ (classified by Berlekamp and Welch [1] according to weight distributions), with respect to the above mentioned cryptographic properties. Partial results for this case on the existence and their number have already been mentioned in [3, 13, 14, 16]. In this paper, we study this problem into more detail and show in which classes these functions appear and how to enumerate them. The method also allows us, if necessary, to generate all the Boolean functions of 5 variables that possess good cryptographic properties. Our approach can also be extended for Boolean functions of higher dimension. As an illustration we apply it to the cubic functions of 6 variables using a proper classification of the cosets of $RM(1, 6)$ in $RM(3, 6)$.

The paper is organized as follows. In Sect. 2, we present some general background on Boolean functions. In Sect. 3, we describe our approach which will be used in Sect. 4 for a complete classification of the affine equivalence classes of the Boolean functions of 5 variables. In Sect. 5, we first show how to derive the $RM(3, 6)/RM(1, 6)$ equivalence classes together with their sizes. Using this information we classify them according to the most important cryptographic properties.

2 Background on Boolean Functions

A Boolean function f is a mapping from \mathbb{F}_2^n into \mathbb{F}_2 . It can be represented by a *truth table*, which is a vector of length 2^n consisting of its function values $(f(\bar{0}), \dots, f(\bar{1}))$. Another way of representing a Boolean function is by means of its *algebraic normal form* (ANF):

$$f(\bar{x}) = \bigoplus_{(a_1, \dots, a_n) \in \mathbb{F}_2} h(a_1, \dots, a_n) x_1^{a_1} \dots x_n^{a_n} ,$$

where f and h are functions on \mathbb{F}_2^n . The *algebraic degree* of f , denoted by $\text{deg}(f)$, is defined as the highest number of variables in the term $x_1^{a_1} \dots x_n^{a_n}$ in the ANF of f .

Two Boolean functions f_1 and f_2 on \mathbb{F}_2^n are called *equivalent* if and only if

$$f_1(\bar{x}) = f_2(\bar{x}A \oplus \bar{a}) \oplus \bar{x}\bar{B}^t \oplus b, \quad \forall x \in \mathbb{F}_2^n, \tag{1}$$

where A is a nonsingular binary $n \times n$ -matrix, b is a binary constant, and \bar{a}, \bar{B} are n -dimensional binary vectors. If \bar{B}, b are zero, the functions f_1 and f_2 are said to be affine equivalent. A property is called affine invariant if it is invariant under affine equivalence.

The study of properties of Boolean functions is related to the study of *Reed-Muller codes*. The codewords of the r -th order Reed-Muller code of length 2^n , denoted by $RM(r, n)$, are the truth tables of Boolean functions with degree less or equal to r . The number of codewords is equal to $2^{\sum_{i=0}^r \binom{n}{i}}$ and the minimum number of positions in which any two codewords \bar{u}, \bar{v} differ (denoted by $d(\bar{u}, \bar{v})$)

is 2^{n-r} . The *Hamming weight* of a vector \bar{v} is denoted by $wt(\bar{v})$ and equals the number of non-zero positions, i.e. $wt(\bar{v}) = d(\bar{v}, \bar{0})$.

In 1972, Berlekamp and Welch classified all 2^{26} cosets of $RM(1, 5)$ into 48 equivalence classes under the action of the general affine group $AGL(2, 5)$ [1]. Moreover for each equivalence class the weight distribution and the number of cosets in that class has been determined.

Before describing the cryptographic properties that are investigated in this paper, we first mention two important tools in the study of Boolean functions f on \mathbb{F}_2^n . The *Walsh transform* of f is a real-valued function over \mathbb{F}_2^n that can be defined as

$$W_f(\bar{\omega}) = \sum_{\bar{x} \in \mathbb{F}_2^n} (-1)^{f(\bar{x}) \oplus \bar{x} \cdot \bar{\omega}} = 2^n - 2wt(f \oplus \bar{x} \cdot \bar{\omega}), \tag{2}$$

where $\bar{x} \cdot \bar{\omega} = \bar{x}\bar{\omega}^t = x_1\omega_1 \oplus x_2\omega_2 \oplus \dots \oplus x_n\omega_n$ is the *dot product* of \bar{x} and $\bar{\omega}$. The *nonlinearity* N_f of the function f is defined as the minimum distance between f and any affine function which can be expressed as $N_f = 2^{n-1} - \frac{1}{2} \max_{\bar{\omega} \in \mathbb{F}_2^n} |W_f(\bar{\omega})|$.

The *autocorrelation function* of f is a real-valued function over \mathbb{F}_2^n that can be defined as

$$r_f(\bar{\omega}) = \sum_{\bar{x} \in \mathbb{F}_2^n} (-1)^{f(\bar{x}) \oplus f(\bar{x} \oplus \bar{\omega})}. \tag{3}$$

For two equivalent functions f_1 and f_2 such that $f_1(\bar{x}) = f_2(\bar{x}A \oplus \bar{a}) \oplus \bar{x}\bar{B}^t \oplus b$, it holds that [15]:

$$W_{f_1}(\bar{\omega}) = (-1)^{\bar{a}A^{-1}\bar{\omega} + \bar{a}A^{-1}\bar{B} + b} W_{f_2}(((\bar{\omega} \oplus \bar{B})(A^{-1})^t) \tag{4}$$

$$r_{f_1}(\bar{\omega}) = (-1)^{\bar{\omega}\bar{B}} r_{f_2}(\bar{\omega}A). \tag{5}$$

A Boolean function is said to be *correlation-immune* of order t , denoted by $CI(t)$, if the output of the function is statistically independent of the combination of any t of its inputs. If the function is also *balanced* (equal number of zeros and ones in the truth table), then it is said to be *resilient* of order t , denoted by $R(t)$. These definitions of correlation-immunity and resiliency can be expressed by spectral characterization as given by Xiao and Massey [8].

Definition 1. [8] *A function $f(\bar{x})$ is $CI(t)$ if and only if its Walsh transform W_f satisfies $W_f(\bar{\omega}) = 0$, for $1 \leq wt(\bar{\omega}) \leq t$. If also $W_f(\bar{0}) = 0$, the function is called t -resilient.*

A Boolean function is said to satisfy the *propagation characteristics* of degree p , denoted by $PC(p)$ if the function $f(\bar{x}) \oplus f(\bar{x} \oplus \bar{\omega})$ is balanced for $1 \leq wt(\bar{\omega}) \leq p$. If the function $f(\bar{x}) \oplus f(\bar{x} \oplus \bar{\omega})$ is also t -resilient, the function f is called a $PC(p)$ function of order t . Or, by using the autocorrelation and Walsh spectrum, the definition can also be expressed as follows:

Definition 2. [14] A function $f(\bar{x})$ is $PC(p)$ if and only if its autocorrelation transform r_f satisfies $r_f(\bar{w}) = 0$, for $1 \leq wt(\bar{w}) \leq p$. If also $W_{f(\bar{x}) \oplus f(\bar{x} \oplus \bar{w})}(\bar{a}) = 0$ for all \bar{a} with $0 \leq wt(\bar{a}) \leq t$, the function f is said to satisfy $PC(p)$ of order t .

If $r_f(\bar{w}) = \pm 2^n$, the vector \bar{w} is called a *linear structure* of the function f . It is easy to prove that the set of linear structures forms a linear space [6].

We now present some known results which will be used in the rest of the paper. First of all, we start with mentioning several trade-offs between the above described properties of a Boolean function.

Theorem 1. (Siegenthaler’s Inequality [17]) If a function f on \mathbb{F}_2^n is $CI(t)$, then $\deg(f) \leq n - t$. If f is t -resilient and $t \leq n - 2$, then $\deg(f) \leq n - t - 1$.

Theorem 2. [14] If a function f on \mathbb{F}_2^n satisfies $PC(p)$ of order t with $0 \leq t < n - 2$, then $\deg(f) \leq n - t - 1$ for all p . If $t = n - 2$ then the degree of f is equal to 2.

Theorem 3. [20] If a function f on \mathbb{F}_2^n is t -resilient and satisfies $PC(p)$, then $p + t \leq n - 1$. If $p + t = n - 1$, then $p = n - 1$, n is odd and $t = 0$.

Another important result is the following divisibility theorem proven by Carlet and Sarkar [4].

Theorem 4. If a coset of the $RM(1, n)$ with representative Boolean function f of degree d contains $CI(t)$ (resp. t -resilient) functions, then the weights of the functions in $f + RM(1, n)$ are divisible by

$$2^{t+\lfloor \frac{-1}{2} \rfloor} \quad (\text{resp. } 2^{t+1+\lfloor \frac{-2}{2} \rfloor}). \tag{6}$$

From this Theorem together with Dickson’s theorem on the canonical representations of quadratic Boolean functions [11], we derive a classification of correlation-immune (resp. resilient) quadratic functions in any dimension.

Proposition 1. If the coset of $RM(1, n)$ with representative $x_1x_2 \oplus x_3x_4 \oplus \dots \oplus x_{2h-1}x_{2h} \oplus \varepsilon$ where ε is an affine function of x_{2h+1} through x_n and $h \leq \lfloor \frac{n}{2} \rfloor$ given by Dickson’s theorem contains $CI(t)$ (resp. t -resilient) functions then

$$h \leq n - t - \left\lfloor \frac{n - t - 1}{2} \right\rfloor - 1 \quad (\text{resp. } h \leq n - t - \left\lfloor \frac{n - t - 2}{2} \right\rfloor - 2).$$

Proof. The weight of the function equals (depending on the parameter h) [11]:

$$\frac{\text{weight}}{\text{number}} \left| \begin{array}{ccc} 2^{n-1} - 2^{n-h-1} & 2^{n-1} & 2^{n-1} - 2^{n-h-1} \\ 2^{2h} & 2^{n+1} - 2^{2h+1} & 2^{2h} \end{array} \right|$$

The statement of the proposition follows from the divisibility theorem of Carlet and Sarkar applied on the weights. □

Remark 1. Using Proposition 1 together with the bound $h \leq \lfloor \frac{n}{2} \rfloor$, we obtain that the order of resiliency for quadratic functions is less or equal to $\lfloor \frac{n}{2} \rfloor - 1$, which was also stated in [18].

3 General Outline of Our Method

In this section we describe our main approach for the classification of equivalence classes (also called orbits) of cosets of the first order Reed-Muller code $RM(1, n)$ with respect to cryptographic properties such as correlation-immunity, resiliency, propagation characteristics and their combinations. For the sake of simplicity we shall refer to such a property as a C -property. For a given function f we denote by ZC_f the set of vectors which are mapped to zero by the transform we denote by the considered C -property (e.g. Walsh transform for correlation-immunity and resiliency, autocorrelation for propagation characteristics) and call it a *zero-set* of f with respect to this C -property. We also refer to any set of n linearly independent vectors in \mathbb{F}_2^n as a basis.

Our method employs the idea behind the “change of basis” construction as previously used by Maitra and Pasalic [12], and Clark et al. [5].

Let \mathcal{R} be a representative coset of a given orbit \mathcal{O} under the action of the general affine group $AGL(2, n)$. \mathcal{R} is partitioned into subsets consisting of affine equivalent functions. Denote by \mathcal{T} the family of these subsets. Let us fix one $T \in \mathcal{T}$ and a function $f \in T$.

From equations (4) and (5) and the definition of the corresponding C -property, it follows that for any function with this property, affine equivalent to f , a basis in ZC_f with certain properties exists. Conversely, for any proper basis in ZC_f and a constant from \mathbb{F}_2^n we can apply an invertible affine transformation to f (derived by the basis and the constant) such that its image \tilde{f} possess the C -property. Therefore the number N_f of functions affine equivalent to f and satisfying a certain C -property can be determined by counting bases in ZC_f . Moreover it can be seen that this number does not depend on the specific choice of f from T , since for two different functions f_1 and f_2 from T there exists one-to-one correspondence between the sets of their proper bases in the zero-sets. It is important to note that in case of Walsh transform we use the fact that vector \bar{B} defined in previous section is $\bar{0}$.

In the following theorem we prove the formula that gives the number \mathcal{N}_C of functions with C -property in the orbit \mathcal{O} .

Theorem 5. *Let \mathcal{R} be a representative coset of a given orbit \mathcal{O} under the action of the general affine group $AGL(2, n)$. Then the number \mathcal{N}_C of functions with C -property in this orbit can be computed by the formula:*

$$\mathcal{N}_C = K_{\mathcal{O}} \sum_{f \in \mathcal{R}} B_f, \quad (7)$$

where B_f is the number of proper bases in ZC_f and $K_{\mathcal{O}} = \frac{n!|\mathcal{O}|}{|GL(2, n)|}$.

Proof. We will find the number of functions with C -property in the orbit \mathcal{O} by counting bases in zero-sets ZC_f . But this way we count each function $|S(f)| = S_f$ times, where $S(f)$ is the stabilizer subgroup of function f in $AGL(2, n)$. Therefore taking into account considerations preceding the theorem, the number

N_T of functions equivalent to the functions from T and satisfying the C -property is equal to

$$N_T = N_f = \frac{2^n n! B_f}{S_f}, \tag{8}$$

where B_f is the number of proper bases in ZC_f . The factor $n!$ appears since any arrangement of a given basis represents different function. Let $|\mathcal{O}|$ be the number of cosets in the orbit \mathcal{O} . Then substituting $S_f = \frac{|AGL(2,n)|}{|\mathcal{O}||T|}$ in (8) we get

$$N_T = \frac{2^n n! |\mathcal{O}| B_f |T|}{|AGL(2, n)|} = K_{\mathcal{O}} B_f |T|, \tag{9}$$

where $K_{\mathcal{O}} = \frac{n! |\mathcal{O}|}{|GL(2,n)|}$ and $GL(2, n)$ is the general linear group.

Therefore the number of all functions with C -property belonging to the orbit \mathcal{O} is:

$$\sum_{T \in \mathcal{T}} N_T = K_{\mathcal{O}} \sum_{T \in \mathcal{T}} B_f |T| = K_{\mathcal{O}} \sum_{f \in \mathcal{R}} B_f. \tag{10}$$

□

In order to avoid difficulties when determining affine equivalent functions in \mathcal{R} we prefer to use the last expression of (10). Thus, to compute the number \mathcal{N}_C of functions with C -property in the orbit \mathcal{O} we shall apply the following formula

$$\mathcal{N}_C = K_{\mathcal{O}} \sum_{f \in \mathcal{R}} B_f. \tag{11}$$

4 Boolean Functions of Less Than 5 Variables

For the study of functions in n variables with $n \leq 4$, we refer to [3] and [14]. In [3, Sect. 4.2], a formula is derived for the number of $(n - 3)$ -resilient functions and the number of balanced quadratic functions of n variables. In [14, Table 1], the number of quadratic functions that satisfy $PC(l)$ of order k with $k + l \leq n$ are determined for $n \leq 7$. Consequently, taking into account the trade-offs mentioned in Sect. 2, to cover all classes only the class with representative $x_1 x_2 x_3 \oplus x_1 x_4$ with $n = 4$ should be considered in relation with its propagation characteristics. It can be easily computed by exhaustive search that its size is 26 880 and that it contains 2 816 $PC(1)$ functions.

We now count the number of functions satisfying correlation-immunity, resiliency, propagation characteristics and their combinations in each of the 48 affine equivalence classes of $RM(1, 5)$ by using the method explained in Sect. 3. Note that only the cosets with even weight need to be considered. Numerical results can be found in tables 1 through 5. In the tables, the functions are represented by means of an abbreviated notation (only the digits of the variables) and the sum should be considered modulo 2. We refer to the extended version of the paper concerning details about the computation.

Table 1. The Number of functions satisfying 1-*CI*, 1-Resilient, 1-*PC*, 1-*PC* with resiliency properties

5 Boolean Functions of 6 Variables and Degree 3

In this section first we show how to find the 34 affine equivalence classes of $RM(3, 6)/RM(1, 6)$, together with the orders of their size. Then we count in each class the number of resilient and PC functions.

5.1 Classification of $RM(3, 6)/RM(1, 6)$

Table 1 in [9] presents the number of affine equivalence classes of $RM(s, 6)$ in $RM(r, 6)$ with $-1 \leq s < r \leq 6$. In $RM(3, 6)/RM(1, 6)$ there are 34 equivalence classes. In order to classify the affine equivalence classes in $RM(3, 6)/RM(1, 6)$, we use the 6 representatives $f_i \oplus RM(2, 6)$ for $1 \leq i \leq 6$ of the equivalence classes of $RM(3, 6)/RM(2, 6)$ as given in [10]: $f_1 = 0, f_2 = 123, f_3 = 123 + 245, f_4 = 123 + 456, f_5 = 123 + 245 + 346, f_6 = 123 + 145 + 246 + 356 + 456$. For each representative, we run through all functions consisting only of quadratic terms and distinguish the affine inequivalent cosets of $RM(1, 6)$ by using the frequency distribution of absolute values of the Walsh and autocorrelation distribution as affine invariants. These indicators suffice to distinguish all 34 affine equivalence classes.

In order to employ the approach described in Sect. 3 we also need to know the sizes of these orbits. They were computed during the classification phase by multiplying the final results by the sizes of the corresponding orbits in $RM(3, 6)/RM(2, 6)$ given in [10]. To check these results in the cases of f_2, f_4 and f_6 we obtained linear systems for unknown sizes by taking into account the weight distributions of the cosets of $RM(1, 6)$ and the weight distribution of the corresponding representative of $RM(3, 6)/RM(2, 6)$ to which these cosets belong. Of course if $f_1 = 0$ one can use also [11, Theorem 1 and Theorem 2, p.436]. The results obtained in these two ways coincide. We refer to Table 6 for the sizes of the orbits.

Remark 2. The 150 357 affine equivalence classes were classified for the first time by Maiorana [7]. They also are mentioned on the webpage maintained by

Fuller: <http://www.isrc.qut.edu.au/people/fuller/> together with the degree, nonlinearity, maximum value in autocorrelation spectrum and truth tables of Boolean functions of dimension 6. Here we describe another approach for finding the 34 affine equivalence classes of functions of degree 3. One reason for this is that our method requires the sizes of the orbits, which are not given by Fuller.

5.2 Cryptographic Properties

In order to count the number of functions that satisfy certain cryptographic properties, the same approach as used for $n = 5$ is applied on these 34 classes of $RM(3, 6)/RM(1, 6)$. In Table 6, we present the classes together with the numbers

of functions in these classes that satisfy t -resiliency with $t \leq 2$ and propagation characteristics of degree less or equal to 2. The last columns represents the sizes of the orbits.

By the Siegenthaler's inequality, 3-resilient functions should have degree less or equal to 2. Only the class with representative x_1x_2 contains 3-resilient functions and there are in total 1 120 3-resilient functions of dimension 6 (see also [3]).

For functions satisfying PC of higher degree, we have the following results. Besides the bent functions which are $PC(6)$, only the class with representative $x_1x_4 \oplus x_2x_3$ contains $PC(3)$ functions with a total of 128×420 , as also computed in [14].

6 Conclusions

In this paper, we present a complete classification of the set of Boolean functions of 5 variables with respect to the most important cryptographic properties. Our method can also be applied to Boolean functions of dimension 6. As an example, we compute the 34 affine equivalence classes of $RM(3,6)/RM(1,6)$ and determine the number of resilient and PC functions belonging to each class. Moreover, we show a practical way to find the affine equivalence classes of Boolean functions. This method can be extended to dimension 7.

Abstract. A finite automaton, simply referred to as a *robot*, has to explore a graph, i.e., visit all the nodes of the graph. The robot has no a priori knowledge of the topology of the graph or of its size. It is known that, for any k -state robot, there exists a $(k+1)$ -node graph of maximum degree 3 that the robot cannot explore. This paper considers the effects of allowing the system designer to add short labels to the graph nodes in a preprocessing stage, and using these labels to guide the exploration by the robot. We describe an exploration algorithm that given appropriate 2-bit labels (in fact, only 3-valued labels) allows a robot to explore all graphs. Furthermore, we describe a suitable labeling algorithm for generating the required labels, in linear time. We also show how to modify our labeling scheme so that a robot can explore all graphs of bounded degree, given appropriate 1-bit labels. In other words, although there is no robot able to explore all graphs of maximum degree 3, there is a robot \mathcal{R} , and a way to color in black or white the nodes of any bounded-degree graph G , so that \mathcal{R} can explore the colored graph G . Finally, we give impossibility results regarding graph exploration by a robot with no internal memory (i.e., a single state automaton).

1 Introduction

Let \mathcal{R} be a finite automaton, simply referred to in this context as a *robot*, moving in an unknown graph $G = (V, E)$. The robot has no a priori information about the topology of G and its size. To allow the robot \mathcal{R} , visiting a node u , to distinguish between its edges, the $d = \deg(u)$ edges incident to u are associated to d distinct *port numbers* in $\{0, \dots, d-1\}$, in a one-to-one manner. The port numbering is given as part of the input graph, and the robot has no a priori information about it. For convenience of terminology, we henceforth refer to

“the edge incident to port number l at node u ” simply as “edge l of u ”. (Clearly, if this edge connects u to v , then it may also be referred to as “edge l' of v ” for the appropriate l' .) The robot has a transition function f , and a finite number of states. If \mathcal{R} enters a node of degree d through port i in state s , then it switches to state s' and exits the node through port i' , where $(s', i') = f(s, i, d)$. The objective of the robot is to *explore* the graph, i.e., to visit all its nodes.

The first known algorithm designed for graph exploration was introduced by Shannon [8]. Since then, several papers have been dedicated to the feasibility of graph exploration by a finite automaton. Rabin [6] conjectured that no finite automaton with a finite number of pebbles can explore all graphs (a *pebble* is a marker that can be dropped at and removed from nodes). The first step towards a formal proof of Rabin’s conjecture is generally attributed to Budach [2], for a robot without pebbles. Blum and Kozen [1] improved Budach’s result by proving that a robot with three pebbles cannot perform exploration of all graphs. Kozen [5] proved that a robot with four pebbles cannot explore all graphs. Finally, Rollik [7] gave a complete proof of Rabin’s conjecture, showing that no robot with a finite number of pebbles can explore all graphs. The result holds even when restricted to planar 3-regular graphs. Without pebbles, it was proved [4] that a robot needs $\Theta(D \log \Delta)$ bits of memory for exploring all graphs of diameter D and maximum degree Δ . On the other hand, if the class of input graphs is restricted to trees, then exploration is possible even by a robot with no memory (i.e., zero states), simply by DFS using the transition function $f(i, d) = i + 1 \bmod d$ (see, e.g., [3]).

The ability of dropping and removing pebbles at nodes can be viewed alternatively as the ability of the robot to dynamically *label* the nodes. If the robot is given k pebbles, then, at any time of the exploration, $\sum_{u \in V} |l_u| \leq k$ where l_u is the label of node u and $|l_u|$ denotes the size of the label in unary. This paper considers the effects of allowing the system designer to assign labels to the nodes in a preprocessing stage, and using these labels to guide the exploration by the robot. The transition function f is augmented to utilize labels as follows. If \mathcal{R} in state s enters a node of degree d , labeled by l , through port i , then it switches to state s' and exits the node through port i' , where

$$(s', i') = f(s, i, d, l).$$

This model can be considered stronger than Rabin’s pebble model since labels are given in a preprocessing stage, but it can also be considered weaker since, once assigned to nodes, the labels cannot be modified.

In this paper, we consider settings where it is expected that the graph will be visited by many exploring robots, and consequently, the system designer would like to preprocess the graph by leaving (preferably small) road-signs, or *labels*, that will aid the robots in their exploration task. As possible scenarios one may consider a network system where finite automata are used for traversing the system and distributing information in a sequential manner.

More formally, we address the design of *exploration labeling schemes*. Such schemes consist of a pair $(\mathcal{L}, \mathcal{R})$ such that, given any graph G with any port

Table 1. Summary of main results

Label size (#bits)	Robot's memory (#bits)	Time (#edge-traversals)
2	$O(1)$	$O(m)$
1	$O(\log \Delta)$	$O(\Delta^{O(1)}m)$

numbering, the algorithm \mathcal{L} labels the nodes of G , and the robot \mathcal{R} explores G with the help of the labeling produced by \mathcal{L} . In particular, we are interested in exploration labeling schemes for which: (1) the preprocessing time required to label the nodes is polynomial, (2) the labels are short, and (3) the exploration is completed after a small number of edge-traversals.

As a consequence of Rollik's result, any exploration labeling scheme must use at least *two* different labels. Our main result states that just *three* labels (e.g., three colors) are sufficient for enabling a robot to explore all graphs. Moreover, we show that our labeling scheme gives to the robot the power to stop once exploration is completed, although, in the general setting of graph exploration, the robot is not required to stop once the exploration has been completed, i.e., once all nodes have been visited. In fact, we show that exploration is completed in time $O(m)$, i.e., after $O(m)$ edge traversals, in any m -edge graph.

For the class of bounded degree graphs, we design an exploration scheme using even smaller labels. More precisely, we show that just *two* labels (i.e., 1-bit labels) are sufficient for enabling a robot to explore all bounded degree graphs. The robot is however required to have a memory of size $O(\log \Delta)$ to explore all graphs of maximum degree Δ . The completion time $O(\Delta^{O(1)}m)$ of the exploration is larger than the one of our previous 2-bit labeling scheme, nevertheless it remains polynomial.

All these results are summarized in Table 1. The two mentioned labeling schemes require polynomial preprocessing time.

We also prove several impossibility results for 1-state robots, i.e., robots that are oblivious. The behavior of 1-state robots depends solely on the input port number, and on the degree and label of the current node. In particular, we prove that for any $d > 4$ and for any 1-state robot using at most $\lfloor \log d \rfloor - 2$ colors, there exists a simple graph of maximum degree d that cannot be explored by the robot. This lower bound on the number of colors needed for exploration can be increased exponentially to $d/2 - 1$ by allowing loops.

2 A 2-Bit Exploration-Labeling Scheme

In this section, we describe an exploration-labeling scheme using only 2-bit (actually, 3-valued) labels. More precisely, we prove the following.

Theorem 1. *There exists a robot with the property that for any graph G , it is possible to color the nodes of G with three colors (or alternatively, assign each node a 2-bit label) so that using the labeling, the robot can explore the entire*

graph G , starting from any given node and terminating after identifying that the entire graph has been traversed. Moreover, the total number of edge-traversals by the robot is $\leq 20m$.

To prove Theorem 1, we first describe the labeling scheme \mathcal{L} and then the exploration algorithm. The node labeling is in fact very simple; it uses three labels, called colors, and denoted WHITE, BLACK, and RED. Let D be the diameter of the graph.

Labeling \mathcal{L} . Pick an arbitrary node r . Node r is called the *root* of the labeling \mathcal{L} . Nodes at distance d from r , $0 \leq d \leq D$, are labeled WHITE if $d \bmod 3 = 0$, BLACK if $d \bmod 3 = 1$, and RED if $d \bmod 3 = 2$.

The neighbor set $\mathcal{N}(u)$ of each node u can be partitioned into three disjoint sets: (1) the set $\text{pred}(u)$ of neighbors closer to r than u ; (2) the set $\text{succ}(u)$ of neighbors farther from r than u ; (3) the set $\text{sibling}(u)$ of neighbors at the same distance from r as u . We also identify the following two special subsets of neighbors:

- $\text{parent}(u)$ is the node $v \in \text{pred}(u)$ such that the edge $\{u, v\}$ has the smallest port number at u among all edges leading to a node in $\text{pred}(u)$.
- $\text{child}(u)$ is the set of nodes $v \in \text{succ}(u)$ such that $\text{parent}(v) = u$.

For the root, set $\text{parent}(r) = \emptyset$. The exploration algorithm is partially based on the following observations.

1. For the root r , $\text{child}(r) = \text{succ}(r) = \mathcal{N}(r)$.
2. For every node u with label $\mathcal{L}(u)$, and for every neighbor $v \in \mathcal{N}(u)$, the label $\mathcal{L}(v)$ uniquely determines whether v belongs to $\text{pred}(u)$, $\text{succ}(u)$ or $\text{sibling}(u)$.
3. Once at node u , a robot can identify $\text{parent}(u)$ by visiting its neighbors successively, starting with the neighbor connected to port 0, then port 1, and so on. Indeed, by observation 2, the nodes in $\text{pred}(u)$ can be identified by their label. The order in which the robot visits the neighbors ensures that $\text{parent}(u)$ is the first visited node in $\text{pred}(u)$.

Remark. The difficulty of graph exploration by a robot with a finite memory is that the robot entering some node u by port p , and aiming at exiting u by the same port p after having performed some local exploration around u , has not enough memory to store the value of p .

Exploration algorithm. Our exploration algorithm uses a procedure called `Check_Edge`. This procedure is specified as follows. When `Check_Edge(j)` is initiated at some node u , the robot starts visiting the neighbors of u one by one, and eventually returns to u reporting one of three possible outcomes: “child”, “parent”, or “false”. These values have the following interpretation:

- (i) if “child” is returned, then edge j at u leads to a child of u ;
- (ii) if “parent” is returned, then edge j at u leads to the parent of u ;

(iii) if “false” is returned, then edge j at u leads to a node in $\mathcal{N}(u) \setminus (\text{parent}(u) \cup \text{child}(u))$.

The implementation of Procedure **Check_Edge** will be described later. Meanwhile, let us describe how the algorithm makes use of this procedure to perform exploration.

Assume that the robot \mathcal{R} is initially at the root r of the 3-coloring \mathcal{L} of the nodes. \mathcal{R} leaves r by port number 0, in state DOWN. Note that, by the above observations, the node at the other endpoint of edge 0 of r is a child of r .

Assume that \mathcal{R} enters a node u via port number i , in state DOWN. Assume u is of degree d ; all arithmetic operations in the following description are modulo d . \mathcal{R} aims at identifying a child of u if one exists, or to backtrack along edge i of u if none exists. To do so it executes Procedure **Check_Edge**(j) for every port number $j = i + 1, i + 2, \dots$ until the procedure eventually returns “child” or “parent” for some port number j . \mathcal{R} then sets its state to DOWN in the former case and UP in the latter, and leaves u by port j .

Assume that \mathcal{R} enters a node u via port number i , in state UP. Assume u is of degree d ; all arithmetic operations in the following description are modulo d . \mathcal{R} aims at identifying a child of u with port number $j \in \{i + 1, \dots, p - 1\}$ if one exists (where p is the port number of the edge leading to $\text{parent}(u)$), or to carry on moving up to the parent of u if there is no such child. To do so, \mathcal{R} executes Procedure **Check_Edge**(j) for every port number $j = i + 1, i + 2, \dots$ until the procedure eventually returns “child” or “parent” for some port number j . \mathcal{R} then sets its state to DOWN in the former case and UP in the latter, and leaves u by port j .

If the robot does not start from the root r of the labeling \mathcal{L} , then it first goes to r by using Procedure **Check_Edge** to identify the parent of every intermediate node, and by identifying r as the only node with $\text{pred}(r) = \emptyset$.

Moreover, the robot can stop after the exploration has been completed. More precisely, this can be done by introducing a slight modification of the robot behavior when it enters a node u of degree d via port number d in state UP. In this case, \mathcal{R} first check whether u has a parent. If yes, then it acts as previously stated (\mathcal{R} does not need to store d since d is the node degree). If not, the robot terminates the exploration.

Procedure Check_Edge. We now describe the actions of the robot \mathcal{R} when Procedure **Check_Edge**(j) is initiated at a node u . The objective of \mathcal{R} is to set the value of the variable **edge** to one of {parent, child, false}. We denote by v the other endpoint of the edge e with port number j at u . First, \mathcal{R} moves to v in state “check_edge”, carrying with it the color of node u . Let i be the port number of edge e at v . There are three cases to be considered.

- (a) $v \in \text{sibling}(u)$: Then \mathcal{R} backtracks through port i and reports “**edge** = false”.
- (b) $v \in \text{pred}(u)$: Then \mathcal{R} aims at checking whether v is the parent of u , that is, whether u is a child of v . For that purpose, \mathcal{R} moves back to u , and proceeds

as follows: \mathcal{R} successively visits edges $j-1, j-2, \dots$ of u until either the other endpoint of the edge belongs to $\text{pred}(u)$, or all edges $j-1, j-2, \dots, 0$ have been visited. \mathcal{R} then sets “**edge=false**” in the former case and “**edge=parent**” in the latter. At this point, let k be the port number at u of the last edge visited by \mathcal{R} . Then \mathcal{R} successively visit edge $k+1, k+2, \dots$ until the other endpoint belongs to $\text{pred}(u)$. Then it moves back to u and reports the value of **edge**.

- (c) $v \in \text{succ}(u)$: Then \mathcal{R} aims at checking whether u is the parent of v . For that purpose, \mathcal{R} proceeds in a way similar to Case (b), i.e., it successively visits edges $i-1, i-2, \dots$ of v until either the other endpoint of the edge belongs to $\text{pred}(v)$, or all edges $i-1, i-2, \dots, 0$ have been visited. \mathcal{R} then sets its variable **edge** to “false” in the former case and to “child” in the latter. At this point of the exploration, let k denotes the port number of the last edge incident to v that \mathcal{R} visited. Then \mathcal{R} successively visits edges $k+1, k+2, \dots$ until the other endpoint w of the edge belongs to $\text{pred}(v)$. Then it moves to w , and reports the value of **edge**.

This completes the description of our exploration procedure.

Proof of Theorem 1. Clearly, labeling all nodes by \mathcal{L} can be done in time linear in m , the number of edges of the graph. Obviously, two bits are enough to encode the label of each node. More specifically, using two bits for a color that is present on at most one third of the nodes, and one bit for the two other colors, we obtain a labeling with average label size $4/3$. It remains to prove the correctness of the exploration algorithm.

It is easy to check that if Procedure **Check_Edge** satisfies its specifications, then the robot \mathcal{R} essentially performs a DFS traversal of the graph using edges $\{u, v\}$ where $u = \text{parent}(v)$ or $u \in \text{child}(v)$. Thus, we focus on the correctness of Procedure **Check_Edge**(j) initiated at node u . Let v be other endpoint of the edge e with port number j at u , and let i be the port number of edge e at v . We check separately the three cases considered in the description of the procedure. By the previous observations, comparing the color of the current node with the color of u allows \mathcal{R} to distinguish between these cases.

If $v \in \text{sibling}(u)$, then v is neither a parent nor a child of u , and thus reporting “false” is correct. Indeed, \mathcal{R} then backtracks to u via port i , as specified in Case (a).

If $v \in \text{pred}(u)$, then $v = \text{parent}(u)$ iff for every neighbor w_k connected to u by an edge with port number $k \in \{j-1, j-2, \dots, 0\}$, $w_k \notin \text{pred}(u)$. The robot does check this property in Case (b) of the description, by returning to u , and visiting all the w_k ’s. Hence, Procedure **Check_Edge** performs correctly in this case.

Finally, if $v \in \text{succ}(u)$, then $v = \text{child}(u)$ iff for every neighbor z_l connected to v by an edge with port number $l \in \{i-1, i-2, \dots, 0\}$, $z_l \notin \text{pred}(v)$. In case (c), the robot does check this property by visiting all the z_l ’s. At this point, it remains for \mathcal{R} to return to u (obviously, the port number leading from v to u cannot be stored in the robot memory since it has only a constant number of states). Let k be the port number of the last edge incident to v that \mathcal{R} visited

before setting its variable `edge` to “false” or “child”. We have $0 \leq k \leq i - 1$, $z_l \notin \text{pred}(v)$ for all $l \in \{k + 1, \dots, i - 1\}$, and $u \in \text{pred}(v)$. Thus u is identified as the first neighbor that is met when visiting all v 's neighbors by successively traversing edges $k + 1, k + 2, \dots$ of v . This is precisely what \mathcal{R} does according to the description of the procedure in Case (c). Hence, Procedure `Check_Edge` performs correctly in this case.

Hence Procedure `Check_Edge` performs correctly in all cases and so does the global exploration algorithm. It remains to compute the number of edge traversals performed by the robot during the exploration (including the several calls to `Check_Edge`).

We use again the same notations as in the description and the proof of Procedure `Check_Edge`. Let us consider the Procedure `Check_Edge(j)` initiated at node u . Let v be other endpoint of the edge e with port number j at u , and let i be the port number of edge e at v . First observe that during the execution of the Procedure `Check_Edge` only edges incident to u and v are traversed. More precisely:

Case (a): $v \in \text{sibling}(u)$. Then edge $e = \{u, v\}$ is traversed twice and no other edges are traversed during this execution of Procedure `Check_Edge`.

Case (b): $v \in \text{pred}(u)$. Then \mathcal{R} traverses only edges incident to u . Let k be the greatest port number of the edges leading to a node in $\text{pred}(u)$ and satisfying $k < j$. If it does not exist, set $k = 0$. \mathcal{R} explores twice each edge $j, j - 1, \dots, k + 1$ of u , then twice edge k , and finally again twice edges $k + 1, \dots, j - 1, j$. To summarize, edge k of u is explored twice, and edges $k + 1, \dots, j - 1, j$ of u are explored four times.

Case (c): $v \in \text{succ}(u)$. Then \mathcal{R} traverses only edges incident to v . Let k be the greatest port number of the edges leading to a node in $\text{pred}(v)$ and satisfying $k < i$. If it does not exist, set $k = 0$. \mathcal{R} explores once edge j of u , twice each edge $i - 1, i - 2, \dots, k + 1$ of v , twice edge k , twice again edges $k + 1, \dots, i - 2, i - 1$, and finally once edge i of v (i.e., j of u). To summarize, edge i of u and edge k of v are explored twice and edges $k + 1, \dots, i - 2, i - 1$ of v are explored four times.

We bound now the number of times each edge e of the graph is traversed. Edge $e = \{u, v\}$ is labeled i at u and j at v . Let us consider different cases:

(1) $e = \{u, v\}$ with $v = \text{parent}(u)$. The edge e is in the spanning tree, and thus is explored twice outside any execution of the Procedure `Check_Edge`. During Procedure `Check_Edge(j)` at v , edge e is explored twice. e is also explored four times during `Check_Edge(i)` at u , except if $i = 0$ where e is only explored twice during `Check_Edge(i)` at u . If there exists an edge $\{u', u\}$ labeled i' at u and i'' at u' such that $i' < i$ and $u' \in \text{pred}(u)$, then edge e is explored twice during Procedure `Check_Edge(i')` at u and twice again during Procedure `Check_Edge(i'')` at u' . If there exists an edge $\{v', v\}$ labeled j' at v and j'' at v' such that $j' < j$ and $v' \in \text{pred}(v)$, then edge e is explored four times during Procedure `Check_Edge(j')` at v and four times again during

Procedure `Check_Edge(j'')` at v' . To summarize, edge e is explored at most 20 times during a DFS.

- (2) $e = \{u, v\}$ with $v \in \text{pred}(u)$ but $v \neq \text{parent}(u)$. During Procedure `Check_Edge(j)` at v , edge e is explored twice. e is also explored four times during `Check_Edge(i)` at u . If there exists an edge $\{u', u\}$ labeled i' at u and i'' at u' such that $i' < i$ and $u' \in \text{pred}(u)$, then edge e is explored twice during Procedure `Check_Edge(i')` at u and twice again during Procedure `Check_Edge(i'')` at u' . If there exists an edge $\{v', v\}$ labeled j' at v and j'' at v' such that $j' < j$ and $v' \in \text{pred}(v)$, then edge e is explored four times during Procedure `Check_Edge(j')` at v and four times again during Procedure `Check_Edge(j'')` at v' . To summarize, edge e is explored at most 18 times during a DFS.
- (3) $e = \{u, v\}$ with $v \in \text{sibling}(u)$. During Procedure `Check_Edge(j)` at v , edge e is explored twice. e is also explored twice during `Check_Edge(i)` at u . If there exists an edge $\{u', u\}$ labeled i' at u and i'' at u' such that $i' < i$ and $u' \in \text{pred}(u)$, then edge e is explored four times during Procedure `Check_Edge(i')` at u and four times again during Procedure `Check_Edge(i'')` at u' . If there exists an edge $\{v', v\}$ labeled j' at v and j'' at v' such that $j' < j$ and $v' \in \text{pred}(v)$, then edge e is explored four times during Procedure `Check_Edge(j')` at v and four times again during Procedure `Check_Edge(j'')` at v' . To summarize, edge e is explored at most 20 times during a DFS.

Therefore, our exploration algorithm completes exploration in time $\leq 20|E|$ where $|E|$ is the number of edges in the graph G . □

3 A 1-Bit Exploration-Labeling Scheme for Bounded Degree Graphs

In this section, we describe an exploration labeling scheme using only 1-bit labels. This scheme requires a robot with $O(\log \Delta)$ bits of memory for the exploration of graphs of maximum degree Δ . More precisely, we prove the following.

Theorem 2. *There exists a robot with the property that for any graph G of degree bounded by a constant Δ , it is possible to color the nodes of G with two colors (or alternatively, assign each node a 1-bit label) so that using the labeling, the robot can explore the entire graph G , starting from any given node and terminating after identifying that the entire graph has been traversed. The robot has $O(\log \Delta)$ bits of memory, and the total number of edge-traversals by the robot is $O(\Delta^{O(1)}m)$.*

To prove Theorem 2, we first describe a 1-bit labeling scheme \mathcal{L}' for $G = (V, E)$, i.e., a coloring of each node in black or white. Then, we will show how to perform exploration using \mathcal{L}' .

Labeling \mathcal{L}' . As for \mathcal{L} , pick an arbitrary node $r \in V$, called the *root*. Nodes at distance d from r are labeled as a function of $d \bmod 8$. Partition the nodes into eight *classes* by letting

$$C_i = \{u \in V \mid \text{dist}_G(r, u) \bmod 8 = i\}$$

for $0 \leq i \leq 7$. Node u is colored white if $u \in C_0 \cup C_2 \cup C_3 \cup C_4$, and black otherwise. Let

$$\begin{aligned} \tilde{C}_1 &= \{u \mid \text{dist}_G(r, u) = 1\} \\ \hat{C} &= \{r\} \cup \{u \in C_2 \mid \text{dist}_G(r, u) = 2 \text{ and } \mathcal{N}(u) = \tilde{C}_1\}. \end{aligned}$$

Lemma 1. *There is a local search procedure enabling a robot of $O(\log \Delta)$ bits of memory to decide whether a node u belongs to \hat{C} and to \tilde{C}_1 , and to identify the class C_i of every node $u \notin \hat{C}$.*

Proof. Let \mathbf{B} (resp., \mathbf{W}) be the set of black (resp., white) nodes which have all their neighbors black (resp., white). One can easily check that the class C_1 and the classes C_3, \dots, C_7 can be redefined as follows:

- $u \in C_6 \Leftrightarrow u \in \mathbf{B}$ and there is a node in \mathbf{W} at distance ≤ 3 from u ;
- $u \in C_7 \Leftrightarrow u \notin C_6$, u has a neighbor in C_6 , and there is no node in \mathbf{W} at distance ≤ 2 from u ;
- $u \in C_1 \Leftrightarrow u$ is black, u has no neighbor in \mathbf{B} , and u has a white neighbor v that has no neighbor in \mathbf{W} .
- $u \in C_5 \Leftrightarrow u$ is black, and $u \notin C_1 \cup C_6 \cup C_7$;
- $u \in C_3 \Leftrightarrow u \in \mathbf{W}$, and there is a node in C_1 at distance ≤ 2 from u ;
- $u \in C_4 \Leftrightarrow u$ has a neighbor in \mathbf{W} , and there is no node in C_1 at distance ≤ 2 from u .

Based on the above characterizations, the classes C_1 and C_3, \dots, C_7 can be easily identified by a robot of $O(\log \Delta)$ bits, via performing a local search. Moreover, the sets \tilde{C}_1 and \hat{C} can also be characterized as follows:

- $u \in \tilde{C}_1 \Leftrightarrow u \in C_1$ and u has no node in C_7 at distance ≤ 2 ;
- $u \in \hat{C} \Leftrightarrow \mathcal{N}(u) \subseteq \tilde{C}_1$ and every node v at distance ≤ 2 from u satisfies $|\mathcal{N}(v) \cap \tilde{C}_1| \leq |\mathcal{N}(u)|$.

Using this we can deduce:

- $u \in C_0 \setminus \hat{C} \Leftrightarrow u \notin (\cup_{i=3}^7 C_i) \cup C_1$ and u has a neighbor in C_7 ;
- $u \in C_2 \setminus \hat{C} \Leftrightarrow u \notin \hat{C}$, has a neighbor in C_1 , but has no neighbor in C_7 .

It follows that a robot of $O(\log \Delta)$ bits can identify the class of every node except for nodes in \hat{C} . □

Proof of Theorem 2. The exploration algorithm for \mathcal{L}' follows the same strategy as the exploration algorithm for \mathcal{L} . Indeed, for $u \in C_i$, we have

$$\begin{aligned} \text{pred}(u) &= \mathcal{N}(u) \cap C_{i-1} \pmod{8} \\ \text{succ}(u) &= \mathcal{N}(u) \cap C_{i+1} \pmod{8} \\ \text{sibling}(u) &= \mathcal{N}(u) \cap C_i \end{aligned}$$

Therefore, due to Lemma 1, all instructions of the exploration algorithm using labeling \mathcal{L} can be executed using labeling \mathcal{L}' , but for the cases not captured in Lemma 1, i.e., \widehat{C} .

To solve the problem of identifying the root, we notice that each of the nodes in \widehat{C} can be used as a root, and all the others can be considered as leaves in C_2 . Thus, when leaving the root, the robot should memorize the port P by which it should return to the root. When the robot arrives at a node $u \in \widetilde{C}_1$ through a tree edge and is in the UP state, it leaves immediately through port P and deletes the contents of P , then it goes down through the next unexplored port if one is left. When the robot is in a node $u \in \widetilde{C}_1$ and in the DOWN state, it will skip the port P .

If the exploration begins at the root, then the above is sufficient. To handle explorations beginning at an arbitrary node, it is necessary to identify the root. Since every node in \widehat{C} can be used as a root, it suffices to find one node of \widehat{C} by going up and then start the exploration from it as described above. \square

4 Impossibility Results

Theorem 3. *For any $d > 4$, and for any 1-state robot using at most $d/2 - 1$ colors, there exists a graph (with loops) with maximum degree d and at most $d+1$ vertices that cannot be explored by the robot.*

Proof. Fix $d > 4$, and assume for contradiction that there exists a 1-state robot exploring all graphs of degree d colored with at most $d/2 - 1$ colors. Recall that when a 1-state robot enters a node v by port i , it will leave v by port j where j is depending only on i , d and the color c of v . Thus for fixed d , each color corresponds to a mapping from entry ports to exit ports, namely, a function from $\{0, 1, \dots, d - 1\}$ to $\{0, 1, \dots, d - 1\}$. Partition the functions corresponding to the colors of nodes of degree d into surjective functions f_1, f_2, \dots, f_t and non-surjective functions g_1, g_2, \dots, g_r . We have $0 < t + r \leq d/2 - 1$. Let c_i be the color corresponding to f_i , and c_{t+i} be the color corresponding to g_i . For each g_i , choose p_i to be some port number not in the range of g_i . Let $p_0 \in \{0, 1, \dots, d - 1\} \setminus \{p_1, p_2, \dots, p_r\}$ (it is possible because $d - r \geq 1$).

We will construct a family $\{G_0, G_1, \dots, G_t\}$ of graphs such that, for every $k \in \{0, 1, \dots, t\}$:

1. G_k has exactly one degree- d vertex v (possibly with loops);
2. the other vertices of G_k are degree-1 neighbors of v ;
3. all edges are either loops incident to v , or edges leading from v to some degree-1 node;
4. edges labeled p_1, p_2, \dots, p_r at v (if any, i.e., if $r > 0$) are not loops (and thus lead to degree-1 nodes);
5. the edge labeled p_0 leads to some degree-1 node, denoted by u_0 ;

6. there exists a set $X_k \subseteq \{0, 1, \dots, d-1\}$ such that $\{p_0, p_1, \dots, p_r\} \subseteq X_k$ and $d - |X_k| > 2(t-k)$, and for which, in G_k , edges with port number not in X_k lead to degree-1 vertices.

We will prove the following property for any $k = 0, \dots, t$:

Property P_k . In G_k , if the color of v is in $\{c_1, \dots, c_k\}$, then the robot, starting at $u_0 \in V(G_k)$, cannot explore G_k . More precisely any vertex attached to v by a port $\notin X$ is not visited by the robot.

We prove P_k by induction on k . Let G_0 be the star composed of one degree- d vertex v and d leaf vertices. Let $X_0 = \{p_0, p_1, p_2, \dots, p_r\}$. Recall that $t+r \leq d/2 - 1$. Thus, $t \leq d/2 - 1$ and hence $2t+r+1 \leq d-1$. Therefore, we have $d - |X_0| = d - (r+1) > 2t$. P_0 is trivially true.

Let $k > 0$, and let G_{k-1} and X_{k-1} be respectively a graph and a set satisfying the induction property for $k-1$. Assume first that v is colored by color c_k and that the robot starts its traversal at u_0 . If the robot never visits vertices attached to v by ports not in X_{k-1} then the graph G_{k-1} and the set X_{k-1} satisfy P_k . I.e., $G_k = G_{k-1}$ and $X_k = X_{k-1}$. Otherwise, let p be the first port not in X_{k-1} that is visited by the robot at v , when starting at u_0 . For a port $i \in \{0, 1, \dots, d-1\}$, set $\text{twin}(i) = j$ if there exists a port j and a loop labeled by i and j in G_{k-1} ; Set $\text{twin}(i) = i$ otherwise. Define a sequence of ports $(i_l)_{l \geq 1}$ as follows. Let i_1 be the port in X_{k-1} such that $f_k(i_1) = p$. For all $l \geq 2$, let i_l be the port such that $f_k(i_l) = \text{twin}(i_{l-1})$. This sequence is well defined because f_k is surjective.

Observe that there exists some l such that $i_l \notin X_{k-1}$. Indeed, suppose, for the purpose of contradiction, that $i_l \in X_{k-1}$ for all l . Since X_{k-1} is finite, there exists some $i_l = i_{l+m}$ for $m \geq 1$. Let i_l be the first port repeated twice in this process. If $l > 1$, then we have $f_k(i_l) = \text{twin}(i_{l-1})$ and $f_k(i_{l+m}) = \text{twin}(i_{l+m-1})$. Therefore $\text{twin}(i_{l-1}) = \text{twin}(i_{l+m-1})$, yielding $i_{l-1} = i_{l+m-1}$ by bijectivity of f_k , which contradicts the minimality of l . If $l = 1$, then we have $i_1 = i_{1+m}$, therefore $i_m = p$, contradicting $i_j \in X_{k-1}$ for all j .

From the above, let h be the smallest index such that $i_h \notin X$. Let $q = i_h$. If $q = p$, then set $G_k = G_{k-1}$ and $X_k = X_{k-1} \cup \{p\}$. If $q \neq p$, then connect ports p and q to create a loop, denote the new graph G_k and let $X_k = X_{k-1} \cup \{p, q\}$.

In G_k , if v is colored by color c_k , then by the choice of p , starting at u_0 , the robot enters and exits v through ports in X_{k-1} until it eventually exits v through port p . After that, the robot goes back to v by port q . Port q was chosen so that it causes the robot to continue entering v on ports $i_{h-1}, i_{h-2}, \dots, i_1$, after which the robot exits v through port p , locking the robot in a cycle. Since the ports of v occurring in this cycle are all from X_k , the robot does not visit any of the ports outside X_k , as claimed. By induction, we have $d - |X_{k-1}| > 2(t - (k-1))$. By the construction of X_k from X_{k-1} , we have $|X_k| \leq |X_{k-1}| + 2$. Therefore $d - |X_k| > 2(t-k)$, which completes the correctness of G_k and X_k .

If the color of v in G_k is in $\{c_1, \dots, c_{k-1}\}$ then the robot is doomed to fail in exploring G_k . Indeed since starting at u_0 in G_{k-1} the robot does not traverse any of the vertices corresponding to ports not in X_{k-1} , then in G_k too, the robot does not traverse any of the vertices corresponding to ports not in $X_k \supseteq X_{k-1}$,

and thus fails to explore G_k because $d - |X_k| \geq 1$. This completes the proof of P_k and thus the induction.

In particular, G_t is not explored by the robot if the node v is colored with a color in c_1, c_2, \dots, c_t . If v is colored c_{t+i} with $1 \leq i \leq r$, then assume that the robot starts the traversal at vertex u_0 . Since the edge labeled p_i leads to a degree-1 vertex in G_t , this vertex will never be visited by the robot, by definition of p_i . Therefore the graph G_t cannot be explored by the robot. \square

The theorem above makes use of graphs with loops. For graphs without loops we have the following theorem.

Theorem 4. *For any $d > 4$ and for any 1-state robot using at most $\lfloor \log d \rfloor - 2$ colors, there exists a graph of maximum degree d , without loops, that cannot be explored by the robot.*

5 Further Investigations

It was known that there is no 0-bit exploration-labeling scheme, even for bounded degree graphs. We proved that there is a 2-bit exploration-labeling scheme for arbitrary graphs, and that there is a 1-bit exploration-labeling scheme for bounded degree graphs. It remains open whether or not there exists a 1-bit exploration-labeling scheme for arbitrary graphs.

Abstract. Radio networks model wireless communication when processing units communicate using one wave frequency. This is captured by the property that multiple messages arriving simultaneously to a node interfere with one another and none of them can be read reliably. We present improved solutions to the problem of waking up such a network. This requires activating all nodes in a scenario when some nodes start to be active spontaneously, while every sleeping node needs to be awoken by receiving successfully a message from a neighbor. Our contributions concern the existence and efficient construction of universal radio synchronizers, which are combinatorial structures introduced in [6] as building blocks of efficient wake-up algorithms. First we show by counting that there are (n, g) -universal synchronizers for $g(k) = \mathcal{O}(k \log k \log n)$. Next we show an explicit construction of (n, g) -universal-synchronizers for $g(k) = \mathcal{O}(k^2 \text{polylog } n)$. By way of applications, we obtain an existential wake-up algorithm which works in time $\mathcal{O}(n \log^2 n)$ and an explicitly instantiated algorithm that works in time $\mathcal{O}(n \Delta \text{polylog } n)$, where n is the number of nodes and Δ is the maximum in-degree in the network. Algorithms for leader-election and synchronization can be developed on top of wake-up ones, as shown in [7], such that they work in time slower by a factor of $\mathcal{O}(\log n)$ than the underlying wake-up ones.

1 Introduction

Radio networks model mobile wireless communication when processing units communicate using one wave frequency. We consider networks that are synchronous in the sense that there is a global time measured in rounds and local

clocks at nodes are ticking at the same rate. Communication has the property that multiple messages arriving at the same round to a node interfere with one another and none can be reliably received. Radio networks are given as directed graphs with edges representing direct-transmission ranges among nodes. A message is said to be *heard* by a receiving node when it can be read correctly. Radio networks are characterized by the following properties:

- (i) A node can transmit at most one message at a round.
- (ii) All the out-neighbors of a transmitting node receive the message in the same round when it was transmitted.
- (iii) A recipient of a transmission can hear it only when the message was the only one received at the round.

Distributed communication protocols may have nodes categorized into *active* and *passive*. The former know that the protocol is being performed and execute it according to the code, while the latter need to be activated to join the execution. A passive node becomes automatically active after hearing a message. In the *wake-up problem*, some node may become spontaneously active at independent rounds and each of them wants to activate the whole network. Observe that wake-up is a generalization of the *broadcast problem*, in which exactly one node is activated spontaneously with the goal to wake up the whole network.

A multi-hop radio network is modeled as a directed strongly-connected graph $G = (V, E)$, with $n = |V|$ nodes. We simply assume $V = [1..n] = [n]$. Size n is the only network parameter included in codes of protocols we consider. Let D be the maximum directed distance between a pair of nodes, measured in terms of lengths of directed paths, and Δ the maximum in-degree of a node.

The rounds when nodes wake up spontaneously are represented as a function $\omega : V \rightarrow \mathbb{N}$, where \mathbb{N} is the set of natural numbers. This means that node v wakes up spontaneously at time $\omega(v) = \omega_v$, unless it was already awoken by hearing a message sent by its active neighbor. Function ω is often referred to as a *shift function*, because it defines shifts of local time at nodes when they wake up spontaneously.

An active node v executes a sequence of transmissions given by some *schedule*, which is a binary sequence \mathcal{R}^v repeated cyclically. An occurrence of 0 means a pause and an occurrence of 1 a transmission. The positions in \mathcal{R}^v correspond to consecutive rounds after wake-up, according to the local clock of v . A collection of schedules good for waking up a radio network is called a radio synchronizer. Next we recall precise definitions of such synchronizers.

Let n and m be positive integers. Let $\mathcal{R} = \{\mathcal{R}^v\}_{1 \leq v \leq n}$ be an $n \times m$ binary array. There are n rows and m columns in the array. Each sequence $\mathcal{R}^v = \mathcal{R}^v(1)\mathcal{R}^v(2) \dots \mathcal{R}^v(m)$ of length m is a row in the array. The number m is called the *length* of \mathcal{R} ; it is often given as a function of the number n of rows.

Consider a shift function ω for \mathcal{R} . We always assume that $0 \leq \omega_v < m$ for $1 \leq v \leq n$. A row v is ω -*active* at position t , or just *active* if ω is understood, if $\omega_v < t \leq \omega_v + m$. Shift function ω can be *applied* to array \mathcal{R} by shifting row v to the right by ω_v columns and padding the empty entries with occurrences of 0. The resulting array \mathcal{R}_ω has at most $2m - 1$ columns. We often refer to

the columns of \mathcal{R}_ω as *positions*. To simplify the exposition, we may assume that array \mathcal{R}_ω has exactly $2m - 1$ positions and if position t satisfies either $1 \leq t \leq \omega_v$ or $\omega_v + m + 1 \leq t \leq 2m - 1$, then $\mathcal{R}_\omega[v, t] = 0$.

If L is a set of rows of \mathcal{R} , then let L_ω denote the sub-array of \mathcal{R}_ω restricted to rows in L . Given a set L of rows, a position t is *successful for L* , if there is exactly one occurrence of 1 at position t of all rows of L_ω . For a shift function ω and such a set L of rows, define $\omega_L = \min_{v \in L} \omega_v$. We assume throughout that $\omega_L = 0$ in a context when rows of L correspond to nodes that wake up spontaneously; this makes positions correspond to rounds counted from the moment when the first in-neighbor of a node became active.

Radio synchronizers:

Array \mathcal{R} is an (n, k) -*synchronizer of length m* , where $1 \leq k \leq n$, if for any shift function ω and any set L of at most k rows, there is a successful position for L .

Let $g : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ be a non-decreasing function called the *delay function* in the context of universal synchronizers.

Universal radio synchronizers:

Array \mathcal{R} is a (n, g) -*universal synchronizer* if, for any shift function ω and any set L of rows, with the property that $\omega_L = \min_{v \in L} \omega_v = 0$, there is a successful position for L between positions 1 and $g(n, |L|)$.

Notice that the length of a (n, g) -universal synchronizer can always be assumed to be equal to $g(n, n)$. Universal radio synchronizers were defined to capture the following quantitative requirement on a wake-up protocol: if the active nodes transmit according to a (n, g) -universal synchronizer, then a node with k in-neighbors always becomes active within $g(n, k)$ rounds from the time when its first in-neighbor becomes awake. Radio synchronizers were defined by Chrobak, Gaśieniec and Kowalski [7] in their solution to the problems of wake-up, leader election and synchronization of local clocks in multi-hop networks. The notion of radio synchronizers was already implicitly used by Gaśieniec, Pelc and Peleg [11] in their algorithms for waking up a multiple-access channel. Universal radio synchronizers were defined by Chlebus and Kowalski [6] as a strengthening of radio synchronizers with the goal to improve the time of wake-up.

A family of combinatorial structures or instantiations of an algorithm parametrized by size n is said to be *explicit*, if the n -th object can be obtained in time polynomial in n .

Our results. We show the existence and present explicit constructions of improved universal radio synchronizers. This is translated into a better performance of known protocols in multi-hop radio networks, that solve problems such as wake-up, leader election and synchronization of local clocks. The contributions are summarized as follows.

- I. We show the existence of (n, g) -universal-synchronizers where $g(n, k)$ is of order $\mathcal{O}(k \log k \log n)$. The best previously known universal radio synchronizers were shown by Chlebus and Kowalski [6] to exist for $g(n, k)$ of order $\mathcal{O}(k \min\{k, \sqrt{n}\} \log n)$.

- II. We construct explicit (n, g) -universal-synchronizers with $g(n, k)$ of order $\mathcal{O}(k^2 \text{polylog } n)$. This is the first explicit construction of universal synchronizers. This generalizes previously known related design of explicit (n, k) -synchronizers of length $\mathcal{O}(k^2 \text{polylog } n)$ given in [6].
- III. Using our new universal synchronizers, we show how to instantiate protocols for wake-up, leader election and local-clocks synchronizations presented in [6, 7] to significantly improve their performance. The resulting existential wake-up solution works in time $\mathcal{O}(\min\{n, D\Delta\} \log \Delta \log n)$ and the explicit solution works in time $\mathcal{O}(\min\{n, D\Delta\} \Delta \text{polylog } n)$. Ours is the first *explicit sub-quadratic* wake-up solution for $\Delta = o(n/\text{polylog } n)$. The best previously known existential wake-up protocol has running time $\mathcal{O}(n^{3/2} \log n)$; it was developed in [6]. The best previously known quasi-explicit wake-up protocol for networks of diameter D operates in time $\mathcal{O}(Dn^{1+\varepsilon})$, for an arbitrary $\varepsilon > 0$; it can be constructed in a quasi-polynomial time $2^{\text{polylog } n}$ following the construction given by Indyk [12]. The leader election and synchronization protocols have time performance slower than wake-up by an additional factor of $\mathcal{O}(\log n)$.

Previous work. Wake-up protocols were first considered for the multiple-access channel by Gašieniec, Pelc and Peleg [11]. Such networks are also called single-hop radio networks and are modeled by complete directed graphs. Randomized wake-up protocols for the multiple-access channel were also studied by Jurdziński and Stachowiak [13], and explicit wake-up protocols were given by Indyk [12]. The general wake-up problem for multi-hop networks was first studied by Chrobak, Gašieniec and Kowalski [7]. They introduced the notion of radio synchronizer and also developed leader-election and synchronization protocols. The fastest known wake-up protocol was given by Chlebus and Kowalski [6], who introduced the notion of universal radio synchronizers. Gašieniec, Pelc and Peleg [11] showed that there are (n, n) -synchronizers of length $\mathcal{O}(n \log^2 n)$. Chrobak, Gašieniec and Kowalski [7] showed that there are (n, k) -synchronizers of length $\mathcal{O}(k^2 \log n)$. Chlebus and Kowalski [6] showed that for each n there is an (n, g) -universal synchronizer with delay $g(n, k)$ upper bounded by the function $\mathcal{O}(k \min\{k, \sqrt{n}\} \log n)$. A construction of (n, n) -synchronizers of length $\mathcal{O}(n^{1+\varepsilon})$, for any constant $\varepsilon > 0$, in a quasi-polynomial time $\mathcal{O}(2^{\text{polylog } n})$ was given by Indyk [12]. Chlebus and Kowalski [6] described explicit (n, k) -synchronizers of length $\mathcal{O}(k^2 \text{polylog } n)$. Prior to this work, there was no known non-trivial explicit construction of *universal* synchronizers.

Clementi, Monti and Silvestri [8] showed that (n, k) -selective-families, as defined in Chlebus *et al.* [5], have to be of a size $\Omega(k \log(n/k))$. Radio synchronizers have the properties of selective families; more precisely, they have the properties of radio synchronizers for the special case where all rows are active at position 1. It follows that (n, k) -synchronizers have to be of length $\Omega(k \log(n/k))$. Indyk [12] gave an explicit construction of (n, k) -selectors of length $\mathcal{O}(k \text{polylog } n)$; such selectors are more general structures than selective families.

Related work. The model of radio communication was introduced by Chlamtac and Kutten [3]. Chlamtac and Weinstein [4] gave a centralized explicit broad-

cast protocol working in time $\mathcal{O}(D \log^2(n/D))$. Clementi et. al [9] developed an explicit protocol for the same problem working in time $\mathcal{O}(D \log \Delta \log(n/D))$. Regarding distributed sub-quadratic broadcast, the first such a randomized protocol was given by Bar-Yehuda, Goldreich, and Itai [2], and the first deterministic one by Chlebus *et al.* [5]. The fastest known distributed deterministic existential broadcast protocol for directed networks works in time $\mathcal{O}(n \log^2 D)$; it was given by Czumaj and Rytter [10].

Document structure. The rest of the document is structured as follows. In Section 2 we show by the probabilistic method that short universal synchronizers exist. A polynomial-time construction of short universal synchronizers is given in Section 3. In Section 4 we present applications of universal synchronizers to the problems of wake-up, leader election and synchronization of local clocks in multi-hop radio networks. We conclude in Section 5. Proofs of statements labelled as Lemmas have been omitted.

2 Short Universal Synchronizers by Counting

In this section we show the existence of (n, g) -universal-synchronizers with a slowly growing delay function g . To avoid rounding, we assume that n is a power of 2. Otherwise prove the existence of (n', g) -universal-synchronizer, where $n' = 2^{\lceil \log n \rceil}$, and remove the last $n' - n$ rows to obtain an (n, g) -universal-synchronizer. The notation $\log x$ denotes the logarithm of x to the base 2. We often write $g(k)$ for $g(n, k)$ when n is understood.

Specification of random universal synchronizers. Now we determine the length m and the delay function g of a (n, g) -universal-synchronizer. Let $c \geq 4$ be a constant to be determined later.

Define $m(\ell) = c2^\ell \log n$, for every $1 \leq \ell \leq \log n$. Let $m = \sum_{\ell \leq \log n} m(\ell)$. Define $g(n, k) = \sum_{\ell \leq \lceil \log k \rceil} m(\ell)$ for $k > 1$, and $g(1) = m(1)$. Note that $g(n, k) = \mathcal{O}(k \log k \log n)$.

Given a column j , for $1 \leq j \leq m$, there is a unique positive integer κ satisfying the inequalities $\sum_{\ell < \kappa} m(\ell) < j \leq \sum_{\ell \leq \kappa} m(\ell)$. This number κ is denoted by κ_j .

Consider a random $n \times m$ array $\mathcal{R} = [\mathcal{R}^v(j)]$, where the binary-valued random variables $\mathcal{R}^v(j)$ are all independent, for $1 \leq v \leq n$ and $1 \leq j \leq m$. Random variable $\mathcal{R}^v(j)$ is defined to be equal to 1 with probability $1/(\kappa_j 2^\kappa)$.

Theorem 1. *The array \mathcal{R} is an (n, g) -universal-synchronizer, for $g(n, k) = \mathcal{O}(k \log k \log n)$, with the probability of at least $1 - 1/n$, for a sufficiently large constant $c \geq 4$.*

The remaining part of this section is devoted to a proof of Theorem 1. Let us fix n , which allows to write $g(k)$ for $g(n, k)$. For a position t , let $A_\omega(t)$ be the set of rows ω -active at t ; we write $A(t)$ when ω is clear from context. Let us partition shift functions into n classes such that ω belongs to the i -th class if i is the smallest positive integer for which the number of ω -active rows at position $g(i)$ is at most i ; this is equivalent for i to be the smallest number such

that the inequality $|A_\omega(g(i))| \leq i$ holds. These classes are well defined because all rows are active at position m by the assumption that $\omega_v < m$, for $1 \leq v \leq n$, and because $m = g(n)$. For a shift function ω in the i -th class, we need to show that the universal synchronizer under consideration has the property that there is a successful position by the position $g(i)$. Therefore it is sufficient to consider only a partial function defined by the values of ω at rows v such that $\omega_v < g(i)$. This partial function is denoted as $\omega|^{g(i)}$.

Consider shift functions in the 1-st class. There is only one row v active on positions $[1..2c \log n]$, by the definition of this class. The probability that all these positions are unsuccessful is at most $2^{-2c \log n} \leq e^{-c \log n}$. There are at most n possible rows v , hence the probability that there is a shift function in the 1-st class, where all positions $t \leq g(1)$ are unsuccessful, is at most $e^{\ln n} \cdot e^{-c \log n} \leq e^{-2 \ln n} = n^{-2}$, for $c \geq 3$.

Consider next the general case of shift functions in the k -th class, for $1 < k \leq n$. By the definition, number k is the smallest positive integer such that there are at most k active rows at position $g(k)$. Let us fix an ω in this class, and let $K = K_\omega$ be the set of rows that are ω -active at position $g(k)$, that is, set K denotes $A(g(k)) = A_\omega(g(k))$.

For row $v \in K$ and position $t \leq g(k)$, let $p_v(t)$ denote the probability that there is 1 in row v at position t , which means $\mathcal{R}^v(t - \omega_v) = 1$, with $p_v(t) = 0$ for every $t \leq \omega_v$. Let $\mu_K(t)$ denote $\sum_{v \in K} p_v(t)$. We call a position $t \leq g(k)$ *balanced* if the inequalities $1/(4\kappa_t) \leq \mu_K(t) \leq 4$ hold. Let κ denote $\kappa_{g(k)}$. Notice that $m(\kappa) = g(k) - g(k/2)$.

Lemma 1. *There are at least $m(\kappa)/2$ balanced positions between position $g(k/2) + 1$ and position $g(k)$.*

Consider a balanced position $t \leq g(k)$. The probability that t is successful is

$$\sum_{v \in K} p_v(t) \cdot \prod_{w \in K, w \neq v} (1 - p_w(t)) \geq \mu_K(t) \cdot 4^{-\mu(t)} \geq \frac{1}{4\kappa} 4^{-4} = \frac{1}{4^5 \kappa},$$

since $p_v(t) \leq 1/2$ for every $v \in K$. Hence, by Lemma 1, the probability that all balanced positions are unsuccessful is at most

$$\left(1 - \frac{1}{4^5 \kappa}\right)^{m(\kappa)/2} \leq e^{-(2c/4^6)2 \log n} \leq e^{-(2c/4^6)k \log n}.$$

The above considerations were for a fixed shift function ω from the k -th class. We do not need to know how ω precisely behaves for rows that are shifted by more than $g(k)$. The set K is uniquely defined by $\omega|^{g(k)}$, and the above probabilistic analysis is based on $\omega|^{g(k)}$. Such a partial function is determined by its domain of k elements and an assignment of values in the range from 0 to $g(k) - 1$ to them. It follows that there are at most $\binom{n}{k} \cdot (g(k))^k \leq e^{k \ln(ne/k) + k \ln g(k)}$ different partial functions $\omega|^{g(k)}$ such that ω is in the k -th class.

The probability that there exists a shift function ω from the k -th class such that there is no successful position $t \leq g(k)$ in \mathcal{R} is at most

$$e^{k \ln(ne/k) + k \ln g(k)} \cdot e^{-(2c/4^6)k \log n} \leq e^{-2k \ln n},$$

for a sufficiently large constant $c \geq 4$, since $\ln g(k) = \mathcal{O}(\log n)$. Summing up all the probabilities for all classes, the probability of the event that there is a shift function in some k -th class such that there is no successful position $t \leq g(k)$ in \mathcal{R} is at most $\sum_{k=1}^n e^{-2k \ln n} \leq 1/n$, for $n > 1$. This completes the proof of Theorem 1.

3 Explicit Constructions

In this section we show how to construct (n, g) -universal-synchronizer with delay $g(n, k) = \mathcal{O}(k^2 \text{polylog } n)$ in time polynomial in n . We recall the construction from [6], and then modify it to obtain synchronizers satisfying certain properties stronger than synchronization, to be used in the construction of universal synchronizers. It is enough to construct universal synchronizers for values of n being powers of 3 to guarantee the same overall asymptotic behavior. We want to construct a universal synchronizer in two steps. First is a concatenation of $(n, 3^x)$ -synchronizers of length $m(3^x)$, for $x = 1, 2, \dots, \log_3 n$, as constructed in [6], denoted by \mathcal{Q} . Second is replacing each occurrence of 0 in the obtained structure by a sequence of zeroes of a specific length $m_* = \text{polylog } n$, and each occurrence of 1 in row v by the corresponding sequence \mathcal{S}^v taken from a suitable synchronizer \mathcal{S} of length m_* .

3.1 Explicit Synchronizers

We first present (n, k) -synchronizers denoted $\mathcal{F}(n, k)$, of length $f(k)$ that is of order $\mathcal{O}(k^2 \text{polylog } n)$, based on the construction from [6]. Then we modify this construction and argue that the obtained synchronizers satisfy a stronger condition than the one in the definition of synchronizers.

Construction of (n, k) -synchronizers $\mathcal{F}(n, k)$. We briefly recall the construction from [6]. Assume that number n is sufficiently large and that k divides n . Let \mathcal{P} be a set of k different primes between $k \log n$ and $3k \log n$. Set \mathcal{P} is well defined by the Chebyshev Theorem, as given in [1]. Let p be in set \mathcal{P} . Denote by π_p a binary sequence of length $3k^2 \log n$ and such that $\pi_p(j) = 1$, when both p divides j and $0 < j \leq 3k^2 \log n$, and let $\pi_p(j) = 0$ otherwise. Let σ denote a sequence of zeroes of length $3k^2 \log n$. Number d is a positive integer, to be determined later, depending on numbers k and n and on applications. Let h be a function from $[n] \times [d]$ to \mathcal{P} . For $v \in [n]$, define schedule \mathcal{S}^v to be a concatenation of schedules of the form $\langle \pi_{h(v,1)}, \sigma, \pi_{h(v,2)}, \sigma, \dots, \pi_{h(v,d)}, \sigma, \sigma^{2d} \rangle$, where σ^{2d} denotes a sequence of zeros of length $6dk^2 \log n$.

Selective functions:

Function $h : [n] \times [d] \rightarrow \mathcal{P}$ is said to be (n, k, d) -selective when for every set $W \subseteq [n]$ of a size at most k , there is a number p in \mathcal{P} such that set $h^{-1}(p) \cap (W \times [d])$ is a singleton.

Lemma 2 ([6]). *If function h is (n, k, d) -selective, then set $\mathcal{S} = \{\mathcal{S}^v\}_{v \in V}$ of schedules is an (n, k) -synchronizer of length $f(n, k) = \mathcal{O}(dk^2 \log n)$.*

The construction of Indyk [12] gives an explicit (n, k, d) -selective function for $d = \text{polylog } n$. It relies on a polynomial-time construction of $(n, k', d', 1/2 - \varepsilon)$ -dispersers developed by Ta-Shma, Umans and Zuckerman [16], for $d' = \mathcal{O}(\text{polylog } n)$ and for a constant $0 < \varepsilon < 1/2$. Using this explicit selective function and Lemma 2, the following fact can be shown:

Lemma 3 ([6]). *A family $\{\mathcal{F}(n, k)\}_{n \geq k}$ of (n, k) -synchronizers of length which is $\mathcal{O}(k^2 \text{polylog } n)$ can be constructed in time polynomial in n .*

Construction of (n, k) -synchronizers $\mathcal{F}^*(n, k)$. We use the general scheme of construction from [6] and modify it to obtain the construction of (n, k) -synchronizers satisfying the following property $\mathcal{M}(k)$. We often write $f(k)$ for $f(n, k)$ when n is understood.

Property $\mathcal{M}(k)$:

We say that an (n, k) -synchronizer of length $f(n, k)$ satisfies property $\mathcal{M}(k)$ if for every set K of at most k rows shifted by at most $3f(n, k) - 1$ positions and such that at least one row is shifted by at least $f(n, k)$ and at most $2f(n, k) - 1$ positions, there is a successful position in the interval $[f(n, k) + 1..3f(n, k)]$.

The main idea is that if we take function h satisfying a certain stronger property, then the obtained structure is also (n, k) -synchronizer, of a somewhat larger length, but it satisfies property $\mathcal{M}(k)$. We need the following property to be satisfied by function h .

Strongly selective functions:

We say that function $h : [n] \times [d] \rightarrow \mathcal{P}$ is (n, k, d) -strongly-selective if for every set $W \subseteq [n]$ of a size at most k and every $w \in W$, there are numbers p in \mathcal{P} and $d' \in [d]$ such that $\{(w, d')\} = h^{-1}(p) \cap (W \times [d])$.

Note that if h is (n, k, d) -strongly-selective, then it is also (n, k, d) -selective.

Lemma 4. *If function h is (n, k, d) -strongly-selective, then set $\mathcal{S} = \{\mathcal{S}^v\}_{v \in V}$ of schedules is an (n, k) -synchronizer of length $f(n, k) = \mathcal{O}(dk^2 \log n)$ and it satisfies property $\mathcal{M}(k)$.*

On the other hand, (n, k, d) -strongly-selective functions can be explicitly constructed for $d = \mathcal{O}(k \log^2 n)$, relying on a construction by Kautz and Singleton [14]. Define $\mathcal{F}^*(n, k)$ to be the structure with (n, k, d) -strongly-selective function h , as constructed explicitly in [14]. Combine an explicit construction of (n, k, d) -strongly-selective functions with $d = \mathcal{O}(k \log^2 n)$ [14] and Lemma 4 to obtain:

Theorem 2. *A family $\{\mathcal{F}^*(n, k)\}_{n \geq k}$ of (n, k) -synchronizers of length $f(n, k) = \mathcal{O}(k^3 \text{polylog } n)$ and satisfying property $\mathcal{M}(k)$ can be constructed in time polynomial in n .*

3.2 Explicit Universal Synchronizers

Let $\mathcal{F}(n, k)$ be the synchronizer, defined in Section 3.1, of the corresponding length $\mathcal{O}(dk^2 \log n)$, for some d being polylog n . Let $\mathcal{S} = \mathcal{F}^*(n, 27d \log^2 n)$ be the explicit $(n, 27d \log^2 n)$ -synchronizer of some length m_* which satisfies property $\mathcal{M}(27d \log^2 n)$, as described in Section 3.1.

To obtain universal synchronizer \mathcal{R}^v , we proceed in two steps:

First step: Concatenate rows of synchronizers $\mathcal{F}(n, k)$, for $k = 3^i$, from $i = 0$ through $i = \log_3 n$,

Denote by \mathcal{Q} the obtained structure.

Second step: Replace each occurrence of 0 in row \mathcal{Q}^v by the sequence of m_* zeros, and each occurrence of 1 in row \mathcal{Q}^v by the sequence \mathcal{S}^v .

Structure \mathcal{Q} is like a universal radio synchronizer but with a notion of a “successful position” replaced with the weaker notion of an “almost successful position,” meant to be a position where 1 occurs at least once but at most $\mathcal{O}(\text{polylog } n)$ times. The reason why structure \mathcal{Q} can only guarantee the existence of “almost successful positions” is that the $\log n$ concatenated synchronizers interfere with one another when the rows are arbitrarily shifted. Structure \mathcal{S} guarantees a successful position in any set of $\mathcal{O}(\text{polylog } n)$ rows. Therefore the operation of expanding each 1 in \mathcal{Q} with structure \mathcal{S} turns each “almost successful position” into a sequence of consecutive positions with at least one of them being successful. A complete proof, that structure \mathcal{R} is indeed a universal synchronizer, needs to account properly for the possibility that rows of \mathcal{R} are shifted in such a way that the copies of structure \mathcal{S} in different rows are not aligned.

Theorem 3. *\mathcal{R} is an explicit (n, g) -universal-synchronizer with $g(n, k)$ of order $\mathcal{O}(k^2 \text{ polylog } n)$.*

In the remaining part of this section we prove Theorem 3. Let us fix n , which allows to write $f(k)$, $g(k)$ and $g'(k)$ rather than $f(n, k)$, $g(n, k)$ and $g'(n, k)$, respectively. Define function $g(n, k) = g(k) = f(3x) \cdot m_*$, where $x = \min\{3^{\lceil \log_3 k \rceil}, n/3\}$. Observe that estimate $g(k) = \mathcal{O}(k^2 \text{ polylog } n)$ holds, since $f(3x)$ is of order $\mathcal{O}(x^2 \text{ polylog } n)$ by Lemma 3, function $27d \log^2 n$ of n is polylog n and hence $m_* = \text{polylog } n$ by Theorem 2.

We first analyze structure \mathcal{Q} . Consider a shift function ω' on \mathcal{Q} , and let $g'(k) = f(3x)$. Let k be the first positive integer such that there are at most k active rows at position $g'(k)$. Recall that $A(t)$ stands for the set of active rows at position t . By the definition of universal synchronizers and how function g' is specified, we obtain that $|A(g'(k))| = k$. Let K denote set $A(g'(k))$.

By the definition of k we also have that $|A(g'(k/3))| > k/3$. Let L denote $A(g'(k/3))$. By the definition of \mathcal{Q} , all rows from L have their components taken from an (n, x) -synchronizer of length $f(x) \leq g'(k)$.

Lemma 5. *There is a prime number $p \in [x \log n, 3x \log n]$ for which there is exactly one row v such that \mathcal{R}^v contains sequence π_p in its prefix by position $g'(k)$.*

Fix a prime number p , let t_* be the first position of sub-sequence π_p of \mathcal{Q}^v and t^* be the last such a position, all as existing by Lemma 5. For every row $w \neq v$ in K , array $\mathcal{Q}^w[t_*..t^*]$ contains at most $d \log_3 x$ different sub-sequences π_q , for primes $q \leq 3x \log n$, all these sequences different from π_p .

(p, q)-Crowded positions:

Position $1 < t \leq g'(k)$ is *(p, q)-crowded* if one of the following holds:

- (a) 1 occurs at position t in both sequences π_p and π_q ,
- (b) 1 occurs at position t in π_p and at position $t - 1$ in π_q ,
- (c) 1 occurs at position t in π_q and at position $t - 1$ in π_p .

Lemma 6. *Any sequence π_q , for a prime $q \leq 3 \cdot 3x \log n$ and $q \neq p$, contributes at most nine (p, q) -crowded positions, if shifted arbitrarily.*

It follows from Lemma 6 that there are at most

$$9 \cdot k \cdot \log_3 x \cdot 3d \log n \leq k \cdot (27d \log^2 n - 1)$$

(p, q) -crowded positions, for some primes $q \neq p$, while there are at least k occurrences of 1 in sequence π_p in row v . For some position t , there is 1 at position t in row v , and at most $27d \log^2 n - 1$ occurrences of 1 in other rows at positions $t - 1, t, t + 1$ in total. Call such t a *candidate position*.

Now consider the whole structure \mathcal{R} , by position $g(k) = g'(k)m_*$, together with the shift function ω . Let ω' be the corresponding shift functions for the underlying structure \mathcal{Q} , determined by $\omega'_v = \lceil \frac{\omega}{m_*} \rceil$. It follows that in structure \mathcal{Q} , with such a shift function ω' , there is a candidate position t' . Denote by $K' \subseteq K$ all rows $v \in K$ such that there is a 1 in row v at positions $t' - 1, t', t' + 1$. The inequality $|K'| \leq 27d \log^2 n$ holds by the definition of t' . It follows that there is a sequence \mathcal{S}^v of length m_* contained in row v in structure \mathcal{R} between positions $(t' - 1)m_* + 1$ and $(t' + 1)m_*$, and at most $27d \log^2 n - 1$ sequences \mathcal{S}^w , for different $w \neq v$, which intersect interval of positions $[(t' - 2)m_* + 1, (t' + 1)m_*]$. There is a successful position in row w in the interval $[(t' - 1)m_* + 1, (t' + 1)m_*]$, by property $\mathcal{M}(27d \log^2 n)$ of $(n, 27d \log^2 n)$ -synchronizer \mathcal{S} . This completes the proof of Theorem 3.

4 Applications

We show that the problems of wake-up, leader election and synchronization can all be solved in deterministic time $\mathcal{O}(n \text{ polylog } n)$ by relying on universal synchronizers shown to exist, and in time $\mathcal{O}(n \Delta \text{ polylog } n)$ by construction of explicit universal synchronizers.

When developing leader-election and synchronization algorithms, one usually assumes that unique names are from some polynomial range, while the difference between the maximum and minimum-value names is $\mathcal{O}(n)$. To simplify the exposition, we assume that there are n nodes with unique names in an interval $[1.. \mathcal{O}(n)]$. Recall that D denotes the diameter of the directed network, and Δ is its maximum in-degree.

For the sake of completeness, we recall briefly the wake-up protocol based on universal synchronizers, as proposed in [6]. It operates as follows. Take a (n, g) -universal synchronizer \mathcal{S} , where rows correspond to nodes. Each node v starts executing its sequence $\mathcal{S}^v \in \mathcal{S}$ immediately when it becomes active. This means that it performs a transmission in the i -th round exactly when the i -th bit in \mathcal{S}^v is a 1. We refer to this protocol as CK.

We develop a general estimate on the complexity of the wake-up protocol CK, which we call β , that depends on parameters of the network and the delay function of the universal synchronizer that is a part of its code. For numbers n, D, Δ and a delay function g of a (n, g) -universal synchronizer, let $\beta(n, D, \Delta, g)$ denote the supremum of the function $\sum_{i=1}^D g(x_i)$, where integers $0 \leq x_i \leq \Delta$, for $1 \leq i \leq D$, satisfy an additional constraint $\sum_{i=1}^D x_i \leq n$.

Lemma 7. *Protocol CK based on (n, g) -universal-synchronizer wakes up a radio network of n nodes with parameters D and Δ in $\beta(n, D, \Delta, g)$ rounds.*

Corollary 1. *Protocol CK can be instantiated such that it solves the wake-up problem in $\mathcal{O}(\min\{n, D\Delta\} \log \Delta \log n)$ rounds.*

Corollary 2. *Protocol CK can be explicitly instantiated such that it solves the wake-up problem within time bound $\mathcal{O}(\min\{n, D\Delta\} \Delta \text{polylog } n)$.*

The estimate given in Corollary 1 is within a logarithmic factor away from $\Omega(\min\{n \log D, D\Delta \log(n/\Delta)\})$, which is a lower bound on broadcasting given in [8] that holds also for wake-up. A general protocol for leader election and synchronizing local clocks was given by Chrobak, Gaśieniec and Kowalski [7], we call it CGK. The protocol is built on top of a wake-up one.

Corollary 3. *Protocol CGK, based on suitably instantiated CK, can solve leader election and synchronization of local clocks in $\mathcal{O}(\min\{n, D\Delta\} \log \Delta \log^2 n)$ rounds.*

Corollary 4. *Protocol CGK, based on an explicitly instantiated CK, can solve leader election and synchronization of local clocks in $\mathcal{O}(\min\{n, D\Delta\} \Delta \text{polylog } n)$ rounds.*

5 Conclusion

We obtain an existential distributed wake-up protocol for multi-hop ad-hoc radio networks working in time $\mathcal{O}(n \log^2 n)$ and an explicitly instantiated distributed protocol that works in time $\mathcal{O}(n \Delta \text{polylog } n)$. Developing explicit sub-quadratic wake-up of radio networks remains an open problem.

On the technical level, our results concern universal synchronizers. We show the existence of (n, g) -universal synchronizers for $g(k)$ of order $\mathcal{O}(k \log k \log n)$. The best known lower bound is $\Omega(k \log(n/k))$, which is derived from a lower bound on selective families given in [8]. Selective families are apparently weaker structures than universal synchronizers. Improving these upper and/or lower

bounds for universal synchronizers, in terms of function g , remains open. In particular, the following is an open problem: is there an explicit construction of (n, g) -universal-synchronizer for $g(k) = \mathcal{O}(k \text{ polylog } n)$?

If we have only an upper bound N on the size of the network and node labels are from the interval $[1..N]$, then we may use a (N, g) -universal synchronizer. Lemma 7 holds true, since its proof relies on the property that nodes are uniquely assigned to rows of the universal synchronizer. For this case we have $g(k) = k \log k \log N$, and so the corresponding modification on the estimates of β , and consequently on all the following results, is that we have expressions $\log N$ and $\text{polylog } N$ instead of $\log n$ and $\text{polylog } n$, respectively.

It is a natural question to ask what is the inherent difference in time performance between broadcast and wake-up protocols. It turns out that such a difference is within a factor of $\mathcal{O}(\log n)$. The answer has already been known for randomized protocols, by the results in [7] for wake-up and [10, 15] for broadcast. This paper settles this for deterministic existential protocols, by obtaining a time $\mathcal{O}(n \log^2 n)$ wake-up, as efficient, in terms of n , as the broadcast in [10].

Abstract. We prove that the $L(2,1)$ -LABELING problem is NP-complete for graphs of treewidth two, thus adding a natural and well studied problem to the short list of problems whose computational complexity separates treewidth one from treewidth two. We prove similar results for other variants of the distance constrained graph labeling problem.

1 Introduction

The notion of distance constrained graph labeling attracted a lot of attention in the past years both for its motivation by the practical frequency assignment problem, and for its interesting graph theoretic properties. The task of assigning frequencies to transmitters to avoid undesired interference of signals is modeled in several ways. The so called *channel assignment problem* assumes that a minimum allowed difference of channels is given for every two transmitters. Thus the input of this problem is a weighted graph whose vertices correspond to the transmitters, and the task is to assign nonnegative integers (channels) to the vertices so that for every edge, the difference of the assigned channels is at least the weight of the edge, and so that the largest channel used is minimized.

Another approach, and this one we follow in the present paper, is the *distance constrained graph labeling*. Here it is assumed that the distance of transmitters can be modeled by a graph, and that the distance of the transmitters influences possible interference in such a way that the closer two transmitters are, the farther apart their frequencies must be. Formally, an assignment of nonnegative integers to the vertices of a graph G is an $L(p_1, \dots, p_k)$ -labeling if for every two vertices at distance at most $i \leq k$, the difference of the integers (labels) assigned to them is at least p_i . Here $k \geq 1$ is the depth to which the distance constraints are applied, and integers $p_1 \geq p_2 \geq \dots \geq p_k$ are parameters of the problem.

Again, the goal is to minimize the maximum label used. The most studied of the distance constrained labelings is the case $k = 2, p_1 = 2, p_2 = 1$, i.e., the $L(2, 1)$ -labeling. In this case adjacent vertices must be assigned labels that differ by at least 2, while nonadjacent vertices with a common neighbor must be assigned distinct labels. The maximum label used is called the *span* of the labeling. The minimum span of an $L(2, 1)$ -labeling of a graph G will be denoted by $L_{(2,1)}(G)$.

The notion of $L(2, 1)$ -labeling was in fact first proposed by Roberts [21] and many nontrivial results were presented in a pioneer paper of Griggs and Yeh [15]. Let us mention their conjecture that $L_{(2,1)}(G) \leq \Delta^2(G)$ (where $\Delta(G)$ stands for the maximum vertex degree in G). This conjecture has been verified for various graph classes, but it is still open for general graphs (with $L_{(2,1)}(G) \leq \Delta(G)^2 + \Delta(G) - 1$ being the current record [16]). From the computational complexity point of view, Griggs and Yeh proved that determining $L_{(2,1)}(G)$ is an NP-hard problem, and this result was later strengthened by Fiala et al. [7] by showing that deciding $L_{(2,1)}(G) \leq k$ is NP-complete for every fixed $k \geq 4$. Griggs and Yeh also conjectured that it is NP-complete to compute the $L_{(2,1)}$ number of a tree, but this was somewhat surprisingly disproved by a dynamic programming polynomial time algorithm of Chang and Kuo [4].

The common expectation says that problems solvable in polynomial time for trees should also be polynomially solvable for graphs of bounded treewidth, though sometimes the extension to bounded treewidth is not straightforward (cf. e.g., the case of chromatic index [2]). (We informally recall that the treewidth is a graph invariant that describes how far is the graph from being a tree. For a formal definition the reader is referred to a survey [3] or to one of the original papers [1] introducing this invariant in terms of so called *partial k -trees*. For our purposes we only need the fact that graphs of treewidth at most two are exactly the graphs that do not contain a subdivision of K_4 as a subgraph, and connected graphs of treewidth one are exactly trees.) Only very few exceptions to this rule of thumb are known, and in fact very few problems are known to be hard for graphs of bounded treewidth. An example is, e.g., the MINIMUM BANDWIDTH problem (which is NP-hard already for trees [12]) or the closely related CHANNEL ASSIGNMENT problem which has been recently shown NP-complete for graphs of treewidth three [19]. The natural question of the complexity of $L(2, 1)$ -labelings for graphs of bounded treewidth has been posed many times and remained open since 1996. The main result of our paper settles it by showing that determining the $L_{(2,1)}$ number of graphs of treewidth two is NP-hard.

Before we formulate the result formally, we specify precisely what problem we deal with. The decision problem whether a given graph admits an $L(2, 1)$ -labeling of *fixed* span can be described in Monadic Second Order Logic (MSOL), and therefore is solvable in linear time for any class of graphs of bounded treewidth by a generic algorithm of Courcelle [5]. Thus we naturally assume that the span is a part of the input, and we consider the following problem.

$L(2, 1)$ -LABELING

Input: An integer λ and a graph G .

Question: Is $L_{(2,1)}(G) \leq \lambda$?

Theorem 1. *The L(2,1)-LABELING problem is NP-complete for graphs of treewidth at most two.*

So far we have only discussed the model in which interference of the frequencies (or channels) decreases linearly with their increasing difference. It is, however, plausible to consider also such models in which frequencies far apart may interfere (e.g., if one is a multiple of the other one). This means more complicated metrics in the frequency space. A concrete step in this direction is the cyclic metric introduced by van den Heuvel et al. [24]. In this metric, the graph of the channel space is the cycle of length λ . Similarly to the linear case, we talk about $C(2,1)$ -labelings and denote by $C_{(2,1)}(G)$ the minimum span of a $C(2,1)$ -labeling of G (note that in the cyclic metric, the span is the number of available channels, not the difference between the largest and smallest one). For general graphs, deciding if $C_{(2,1)}(G) \leq \lambda$ is NP-complete for every fixed $\lambda \geq 6$ [9]. For λ part of the input and graphs of bounded treewidth, we fully characterize the complexity of the $C(2,1)$ -LABELING problem (which, given a graph G and an integer λ as input, asks if $C_{(2,1)}(G) \leq \lambda$):

Proposition 1. ([18, 17]) *Let T be a tree with at least one edge, and $p \geq q$ nonnegative integers. Then $C_{(p,q)}(T) = q\Delta(T) + 2p - q$ where $\Delta(T)$ is the maximum degree of a vertex in T .*

Theorem 2. *The C(2,1)-LABELING problem is NP-complete for graphs of treewidth at most two.*

This theorem will be proven in the full version of the paper.

Fiala and Kratochvíl [9] defined the notion of $H(2,1)$ -labeling as the utmost generalization in the case when the metric of the channel space can be described by a graph H , and showed that $H(2,1)$ -labelings of a graph G are exactly locally injective homomorphisms from G into the complement of H . The complexity of the $H(2,1)$ -LABELING problem for some parameter graphs H then follows from [8], but the complete characterization is not even in sight. On the other hand, if G has bounded treewidth, the $H(2,1)$ -LABELING problem is solvable in polynomial time since for a fixed graph H , the existence of an $H(2,1)$ -labeling of G can be expressed in MSOL.

It remains to study the case when both G and H are part of the input and we refer to it as the $(2,1)$ -LABELING problem. Observe that the L(2,1)-LABELING problem is the restriction of $(2,1)$ -LABELING to inputs such that H is a path. Hence it follows from Theorem 1 that $(2,1)$ -LABELING is NP-complete for graphs of treewidth two. However, in this most general setting, we are able to prove dichotomy even with respect to pathwidth (for definition of pathwidth see [22, 23, 3], just recall that connected graphs of pathwidth one are exactly caterpillars):

Theorem 3. *For a tree T with m vertices and an arbitrary graph H with n vertices, one can decide in time $O(n^3m^2)$ whether T allows an $H(2,1)$ -labeling.*

Theorem 4. *The $(2,1)$ -LABELING problem is NP-complete for graphs G of pathwidth at most two (the graph H may be arbitrary).*

The paper is organized as follows. In Section 2 we review technical definitions and notation and prove an auxiliary result on systems of distant representatives for symmetric sets. The main result, Theorem 1, is proved in Section 3. The technical proofs for the case of cyclic metric are omitted due to space restrictions. Theorems 3 and 4 are proved in Section 4. The last section contains concluding remarks and open questions.

2 Preliminaries

All graphs considered are finite and simple, i.e., with a finite vertex set and without loops or multiple edges. For a vertex u , the symbol $N(u)$ denotes the *open neighborhood* of u , i.e., the set of all vertices adjacent to u , and we denote by $\deg u = |N(u)|$ the *degree* of u .

A graph is called *series-parallel* if it can be built from isolated edges with end-vertices called South and North poles by a sequence of series and parallel compositions (the former identifies the North pole of one component with the South pole of the other one, the latter unifies the North poles of the components into a common North pole, and likewise the South poles). It is well known that a graph has treewidth at most two if and only if all its 2-connected subgraphs are series-parallel.

The labels are always nonnegative integers, with 0 being the smallest label used. We use the notation $[x, y] = \{x, x + 1, \dots, y - 1, y\}$ to denote intervals of consecutive integers. We say that a set S of integers is *symmetric within* an interval $[x, y]$ if $S \subseteq [x, y]$ and for every $i \in [x, y]$, $i \in S$ if and only if $y + x - i \in S$.

A system of distinct representatives for a set system S_1, S_2, \dots, S_n is a system of distinct elements $s_i \in S_i, i = 1, 2, \dots, n$. The theory of SDR's is well developed, the necessary and sufficient condition for their existence is given by the well known Hall theorem, and an SDR can be found in polynomial time (e.g., by a bipartite matching algorithm). If the ground set $\bigcup_{i=1}^n S_i$ is equipped with a metric function, we can further impose conditions on the distance of the chosen representatives. We refer the reader to [11, 14] for a survey on the computational complexity of finding systems of distant representatives for sets in metric spaces and their applications in various graph labeling problems. Now we will use a special variant of this problem as an auxiliary tool:

SRL (Special representatives in the linear metric)

Input: An integer n and a collection of sets of integers S_1, S_2, \dots, S_m symmetric within the interval $[2, \lambda - 2]$, where $\lambda = 4n + 5$.

Question: Does there exist a collection of distinct integers

- $s_1, s_2, \dots, s_m, t_1, t_2, \dots, t_n, u_1, u_2, \dots, u_n$ such that
- $s_i \in S_i$ for every $i = 1, \dots, m$,
- $t_i \in \{2i, \lambda - 2i - 1\}$ for every $i = 1, \dots, n$,
- $u_i \in \{2i + 1, \lambda - 2i\}$ for every $i = 1, \dots, n$,
- $|t_i - u_i| \geq 2$ for every $i = 1, 2, \dots, n$?

Lemma 1. *The problem SRL is NP-complete.*

Proof. The proof is provided by a reduction from the following special variant of the 3-SAT problem (known NP-complete, cf. e.g. [6]).

2-3-SAT

Input: A Boolean formula Φ in conjunctive normal form, whose each clause consists of 2 or 3 literals and whose every variable has at most 2 positive and at most 2 negative occurrences.

Question: Is Φ satisfiable?

Let Φ have n variables x_1, \dots, x_n and m clauses C_1, \dots, C_m . The number of variables n will be the n for the input of SRL. Recall that $\lambda = 4n + 5$. For every $j = 1, 2, \dots, m$ the set S_j is constructed from the clause C_j as follows

$$S_j = \bigcup_{i: x_i \in C} \{2i, \lambda - 2i\} \cup \bigcup_{i: \neg x_i \in C} \{2i + 1, \lambda - 2i - 1\}.$$

Thus every set S_j has 4 or 6 elements and is symmetric within $[0, \lambda]$.

Assume that Φ allows a satisfying assignment. If a variable x_i is assigned the value true, we set $t_i = 2i - 1$, $u_i = \lambda - 2i - 1$. Analogously for x_i negatively valued, we let $t_i = 2i$, $u_i = \lambda - 2i$. For each clause C_j we choose one satisfying literal. If C_j is satisfied by the literal x_i for some $i = 1, 2, \dots, n$, we let $s_j = 2i$, if x_i is the first occurrence of x_i in Φ , and $s_j = \lambda - 2i$ for the second occurrence of x_i in Φ . In the case C_j is satisfied by $\neg x_i$ we choose $s_j = 2i + 1$ for the first occurrence of $\neg x_i$ and $s_j = \lambda - 2i - 1$ otherwise. Straightforwardly, the collection s_1, \dots, u_n satisfies all four properties from the definition of the SRL problem.

For the opposite direction suppose that s_1, \dots, u_n is a valid solution for the SRL problem. The crucial observation is that for every $i = 1, 2, \dots, n$, there are only two possible choices for the values of t_i and u_i so that $|t_i - u_i| \geq 2$. Namely, either $t_i = 2i$ and $u_i = \lambda - 2i$ or alternatively $t_i = 2i + 1$ and $u_i = \lambda - 2i - 1$. In the first case we assign $x_i = \text{false}$, and in the second one $x_i = \text{true}$.

Then for each $j = 1, \dots, m$, the value of u_j indicates the satisfying literal for the clause C_j : If $u_j = 2i$ or $\lambda - 2i$, then C_j is satisfied by the true assignment to the variable x_i . Alternatively, if $u_j = 2i + 1$ or $\lambda - 2i - 1$ then the literal $\neg x_i$ satisfies C_j as the variable x_i is assigned false.

Since the size of the family S_1, S_2, \dots, S_m is polynomial in the size of Φ , 2-3-SAT \propto SRL as claimed.

3 $L(2, 1)$ -Labeling of Graphs of Treewidth Two

This entire section is devoted to the proof of Theorem 1. We will utilize Lemma 1 and reduce from the SRL problem. Suppose we are given integers n and $\lambda = 4n + 5$, and m subsets S_1, \dots, S_m of $[2, \lambda - 2]$ which are all symmetric within this interval (we may further assume that all of them have size at most 6, but this is not important for our proof). Our aim is to construct a graph G' of treewidth two such that $L_{(2,1)}(G') \leq \lambda$ if and only if the given instance of SRL is feasible. The construction of G' is achieved in several steps.

3.1 Reduction to List Labeling

Construct the graph G on vertices $V_G = (v_0, v_1^s, \dots, v_m^s, v_1^t, \dots, v_n^t, v_1^u, \dots, v_n^u)$ where v_0 is adjacent to all other vertices, and furthermore $(v_i^t, v_i^u) \in E_G$ for all $i = 1, \dots, n$. (See Fig. 1.) To each vertex of $x \in V_G$ we assign a set of admissible labels as follows

Fig. 1. The graph G

- $T(v_0) = \{0, \lambda\}$
- $T(v_i^s) = S_i$ for all $i = 1, \dots, m$
- $T(v_i^t) = \{2i, \lambda - 2i - 1\}$ for all $i = 1, \dots, n$
- $T(v_i^u) = \{2i + 1, \lambda - 2i\}$ for all $i = 1, \dots, n$

and we call an $L(2, 1)$ -labeling c admissible if $c(x) \in T(x)$ for every $x \in V_G$. In any admissible $L(2, 1)$ -labeling, any pair of vertices must get distinct labels since G has diameter two. Moreover, as the vertices v_i^t and v_i^u are adjacent, they must be assigned labels that are at least two apart.

Hence $c(v_i^s) = s_i$, $c(v_i^t) = t_i$, and $c(v_i^u) = u_i$ is a one-to-one correspondence between admissible $L(2, 1)$ -labelings of G and systems of special representatives for S_1, \dots, S_m (the choice of $c(v_0) = 0$ or λ does not interfere with the labels of the remaining vertices). The graph G has clearly treewidth two. We will further design a collection of gadgets that will force the desired lists on the vertices of the graph G .

3.2 Labels of Neighbors of Vertices of Large Degrees

The following simple observation will be used repeatedly in our arguments. Let v be a vertex whose two neighbors w and w' have degree $\lambda - 1$, and let c be an $L(2, 1)$ -labeling of span λ . Denote $S = c(N(w) \setminus \{v\})$ the set of labels used on the neighbors of w other than v . Since w and w' have the maximum possible degree, they are assigned labels 0 and λ , and hence $c(v) \in [2, \lambda - 2] \setminus S$.

3.3 The Crucial Gadget

For every $i \in [1, \frac{\lambda-1}{2}]$, we construct the graph H_i with nonadjacent vertices z_i, z'_i of degree one inductively as follows.

- 1) H_0 is the cycle of length four and z_0, z'_0 are two nonadjacent vertices (of degree two).
- 2) To construct H_{i+1} , we take the graph H_i and
 - insert the edge (z_i, z'_i) ,
 - insert two new vertices z_{i+1}, z'_{i+1} and edges $(z_i, z_{i+1}), (z'_i, z'_{i+1})$,
 - insert $\lambda - 5$ new common neighbors of z_i and z'_i .

(See Fig. 2 for an example.) Then H_i is a series-parallel graph whose number of vertices is polynomial in i and n (precisely, $|V_H| = i(\lambda - 3) + 4$). It has the following crucial property.

Fig. 2. Construction of the graph H_i

Lemma 2. For every $i \geq 1$, in any $L(2, 1)$ -labeling of H_i of span λ , the vertices $z_{i-1}, z_i, z'_{i-1}, z'_i$ are assigned (in this order) labels $i - 1, \lambda - i, \lambda - i + 1, i$ or $\lambda - i + 1, i, i - 1, \lambda - i$.

Proof. We prove the statement by induction on i . Let c be an $L(2, 1)$ -labeling of H_i of span λ .

1) For $i = 1$, observe that since z_0 and z'_0 have degree $\lambda - 1$, they must be assigned labels 0 and λ , or vice versa. Their $\lambda - 3$ common neighbors are assigned distinct labels forming the interval $[2, \lambda - 2]$ and hence $\{c(z_1), c(z'_1)\} = \{1, \lambda - 1\}$.

2) By induction hypothesis, $\{c(z_{i-1}), c(z'_{i-1})\} = \{i - 1, \lambda - i + 1\}$ and $\{c(z_i), c(z'_i)\} = \{i, \lambda - i\}$. These two vertices have further $\lambda - 5$ common neighbors that could be assigned only the labels forming the set $[0, i - 2] \cup [i + 2, \lambda - i - 2] \cup [\lambda - i + 2, \lambda]$. It is therefore easy to conclude that the two triples $(c(z_{i-1}), c(z'_i), c(z_{i+1}))$ and $(c(z'_{i-1}), c(z_i), c(z'_{i+1}))$ could be only the two consecutive triples $(i - 1, i, i + 1)$ and $(\lambda - i + 1, \lambda - i, \lambda - i - 1)$.

3.4 Forcing $T(v_0)$

Add $\lambda - 1 - 2n - m = 2n + 4 - m$ new neighbors to the vertex v_0 . (We may assume $2n + 4 - m \geq 0$ since the SRL problem trivially has no system of distinct representatives if $2n + m > 2\lambda - 1$.) Then v_0 has degree $\lambda - 1$ and it can be assigned only labels 0 or λ by any $L(2, 1)$ -labeling of span λ .

3.5 Forcing $T(v_i^s)$

For each vertex $i \in [1, m]$, insert a new vertex x_i and make it adjacent to v_i^s . Further for each pair of labels l and $\lambda - l$ in the set $[2, \lambda - 2] \setminus S_i$, insert a new copy of the graph H_l and make x_i adjacent to the vertices z_l and z'_l of this new copy. Finally, add further new neighbors to the vertex x_i so that it has degree $\lambda - 1$ (see Fig. 3). It follows from the observation in 3.2 and Lemma 2 that the vertex v_i^s is now allowed to be assigned only a label from the set S_i as required.

Fig. 3. Forcing list S_i on the vertex v_i^s

3.6 Forcing $T(v_i^t)$ and $T(v_i^u)$

For each $i \in [1, n]$, insert vertices y_i, y'_i adjacent to v_i^t and v_i^u , respectively. Further take a copy of the graph H_{2i+1} , remove one common neighbor of z_{2i} and z'_{2i} and make y_i adjacent to z_{2i}, z_{2i+1} and y'_i to z'_{2i}, z'_{2i+1} of this copy. For each label $l \in [2, \frac{\lambda-1}{2}] \setminus \{2i, 2i + 1\}$, insert two new copies of the graph H_l (the second copy is denoted by H_l^*) and connect both vertices z_l, z_l^* to y_i and both z'_l, z'_l^* to y'_i . Finally, add three new neighbors to each vertex y_i, y'_i so that both have degree $\lambda - 1$ (see Fig. 4).

Suppose c is an $L(2, 1)$ -labeling of span λ . Since both y_i, y'_i have degree $\lambda - 1$ and are at distance 2 from v_0 of the same degree, they are both assigned the same label, either 0 or λ . It also follows that in the copy H_{2i+1} the vertices z_{2i}, z'_{2i}

Fig. 4. Forcing lists $\{2i, \lambda - 2i - 1\}$ and $\{2i + 1, \lambda - 2i\}$ on the vertices v_i^t, v_i^u

behave as stated in Lemma 2, even if we removed one common neighbor (whose role was taken over by y_i and y'_i). Now according to observation in 3.2, the vertex v_i^t can be assigned only labels from $\{2i, 2i+1, \lambda-2i-1, \lambda-2i\} \setminus \{c(z_{2i}), c(z_{2i+1})\}$ and similarly for $c(v_i^u) \in \{2i, 2i+1, \lambda-2i-1, \lambda-2i\} \setminus \{c(z'_{2i}), c(z'_{2i+1})\}$. Since by Lemma 2 either $\{c(z_{2i}), c(z_{2i+1})\} = \{\lambda-2i, 2i+1\}$ or $\{2i, \lambda-2i-1\}$, and respectively, $\{c(z'_{2i}), c(z'_{2i+1})\} = \{2i, \lambda-2i-1\}$ or $\{\lambda-2i, 2i+1\}$, we get the desired admissible sets for both v_i^t and v_i^u (note here that the entire construction is symmetric with respect to vertices v_i^t and v_i^u).

By the above discussion, any $L(2, 1)$ -labeling of the resulting graph G' forces every vertex x of its subgraph G to be assigned labels from the list $T(x)$. During the construction of G' the distances between the original vertices of G were not changed, and hence any $L(2, 1)$ -labeling of G' restricted to G is an admissible $L(2, 1)$ -labeling for the lists $T(x)$, $x \in V_G$.

The proof of the opposite implication (i.e., that any admissible $L(2, 1)$ -labeling of G can be extended to an $L(2, 1)$ -labeling of G') follows from the construction of all the gadgets and is straightforward.

Finally, observe that the size of G' is polynomial in the size of G (more precisely $|G'| = O(|G|^4)$), and also that all gadgets were constructed so that G' maintains treewidth two. This concludes the proof of Theorem 1.

4 (2, 1)-Labelings of Graphs of Bounded Treewidth

Given graphs G and H , an $H(2, 1)$ -labeling of G is a mapping $f : V_G \rightarrow V_H$ such that adjacent vertices of G are mapped onto distinct nonadjacent vertices of H (i.e., distance of the target vertices is at least 2, measured in the target graph H) and vertices with a common neighbor in G are mapped onto distinct vertices of H (i.e., the distance of the target vertices is at least 1) [9]. This definition generalizes both the $L(2, 1)$ -labelings (when H is a path whose length equals the span of the labeling) and the $C(2, 1)$ -labelings (when H is a cycle whose length again equals the span). The computational complexity of this problem for fixed parameter graphs H was studied and many particular results were proven in [8]. The case when the span is also part of the input corresponds to the following decision problem:

(2, 1)-LABELING

Input: Graphs G and H .

Question: Does G allow an $H(2, 1)$ -labeling?

Of course this problem is NP-complete for graphs G of treewidth two, since both $L(2, 1)$ -LABELING and $C(2, 1)$ -LABELING are its special cases. In this section we give a subtler separation of bounded width classes, namely in terms of pathwidth. Graphs of pathwidth one are caterpillars (trees obtained by pending any number of leaves to vertices of a path), and so the claim that (2, 1)-LABELING is solvable in polynomial time for graphs G of pathwidth one (and arbitrary H) follows from our Theorem 3.

Proof (of Theorem 3). The following algorithm is a straightforward extension of the algorithm for $L(2, 1)$ -labeling of trees of [4].

Given a tree T with m vertices, choose a leaf $r \in V_T$ and regard it as a root of T . For every edge $(u, v) \in E_T$ such that u is a child of v , denote by $T_{u,v}$ the subtree of T rooted in v and containing u and all its descendants. For every such edge and for every pair of vertices $x, y \in V_H$, we introduce a Boolean variable $\phi(u, v, x, y)$ which is true if and only if $T_{u,v}$ allows an $H(2, 1)$ -labeling f such that $f(u) = x$ and $f(v) = y$. Then T allows an $H(2, 1)$ -labeling if and only if $\phi(u, r, x, y) = \text{true}$ for some vertices $x, y \in V_H$ (and u being the only child of the root r). The function ϕ can be computed by the following dynamic programming algorithm:

1. Set the initial values $\phi(u, v, x, y) = \text{false}$ for all edges $(u, v) \in E_T$ and vertices $x, y \in V_H$.
2. If u is a leaf of T adjacent to its parent v , then set $\phi(u, v, x, y) = \text{true}$ for all distinct nonadjacent vertices $x, y \in V_H$.
3. Suppose that ϕ is already calculated for all edges of $T_{u,v}$ except (u, v) . Denote by v_1, v_2, \dots, v_k the children of u . For all pairs of distinct nonadjacent vertices $x, y \in V_H$, construct the set system $\{M_1, M_2, \dots, M_k\}$, where

$$M_i = \{z : z \in V_H, z \neq y \text{ and } \phi(v_i, u, z, x) = \text{true}\}$$

and set $\phi(u, v, x, y) = \text{true}$ if the set system $\{M_1, M_2, \dots, M_k\}$ has a system of distinct representatives.

For the time analysis note that the recursive step requires, for each pair $x, y \in V_H$, time $O(nk)$ to construct the set system and time $O(k \cdot nk)$ for deciding if it has an SDR (e.g., by using the augmenting paths algorithm for a bipartite graph with at most nk edges and with k vertices in one bipartition class). Altogether the recursive step requires time $O(n^3k^2)$. If we denote by k_u the number of children of a nonleaf vertex $u \in V_T$, we have $\sum_{u \in V} k_u = m - 1$ (the number of edges of T), and hence the total running time is majorized by $O(\sum_{u \in V} n^3k_u^2) = O(n^3 \sum_{u \in V} k_u^2) = O(n^3m^2)$.

A *2-path* is a graph constructed from a triangle (say Δ_0) by consecutive augmentation of triangles so that each Δ_i shares one edge with the previously augmented Δ_{i-1} , while the third vertex of Δ_i is a vertex newly added in this step. A graph has pathwidth at most two if and only if it is a subgraph of a 2-path. In particular, a fan of triangles obtained from a path by adding a vertex adjacent to all vertices of the path, has pathwidth two.

Proof (of Theorem 4). We reduce from HAMILTONIAN PATH which is well known to be NP-complete [13]. Given a graph H' with n vertices, let H be the disjoint union of the complement of H' and an isolated vertex x . Let G be obtained from a path of length $n - 1$ on vertices v_1, v_2, \dots, v_n by adding a vertex w ,

which is adjacent to all v_i 's. Then every $H(2,1)$ -labeling f of G is an injective mapping from V_G to V_H (since G has diameter two), and f is necessarily bijective (since $|V_G| = |V_H|$). Without loss of generality $f(w) = x$, and hence $f(v_1), f(v_2), \dots, f(v_n)$ is a Hamiltonian path in H' , since $(v_i, v_{i+1}) \in E_G$ implies that $(f(v_i), f(v_{i+1})) \notin E_H$. The opposite implication is straightforward.

5 Concluding Remarks

1. We have fully characterized the computational complexity of $(2,1)$ -distance constrained graph labelings in the case of linear and cyclic metrics in the channel space, with respect to the treewidth of the input graphs. Our results prove polynomial/NP-completeness dichotomy separating treewidth one from treewidth two, which is a rare phenomenon and has so far been known only for very few problems (namely the CUTWIDTH or MINIMUM LINEAR ARRANGEMENT which is polynomial for trees [25] while NP-hardness for graphs of treewidth two follows from [20]). With distance constrained labelings we have added a natural and important problem to this short list.

2. Let us remark that our main result is independent on the NP-completeness of the CHANNEL ASSIGNMENT problem, though both problems are related by the motivation in frequency assignment. The CHANNEL ASSIGNMENT is known NP-complete for graphs of treewidth three, but its complexity for treewidth two graphs is still open. The core of the NP-hardness of the two problems lies in different aspects of the problems and one does not straightforwardly follow from the other. On one hand, $L(2,1)$ -LABELING relays to CHANNEL ASSIGNMENT by considering the second (distance) power of the input graph and assigning weights 2 to the original edges and 1 to the new ones. However, the graph constructed in this way will not have bounded treewidth. On the other hand, $L(2,1)$ -LABELING involves only weights 2 and 1, while the NP-hardness of the CHANNEL ASSIGNMENT problem is based on large weights, the problem is not strongly NP-complete for graphs of bounded treewidth (it can be solved by dynamic programming algorithm in polynomial time if the weights are considered in unary encoding).

3. In the general $(2,1)$ -LABELING problem, when both graphs come as parts of the input, we prove tight dichotomy with respect to pathwidth of the input (transmitters) graph. For both special metrics, $L(2,1)$ and $C(2,1)$, the complexity for graphs of bounded pathwidth is open.

4. To keep the paper well focused, we have stated most of the results for the simplest case of distance constraints $(2,1)$. However, most of them can be extended to (p,q) - or at least $(p,1)$ -labelings, see e.g. Proposition 1. It is known that $L(p,1)$ -LABELING is polynomial for trees for every p (even the list and pre-labeled versions), but when q does not divide p , the complexity of $L(p,q)$ -LABELING for trees is open for all $q > 1$ (the list and pre-labeled versions are known to be NP-complete [10]). To the contrary, $C(p,q)$ -LABELING is polynomial for trees

for all p, q as is shown by Proposition 1. Extension of our Theorem 3 to general $(p, 1)$ -LABELING of trees is trivial, since that follows by replacing H by its p -th distance power. An analog of Theorem 4 for general (p, q) -labelings can be proved by a more technical reduction.

Abstract. We give an $O(n^3)$ time algorithm for constructing a minimum-width branch-decomposition of a given planar graph with n vertices. This is achieved through a refinement to the previously best known algorithm of Seymour and Thomas, which runs in $O(n^4)$ time.

1 Introduction

Let G be a graph. (Unless otherwise stated, all graphs in this paper are undirected). A *branch-decomposition* of G is a tree T such that the set of leaves of T is $E(G)$ and each internal node of T has degree 3. For each edge $\{p, q\}$ of T , let $L_T(p, q) \subseteq E(G)$ denote the set of leaves of T reachable in T from p without passing q . The *width* of edge $\{p, q\}$ in T with respect to G is the number of vertices of G incident with both an edge in $L_T(p, q)$ and an edge in $L_T(q, p)$. The width of T with respect to G is the maximum width of all the edges of T . Finally, the *branchwidth* of G is the minimum width of all the branch-decompositions of G .

Branchwidth is introduced by Robertson and Seymour [8] in relation to the more celebrated notion of treewidth [6, 7]. They show that the branchwidth and treewidth of a graph G are very closely related, not only structurally but also in values: $\beta(G) \leq \omega(G) + 1 \leq \lfloor (3/2)\beta(G) \rfloor$, where $\beta(G)$ denotes the branchwidth and $\omega(G)$ the treewidth of G . A graph of small branchwidth or treewidth admits efficient dynamic programming algorithms for a vast class of problems [2, 3] and therefore the problem of deciding the width and that of constructing the associated decomposition are of extreme importance. When the width of the graph is bounded by a constant, both of these tasks can be performed in linear time [4]. However, deciding whether the width of a given graph exceeds k is NP-complete if k is part of the input, both for treewidth [1] and for branchwidth [9]. Thus the tractability of treewidth and branchwidth are quite similar on general graphs. The situation is different on planar graphs: while no polynomial time algorithm is known for deciding the treewidth of a given planar graph, Seymour and Thomas [9] give a polynomial time decision algorithm for the branchwidth of planar graphs. Given a planar graph G with n vertices and a positive integer

k , their algorithm takes $O(n^2)$ time to decide whether G has a branchwidth not exceeding k . Through the relationship above between the two width values, this also gives a 1.5-approximation of the treewidth of planar graphs. Based on this result, Demaine *et al.* [5] develop approximation algorithms for the treewidth and branchwidth of graphs more general than planar graphs. For some other classes of graphs for which the treewidth can be computed in polynomial time, see Bodlaender's survey [3].

The decision algorithm of Seymour and Thomas for planar graphs works with a certain type of obstructions to the branch-decomposition and returns a positive answer when it detects the absence of such obstructions. Unfortunately, the evidence of the absence of obstructions that the algorithm constructs does not seem to provide a direct clue to the structure of a branch-decomposition within the specified width. Nonetheless, using the decision procedure as a subroutine, they give, in the same paper, an algorithm for constructing a minimum-width branch-decomposition of a given planar graph. This algorithm calls the decision procedure $O(n^2)$ times and runs in $O(n^4)$ time. We improve the running time to $O(n^3)$ in this paper.

Theorem 1. *Given a planar graph G with n vertices, a minimum-width branch-decomposition of G can be constructed in $O(n^3)$ time.*

We achieve this improvement within the framework of Seymour and Thomas through a non-trivial refinement that reduces the number of times the decision procedure is called to $O(n)$.

The rest of this paper is organized as follows. Section 2 gives basic material and summarizes the approach of Seymour and Thomas. Section 3 proves a key lemma that enables our savings in the use of the expensive decision procedure. Section 4 describes our refinement to the algorithm based on this lemma and proves that the number of calls to the decision procedure is $O(n)$ during the execution of the algorithm with this refinement. Section 5 sketches a rather straightforward analysis that the rest of the computation takes $O(n^3)$ time.

2 Preliminaries

In this paper, graphs are simple, i.e., without parallel edges or self-loops, unless they are explicitly referred to as multigraphs. We have already used some of the following standard graph notation. For a multigraph G , we denote by $V(G)$ the set of vertices of G and by $E(G)$ the set of edges of G . For each $X \subseteq V(G)$, we denote by $\delta_G(X)$ the set of edges incident with a vertex in X and a vertex in $V(G) \setminus X$. For disjoint $U, V \subseteq V(G)$, we denote by $E_G(U, V)$ the edge set $\delta_G(U) \cap \delta_G(V)$. We use symbols \supset and \subset for proper set inclusion.

Both the branchwidth and branch-decomposition algorithms of Seymour and Thomas for planar graphs use a reduction to the *carvingwidth/-decomposition* of a related multigraph.

A carving-decomposition of a multigraph G is a tree T such that the set of leaves of T is $V(G)$ (not $E(G)$ as in branch-decomposition) and the degree of

each internal node of T is 3. The width of T with respect to G is defined to be the maximum of $\delta_G(L'_T(p, q))$ over all edges $\{p, q\}$ of T , where $L'_T(p, q) \subseteq V(G)$ is the set of leaves of T reachable in T from p without passing q . The *carvingwidth* of G is the minimum width of all the carving-decompositions of G .

Let G be a planar graph with a fixed embedding. The *medial graph* [9] $M(G)$ of G is the planar dual of the graph of incidences between the vertex set and the face set of G . Note that $M(G)$ in general is a multigraph but the number of edges of $M(G)$ is linear in the number of vertices of G . Seymour and Thomas [9] show that the carvingwidth of $M(G)$ is exactly twice the branchwidth of G . Moreover, an optimal carving-decomposition of $M(G)$ can be translated into an optimal branch-decomposition of G in linear time. The algorithms of Seymour and Thomas mentioned in the introduction indeed work on carvingwidth and decompositions. Similarly, Theorem 1 is an immediate corollary to the following theorem, which we prove in the sequel.

Theorem 2. *Given a planar multigraph G with n vertices and $O(n)$ edges, a minimum-width carving-decomposition of G can be constructed in $O(n^3)$ time.*

This is an improvement over the $O(n^4)$ result of Seymour and Thomas. We must remark, however, that their result for carving-decompositions is more general: it allows positive integer weights on edges and defines the width as the sum of these edge weights. Although this generalization does not seem to be relevant for our present application, namely the branch-decomposition, it does make a difference for another application of carving-decompositions, namely call routing. See [9] for details. Our algorithm runs for this general problem in $O(\min\{n^4, Wn^2\})$ time, where W is the total weight of the edges.

In the rest of this paper, G will always denote the planar multigraph that is the input to our algorithm, n the number of vertices of G , and k the carvingwidth of G . We also assume that G has at least 2 vertices and the number of edges of G is $O(n)$.

For the purpose of our prospective refinement, it turns out convenient to describe the carving decomposition algorithm of Seymour and Thomas [9] in a slightly different language.

We begin with viewing carving-decompositions as rooted binary trees. Let $\sigma(V)$ denote the set of all singleton subsets of a finite set V . A *binary merging* in V is defined inductively as follows.

1. $\sigma(V)$ is a binary merging in V .
2. If \mathcal{M} is a binary merging in V and X, Y are two distinct maximal subsets of V in \mathcal{M} , then $\mathcal{M} \cup \{X \cup Y\}$ is a binary merging in V .

We say that a binary merging in V is *full* if V belongs to it. Each full binary merging \mathcal{M} in $V(G)$ represents a carving decomposition $T_{\mathcal{M}}$ of G as follows. The node set of $T_{\mathcal{M}}$ is $\mathcal{M} \setminus \{V(G)\}$ and $T_{\mathcal{M}}$ has an edge between $X, Y \in \mathcal{M} \setminus \{V(G)\}$ if and only if X is a maximal proper subset of Y in \mathcal{M} , Y is a maximal proper subset of X in \mathcal{M} , or $X \cup Y = V(G)$. We may view \mathcal{M} as representing a rooted version of tree $T_{\mathcal{M}}$, where the root is placed in the middle of the edge of the

last type above. We define the width of a binary merging \mathcal{M} in $V(G)$ to be the maximum of $|\delta_G(X)|$ over all $X \in \mathcal{M}$. When \mathcal{M} is full, this definition of width coincides with the width of the carving decomposition $T_{\mathcal{M}}$. We say that a binary merging \mathcal{M}' *extends* a binary merging \mathcal{M} if $\mathcal{M}' \supseteq \mathcal{M}$. Let \mathcal{M} be a binary merging in $V(G)$ with width k . We say that maximal elements X, Y of \mathcal{M} are *mergeable* in \mathcal{M} if there is a full binary merging of width k that extends $\mathcal{M} \cup \{X \cup Y\}$. We say disjoint subsets X, Y of $V(G)$ are *adjacent* if $E_G(X, Y) \neq \emptyset$.

We formulate the carving-decomposition algorithm of Seymour and Thomas in terms of binary mergings as follows. The algorithm grows a binary merging starting from $\sigma(V(G))$ towards a full one, keeping the invariant that the binary merging maintained is extendable to a full binary merging of width k . We assume that the input multigraph G is connected: if not, we can work on each connected component and trivially combine the results.

Algorithm ST

Input: A connected planar multigraph G with n vertices and $O(n)$ edges.

Output: A carving-decomposition in $V(G)$ of minimum width

- (1) Decide the carvingwidth k of G .
- (2) Set $\mathcal{M}^0 = \sigma(V(G))$, the set of all singleton subsets of $V(G)$. Set $i = 1$.
- (3) Repeat the following while $i < n$.
 - (3.1) Scan adjacent pairs $\{X, Y\}$ of maximal elements of \mathcal{M}^{i-1} , testing if X and Y are mergeable, until a mergeable pair $\{X, Y\}$ is found, and set $X^i = X \cup Y$.
 - (3.2) Set $\mathcal{M}^i = \mathcal{M}^{i-1} \cup \{X^i\}$ and set i to $i + 1$.
- (4) Return the carving-decomposition represented by \mathcal{M}^{n-1} .

The correctness proof of this algorithm consists in showing, by induction on i , that each \mathcal{M}^i is a well-defined binary merging in $V(G)$ and is extendable to a full binary merging of width k . The base case is trivial and the induction step is a straightforward consequence of the following lemma.

Lemma 1. *Let \mathcal{M} be a binary merging in $V(G)$ that is extendable to a full binary merging of the optimal width k . Then there are adjacent maximal elements X and Y of \mathcal{M} that are mergeable.*

Proof. The following proof sketch is a translation of the original argument by Seymour and Thomas into our language. Let $G_{\mathcal{M}}$ denote the multigraph whose vertex set is the set of maximal elements of \mathcal{M} and the edge set is $E(G)$, with each pair of vertices X and Y of this multigraph connected by all the edges in $E_G(X, Y)$. Since \mathcal{M} is extendable to a full binary merging of width k , the carvingwidth of $G_{\mathcal{M}}$ is k or smaller. Seymour and Thomas [9] show that every connected planar multigraph H of carvingwidth k has a *bond-carving* of width k , where a bond-carving of H is a carving-decomposition T of H such that for every edge $\{p, q\}$ of T , the subgraph of H induced by $L'_T(p, q) \subseteq V(H)$ is connected. Let T be a bond-carving of $G_{\mathcal{M}}$ with width k or smaller. Then, T contains an internal node p_0 adjacent to two distinct leaves $X, Y \in V(G_{\mathcal{M}})$. Since T is a bond-carving, X and Y must be adjacent in $G_{\mathcal{M}}$. Let $\mathcal{M}' = \mathcal{M} \cup \{X \cup Y\}$. We may convert T into a carving-decomposition T' of $G_{\mathcal{M}'}$ by replacing p_0 , together

with the two incident leaves X and Y , by a leaf $X \cup Y$. Clearly the width of T' is k or smaller. Following the structure of T' , we may extend \mathcal{M}' into a full binary merging of width k . Therefore, the adjacent pair X and Y are mergeable in \mathcal{M} . \square

To test if X and Y are mergeable in \mathcal{M} , we call the $O(n^2)$ time procedure of Seymour and Thomas to decide if $G_{\mathcal{M}'}$ has carving width not exceeding k , where $\mathcal{M}' = \mathcal{M} \cup \{X \cup Y\}$. We remark that their decision algorithm works for planar multigraphs, where the running time is quadratic in the number of edges. We call this mergeability test an *expensive test*. Since $O(n^2)$ expensive tests are performed during the execution of algorithm ST and the time for this task is clearly dominating, algorithm ST runs in $O(n^4)$ time.

3 Barrier Lemma

In this section, we prove a key lemma, called the barrier lemma, which enables our savings in the use of expensive tests.

Lemma 2. *Let \mathcal{M} be a binary merging in $V(G)$ and X, Y distinct maximal elements of \mathcal{M} . Suppose that $X = X' \cup Z$ and $Y = Y' \cup W$ where $X', Y', Z, W \in \mathcal{M}$ and that $E_G(Z, W) = \emptyset$. If X and Y are mergeable in \mathcal{M} and $|\delta_G(X' \cup Y')| \leq k$ then X' and Y' are mergeable in $\mathcal{M} \setminus \{X, Y\}$.*

Proof. Let $\mathcal{M}' = \mathcal{M} \setminus \{X, Y\}$ and \mathcal{M}^* a full binary merging in $V(G)$ with width k that extends $\mathcal{M} \cup \{X \cup Y\}$, which exists because X and Y are mergeable in \mathcal{M} . Let $\mathcal{M}_1 = \mathcal{M}' \cup \{X' \cup Y', X' \cup Y' \cup Z\} \cup (\mathcal{M}^* \setminus \mathcal{M})$ and $\mathcal{M}_2 = \mathcal{M}' \cup \{X' \cup Y', X' \cup Y' \cup W\} \cup (\mathcal{M}^* \setminus \mathcal{M})$. Then, both \mathcal{M}_1 and \mathcal{M}_2 are full binary mergings in $V(G)$ that extend $\mathcal{M}' \cup \{X' \cup Y'\}$. See Figure 1. Therefore, in order to show that X' and Y' are mergeable in \mathcal{M}' , it suffices to show that either \mathcal{M}_1 or \mathcal{M}_2 has width k . Since $\mathcal{M}_1 \setminus \mathcal{M}^* = \{X' \cup Y', X' \cup Y' \cup Z\}$, $\mathcal{M}_2 \setminus \mathcal{M}^* = \{X' \cup Y', X' \cup Y' \cup W\}$, and $|\delta_G(X' \cup Y')| \leq k$ by assumption, it in turn suffices to show that either $|\delta_G(X' \cup Y' \cup Z)| \leq k$ or $|\delta_G(X' \cup Y' \cup W)| \leq k$. Let $A = X' \cup Y'$ and $B = V(G) \setminus (X \cup Y)$. We have

$$\delta_G(A \cup Z) = E_G(A, B) \cup E_G(Z, B) \cup E_G(A, W),$$

since $E_G(Z, W) = \emptyset$ by assumption, and hence

$$|\delta_G(A \cup Z)| = |E_G(A, B)| + |E_G(Z, B)| + |E_G(A, W)|,$$

since the edge sets in the right hand side are disjoint. Similarly, we have

$$\begin{aligned} |\delta_G(A \cup W)| &= |E_G(A, B)| + |E_G(W, B)| + |E_G(A, Z)| \\ |\delta_G(A)| &= |E_G(A, B)| + |E_G(A, Z)| + |E_G(A, W)| \\ |\delta_G(B)| &= |E_G(A, B)| + |E_G(Z, B)| + |E_G(W, B)|. \end{aligned}$$

Fig. 1. Binary mergings in Lemma 2: (a) $\mathcal{M}, \mathcal{M}', \mathcal{M}^*$ and (b) \mathcal{M}_1

Therefore, we have

$$\begin{aligned}
 & |\delta_G(A \cup Z)| + |\delta_G(A \cup W)| \\
 &= 2|E_G(A, B)| + |E_G(Z, B)| + |E_G(W, B)| + |E_G(A, Z)| + |E_G(A, W)| \\
 &= |\delta_G(A)| + |\delta_G(B)|.
 \end{aligned}$$

Moreover, $|\delta_G(A)| \leq k$ is one of the assumptions in the lemma and we also have $|\delta_G(B)| = |\delta_G(X \cup Y)| \leq k$ since X and Y are mergeable in \mathcal{M} . Therefore, we have

$$|\delta_G(A \cup Z)| + |\delta_G(A \cup W)| \leq 2k$$

and hence either $|\delta_G(A \cup Z)| \leq k$ or $|\delta_G(A \cup W)| \leq k$ as desired. □

Let \mathcal{M} be a binary merging in $V(G)$. A sequence $X_0 \supset X_1 \supset \dots \supset X_m$ of elements of \mathcal{M} is called a *chain* in \mathcal{M} if each X_i for $1 \leq i \leq m$ is a maximal proper subset of X_{i-1} in \mathcal{M} . If we denote by C the chain above, then X_0 is called the *top* of C , denoted by $\top C$, and X_m is called the *bottom* of C , denoted by $\perp C$. A chain C is called a *barrier* if $|\delta_G(\top C \setminus \perp C)| > k$.

Lemma 3. (*Barrier lemma*) *Let \mathcal{M} be a binary merging in $V(G)$ with width k or smaller and X, Y two maximal elements of \mathcal{M} . Suppose there is a binary merging $\mathcal{M}' \subseteq \mathcal{M}$ and maximal elements X' and Y' of \mathcal{M}' with $X' \subseteq X$ and $Y' \subseteq Y$ such that the following conditions hold.*

1. X and Y are mergeable in \mathcal{M} ;
2. $|\delta(X' \cup Y')| \leq k$;
3. $E_G(X \setminus X', Y \setminus Y') = \emptyset$;
4. there is no barrier B in \mathcal{M} with $\top B = X$ and $\perp B \supseteq X'$;
5. there is no barrier B in \mathcal{M} with $\top B = Y$ and $\perp B \supseteq Y'$;

Then, X' and Y' are mergeable in \mathcal{M}' .

Proof. Let $Z = X \setminus X'$ and $W = Y \setminus Y'$. Let $X_0 \supset X_1 \supset \dots \supset X_h$ be the chain in \mathcal{M} with top $X_0 = X$ and bottom $X_h = X'$. Similarly, let $Y_0 \supset Y_1 \supset \dots \supset Y_j$ be the chain in \mathcal{M} with top $Y_0 = Y$ and bottom $Y_j = Y'$. Let \mathcal{M}_1 be the binary merging in $V(G)$ obtained from \mathcal{M} by removing X_i for $0 \leq i < h$ and Y_i for

Fig. 2. Binary mergings in Lemma 3: (a) \mathcal{M} is transformed into (b) \mathcal{M}_2

$0 \leq i < j$. Then, \mathcal{M}_1 extends \mathcal{M}' , $X_i \setminus X_{i+1}$ is a maximal element of \mathcal{M}_1 for $0 \leq i < h$, and $Y_i \setminus Y_{i+1}$ is a maximal element of \mathcal{M}_1 for $0 \leq i < j$. We extend \mathcal{M}_1 into \mathcal{M}_2 with X and Y as maximal elements, in which the two maximal subsets of X are X' and Z , and the two maximal subsets of Y are Y' and W , as follows. First, we successively extend \mathcal{M}_1 by adding $X_0 \setminus X_i$ for $i = 2, \dots, h$, creating a chain with bottom $X_0 \setminus X_1$ and top $X_0 \setminus X_h = Z$. Similarly, we add a chain with bottom $Y_0 \setminus Y_1$ and top W . Finally, we add X and Y and call the result \mathcal{M}_2 . See Figure 2. We have $\delta_G(X_0 \setminus X_i) \leq k$ for $i = 2, \dots, h$, since if $\delta_G(X_0 \setminus X_i) > k$ then the chain in \mathcal{M} with top X_0 and bottom X_i would be a barrier contradicting our assumption. Similarly, we have $\delta_G(Y_0 \setminus Y_i) \leq k$ for $i = 2, \dots, j$. Since these are the only elements in $\mathcal{M}_2 \setminus \mathcal{M}$, the width of \mathcal{M}_2 does not exceed k . Since the set of maximal elements of \mathcal{M}_2 is equal to that of \mathcal{M} , the assumption that X and Y are mergeable in \mathcal{M} implies that they are also mergeable in \mathcal{M}_2 .

Thus, we have $X', Y', Z, W \in \mathcal{M}_2$, $X = X' \cup Z$ and $Y = Y' \cup W$ are maximal in \mathcal{M}_2 , and X and Y are mergeable in \mathcal{M}_2 . Moreover, by assumptions, we have $E_G(Z, W) = \emptyset$ and $|\delta_G(X' \cup Y')| \leq k$. Therefore we may apply Lemma 2 to conclude that X' and Y' are mergeable in $\mathcal{M}_2 \setminus \{X, Y\}$. Since $\mathcal{M}_2 \setminus \{X, Y\}$ extends \mathcal{M}' , X' and Y' are mergeable in \mathcal{M}' . \square

4 Saving Expensive Tests

In this section, \mathcal{M}^i , $0 \leq i \leq n - 1$, denotes the sequence of binary mergings in $V(G)$ as constructed by the execution of Algorithm ST. We assume Algorithm ST is executed with the method of mergeability testing described in this section. Even though the description of our testing method involves \mathcal{M}^i , the definitions

are not circular, as the action taken by our method at the i th iteration step of algorithm ST depends only on \mathcal{M}^{i-1} .

The following notation is used in the description of our testing method. We denote by P^i the set of all unordered pairs on which the expensive test is performed since the start of the algorithm execution and prior to the addition of the element X^i . We denote by Q^i the set of pairs in P^i on which the test result was negative, i.e., “unmergeable”.

Let X, Y be disjoint elements of \mathcal{M}^{n-1} such that $E_G(X, Y) \neq \emptyset$. We denote by $\mu_Y(X)$ the minimal subset X' of X such that $E_G(X, Y) = E_G(X', Y)$. We also denote by $Q(X, Y)$ the set of distinct unordered pairs $\{X', Y'\} \in Q^{n-1}$ with $X \supseteq X' \supseteq \mu_Y(X)$ and $Y \supseteq Y' \supseteq \mu_X(Y)$. Note that $\mu_Y(X)$ and $Q(X, Y)$ can be determined from \mathcal{M}^i and Q^i where i is the smallest index with $X, Y \in \mathcal{M}^i$ and therefore these sets are accessible by the algorithm when testing the mergeability of X and Y . Note also that the pairs in $Q(X, Y)$ are totally ordered by the element-wise set inclusion.

Parsimonious mergeability test

Input: maximal elements X and Y of \mathcal{M}^{i-1} .
 Reports: if X and Y are mergeable in \mathcal{M}^{i-1} .

- (1) If $|\delta(X \cup Y)| > k$ then report “NO”.
- (2) Otherwise, if $Q(X, Y) = \emptyset$ then do the expensive test and report the result.
- (3) Otherwise, let $\{X', Y'\}$ be the maximal pair in $Q(X, Y)$. If there is no barrier B with $\top B = X$ and $\perp B \supseteq X'$ or $\top B = Y$ and $\perp B \supseteq Y'$, then report “NO”. Otherwise, do the expensive test and report the result.

Lemma 4. *The testing procedure above reports a correct answer.*

Proof. We need only to show that, whenever the procedure skips the expensive test and reports “NO”, X and Y are not mergeable. This is trivially the case, when the test returns in step (1). Consider the case where the procedure skips the expensive test in step (3). Let $\{X', Y'\}$ be as defined in the procedure and set $Z = X \setminus X'$ and $W = Y \setminus Y'$. The definition of $Q(X, Y)$ implies that $E_G(Z, W) = \emptyset$. Therefore, we may apply the barrier lemma with $\mathcal{M} = \mathcal{M}^{i-1}$ and \mathcal{M}' being \mathcal{M}^j with the smallest j that contains X' and Y' and conclude that X, Y are not mergeable in \mathcal{M}^{i-1} . □

In the remainder of this section, we concentrate on showing that, with this parsimonious mergeability testing, $O(n)$ expensive tests are performed during the execution of Algorithm ST.

We start with some properties of barriers. Let C be a chain in a binary merging \mathcal{M} in $V(G)$. We define three disjoint edge sets:

$$\begin{aligned} \text{pass}(C) &= E_G(\perp C, V(G) \setminus \top C) \\ \text{in}(C) &= E_G(\perp C, \top C \setminus \perp C) \\ \text{out}(C) &= E_G(\top C \setminus \perp C, V(G) \setminus \top C). \end{aligned}$$

Proposition 1. *Assuming that the width of binary merging \mathcal{M} does not exceed k , $|\text{pass}(B)| < |\text{in}(B)|$ for every barrier B in \mathcal{M} .*

Proof. Since the width of \mathcal{M} does not exceed k , we have $|\delta_G(\top B)| \leq k$. Since $\delta_G(\top B) = \text{pass}(B) \cup \text{out}(B)$ and these two sets are disjoint, we have $|\text{pass}(B)| + |\text{out}(B)| \leq k$. Since B is a barrier and hence $|\text{in}(B)| + |\text{out}(B)| > k$, it follows that $|\text{pass}(B)| < |\text{in}(B)|$. \square

We say that a chain C is *rich* if $|\text{in}(C)| \geq k/4$.

Proposition 2. *Let B be a barrier in a binary merging in $V(G)$ of width k or smaller. If either $|\delta_G(\top B)| \leq 3k/4$ or $|\delta_G(\perp B)| \geq k/2$ then B is rich.*

Proof. If $|\delta_G(\top B)| \leq 3k/4$ then $|\text{out}(B)| \leq 3k/4$ and hence $|\text{in}(B)| > k/4$ since B is a barrier. If $|\delta_G(\perp B)| \geq k/2$ then, since $\delta_G(\perp B) = \text{in}(B) \cup \text{pass}(B)$, it follows from the proposition above that $|\text{in}(B)| \geq k/4$. \square

The following proposition is an immediate consequence of the above.

Proposition 3. *Let B_1 and B_2 be two barriers with $\perp B_1 \supseteq \top B_2$. If neither B_1 nor B_2 is rich, then the chain C with $\top C = \perp B_1$ and $\perp C = \top B_2$ is rich.*

Recall that \mathcal{M}^{n-1} denotes the full binary merging constructed by the algorithm, P^{n-1} the set of unordered pairs from \mathcal{M}^{n-1} on which the expensive test is performed. Also recall related notation $\mu_X(Y)$ and $Q(X, Y)$.

Call a disjoint pair $\{X, Y\}$ with $X, Y \in \mathcal{M}^{n-1}$ *relevant* if $E_G(X, Y)$ is nonempty and there is some $i < n$ such that both X and Y are maximal in \mathcal{M}^i . Clearly, all pairs in P^{n-1} are relevant. We call a pair $\{X, Y\}$ from \mathcal{M}^{n-1} *essential* if it is relevant and $\mu_Y(X) = X$ and $\mu_X(Y) = Y$. We first note that there are at most $O(n)$ essential pairs from \mathcal{M}^{n-1} . To see this, consider subsets of $E(G)$ of the form $E_G(X, Y)$ for an essential $\{X, Y\}$ from \mathcal{M}^{n-1} . Since those subsets are formed through successive binary merging, starting from singleton subsets, the number of such subsets is at most $2|E(G)|$. Since $E_G(X, Y) = E_G(\mu_Y(X), \mu_X(Y))$, by definition of $\mu_Y(X)$ and $\mu_X(Y)$, the number of such edge subsets is exactly the number of essential pairs from \mathcal{M}^{n-1} .

We are ready to bound the number of expensive tests. The conditions of the testing algorithm implies that exactly one expensive test is applied to each pair $X, Y \in P^{n-1}$. Therefore, it suffices to show that $|P^{n-1}| = O(n)$. Let $P' = \{\{X, Y\} \in P^{n-1} \mid |Q(X, Y)| \leq 2\}$. Then, the cardinality of P' is at most three times the number of essential pairs from \mathcal{M}^{n-1} and therefore is $O(n)$. To bound the cardinality of $P^{n-1} \setminus P'$, we need the following lemma. Recall that the pairs in $Q(X, Y)$ are totally ordered by element-wise set inclusion and note that, for $\{X, Y\} \in P^{n-1} \setminus P'$, we have $|Q(X, Y)| \geq 3$.

Lemma 5. *Let $(X, Y) \in P^{n-1} \setminus P'$ and let $\{X_1, Y_1\}$, $\{X_2, Y_2\}$, and $\{X_3, Y_3\}$ be the first, second, and third maximal elements of $Q(X, Y)$ respectively, with $X_1 \supseteq X_2 \supseteq X_3$ and $Y_1 \supseteq Y_2 \supseteq Y_3$. Then, there exists a rich chain C with either $X \supseteq \top C$ and $\perp C \supseteq X_3$ or $Y \supseteq \top C$ and $\perp C \supseteq Y_3$.*

Proof. The rule of our testing method demands that, in order for all the pairs $\{X_2, Y_2\}$, $\{X_1, Y_1\}$, and $\{X, Y\}$ to be included in P^{n-1} , there must be a barrier B_i with either $X_i \supseteq \top B_i$ and $\perp B_i \supseteq X_{i+1}$ or $Y_i \supseteq \top B_i$ and $\perp B_i \supseteq Y_{i+1}$ for $0 \leq i \leq 2$, where we set $X_0 = X$ and $Y_0 = Y$. We may assume without loss of generality that for at least two values of i we have $X_i \supseteq \top B_i$ and $\perp B_i \supseteq X_{i+1}$. If either of these two barriers are rich, then we are done. Otherwise, we obtain a desired rich chain between these two barriers applying Proposition 3. \square

We say that a chain C is *minimal rich*, if it is rich and no proper subchain of C is rich. Let \mathcal{R}^* denote the set of all minimal rich chains in \mathcal{M}^{n-1} . We say that a chain C *supports* a chain C' if $\top C \supseteq \perp C' \supseteq \perp C$. We say that a subset \mathcal{R} of \mathcal{R}^* *supports* \mathcal{R}^* if for each $C \in \mathcal{R}^*$ there is some chain in \mathcal{R} that supports C . We choose an arbitrary minimal subset of \mathcal{R}^* that supports \mathcal{R}^* and call it $\hat{\mathcal{R}}$.

Let \mathbf{G} denote the directed version of G with directed edges (u, v) and (v, u) for each undirected edge $\{u, v\}$ of G . For a chain C , we define $\mathbf{in}(C) = \{(u, v) \in E(\mathbf{G}) \mid u \in \perp C, v \in \top C \setminus \perp C\}$. The directed edges in $\mathbf{in}(C)$ and undirected edges in $\mathbf{in}(C)$ are in a natural one-to-one correspondence.

Proposition 4. *For each directed edge e of \mathbf{G} , there are at most two chains $C \in \hat{\mathcal{R}}$ such that $e \in \mathbf{in}(C)$.*

Proof. Suppose to the contrary that some $(u, v) \in E(\mathbf{G})$ belongs to $\mathbf{in}(C)$ for three distinct chains C_1, C_2, C_3 in $\hat{\mathcal{R}}$. Since $\perp C_i$ contains u for $i = 1, 2, 3$, all these chains are subchains of the chain in \mathcal{M}^{n-1} with top $V(G)$ and bottom $\{u\}$. Without loss of generality, we assume $\top C_1 \supseteq \top C_2 \supseteq \top C_3$. Note here that the tops of these chains are mutually distinct, due to the minimality of these chains with respect to richness. Let X be the minimal element of \mathcal{M}^{n-1} that contains both u and v . Then, we must have $\top C_i \supseteq X \supseteq \perp C_i$ for $i = 1, 2, 3$. Therefore, we have

$$\top C_1 \supseteq \top C_2 \supseteq \top C_3 \supseteq \perp C_1 \supseteq \perp C_2 \supseteq \perp C_3$$

Let C be an arbitrary chain in \mathcal{R}^* supported by C_2 . We have $\top C_2 \supseteq \perp C \supseteq \perp C_2$ by the definition of supporting. If $\perp C \supseteq \perp C_1$ then C_1 supports C , since $\top C_1 \supseteq \top C_2 \supseteq \perp C$. Otherwise, i.e., if $\perp C_1 \supseteq \perp C$, we have $\top C_3 \supseteq \perp C$ and C_3 supports C , since $\perp C \supseteq \perp C_2 \supseteq \perp C_3$. Therefore, $\hat{\mathcal{R}} \setminus \{C_2\}$ supports \mathcal{R}^* , contradicting the minimality of $\hat{\mathcal{R}}$. \square

Corollary 1. $|\hat{\mathcal{R}}| \leq 16|E(G)|/k$.

Proof. Each chain $C \in \hat{\mathcal{R}}$ is rich and hence $|\mathbf{in}(C)| \geq k/4$. Each of $2|E(G)|$ edges of \mathbf{G} belongs to $\mathbf{in}(C)$ for at most two chains of $\hat{\mathcal{R}}$ and hence $|\hat{\mathcal{R}}| \cdot \frac{k}{4} \leq \sum_{C \in \hat{\mathcal{R}}} |\mathbf{in}(C)| \leq 4|E(G)|$, from which the inequality of the corollary follows. \square

For each $C \in \hat{\mathcal{R}}$, we define a subset P_C of $P^{n-1} \setminus P'$ as follows. Let $\{X, Y\} \in P^{n-1} \setminus P'$ and $\{X_3, Y_3\}$ the third maximal pair in $Q(X, Y)$ with $X \supseteq X_3$ and $Y \supseteq Y_3$. Then, we put $\{X, Y\}$ in P_C if and only if either $X \supseteq \top C \supseteq X_3$ or $Y \supseteq \top C \supseteq Y_3$. Lemma 5 and the definition of $\hat{\mathcal{R}}$ imply that $P^{n-1} \setminus P' \subseteq \bigcup_{C \in \hat{\mathcal{R}}} P_C$.

We now bound the cardinality of each P_C . The definition of $Q(X, Y)$ implies that $E_G(X, Y) = E_G(X_3, Y)$ and hence that for each W such that $X \supseteq W \supseteq X_3$, $E_G(X, Y)$ is a subset of $\delta_G(W)$. The same holds for each W such that $Y \supseteq W \supseteq Y_3$. Therefore, for pair $\{X, Y\}$ to be in P_C , $E_G(X, Y)$ must contain some edge in $\delta_G(\top C)$.

Let $e = \{u, v\}$ be an arbitrary edge in $\delta_G(\top C)$ with $u \in \top C$ and $v \in V(G) \setminus \top C$. We want to know how many pairs X, Y with $e \in E_G(X, Y)$ can be in P_C . Let $\{X_i, Y_i\}$, $1 \leq i \leq a$, be the list of all pairs $\{X, Y\}$ in P^{n-1} such that $e \in E_G(X, Y)$. Assume without loss of generality that these pairs are ordered so that $X_1 \supseteq X_2 \supseteq \dots \supseteq X_a \supseteq \{u\}$ and $Y_1 \supseteq Y_2 \supseteq \dots \supseteq Y_a \supseteq \{v\}$. Suppose $\{X_i, Y_i\} \in P_C$ for some $1 \leq i \leq a$. Then, it must be that $|Q(X_i, Y_i)| \geq 3$ and the first, second and third maximal elements of $Q(X_i, Y_i)$ are $\{X_{i+1}, Y_{i+1}\}$, $\{X_{i+2}, Y_{i+2}\}$ and $\{X_{i+3}, Y_{i+3}\}$. Note that the expensive test on all of these three pairs must have failed, since if any of these pairs had been merged then the pair $\{X_i, Y_i\}$ would not appear later in the process. From the definition of P_C , we must have $X_i \supseteq \top C \supset X_{i+3}$ or $Y_i \supseteq \top C \supset Y_{i+3}$. The latter condition, however, cannot hold because $u \notin Y_i$. For a fixed C , at most three values of i can satisfy this condition. Therefore, for each C and each $e \in \delta_G(\top C)$, there are at most 3 pairs $\{X, Y\} \in P_C$ with $e \in E_G(X, Y)$. As $|\delta_G(\top C)| \leq k$, we have $|P_C| \leq 3k$.

Combining this with Corollary 1, we have $|P^{n-1} \setminus P'| \leq \sum_{C \in \hat{\mathcal{R}}} |P_C| \leq 48|E(G)|$ and therefore $|P^{n-1}| = O(n)$.

5 Total Running Time

In this section, we show that the total running time of Algorithm ST is $O(n^3)$, when the parsimonious mergeability test described in the previous section is used. We need only elementary data structures and the analysis is straightforward.

We represent the binary merging \mathcal{M}^i constructed by the algorithm naturally by a binary forest. With each node of this forest we associate a member X of \mathcal{M}^i , in the form of a sorted list, and the edge set $\delta_G(X)$ also in the form a sorted list. As the merging of two members of \mathcal{M}^i can be done in $O(n)$ time in this representation, the total time for maintaining this binary forest is $O(n^2)$. In addition, we maintain a graph G^i for each $0 \leq i \leq n - 1$, where the vertices of G^i are the maximal elements of \mathcal{M}^i and $X, Y \in V(G^i)$ are adjacent in G^i if and only if $E_G(X, Y) \neq \emptyset$. We maintain G^i in the standard edge list representation. Moreover, with each edge e of G^i , $0 < i \leq n - 1$, we associate the corresponding edge(s) in G^{i-1} : if the endvertices X and Y of e are both in $V(G^{i-1})$, then this association is to the edge between X and Y in G^{i-1} ; otherwise, i.e., if $X = X_1 \cup X_2$ with $X_1, X_2 \in V(G^{i-1})$, say, then this association is to the edge between X_1 and Y , if present, and to the edge between X_2 and Y , if present. The representation of G^i can be constructed in $O(n)$ time, so the total maintenance cost of this part is $O(n^2)$. The set Q , the set of unordered pairs $\{X, Y\}$ on which the expensive test is performed with a negative result, is represented by marking the corresponding edge of G^i .

We now bound the cost of mergeability testing. We have already proved that the number of expensive tests is $O(n)$ and therefore the total running time for expensive tests is $O(n^3)$. Since the mergeability testing is performed $O(n^2)$ times, it suffices to show that other parts of the testing takes $O(n)$ time for each tested pair. The time for the degree test in step (1) is trivially $O(n)$. The set $Q(X, Y)$ in step (2) can be constructed as follows. We start from the edge e between X and Y in the current G^i and trace back its origin in G^{i-1}, G^{i-2}, \dots . This tracing stops when we reach G^0 or encounter an edge between an essential pair. Using the marks of the edges in the traced sequence, we construct $Q(X, Y)$ in $O(n)$ time. The maximal pair $\{X', Y'\} \in Q(X, Y)$ is the first element of $Q(X, Y)$ found in this process. Finally, the barrier computation can be done in $O(n)$ time as follows. Let $X_1 \supset X_2 \supset \dots \supset X_h$ be the chain with top $X_1 = X$ and bottom $X_h = X'$. For $j = 2, \dots, h$, we successively construct the edge set $\delta_G(X_1 \setminus X_j)$. Noting that $\delta_G(X_1 \setminus X_j)$ for $2 \leq j \leq h$ is the symmetric difference between $\delta_G(X_1 \setminus X_{j-1})$ and $\delta_G(X_{j-1} \setminus X_j)$, we represent the sets in this process with a single membership bit for each edge of G and a single counter for the cardinality of the set: when we process $\delta_G(X_{j-1} \setminus X_j)$, we flip the bit of each edge in this set and count up or down according to the result of this flip. Since the set $\delta_G(X_{j-1} \setminus X_j)$ for each j is available in the data structure and each edge enters the constructed set at most once and exits at most once, the total time for the construction is $O(n)$. If any of these constructed edge sets has cardinality greater than k , then we have detected a barrier.

This concludes the analysis of the running time and we have proved Theorem 2.

Abstract. The construction of an ε -free nondeterministic finite automaton (NFA) from a given NFA is a basic step in the development of compilers and computer systems. The standard conversion may increase the number of transitions quadratically and its optimality with respect to the number of transitions is a long standing open problem. We show that there exist regular languages L_n that can be recognized by NFAs with $O(n \log_2 n)$ transitions, but ε -free NFAs need $\Omega(n^2)$ transitions to accept L_n . Hence the standard conversion cannot be improved significantly. However L_n requires an alphabet of size n , but we also construct regular languages K_n over $\{0, 1\}$ with NFAs of size $O(n \log_2 n)$, whereas ε -free NFAs require size $n \cdot 2^{c \sqrt{\log_2 n}}$ for every $c < 1/2$.

1 Introduction

One of the central tasks on the border between formal language theory and complexity theory is to describe infinite objects such as languages by finite formalisms such as automata, grammars, expressions etc., and to investigate the descriptonal complexity and capabilities of these formalisms. Formalisms like expressions and finite automata have proven to be very useful in building compilers, and techniques converting one formalism into the other are used as basic tools in the design of computer systems [Tho68] such as UNIX (see [HMU01], p. 123). A typical application in lexicographical analysis starts with a regular expression that has to be converted into an ε -free nondeterministic finite automaton. Here, the descriptonal complexity of an expression is its length and the descriptonal complexity of a nondeterministic finite automaton (NFA) is the number of its transitions (edges).

Surprisingly ε -free NFA are capable of simulating regular expressions of length n with at most $O(n(\log_2 n)^2)$ transitions [HSW97] and hence in this case the loss of ε -transitions does only weakly deteriorate the conciseness of ε -free NFAs. In [Lif03] a lower bound of $\Omega(n(\log_2 n)^2 / \log_2 \log_2 n)$ is shown and as a consequence the upper bound of [HSW97] is almost tight.

In contrast to translating regular expressions into ε -free NFAs, no subquadratic transformation from NFAs into ε -free NFAs is known. Since any regular

* Supported in part by SNF grant 200021-107327/1 and DFG grant SCHN 503/2-2.

expression of length n can be recognized by unrestricted NFAs with $O(n)$ transitions, ε -free NFAs of size at least $\Omega(n(\log_2 n)^2 / \log_2 \log_2 n)$ are required for given NFAs of size n . We considerably improve this lower bound and show an almost quadratic increase in size.

Theorem 1. *Sequences $\{L_n\}_{n=1}^\infty, \{K_n\}_{n=1}^\infty$ of regular languages exist such that*

- (i) L_n is defined over the alphabet $\{0, 1\}^n$, K_n is defined over the alphabet $\{0, 1\}$,
- (ii) L_n and K_n can be accepted by NFAs with $O(n \cdot 2^n)$ transitions,
- (iii) every ε -free NFA accepting L_n has at least $\Omega(2^{2^n})$ transitions and
- (iv) every ε -free NFA accepting K_n has at least $\Omega(2^{n+c\sqrt{n}})$ transitions for every constant $c < 1/2$.

Hence, for $m = 2^n$, L_n and K_n can be accepted by NFAs with $O(m \log_2 m)$ transitions, but every ε -free NFA for L_n has at least $\Omega(m^2)$ transitions, whereas K_n requires ε -free NFAs of size $O(m \cdot 2^{c\sqrt{\log_2 m}})$ for every $c < 1/2$. Thus ε -free NFAs for L_n require almost quadratically more transitions than unrestricted NFAs for L_n and the obvious transformation from NFAs to ε -free NFAs cannot be improved considerably. The provable gap for binary alphabets is smaller, but still a far larger than poly-logarithmic gap is required. Moreover, for a large class of NFAs, we show in Lemma 4 that the lower bound of Theorem 1 (iv) is almost optimal.

We use methods from communication complexity. However communication arguments can be applied to ε -free NFAs and NFAs alike and hence we have to carefully mix communication arguments with graph-theoretical arguments.

The rest of this paper is organized as follows. In Section 2 we describe the languages L_n which are hard for ε -free NFAs. Lower bounds for large and small alphabets are presented in Sections 3 and 4 respectively. Conclusions and open problems are stated in Section 5.

2 Hard Languages for ε -Free NFAs

Our goal is to construct a sequence $\{L_n\}_{n=1}^\infty$ of regular languages that is considerably harder for ε -free NFAs than for NFAs. Since the basic component of our construction of L_n is the **Hadamard matrix** H_n , we start by describing its properties. H_n is a 1/-1 matrix with 2^n rows and columns. H_n is defined recursively by setting $H_0[1, 1] = 1$ and

$$H_{n+1} = \begin{bmatrix} H_n & H_n \\ H_n & -H_n \end{bmatrix}.$$

An inductive argument shows that the columns of H_n are pairwise orthogonal, and that every column (resp. row) of H_n , except for the first which consists of 1's only, has the same number of 1's and -1's.

H_n has the following crucial property: If a submatrix of H_n with row set X and column set Y covers only 1-entries, then

$$|X| \cdot |Y| \leq 2^n. \tag{1}$$

To show this fact replace any 1 (resp. -1) by a 0 (resp. 1) and call the resulting matrix \overline{H}_n . Another inductive argument verifies that \overline{H}_n is the matrix of inner products modulo two: we may label rows and columns by vectors $u, v \in \mathbb{Z}_2^n$ such that $\overline{H}_n[u, v] = \langle u, v \rangle \pmod 2$. If the sets $X, Y \subseteq \mathbb{Z}_2^n$ define a 0-chromatic submatrix of \overline{H}_n , then we may close X and Y under addition to obtain vector spaces \overline{X} and \overline{Y} (with $X \subseteq \overline{X}$ and $Y \subseteq \overline{Y}$) which still define a 0-chromatic submatrix. Thus \overline{X} and \overline{Y} are orthogonal vector spaces and $\dim(\overline{X}) + \dim(\overline{Y}) \leq n$ follows. Hence $|X| \cdot |Y| \leq 2^n$.

The language L_n is defined over the alphabet $\Sigma_n = \{0, 1\}^n$ and we set

$$L_n = \{\varepsilon\} \cup \Sigma_n \cup \bigcup_{k \geq 2} L_{n,k}, \text{ where} \tag{2}$$

$$L_{n,k} = \{u_1 \cdots u_k \in \Sigma_n^k \mid H_n[u_i, u_{i+1}] = 1 \text{ for all } i < k\}. \tag{3}$$

Thus a sequence of letters of length n belongs to L_n iff the inner product of any two successive letters of the sequence is zero. (Observe that all words of length at most one belong to L_n .)

Proposition 1. *There is an NFA which accepts L_n with $O(n \cdot 2^n)$ transitions.*

Proof Sketch. One can construct a bounded degree switching network G_n of depth n that contains a path between one of the 2^n sources labelled by symbols from Σ_n to one of the 2^n sinks labelled by symbols from Σ_n if and only if the inner product between the corresponding labels is zero. We obtain an NFA for L_n , if we replace sources by “source transitions” of the same label, utilize all other transitions as ε -transitions and redirect edges, previously directed into a sink, into the starting point of the corresponding source transition instead. \square

3 Large Alphabets

We first sketch the argument verifying that every ε -free NFA for L_n has at least $\Omega(2^{2^n})$ transitions (edges). We state without proof that $L_{n,k}$ (see (3)) has surprisingly small ε -free NFA’s for small values of k and, as a consequence, our argument has to concentrate on $L_{n,k}$ for large values of k .

Lemma 1. *$L_{n,k}$ is recognizable by ε -free NFA’s of size at most $O(k \cdot 2^{2^n - k})$.*

Let A_n be an NFA without ε -transitions which recognizes L_n and let k be an arbitrary integer. We first observe that A_n implicitly also recognizes $L_{n,k}$: we unravel the transition diagram of A_n into a layered directed acyclic graph $F_{n,k}$ with $k + 1$ layers. Layer V_i (for $0 \leq i \leq k$) consists of all vertices (x, i) such that x is a vertex of the transition diagram of A_n and x is endpoint of a path of A_n which starts in q_0 and traverses i edges. Observe that layer V_0 consists only of the starting state q_0 . We insert an edge $((x, i), (y, i + 1))$ with label $a \in \{0, 1\}^n$ into $F_{n,k}$ iff (x, y) is an edge of A_n with label a .

Next we remove all vertices of $F_{n,k}$ which are not traversed by an accepting path starting in q_0 and ending in a vertex of the last layer V_k . Finally we replace

all vertices of V_k by the new vertex q_f and insert an edge from $(u, k - 1) \in V_{k-1}$ to q_f with label a , provided there was an a -transition from $(u, k - 1)$ to an accepting vertex of V_k . Let $F_{n,k}$ be the resulting labelled graph.

- Proposition 2.** (a) $F_{n,k}$ is a layered acyclic graph with $k + 1$ layers.
 (b) $F_{n,k}$ has a path $q_0 \xrightarrow{*} q_f$ with label sequence (u_1, \dots, u_k) iff $u_1 \cdots u_k \in L_n$.
 (c) For any i , the number of edges between vertices in V_i and V_{i+1} is bounded by the number of edges of the transition diagram of A_n .

Our goal is to show that there are successive layers V_i and V_{i+1} such that the number of edges between V_i and V_{i+1} has to be large, provided the total number $k + 1$ of layers is sufficiently large. We utilize that the Hadamard matrix H_n has only monochromatic submatrices of size at most 2^n (see (1)). To apply this property we show that any inner vertex x of $F_{n,k}$ (i.e., any vertex different from q_0 and q_f) defines a monochromatic submatrix of H_n spanned by the rows with labels in $S(x)$ (resp. columns with labels in $T(x)$), where $S(x)$ and $T(x)$ are the sets of incoming and leaving labels of x respectively. As a consequence of (1) we obtain $|S(x)| \times |T(x)| \leq 2^n$, whereas in total at least 2^{2n-1} pairs of labels, namely all pairs (u, v) with $H_n[u, v] = 1$, have to be supported. Hence, if the sets $S(x)$ and $T(x)$ are all of identical size s respectively t , then $s \cdot t \leq 2^n$ and $\sum_{x \in V_1} |S(x)| \cdot |T(x)| = \sum_{x \in V_1} s \cdot t \geq 2^{2n-1}$ holds. Thus V_1 has to consist of at least 2^{n-1} vertices and it is optimal to choose $s = t = 2^{n/2}$. Thus at least $2^{3n/2}$ transitions are required.

We apply this procedure to vertices of the second layer by considering paths of length three starting in q_0 . However this time we select for any label v a label $u(v)$ such that the pair $u(v)v$ is supported by the *least* number of paths of length two originating in q_0 . Thus when considering all label sequences $u(v)vw$ we have in effect decreased the “fanin multiplicity” of label v for vertices of the second layer and this reduction can only be compensated for by increasing the “fanout multiplicity” of labels w for vertices of the second layer. (The construction in Lemma 1 also explicitly increases fanout multiplicity by copying edges.) We repeat this procedure n times to verify the required large number of transitions.

3.1 The Details

We start with the “submatrix property” of vertices and associate with an inner vertex x the set **fanin**(x) (resp. **fanout**(x)) of labels of incoming (resp. leaving) edges. In both sets we disregard multiple copies of the same label and hence we also introduce the *multisets* **fanin**^{*}(x) and **fanout**^{*}(x), where all labels of edges entering resp. leaving x are collected according to their true multiplicity.

We say that $(u, v) \in \{0, 1\}^n \times \{0, 1\}^n$ is a **Hadamard pair**, if $H_n[u, v] = 1$. Since any edge of $F_{n,k}$ is traversed by an “accepting path” of $F_{n,k}$, every pair $(u, v) \in \text{fanin}(x) \times \text{fanout}(x)$ is a Hadamard pair: we obtain an accepting path traversing both the incoming and outgoing edge by splicing together two accepting paths traversing the incoming edge and the outgoing edge respectively.

Thus the submatrix $\text{fanin}(x) \times \text{fanout}(x)$ is a 1-chromatic submatrix of H_n and we say that the entries in $\text{fanin}(x) \times \text{fanout}(x)$ are **covered by** x . Therefore,

as a consequence of (1), we have

$$|\text{fanin}(x)| \cdot |\text{fanout}(x)| \leq 2^n. \tag{4}$$

Observe that all ones of H_n are covered by submatrices and, since at least one half of all entries of a row of H_n are 1-entries, we obtain

$$\sum_{x \in V} |\text{fanin}(x) \cap K| \cdot |\text{fanout}(x)| \geq |K| \cdot 2^{n-1} \tag{5}$$

for an arbitrary subset K of labels. We say that vertex $x \in V_1$ covers the 1-entry (u, v) of H_n with multiplicity $m_x(u, v) = a \cdot b$, if u occurs in $\text{fanin}^*(x)$ with multiplicity a and v occurs in $\text{fanout}^*(x)$ with multiplicity b . Finally we say that (u, v) is covered with **multiplicity** $m(u, v) = \sum_{x \in V_1} m_x(u, v)$.

For a given set $K \subseteq \{0, 1\}^n$ of labels we define $\mathbf{L}_{n,k}(\mathbf{K})$ as the subset of L_n consisting of all words of length k beginning with a letter in K . Finally let $\mathbf{F}_{n,k}(\mathbf{K})$ be the subgraph of $F_{n,k}$ obtained by removing all edges between q_0 and V_1 with label outside of K . We say that a graph G recognizes $L_{n,k}(K)$, if G is a layered directed acyclic graph with $k + 1$ layers V_0, \dots, V_k . Moreover V_0 and V_k consist of exactly one state each and exactly the words from $L_{n,k}(K)$ appear as label sequences of paths starting in V_0 and ending in V_k . Observe that Proposition 2 implies that $F_{n,k}(K)$ recognizes $L_{n,k}(K)$.

Assume that graph G recognizes $L_{n,k}(K)$. We show that G has many edges incident with vertices in V_1 , provided many 1-entries have to be covered often.

Lemma 2. *Let $K \subseteq \{0, 1\}^n$ be an arbitrary subset of at least 2^{n-1} labels. Assume that the graph G recognizes $L_{n,k}(K)$ and that*

$$\sum_{x \in V_1} |\text{fanin}^*(x)| = a_1 \cdot 2^n \quad \text{and} \quad \sum_{x \in V_1} |\text{fanout}^*(x)| = a_2 \cdot 2^n$$

holds for layer V_1 of G . If at least $|K| \cdot 2^{n-2}$ 1-entries from $K \times \{0, 1\}^n$ are covered with multiplicity at least b , then $a_1 \cdot a_2 \geq b \cdot 2^{n-8}$.

Proof. We say that vertex $x \in V_1$ is *large*, if $|\text{fanin}^*(x)| \geq 2^4 \cdot a_1$, and *small* otherwise. Since $\sum_{x \in V_1} |\text{fanin}^*(x)| = a_1 \cdot 2^n$, there are at most 2^{n-4} large vertices. But according to (4) the submatrix $\text{fanin}(x) \times \text{fanout}(x)$ of a vertex $x \in V_1$ covers at most 2^n 1-entries and hence $\text{fanin}^*(x) \times \text{fanout}^*(x)$ also covers at most 2^n 1-entries, since no new 1-entries are introduced. Therefore at most $2^{n-4} \cdot 2^n = 2^{2n-4}$ 1-entries of H_n are covered by large vertices.

By assumption at least $|K| \cdot 2^{n-2} \geq 2^{2n-3}$ 1-entries from $K \times \{0, 1\}^n$ are covered with multiplicity at least b . But then at least $2^{2n-3} - 2^{2n-4} = 2^{2n-4}$ 1-entries from $K \times \{0, 1\}^n$ have to be covered with multiplicity at least b by small vertices only. We have

$$\begin{aligned} b \cdot 2^{2n-4} &\leq \sum_{x \in V_1, x \text{ small}} |\text{fanin}^*(x)| \cdot |\text{fanout}^*(x)| \\ &\leq \sum_{x \in V_1} 2^4 \cdot a_1 \cdot |\text{fanout}^*(x)| = 2^4 \cdot a_1 \cdot a_2 \cdot 2^n \end{aligned}$$

and the claim follows. \square

Observe as a first consequence of Lemma 2 that at least $\sqrt{b/2^8} \cdot 2^{3n/2}$ edges incident with vertices in V_1 are required, if the vertices of V_1 cover at least one fourth of all ones of H_n at least b times. This follows for $K = \{0, 1\}^n$, since $\max\{a_1 \cdot 2^n, a_2 \cdot 2^n\}$, with $a_1 \cdot a_2 \geq b \cdot 2^{n-8}$ is minimized for $a_1 = a_2 = \sqrt{b/2^8} \cdot 2^{n/2}$. Thus at least $\Omega(2^{3n/2})$ edges are required to recognize $L_{n,2}(\{0, 1\}^n)$. We improve this bound for $L_{n,k}(K)$ by repeatedly searching for inputs with low multiplicity.

Lemma 3. *Let $K \subseteq \{0, 1\}^n$ be an arbitrary subset of at least 2^{n-1} labels. Assume that the graph G recognizes $L_{n,k}(K)$ and that*

$$\sum_{x \in V_1} |\text{fanin}^*(x)| = a_1 \cdot 2^n \quad \text{and} \quad \sum_{x \in V_1} |\text{fanout}^*(x)| = a_2 \cdot 2^n$$

holds for layer V_1 of G . Then there is a subset $K' \subseteq \{0, 1\}^n$ of size 2^{n-1} and a graph G' which accepts exactly all words in $L_{n,k-1}(K')$. G' results from G by removing the first layer of G and introducing at most $2^9 \cdot a_1 \cdot a_2$ new edges from the starting state to the new first layer.

Proof. We first observe that less than $|K| \cdot 2^{n-2}$ pairs from $K \times \{0, 1\}^n$ are covered with multiplicity at least $b = a_1 \cdot a_2 / 2^{n-9}$, since otherwise we get $a_1 \cdot a_2 / 2^{n-8} \geq b = a_1 \cdot a_2 / 2^{n-9}$ with Lemma 2.

For every label v select a label $u = u(v)$ such that the multiplicity $m(u, v)$ is minimal among all labels u with $H_n[u, v] = 1$. Observe that $m(u(v), v) \geq b$ holds for less than 2^{n-2} labels $v \in \{0, 1\}^n$, since $m(u(v), v) \geq b$ implies that the $|K|$ pairs $K \times \{v\}$ are covered with multiplicity at least b . Thus we find a set K' of more than $2^n - 2^{n-2} \geq 2^{n-1}$ labels v with $m(u(v), v) \leq b$.

We say that edge e belongs to label v , if e leaves a vertex of layer V_1 and e is traversed by an accepting path for some input with prefix $u(v)v$. We say that e belongs to K' iff e belongs to a label of K' . A label $v \in K'$ appears on at most b accepting paths with prefix $u(v)v$ and hence at most $b \cdot |K'|$ edges belong to K' .

In order to construct G' from G we remove all vertices of layer V_1 and insert an edge (q_0, x) (with label $v \in K'$) from q_0 to a vertex $x \in V_2$ iff there is an accepting path from q_0 to x with prefix $u(v)v$. The number of layers decreases from $k + 1$ to k after insertion of at most $b \cdot |K'| \leq b \cdot 2^n$ edges. The new graph G' recognizes $L_{n,k-1}(K')$. We are done, since $b \cdot 2^n = a_1 a_2 / 2^{n-9} \cdot 2^n = 2^9 \cdot a_1 a_2$. \square

We can now conclude the argument. Let us assume that $F_{n,k}$ has $a_i \cdot 2^n$ edges ending in a vertex of V_i . We apply Lemma 3 and obtain a graph $F_{n,k}^{(1)}$ as well as a subset K_1 of at least 2^{n-1} labels such that $F_{n,k}^{(1)}$ accepts $L_{n,k-1}(K_1)$. We set

$$a_1^{(0)} = a_1 \quad \text{and} \quad a_1^{(i)} = \frac{2^9 \cdot a_1^{(i-1)} \cdot a_{i+1}}{2^n}$$

and instead of $a_1^{(0)} \cdot 2^n$ edges between layers V_0 and V_1 we now have at most $2^9 \cdot a_1^{(0)} \cdot a_2 = a_1^{(1)} \cdot 2^n$ edges between layer zero and the new layer one. We repeat

this procedure i times and obtain a graph $F_{n,k}^{(i)}$ as well as a set K_i of 2^{n-1} labels such that $F_{n,k}^{(i)}$ recognizes $L_{n,k-i}(K_i)$ with at most $\frac{2^9 \cdot a_1^{(-1)} \cdot a_{+1}}{2} \cdot 2^n = a_1^{(i)} \cdot 2^n$ edges between layer zero and the new layer one. Hence we obtain

$$a_1^{(k-2)} = \frac{2^9 \cdot a_1^{(k-3)} \cdot a_{k-1}}{2^n} = \dots = \frac{2^{9(k-2)} \cdot a_1 \dots a_{k-1}}{2^{(k-2) \cdot n}}.$$

We apply Lemma 2 to $G = F_{n,k}^{(k-1)}$ (with $b = 1$) and obtain

$$\frac{2^{9(k-2)} \cdot a_1 \dots a_k}{2^{(k-2) \cdot n}} = a_1^{(k-2)} \cdot a_k \geq 2^{n-8}.$$

Thus $a_1 \dots a_k \geq 2^{(k-1) \cdot n} / (2^8 \cdot 2^{9(k-2)}) \geq 2^{(k-1) \cdot n} / 2^{9(k-1)}$ and we have to solve the optimization problem

$$\text{minimize } \max\{a_1 \cdot 2^n, \dots, a_k \cdot 2^n\} \text{ subject to } a_1 \dots a_k \geq 2^{(k-1) \cdot n} / 2^{9(k-1)}.$$

The optimal solution is obtained for $a_1 = \dots = a_k$ and hence we obtain

$$\max\{a_1 \cdot 2^n, \dots, a_k \cdot 2^n\} \geq 2^{n + \frac{-1}{k} \cdot n} / 2^{9(k-1)/k} \geq 2^{2n - \dots} / 2^9.$$

Theorem 1 follows, if we set $k = n$. Observe that we have also shown that the construction in Lemma 1 is almost optimal. □

4 Small Alphabets

We apply our approach for large alphabets to small alphabets and first show an upper bound. In Section 4.1 we investigate a family of languages over $\{0, 1\}$ which is hard for ϵ -free NFAs. The argument concludes in Section 4.2.

The regular language $L_{n,2}$ can be recognized by an NFA whose transition diagram consists of a layered acyclic graph with 2^n sources, 2^n sinks and $O(n)$ layers. Sources and sinks have to be expanded into edges labelled by letters from the alphabet $\{0, 1\}^n$. What happens, if we work with the binary alphabet instead and expand sources and sinks into 0-1 labelled paths of length n ? We call the corresponding class of NFAs “ n -bipartite” NFAs.

Definition 1. *An NFA N is called n -bipartite iff its transition diagram G is a layered acyclic graph with 2^n sources and 2^n sinks. Each source (resp. sink) is starting point (resp. endpoint) of its own 0-1 labelled path of length n ; the paths are node-disjoint. The endpoints of source paths and the starting points of sink paths are connected by n layers of 2^n vertices each. (The endpoints of source paths define layer one and the starting points of sink paths define layer n .) All edges between two layers are ϵ -transitions. The 2^n sources are the only initial states and the 2^n sinks are the only accepting states.*

The advantage of ϵ -transition decreases for the binary alphabet in comparison to large alphabets as the following observation shows.

Lemma 4. *If N is an n -bipartite NFA whose transition diagram has bounded fan-out, then there is an equivalent ε -free NFA with at most $2^{O(\sqrt{n})} \cdot 2^n$ transitions. (Observe that N has at most $O(n \cdot 2^n)$ transitions.)*

We omit the proof due to space limitations. Observe that we do not obtain asymptotically larger bounds, if arbitrary sequences of n -bit strings, as in the language L_n , have to be accepted: it suffices to provide transitions from a sink path back to the corresponding source path.

4.1 A Family of Hard Languages

We now introduce languages which turn out to be hard for ε -free NFAs.

Definition 2. *Let $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$ be given. Then we define*

$$L_n(f) = \{u_1u_2 \mid u_1, u_2 \in \{0, 1\}^n, H_n[f(u_1), f(u_2)] = 1\}$$

as a language over the binary alphabet.

Observe that $L_n(f)$ can be recognized by an NFA with at most $O(n \cdot 2^n)$ transitions, if we proceed as in the proof of Proposition 1. Our goal is to show that $L_n(f)$ requires ε -free NFAs with $2^{n+\Omega(\sqrt{n})}$ transitions, provided f is chosen at random. We fix a function f and investigate an ε -free NFA $A_n(f)$ for $L_n(f)$. We unravel the transition diagram of $A_n(f)$ to obtain a layered acyclic graph $F_n(f)$ such that $F_n(f)$ has $2n + 1$ layers and $O(n \cdot t(f))$ transitions, where $t(f)$ is the number of transitions of $A_n(f)$. Moreover $F_n(f)$ has a path with label sequence $u_1u_2 \in \{0, 1\}^{2n}$ iff $u_1u_2 \in L_n(f)$ and all edges of $F_n(f)$ are traversed by paths of length $2n$.

Let V_i be the set of vertices of $F_n(f)$ in layer i . For a vertex $u \in \bigcup_{i=0}^n V_i$ we define $\text{fanin}'(u)$ as the set of label sequences of paths starting in the source of $F_n(f)$ and ending in u . The set $\text{fanout}'(u)$ consists of all label sequences of paths starting in u and ending in a vertex of V_n . We now make the crucial observation that, for f chosen at random, $\text{fanin}'(u)$ can only be large, if $\text{fanout}'(u)$ is small.

Proposition 3. *For sufficiently large n there is a function f such that*

- (a) $|f^{-1}(y)| \leq 2 \cdot \sqrt{n}$ for all $y \in \{0, 1\}^n$.
- (b) For any $l \leq n$, any $w \in \{0, 1\}^l$ and any subspace V of \mathbb{Z}_2^n with $\dim(V) \geq l$,

$$|f(\{0, 1\}^{n-l}w) \cap V| \leq 2n \cdot \frac{|V|}{2^l}.$$

- (c) $|\text{fanin}'(u)| \leq 7 \cdot n$ or $|\text{fanout}'(u)| \leq 5 \cdot n$ for any vertex $u \in \bigcup_{i=0}^n V_i$, provided $F_n(f)$ has at most 2^{2n} vertices.

Proof. It suffices to show that any property (a), (b) or (c) does not hold with probability at most $\frac{1}{4}$, provided n is sufficiently large.

(a) We interpret a function f as the result of 2^n independent random trials x fixing the value $f(x)$. For any $x, y \in \{0, 1\}^n$ we have $f(x) = y$ with probability 2^{-n} and hence the expected size of $f^{-1}(y)$ is one. We apply the Chernoff inequality and obtain

$$\text{prob}[|f^{-1}(y)| > 1 + \beta] \leq e^{-\beta^2/3}.$$

Hence size $2 \cdot \sqrt{n}$ is exceeded with probability bounded by $e^{-(2\sqrt{n}-1)^2/3} \leq 2^{-n-2}$ for large n and, with probability at most $\frac{1}{4}$, $|f^{-1}(y)| \geq 2 \cdot \sqrt{n}$ for some y .

(b) We fix l and $w \in \{0, 1\}^l$ and again interpret f , restricted to $\text{Suffix}(w) = \{0, 1\}^{n-l}w$, as the result of 2^{n-l} random trials. $f(y) \in V$ happens with probability $p = \frac{|V|}{2}$ and hence the expected size of $f(\text{Suffix}(w)) \cap V$ is $2^{n-l} \cdot p = \frac{|V|}{2}$. We again apply the Chernoff inequality and obtain

$$\text{prob}[|f(\text{Suffix}(w)) \cap V| > (1 + \beta) \cdot \frac{|V|}{2}] \leq e^{-\beta^2 \cdot |V|/(3 \cdot 2)} \leq e^{-\beta^2/3}.$$

There are at most $n \cdot 2^n$ ways to fix l and w and there are at most 2^{n^2} subspaces V . We set $\beta = 2 \cdot n - 1$ and property (b) fails with probability at most $n \cdot 2^{n+n^2} \cdot e^{-(2n-1)^2/3} < 1/4$ for sufficiently large n .

(c) Assume that $|\text{fanin}'(u)| = s$ and $|\text{fanout}'(u)| = t$. Hence $s \cdot t$ label sequences $x^i y^j$ ($1 \leq i \leq s$, $1 \leq j \leq t$) have paths travelling through u and ending in vertices of V_n . The f -values of those label sequences, which end in the same vertex of V_n , induce a space of dimension at most $n - 1$. Thus there are vectors $z^1, \dots, z^t \in \{0, 1\}^n$ with the restriction $\langle f(x^i y^j), z^j \rangle = 0$. We fix x^i, y^j, z^j for all i, j and the $s \cdot t$ restrictions hold with probability at most $2^{-s \cdot t}$.

There are at most $2^{n \cdot s} \cdot 2^{2n \cdot t} = 2^{n(s+2t)}$ ways to fix the $s \cdot t$ vectors. But $2^{n(s+2t)} < 2^{s \cdot t - 2n}/4$, provided $s \geq 7 \cdot n$ and $t \geq 5 \cdot n$. (If $s \geq 2t$, then $n \cdot (s+2t) \leq n \cdot 2s \leq s \cdot t - 2n - 2$. If $s < 2t$, then $n \cdot (s+2t) < n \cdot 4t \leq s \cdot t - 2n - 2$.) Thus *some* vertex u with too large fanin' and fanout' sets exists with probability at most $\frac{1}{4}$. \square

4.2 The Lower Bound

We fix a function f as guaranteed by Proposition 3 and have to show that the ε -free NFA $F_n(f)$ is large. Let $l = c \cdot \sqrt{n}$, where $c < 1/2$ is arbitrary, and define the set

$$X = \{u \mid u \in V_{n-l} \text{ and } |\text{fanin}'(u)| \geq 2\sqrt{n}\}$$

of high fanin vertices. We say that string $s \in \{0, 1\}^{2n}$ *hits* vertex u of $F_n(f)$ iff there is an accepting path with label sequence s which traverses u . If sufficiently many strings hit vertices in X , then we show in Lemma 5 that V_{n-l} has to contain many high fanin vertices and we are done. Thus we may assume that only “low fanin ” vertices in V_{n-l} “count”. But then Lemma 6 shows that the fanin' sets increase only gradually in size between layers V_{n-l} and V_n , if we disregard a few “exceptional” vertices. Since the situation is similar for “high fanout ” vertices in V_{n+l} , the argument concludes with Lemma 7, which shows

that the overall fanin or the overall fanout of vertices in V_n has to be large. We begin by showing that X has to be large, if X is hit by many strings.

Lemma 5. *Let $\alpha > 0$ be arbitrary. If at least $\alpha \cdot 2^{2n}$ strings hit vertices in X , then $|X| \geq \alpha \cdot \frac{2}{10n^2}$.*

Proof. Remember $l = c \cdot \sqrt{n}$. For $w \in \{0, 1\}^l$ let $X(w)$ be the set of vertices in X which are hit by at least $2\sqrt{n}$ strings from $\{0, 1\}^{n-l} \cdot w \cdot \{0, 1\}^n$. We pick an arbitrary vertex $u \in X(w)$ which is hit by t strings $\alpha_1 w \beta_1, \dots, \alpha_t w \beta_t$. We define $V_u(w)$ as the vector space spanned by $f(\alpha_1 w), \dots, f(\alpha_t w)$ and observe that $V_u(w)$ has dimension at least $\sqrt{n} \geq l$. Hence we may apply Proposition 3(b) and obtain that $t \leq |f(\{0, 1\}^{n-l} w) \cap V_u(w)| \leq 2n \cdot \frac{|V(w)|}{2}$.

But then vertex u hits at most $2n \cdot \frac{|V(w)|}{2} \cdot \frac{2}{|V(w)|} = 2n \cdot 2^{n-l}$ strings from $\{0, 1\}^{n-l} \cdot w \cdot \{0, 1\}^n$, since all n -bit suffices belong to the orthogonal space $V_u(w)^\perp$. If $x(w)$ is the number of strings from $\{0, 1\}^{n-l} \cdot w \cdot \{0, 1\}^n$ hitting X , then $X(w)$ has to consist of at least $\frac{x(w)}{2n \cdot 2^{n-l}}$ vertices. We observe as a consequence of Proposition 3(c) that a vertex $u \in X$ satisfies $|\text{fanout}'(u)| \leq 5n$ and hence u appears in at most $5n$ sets $X(w)$. But $\sum_w x(w) \geq \alpha \cdot 2^{2n}$ by assumption and therefore

$$|X| \geq \sum_w \frac{|X_w|}{5n} \geq \sum_w \frac{1}{5n} \cdot \frac{x(w)}{2n \cdot 2^{n-l}} \geq \sum_w \frac{x_w}{10n^2 \cdot 2^{n-l}} \geq \alpha \frac{2^{2n}}{10n^2 \cdot 2^{n-l}} = \alpha \frac{2^{n+l}}{10n^2}.$$

The claim follows. □

The same result holds if we consider vertices u of depth $n + c \cdot \sqrt{n}$. In particular, if $l = c \cdot \sqrt{n}$, then define $\text{fanin}''(u)$ (resp. $\text{fanout}''(u)$) as the set of all l -bit (resp. $n - l$ -bit) label sequences of paths from a vertex in V_n to u (resp. of paths from u to the sink of $F_n(f)$). We consider the set $X' = \{u \mid u \in V_{n+l} \text{ and } |\text{fanout}''(u)| \geq 2\sqrt{n}\}$ and obtain $|X'| \geq \alpha \cdot \frac{2}{10n^2}$, provided at least $\alpha \cdot 2^{2n}$ strings hit vertices in X' . Since our goal is to show that ε -free NFAs have size $2^{n+\Omega(l)}$, we only have to deal with the situation that vertices in X as well as X' are hit by too few strings.

We remove X and X' and observe that only accepting paths for a set S of at most $2\alpha \cdot 2^{2n}$ different label sequences are lost. But now all vertices $u \in V_{n-c\sqrt{n}}$ and $v \in V_{n+c\sqrt{n}}$ have small fanin (i.e., $|\text{fanin}'(u)| \leq 2\sqrt{n}$) and small fanout (i.e., $|\text{fanout}'(v)| \leq 2\sqrt{n}$) respectively. If $F_n(f)$ has few edges, then we show next that fanins increase only gradually in the intermediate $c \cdot \sqrt{n}$ layers. The situation for fanouts is analogous. Let $t_0 = n - c \cdot \sqrt{n}, t_1 = n + c \cdot \sqrt{n}$ and set $\alpha = 1/16$.

Lemma 6. *Remove X and X' . If $|\text{fanin}'(u)| \leq 2\sqrt{n}$ for all $u \in V_{t_0}$ and $|\text{fanout}''(u)| \leq 2\sqrt{n}$ for all $u \in V_{t_1}$ and if $F_n(f)$ has at most $2^{n+\sqrt{n}}/(320 \cdot n^2)$ edges, then there is a subset $V_n^* \subseteq V_n$ of vertices v with $|\text{fanin}'(v)|, |\text{fanout}''(v)| \leq 2\sqrt{n+c\sqrt{n}}$ which is hit by at least $2^{2n}/4$ strings.*

Proof. For $t_0 \leq t < n$ let e_t be the number of edges between vertices in V_t and V_{t+1} . For the parameter β to be fixed later, we call a vertex $u \in V_{t+1}$ *fat*, if it

receives more than $\beta \cdot e_t / 2^n$ edges and if $|\text{fanin}'(u)| > 7n$. Observe that there is a total of at most $c\sqrt{n} \cdot \frac{2}{\beta}$ fat vertices in V_t for $t_0 \leq t < n$.

We claim that not too many strings hit fat vertices u . To see why, we first observe $|\text{fanout}'(u)| \leq 5n$. Hence there are at most $5n$ vector spaces $V_1 \times V_1^\perp, \dots, V_{5n} \times V_{5n}^\perp$ such that $(f(x), f(y))$ belongs to one of the spaces for any string xy that hits u . Thus, with Proposition 3(a) at most $5n \cdot (2\sqrt{n})^2 \cdot 2^n = 20n^2 \cdot 2^n$ strings hit u and at most $(c\sqrt{n} \cdot \frac{2}{\beta}) \cdot (20n^2 \cdot 2^n) = 20c \cdot n^{2.5} \cdot \frac{2^2}{\beta}$ strings hit fat vertices. Set $\beta = 320c \cdot n^{2.5}$.

We remove all fat vertices and destroy accepting paths for at most $2^{2n}/16$ strings. An inductive argument shows that $|\text{fanin}'(u)| \leq 2\sqrt{n} \cdot \prod_{\tau=t_0}^{t-1} (\beta e_\tau / 2^n)$ for all vertices $u \in V_t$ for $t_0 \leq t < n$. Hence, since $e = \sum_{\tau=t_0}^t e_\tau \leq 2^{n+\sqrt{n}} / (320 \cdot n^2)$ by assumption, all fanin' sets have size bounded by

$$2\sqrt{n} \cdot \left(\beta \cdot \frac{e}{c\sqrt{n} \cdot 2^n} \right)^{c\sqrt{n}} = 2\sqrt{n} \cdot \left(\frac{320 \cdot n^2 \cdot e}{2^n} \right)^{c\sqrt{n}} \leq 2\sqrt{n} \cdot 2^{c \cdot n}.$$

We repeat this procedure, but now utilize the fanout restrictions. We remove (a new set of) fat vertices and lose additionally 2^{2n-4} strings. Counting also the strings lost by removing $X \cup X'$ and observing $\alpha = 1/16$, we have lost at most $2\alpha 2^{2n} + 2 \cdot 2^{2n-4} = 2^{2n-2}$ strings and at least 2^{2n-2} strings are still “alive”. \square

Hence, if $F_n(f)$ is not too large, then one half of all strings hit vertices in V_n with small fanin and small fanout . However we now show that the overall fanin or the overall fanout of V_n^* has to be large.

Lemma 7. *Remove X and X' . Then*

$$\sum_{v \in V^*} |\text{fanin}'(v)| \geq 2^{3n/2} / (16\sqrt{n}) \quad \text{or} \quad \sum_{v \in V^*} |\text{fanout}''(v)| \geq 2^{3n/2} / (16\sqrt{n}).$$

Proof. Remove all vertices in X and X' . According to Lemma 6 the vertices $v \in V_n^*$ define a cover of at least one half of all ones of H_n , if we associate the submatrix $\text{fanin}'(v) \times \text{fanout}''(v)$ with v . We observe, with Proposition 3(a) and inequality (1), that vertex v is hit by at most $(2\sqrt{n})^2 \cdot 2^n = 4n \cdot 2^n$ different strings $u_1 u_2 \in L_n(f)$. Assume that the claim is false and we obtain

$$\sum_{v \in V^*} |\text{fanin}'(v)|, \sum_{v \in V^*} |\text{fanout}''(v)| \leq \frac{2^{3n/2}}{16\sqrt{n}} \quad \text{as well as} \quad (6)$$

$$|\text{fanin}'(v)| \cdot |\text{fanout}''(v)| \leq 4n \cdot 2^n. \quad (7)$$

When maximizing $\sum_{v \in V^*} |\text{fanin}'(v)| \cdot |\text{fanout}''(v)|$ subject to restrictions (6) and (7), it is optimal to choose $|\text{fanin}'(v)| = |\text{fanout}''(v)| = \sqrt{4n \cdot 2^n}$ for all $v \in V_n^*$. But then $|V_n^*| \leq \frac{2^{3/2}}{16\sqrt{n}} \cdot \frac{1}{\sqrt{4n \cdot 2}}$ and hence $\sum_{v \in V^*} |\text{fanin}'(v)| \cdot |\text{fanout}''(v)| \leq \frac{2^{3/2}}{16\sqrt{n}\sqrt{4n2}} \cdot (4n2^n) = 2^{2n-3}$, but H has at least 2^{2n-2} 1-entries. \square

Proof of Theorem 1 (iv). If X or X' is hit by sufficiently many strings, then, according to Lemma 5, $F_n(f)$ consists of at least $\alpha \cdot \frac{2^+}{10n^2} = \Omega(\frac{2^+}{n^2})$ vertices, where $l = c \cdot \sqrt{n}$. Otherwise we have to differentiate two cases. Firstly $F_n(f)$ has at least $2^{n+\sqrt{n}}/(320 \cdot n^2) = \Omega(2^{n+\sqrt{n}}/n^2)$ edges. Secondly $F_n(f)$ has fewer edges and we may apply Lemma 6: we obtain a subset $V_n^* \subseteq V_n$ of vertices with individual fanin and fanout bounded by $2^{\sqrt{n}+c \cdot n}$ such that V_n^* is hit by at least $2^{2n}/4$ edges. But then Lemma 7 requires an overall fanin or an overall fanout of at least $\Omega(2^{3n/2}/\sqrt{n})$ and hence $\Omega(2^{3n/2}/(\sqrt{n} \cdot 2^{\sqrt{n}+c \cdot n})) = \Omega(2^{(3/2-c)n}/(\sqrt{n} \cdot 2^{\sqrt{n}}))$ vertices are required. For any constant $c < 1/2$ the graph $F_n(f)$ has size at least $\Omega(2^{n+c \cdot \sqrt{n}}/n^2)$ and we may drop the factor $1/n^2$ by increasing c slightly. □

5 Conclusions and Open Problems

We have shown an almost quadratic gap between the descriptive complexity of NFAs and ε -free NFAs. Our approach is based on communication complexity: “inner” vertices of an NFA recognizing $\{xy \mid x, y \in \{0, 1\}^n, (x, y) \in L\}$ define a cover of the communication matrix of L . Additional graph-theoretic arguments are required for large as well as for small alphabets to obtain a separation of NFA and ε -free NFA.

Whereas Theorem 1 shows for large alphabets that the obvious transformation from NFAs to ε -free NFAs cannot be improved significantly, considerable improvements for small alphabets are not ruled out. Observe however that improvements of our lower bound require new ideas, since our analysis of “bipartite NFAs” is close to optimal according to Lemma 4.

Abstract. We prove that two automata with multiplicity in \mathbb{Z} are equivalent, *i.e.* define the same rational series, if and only if there is a sequence of \mathbb{Z} -coverings, co- \mathbb{Z} -coverings, and circulations of -1 , which transforms one automaton into the other. Moreover, the construction of these transformations is effective.

This is obtained by combining two results: the first one relates coverings to conjugacy of automata, and is modeled after a theorem from symbolic dynamics; the second one is an adaptation of Schützenberger’s reduction algorithm of representations in a field to representations in an Euclidean domain (and thus in \mathbb{Z}).

1 Introduction

Equivalence of \mathbb{Z} -automata is decidable with polynomial (cubic) complexity. This is not a new result: it is more than forty years old. We investigate it again in order to give more *structural information* on two equivalent \mathbb{Z} -automata. A first and simple example should make clear what we mean by that before we state the precise results we are aiming at.

An Example. Let us consider the two \mathbb{Z} -automata \mathcal{A}_1 and \mathcal{B}_1 of Figure 1. They are equivalent.¹ This can be proved by checking that series $|\mathcal{A}_1|$ and $|\mathcal{B}_1|$ have the same coefficients on every word of $\{a, b\}^*$ up to length 8 — which would be the algorithm derived from the *Equality Theorem* — or by verifying that the *reduced representation* of the series $|\mathcal{A}_1| - |\mathcal{B}_1|$ has dimension 0.

We aim here at the construction of the two \mathbb{Z} -automata \mathcal{C}_1 and \mathcal{D}_1 of Figure 2. They are equivalent as one is obtained from the other by multiplying by -1 the coefficients of both the incoming and outgoing transitions around the state 1. The automata \mathcal{C}_1 and \mathcal{A}_1 are equivalent as \mathcal{A}_1 is obtained from \mathcal{C}_1 by merging the states 1 and 3 on one hand, the states 2 and 4 on the other hand, as these merged states have *the same incoming transitions* and as the outgoing transitions are added. The automata \mathcal{D}_1 and \mathcal{B}_1 are equivalent as \mathcal{B}_1 is obtained from \mathcal{D}_1 by

¹ This equivalence expresses a “shuffle identity”: $(ab)^* \check{\vee} (-ab)^* = (-4a^2b^2)^*$ that was mentioned to us by M. Waldschmidt (personnal communication).

Fig. 1. Two equivalent \mathbb{Z} -automata

Fig. 2. Two other equivalent \mathbb{Z} -automata

merging the states 1 and 2 on one hand, the states 3 and 4 on the other hand, as these merged states have *the same outgoing transitions* and as the incoming transitions are added.

Equivalence of \mathcal{A}_1 and \mathcal{B}_1 boils down to the obvious three equivalences: \mathcal{A}_1 and \mathcal{C}_1 , \mathcal{C}_1 and \mathcal{D}_1 , and \mathcal{D}_1 and \mathcal{B}_1 . The general case will not be that simple, but will nevertheless follow the same scheme.

The General Framework and Our Results. Finite automata with multiplicity in \mathbb{Z} — with multiplicity in \mathbb{Q} or in a commutative field \mathbb{F} as well — were introduced as soon as 1961 by M.P. Schützenberger in a paper entitled: *On the definition of a family of automata* [17]. At that time, the emphasis was put on the investigation of new models of computation that allow the definition of *new families of languages* inside or outside Chomsky’s hierarchy. The \mathbb{Z} -automata define one of the latter by way of the support of the series they realize. But Schützenberger’s seminal paper also generalizes the theory of *rational formal power series* from one variable to several non commuting variables. Among other things, the existence of reduced \mathbb{F} -automata that realize a given \mathbb{F} -rational series, and the similarity between two equivalent reduced \mathbb{F} -automata is shown there. An algorithm is given — more or less explicitly — that computes a reduced \mathbb{F} -automaton. The decidability of the equivalence of \mathbb{Z} -automata is a direct consequence of the latter.

In [6] Eilenberg stated the *Equality Theorem* but disregarded the notion of reduced representation although the complexity of the corresponding equivalence algorithms blows up from polynomial to exponential without the latter. In other books on automata with multiplicity ([15, 10]) the equivalence of \mathbb{Z} -automata is reduced to the one of rational series over one variable. Schützenberger’s reduction

algorithm was made explicit in [5]² and above all in [3]. The generalization to skew fields of coefficients is straightforward (as was noted for instance in [8]). The importance of the decidability of the equivalence of automata with multiplicity in a (sub-semiring of a) skew field appears clearly with its role in the proof of the decidability of the equivalence of deterministic k -tape transducers [9].

Our contribution to this now well-established chapter of automata theory is based on two notions: *covering* and *conjugacy* of automata and develops in two directions: the generalization and reinterpretation of the *Finite Equivalence Theorem* of symbolic dynamics for \mathbb{Z} -automata on one hand and of the reduction algorithm for automata with multiplicity in an Euclidean domain on the other hand. The two results are combined in our last theorem (Theorem 4) that expresses the equivalence of two \mathbb{Z} -automata as a sequence of six coverings and a conjugacy of a special kind, all effectively computable.

Coverings, Conjugacy and the Conjugacy Theorems. A *finite* automaton \mathcal{A} over an alphabet A with multiplicity in a semiring \mathbb{K} , or \mathbb{K} -automaton for short, can be written in a compact way as $\mathcal{A} = \langle I, E, T \rangle$ where E is a square matrix of finite dimension Q whose entries are linear combinations of letters (with coefficients in \mathbb{K}) and where I and T are two vectors — respectively row vector and column vector — with entries in \mathbb{K} as well. We can view each entry $E_{p,q}$ as the label of a unique arc which goes from state p to state q in the graph whose set of vertices is Q (if $E_{p,q} = 0_{\mathbb{K}}$, we consider that there is *no* arc from p and q).

The *behaviour* of \mathcal{A} , denoted $|\mathcal{A}|$, is the series such that the coefficient of a word w is the coefficient of w in $I \cdot E^{|w|} \cdot T$. It is part of Kleene-Schützenberger Theorem that every \mathbb{K} -rational series is the behaviour of a \mathbb{K} -automaton of the form we have just defined. For missing definitions, we refer to [6, 3, 14].

\mathbb{K} -coverings and co- \mathbb{K} -coverings are generalizations of morphisms of classical (Boolean) automata to \mathbb{K} -automata; the precise definition will be given and discussed in Section 2 but typically a *\mathbb{K} -covering* is the map that sends the above automaton \mathcal{D}_1 onto \mathcal{B}_1 and a *co- \mathbb{K} -covering* is the map that sends \mathcal{C}_1 onto \mathcal{A}_1 . The second notion, the conjugacy of (\mathbb{K} -)automata, comes from symbolic dynamics (we follow [12]) and can be described as follow.

Definition 1. An automaton $\mathcal{A} = \langle I, E, T \rangle$ is conjugate to an automaton $\mathcal{B} = \langle J, F, U \rangle$ if there exists a matrix X with entries in \mathbb{K} such that

$$IX = J, \quad EX = XF, \quad \text{and} \quad T = XU.$$

The matrix X is the transfer matrix of the conjugacy and we write $\mathcal{A} \xrightarrow{X} \mathcal{B}$.

Obviously two conjugate automata are equivalent (*i.e.* have the same behaviour). Remark that in spite of the idea conveyed by the terminology, the conjugacy relation³ is *not an equivalence* but a *preorder* relation. Suppose that

² If a paper written in French is not considered to be cryptic.

³ A conjugacy of automata was called a *backward elementary equivalence* in [2]. The transfer matrix X is called a *simulation* from \mathcal{A} to \mathcal{B} in [4].

$\mathcal{A} \xrightarrow{X} \mathcal{B}$ holds; if $\mathcal{B} \xrightarrow{Y} \mathcal{C}$ then $\mathcal{A} \xrightarrow{XY} \mathcal{C}$, but if $\mathcal{C} \xrightarrow{Y} \mathcal{B}$ then \mathcal{A} is not necessarily conjugate to \mathcal{C} , we write $\mathcal{A} \xrightarrow{X} \mathcal{B} \xleftarrow{Y} \mathcal{C}$ and we refer to this situation as “a chain of two (convergent) conjugacies”.

We shall see that \mathbb{K} -coverings are realized by conjugacy with special transfer matrices. The following theorems express a kind of converse. (A matrix is *non degenerate* if it contains no zero row nor zero column.)

Theorem 1. *Let \mathcal{A} and \mathcal{B} be two \mathbb{Z} -automata. We have $\mathcal{A} \xrightarrow{X} \mathcal{B}$ with a non-negative and nondegenerate transfer matrix X if and only if there exists a \mathbb{Z} -automaton \mathcal{C} that is a co- \mathbb{Z} -covering of \mathcal{A} and a \mathbb{Z} -covering of \mathcal{B} .*

One of the reasons that make Theorem 1 interesting in our opinion is the relationship it bears with the Finite Equivalence Theorem of symbolic dynamics and we develop this point at Section 2.3. In order to state the results under the most general form in the sequel, let us write \mathbb{H} for a ring that is either \mathbb{Z} or a division ring⁴. By the following, we free ourselves from the two hypotheses on the transfer matrix (we call *circulation matrix* a diagonal invertible matrix).

Theorem 2. *Let \mathcal{A} and \mathcal{B} be two \mathbb{H} -automata. We have $\mathcal{A} \xrightarrow{X} \mathcal{B}$ if and only if there exists two \mathbb{H} -automata \mathcal{C} and \mathcal{D} and a circulation matrix D such that \mathcal{C} is a co- \mathbb{H} -covering of \mathcal{A} , \mathcal{D} and a \mathbb{H} -covering of \mathcal{B} and $\mathcal{C} \xrightarrow{D} \mathcal{D}$.*

This theorem describes precisely the situation in our first example: \mathcal{A}_1 is conjugate to \mathcal{B}_1 with the transfer matrix X_1 shown opposite.

$$X_1 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

Equivalence, Conjugacy and the Reduction Theorems. Our second contribution consists in establishing a kind of converse to the equivalence of conjugate \mathbb{K} -automata in two important cases: skew fields and Euclidean domains⁵.

Theorem 3. *Let \mathbb{L} be a skew field, or an Euclidean domain. If \mathcal{A} and \mathcal{B} are two equivalent \mathbb{L} -automata, then there exist two \mathbb{L} -automata \mathcal{C} and \mathcal{D} and three \mathbb{L} -matrices X, Y and Z such that:*

$$\mathcal{A} \xrightarrow{X} \mathcal{C} \xleftarrow{Y} \mathcal{D} \xrightarrow{Z} \mathcal{B}. \tag{1}$$

The alternative hypotheses correspond indeed to two different results, and two distinct proofs.

If \mathbb{L} is a skew field, the proof is based on Schützenberger’s algorithm that computes a reduced representation (*i.e.* an automaton with a minimal number of states) for a given \mathbb{L} -rational series. This algorithm may be interpreted as the effective computation of the transfer matrices of a chain of two (divergent

⁴ *i.e.* a skew field. In Section 2.2, we take even more general hypotheses.

⁵ An Euclidean domain is a principal *commutative* ring with no divisors of zero and where the gcd of any two elements is effectively computable.

Fig. 3. The decomposition of the equivalence between \mathbb{H} -automata

or convergent) conjugacies. As the same algorithm implies that two minimal \mathbb{L} -automata are similar⁶, Equation 1 holds, with the supplementary condition that the \mathbb{L} -automata \mathcal{C} and \mathcal{D} are minimal.

In the case where \mathbb{L} is an Euclidean domain (\mathbb{Z} for instance), we prove that the above reduction algorithm can be transformed in such a way that it still computes a reduced \mathbb{L} -representation. As far as we know, this is the first reduction algorithm for automata with multiplicity in such rings. Another step of proof is then necessary to establish Theorem 3 in this case, for minimal automata are not necessarily conjugate anymore.

Combining Theorem 2 and Theorem 3 together with some further properties of coverings yields the final result of this paper, illustrated in Figure 3 [as we shall see below, coverings and co-coverings are special cases of conjugacy, which we represent with simple arrows, solid for coverings, dashed for co-coverings; a dotted simple arrow represents conjugacy with a circulation matrix].

Theorem 4. *Two \mathbb{H} -automata \mathcal{A} and \mathcal{B} are equivalent if and only if there exist two \mathbb{H} -automata \mathcal{C} and \mathcal{D} such that there is a sequence of three \mathbb{H} -coverings and co- \mathbb{H} -coverings from \mathcal{C} onto \mathcal{A} on one hand and from \mathcal{D} onto \mathcal{B} on the other hand, and a conjugacy by a circulation matrix between \mathcal{C} and \mathcal{D} .*

2 The Conjugacy Theorems

The two main ingredients in Theorem 2 are the notion of coverings and the property of *equisubtractivity* in a semiring, which albeit simple will be crucial for the proof.

2.1 \mathbb{K} -Coverings and Co- \mathbb{K} -coverings

The standard notion of morphisms of automata is not well-suited to automata with multiplicity in that it does not capture some similarities between these automata that we would like to be able to describe. Hence the definitions we take now. For the rest of the section, $\mathcal{A} = \langle I, E, T \rangle$ is a \mathbb{K} -automaton of dimension Q .

An equivalence φ on Q or, which is the same, a surjective map $\varphi: Q \rightarrow R$ is *Out-licit* (understood, *with respect to \mathcal{A}*) if for any two equivalent states p and p' modulo φ the *sum* of the labels of the transitions that go from p to *all the states of a whole class* modulo φ is equal to the *sum* of the labels of the transitions that go from p' to the same states *and* if any two entries of T indexed by equivalent states modulo φ are equal.⁷ We denote by $[q]_\varphi$ the class of q modulo φ .

⁶ *i.e.* conjugate with a transfer matrix which is invertible.

⁷ This definition bears some resemblance with the one of block-stochastic matrix, as given in [10, Ex. 4.5]

Definition 2 ([14]). *A surjective map $\varphi: Q \rightarrow R$ is Out-licit with respect to \mathcal{A} if the following holds:*

$$\forall p, p', q \in Q \quad p \equiv p' \pmod{\varphi} \implies \begin{cases} \text{(i)} & \sum_{r \in [q]} E_{p,r} = \sum_{s \in [q]} E_{p',s} \\ \text{(ii)} & T_p = T_{p'} \end{cases} \quad (2)$$

If $\varphi: Q \rightarrow R$ is Out-licit, the \mathbb{K} -quotient of \mathcal{A} by φ is the automaton $\mathcal{B} = \langle J, F, U \rangle$ of dimension R , defined by the following:

$$\begin{aligned} \forall (r, s) \in R^2, \quad \forall p \in \varphi^{-1}(r), \\ J_s = \sum_{q \in \varphi^{-1}(s)} I_q, \quad F_{r,s} = \sum_{q \in \varphi^{-1}(s)} E_{p,q}, \quad U_r = T_p. \end{aligned} \quad (3)$$

The automaton \mathcal{B} is called a \mathbb{K} -quotient of \mathcal{A} and, conversely, \mathcal{A} is called a \mathbb{K} -covering of \mathcal{B} . We write also $\varphi: \mathcal{A} \rightarrow \mathcal{B}$ and call it, by way of metonymy, a \mathbb{K} -covering from \mathcal{A} onto \mathcal{B} .⁸

If $\varphi: Q \rightarrow R$ is a map, the above condition and construction may be elegantly described by means of the $Q \times R$ -matrix H_φ naturally associated with φ : its (q, r) entry is 1 if $\varphi(q) = r$, 0 otherwise. Since φ is a map, each row of H_φ contains exactly one 1 and since φ is surjective, each column of H_φ contains at least one 1. We call H_φ the amalgamation matrix⁹ associated with φ . The following expresses that a quotient is a conjugate.

Proposition 1. *There is a \mathbb{K} -covering φ from \mathcal{A} onto \mathcal{B} if and only if there exists an amalgamation matrix X such that $\mathcal{A} \xrightarrow{X} \mathcal{B}$ (and in this case $X = H_\varphi$).*

The notion of \mathbb{K} -quotient is lateralized in that it refers not to the transitions of the automaton but to the outgoing transitions from the states of the automaton. Somehow, it is the price we pay for extending the notion of morphism of automata. Therefore the dual notions of In-licit map, co- \mathbb{K} -quotient and co- \mathbb{K} -covering are defined in a natural way and we have:

Proposition 2. *There is a co- \mathbb{K} -covering ψ from \mathcal{A} onto \mathcal{B} if and only if there exists an amalgamation matrix X such that $\mathcal{A} \xrightarrow{X} \mathcal{B}$ (and in this case $X = H_\psi$).*

It follows that every \mathbb{K} -automaton is equivalent to any of its \mathbb{K} -quotients or co- \mathbb{K} -quotients. Clearly, if $\varphi: Q \rightarrow R$ and $\psi: R \rightarrow S$ are surjective maps, then $H_{\varphi\psi} = H_\varphi H_\psi$. Hence \mathbb{K} -coverings (resp. co- \mathbb{K} -coverings) are closed under composition.

⁸ Definition 2 has probably been stated independently a number of times. We relied on [14] where both the definition and its matrix expression are given. It was used in full generality in [13]. If $\mathbb{K} = \mathbb{B}$, the Boolean semiring, a \mathbb{B} -quotient is a simulation in the sense of [1].

⁹ This is the terminology proposed in [12, Def. 8.2.4].

2.2 Decomposition of Conjugacy

The proof of Theorem 2 involves indeed two properties.

We call *equisubtractive* a semiring is in which for all p, q, r and s such that $p+q = r+s$ there exist x, y, z and t such that $p = x+y, q = z+t, r = x+z$ and $s = y+t$. The semiring \mathbb{N} and all rings are equisubtractive, and if \mathbb{K} is equisubtractive, then so are $\mathbb{K}\langle A^* \rangle$ and $\mathbb{K}\langle\langle A^* \rangle\rangle$.

We say that a semiring has property (P) if *every element is a sum of units*. The ring \mathbb{Z} and all fields have property (P). In any semiring with (P), every matrix X can be written as $X = CDR$ where C is an amalgamation, R a co-amalgamation and D a circulation matrix. In \mathbb{Z} , the dimension of D will be the sum of the absolute value of the entries of X .

Theorem 2 indeed holds for equisubtractive semiring \mathbb{K} with (P). Its proof will be sketched with the following example.

Example 2. Let $\mathcal{A}_2 = \langle I_2, E_2, T_2 \rangle$ and $\mathcal{B}_2 = \langle J_2, F_2, U_2 \rangle$ be the two \mathbb{Z} -automata defined by:

$$I_2 = \begin{pmatrix} 1 & 1 & 0 \end{pmatrix}, \quad E_2 = \begin{pmatrix} b & 2a+b & a \\ b & a+b & a \\ 0 & a & 0 \end{pmatrix}, \quad T_2 = \begin{pmatrix} 0 \\ -1 \\ 1 \end{pmatrix},$$

and

$$J_2 = \begin{pmatrix} 2 & -1 \end{pmatrix}, \quad F_2 = \begin{pmatrix} 2a+2b & -a-b \\ a & -a \end{pmatrix}, \quad U_2 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

One can check that $\mathcal{A}_2 \xrightarrow{X_2} \mathcal{B}_2$, with $X_2 = \begin{pmatrix} 1 & 0 \\ 1 & -1 \\ 0 & 1 \end{pmatrix}$.

It then comes, $X_2 = C_2 D_2 R_2$ with

$$C_2 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad D_2 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad \text{and} \quad R_2 = \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \end{pmatrix}.$$

The proof of Theorem 2 amounts then to computing $\mathcal{C}_2 = \langle K_2, G_2, V_2 \rangle$ and $\mathcal{D}_2 = \langle L_2, H_2, W_2 \rangle$ such that:

$$\mathcal{A}_2 \xrightarrow{C_2} \mathcal{C}_2 \xrightarrow{D_2} \mathcal{D}_2 \xrightarrow{R_2} \mathcal{B}_2.$$

We set $K_2 = I_2 C_2, L_2 = K_2 D_2, W_2 = R_2 U_2, V_2 = D_2 W_2$ and we are left with the computation of $G_2 D_2 = D_2 H_2$, a 4×4 matrix. This matrix is composed of sub-matrices and the sum of the entries on every column and every row of each of these sub-matrices is given by the products $E_2 C_2 D_2$ and $D_2 R_2 F_2$. The sub-matrix decomposition and the “constraints” of our example are shown at Figure 4. The fact that \mathcal{B}_2 is conjugate to \mathcal{A}_2 ensures that

The dots figure the coefficients of the matrix, the cartouches figure their sums.

Fig. 4. Computation of $G_2 D_2 = D_2 H_2$ in Theorem 2

these constraints are consistent and the equisubtractivity of \mathbb{Z} allows to compute a solution:

$$G_2 = \begin{pmatrix} b & 2a+b & 2a+b & a \\ b & 2a+b & a+b & 0 \\ 0 & -a & 0 & a \\ 0 & a & a & 0 \end{pmatrix}, \quad H_2 = \begin{pmatrix} b & 2a+b & -2a-b & a \\ b & 2a+b & -a-b & 0 \\ 0 & a & 0 & -a \\ 0 & a & -a & 0 \end{pmatrix}.$$

This completes Example 2, and with it the proof of Theorem 2.

Finally, we note that if X is a non negative and non degenerate matrix, D is the identity matrix and Theorem 1 follows.

2.3 The Link with Symbolic Dynamics

We claim that Theorem 1 is a generalization of (a part of) the Finite Equivalence Theorem, a standard result in symbolic dynamics (cf. [12, Theorem 8.3.7]).

Theorem 5 (FET). *Two irreducible sofic shifts are finitely equivalent if and only if they have the same entropy.*

This requires some definitions to be understood. Symbolic dynamics deals with sets of *bi-infinite words*, i.e. subsets of $A^{\mathbb{Z}}$, closed under the *shift operation* and called *shifts*. A *sofic shift* X is the set of labels of bi-infinite paths in a finite labelled graph G and is *irreducible* if such G can be chosen to be a strongly connected graph. The set of finite factors of words in a shift X is denoted $F(X)$, the *entropy* of X is defined by: $h(X) = \lim_{n \rightarrow \infty} \frac{1}{n} \log_2 \text{Card}(F(X) \cap A^n)$ and is an effectively computable “dynamic invariant” of a sofic shift. A shift X is of *finite type* if it is defined by the condition that $F(X)$ does not contain a finite set of words (i.e. $A^* \setminus F(X)$ is a finitely generated ideal).

Let $X \subseteq A^{\mathbb{Z}}$ and $W \subseteq C^{\mathbb{Z}}$ be two sofic shifts. A map $\Phi: W \rightarrow X$ is called a *k-block map* if there exist a map $\bar{\Phi}: C^k \rightarrow A$ and two nonnegative integers m (for memory) and a (for anticipation) with $k = m + 1 + a$ such that $\Phi((c_n)_{n \in \mathbb{Z}}) = (a_n)_{n \in \mathbb{Z}}$ iff $\bar{\Phi}(c_{n-m} \dots c_n \dots c_{n+a}) = a_n$ for every $n \in \mathbb{Z}$. A *block map* is a

k -block map for some positive integer k . A block map¹⁰ is *finite-to-one* if the cardinal of $\Phi^{-1}(\mathbf{x})$ is bounded (independently of \mathbf{x}).

Two sofic shifts X and Y are *finitely equivalent* if there is a shift of finite type W together with finite-to-one and onto block maps such that $\Phi: W \rightarrow X$ and $\Psi: W \rightarrow Y$. All terms used in the FET are now defined. The connection with Theorem 1 requires one more definition, and a double encoding.

An *edge shift* X is a sofic shift with an underlying graph G whose edges all have distinct labels. It is thus completely described by the adjacency matrix X of G , a matrix with entries in \mathbb{N} .

Standard techniques in symbolic dynamics reduce the FET to the case of edge shifts X and Y whose adjacency matrices are denoted by X and Y respectively. The proof of sufficiency of the entropy condition relies then on two steps. The first step, known as Furstenberg’s lemma, shows that, when X and Y have equal entropy, there is a nonnegative and nonnull matrix F such that $XF = FY$. The second step constructs the adjacency matrix W of an edge shift W , together with finite-to-one and onto block maps $\Phi: W \rightarrow X$ and $\Psi: W \rightarrow Y$.

Now, the edge shifts X and Y may be seen as \mathbb{N} -automata over a one letter alphabet. Theorem 1 then applies to these two automata and yields an automaton that corresponds to the edge shift W , the covering and co-covering corresponding to block maps Φ and Ψ . The computation of the matrix G in the proof of Theorem 2 corresponds to the original construction for the second step of the proof of the FET, known as “filling in the tableau” (see [12, Example 8.3.11]).

3 The Reduction Theorems

A \mathbb{K} -automaton $\mathcal{A} = \langle I, E, T \rangle$ can be seen as a triple (I, μ, T) , where μ is the morphism from A^* into $\mathbb{K}^{n \times n}$ such that $E = \sum_{a \in A} \mu(a)a$. A \mathbb{K} -representation, or a \mathbb{K} -automaton, is *minimal* if it has a minimal dimension, or a minimal number of states, among all \mathbb{K} -representations, or all \mathbb{K} -automata, that realize the same series.

3.1 Reduction in a Skew Field

The computation of a minimal representation by Schützenberger’s reduction algorithm [17, 3] has two symmetrical steps: a *left reduction* and a *right reduction*; it may be described within the framework of conjugacy of automata.

The left reduction of $\mathcal{A} = (I, \mu, T)$ consists in computing a matrix X whose rows form a basis of the vector space¹¹ $\langle I\mu(A^*) \rangle$. The matrix X uniquely defines

¹⁰ Note that for $\Phi: W \rightarrow X$ being a (k -)block map does not depend on W and X whereas the property of being finite-to-one does, and this is the reason why we consider that the definition of Φ depend on W and X .

¹¹ Modules over a skew field are called vector spaces (cf. [11]). As \mathbb{F} is non commutative, one should distinguish between *left* and *right* vector spaces. $I\mu(S)$ is the set of vectors $I\mu(w)$ for $w \in S$; $\langle U \rangle$ is the vector space generated by the set U of vectors.

the automaton \mathcal{B} such that $\mathcal{B} \xrightarrow{X} \mathcal{A}$; the dimension of \mathcal{B} is equal to the one of $\langle I\mu(A^*) \rangle$. Likewise, the right reduction of \mathcal{A} consists in computing a matrix Y whose columns form a basis of the (right) vector space $\langle \mu(A^*)T \rangle$ and Y uniquely defines the automaton \mathcal{C} such that $\mathcal{A} \xrightarrow{Y} \mathcal{C}$; the dimension of \mathcal{C} is equal to the one of $\langle \mu(A^*)T \rangle$. The following property is the basis of the reduction algorithm:

Proposition 3. *Let \mathbb{F} be a skew field. A left reduction followed by a right reduction applied to a \mathbb{F} -automaton \mathcal{A} yields an equivalent minimal automaton.*

The computation of a left or right reduction (*i.e* the computation of bases of the appropriate subspaces) is made effective, *via* the *completion basis theorem* by the following lemma.

Lemma 1. *Let (I, μ, T) be a \mathbb{F} -representation and P a finite subset of A^* which contains the empty word 1_{A^*} . If, for every a in A and every w in P , $I\mu(wa)$ belongs to $\langle I\mu(P) \rangle$ then $\langle I\mu(P) \rangle = \langle I\mu(A^*) \rangle$ (and the symmetric for $\langle \mu(P)T \rangle$).*

The algorithm of left reduction consists in finding such a finite set P by considering words of A^* in the lexicographic order; P is prefix-closed and the set $I\mu(P)$ is a basis of $\langle I\mu(A^*) \rangle$. Likewise, the algorithm of right reduction yields a suffix-closed set of words. The reduction algorithm applied to two equivalent \mathbb{F} -automata (using the same order) yields the *same* minimal automaton and conversely we have the following.

Lemma 2 ([7]). *If \mathbb{F} is a skew field, two minimal equivalent \mathbb{F} -automata are similar, *i.e.* conjugate with an invertible transfer matrix.*

If \mathcal{A} and \mathcal{B} are two equivalent \mathbb{F} -automata, then there exist two reduced automata \mathcal{R} and \mathcal{R}' such that $\mathcal{A} \xleftarrow{X} \xrightarrow{Y} \mathcal{R}$, and symmetrically $\mathcal{B} \xrightarrow{X'} \xleftarrow{Y'} \mathcal{R}'$. By Lemma 2, $\mathcal{R} \xrightarrow{Z} \mathcal{R}'$. Hence, $\mathcal{A} \xleftarrow{X} \xrightarrow{YZY'} \xleftarrow{X'} \mathcal{B}$, which proves Theorem 3.

3.2 Reduction in an Euclidean Domain

We now deal with automata with multiplicity in an Euclidean domain \mathbb{K} instead of in a skew field \mathbb{F} . (In particular, \mathbb{Z} is an Euclidean domain.) There is a *dimension theory* for the free modules¹² over \mathbb{K} just as the one for the vector spaces over \mathbb{F} — that is any two bases of a \mathbb{K} -module have the same cardinal. On the other hand the completion basis theorem does not hold anymore in \mathbb{K} -modules. We present here a reduction algorithm that overcomes this difficulty.

In fact the proof of Proposition 3 and Lemma 1 readily extends for Euclidean domain but does not yields an effective procedure anymore. The problem arises from the fact that two \mathbb{K} -modules can be strictly contained one in the other and still have the same dimension. Nevertheless, the following result implies the existence of an effective procedure for the reduction algorithm.

¹² All the modules we consider here are free and we just call them modules.

Proposition 4. *Let (I, μ, T) be a \mathbb{K} -representation. There exists a finite subset P of A^* such that $\langle I\mu(P) \rangle = \langle I\mu(A^*) \rangle$.*

In contrast with the case where the multiplicity is taken in a field, we have no a priori bound (given the dimension of (I, μ, T)) on the number of elements in the set P and the basis of $\langle I\mu(P) \rangle$ is not found in the set of vectors $\{I\mu(w) \mid w \in P\}$ but in the set of the linear combinations of them.

Example 3. Let $\mathcal{A}_3 = \langle I_3, \mu_3, T_3 \rangle$ be the \mathbb{Z} -automaton defined by:

$$I_3 = \begin{pmatrix} 3 & 4 \end{pmatrix}, \mu_3(a) = \begin{pmatrix} -1 & 4 \\ 1 & -3 \end{pmatrix}, \mu_3(b) = \begin{pmatrix} -4 & 3 \\ 3 & -2 \end{pmatrix}, T_3 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

Here $\langle I\mu(A^*) \rangle$ is \mathbb{Z}^2 and a finite set P such that $\langle I\mu(P) \rangle = \mathbb{Z}^2$ is for instance $\{\varepsilon, a, ab\}$. Neither $\{\varepsilon, a\}$ nor $\{\varepsilon, b\}$ — that are the only prefix-closed sets of cardinal 2 — corresponds to a basis.

The reduction algorithm yields then directly a chain of four conjugacies between two equivalent \mathbb{K} -automata. Lemma 2 does not hold anymore and reducing the length of the chain from four to three requires a new result from which Theorem 3 then follows easily.

Proposition 5. *Let \mathbb{K} be an Euclidean domain. If \mathcal{A} and \mathcal{B} are equivalent \mathbb{K} -automata, with \mathcal{B} right reduced, then there are a \mathbb{K} -automaton \mathcal{C} and matrices X and Y such that: $\mathcal{A} \xleftarrow{X} \mathcal{C} \xrightarrow{Y} \mathcal{B}$.*

4 Final Result

We first establish a number of properties for coverings that can be seen as “backward Church-Rosser properties”, that is properties that allow to complete a commutative diagram when the lower part of it is known.

Proposition 6. *Let \mathbb{K} be an equisubtractive semiring and let \mathcal{A} , \mathcal{B} and \mathcal{C} be three \mathbb{K} -automata.*

- (a) *If \mathcal{A} and \mathcal{B} are \mathbb{K} -coverings of \mathcal{C} (resp. co- \mathbb{K} -coverings of \mathcal{C}), there exists a \mathbb{K} -automaton \mathcal{D} which is a \mathbb{K} -covering (resp. a co- \mathbb{K} -covering) of both \mathcal{A} and \mathcal{B} .*
- (b) *If \mathcal{A} is a \mathbb{K} -covering of \mathcal{C} and \mathcal{B} is a co- \mathbb{K} -covering of \mathcal{C} , there exists a \mathbb{K} -automaton \mathcal{D} which is both a co- \mathbb{K} -covering of \mathcal{A} and a \mathbb{K} -covering of \mathcal{B} .*

Lemma 3. *Let D be a circulation, C a co-amalgamation and R an amalgamation matrix such that DC and RD are defined. Then there exist circulation matrices D' and D'' such that $DC = CD'$ and $RD = D''R$.*

The proof of Theorem 4 now boils down to the diagram of Figure 5. Given equivalent \mathbb{H} -automata \mathcal{A} and \mathcal{B} , Theorem 3 yields the bottom line of the diagram whereas Theorem 2 allows to build the diagrams 1, 2 and 3; Proposition 5 (a) gives 4 and 5, Lemma 3 6, 7 and 8; Proposition 5 (b) gives 9 and Lemma 3 again completes the full diagram with 10 and 11.

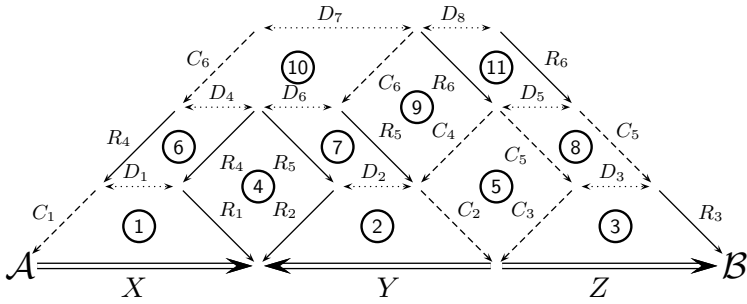

Fig. 5. Proof of Theorem 4

5 The Way for Further Developments

The gap that still remains between the above results and those formerly known raise a number of questions. Let \mathcal{A} and \mathcal{B} be two equivalent \mathbb{Z} -automata. We know that they are not always conjugate one to the other and it is decidable (cf. [16]) in polynomial time (resp. in exponential time) if \mathcal{A} is conjugate to \mathcal{B} with a transfer matrix in \mathbb{Z} (resp. with a transfer matrix in \mathbb{N}). Theorem 2 states the existence of a chain of three conjugacies between \mathcal{A} and \mathcal{B} .

One then may ask whether *three* conjugacies are necessary (in general), and, if yes, whether it is decidable when *two* conjugacies suffice.

If moreover \mathcal{A} and \mathcal{B} are (equivalent) \mathbb{N} -automata, one may ask also whether the chain of conjugacies could be always realized with transfer matrices in \mathbb{N} and, if not, whether it is decidable when this property holds.

By means of techniques different from the ones presented here, it can be shown that in both cases the stronger property holds: the answer to the first question is no and two conjugacies always suffice, the answer to the second question is yes and two equivalent \mathbb{N} -automata are joined by a chain of *four* conjugacies with transfer matrices in \mathbb{N} . This is the object of on-going work of the authors and will be presented in a forthcoming publication.¹³

Abstract. Reversible cellular automata (RCA) are models of massively parallel computation that preserve information. They consist of an array of identical finite state machines that change their states synchronously according to a local update rule. By selecting the update rule properly the system has been made information preserving, which means that any computation process can be traced back step-by-step using an inverse automaton. We investigate the maximum range in the array that a cell may need to see in order to determine its previous state. We provide a tight upper bound on this inverse neighborhood size in the one-dimensional case: we prove that in a RCA with n states the inverse neighborhood is not wider than $n - 1$, when the neighborhood in the forward direction consists of two consecutive cells. Examples are known where range $n - 1$ is needed, so the bound is tight. If the forward neighborhood consists of m consecutive cells then the same technique provides the upper bound $n^{m-1} - 1$ for the inverse direction.

1 Introduction

Cellular automata (CA) are discrete dynamical systems consisting of a grid of identical finite state machines whose states are updated synchronously at discrete time steps according to a local update rule. Cellular automata possess several fundamental properties of the physical world: they are massively parallel, homogeneous and all interactions are local. It is therefore not surprising that physical and biological systems have been successfully simulated using cellular automata models. The physical nature of cellular automata may have even greater importance when applied in the opposite direction, that is, when using the physics to simulate cellular automata. Many cellular automata are computationally universal — including some extremely simple ones, as reported recently

* Research supported by the Academy of Finland grant 54102.

by S. Wolfram [12] — so the most powerful massively parallel computers in the future may be implementations of cellular automata based on some physical phenomena of microscopic scale. Energy efficiency of such an implementation requires that the simulated universal CA obeys the rules of physics, including reversibility and conservation laws. Non-reversibility always implies energy dissipation, usually in the form of heat.

A cellular automaton is called *reversible* if there is another cellular automaton — the *inverse CA* — that computes the inverse function. The inverse CA retraces the computation steps back in time. There are simple reversible cellular automata that are computationally universal [5]. Universality is even possible in the one-dimensional space [7], that is, when the cells are organized along a line. Reversible CA have been popular topics of study since the early years of CA research, and many interesting facts have been discovered.

It is well known that injectivity and reversibility of CA are equivalent concepts: if a CA function has an inverse (i.e. it is one-to-one) then this inverse is always a CA function [2, 9]. This means that in order to backtrack the computation, each cell only needs to know the states of a finite number of its neighbors. The question this article investigates is the extent of the neighborhood that may be needed. In two- and higher dimensional cellular automata this inverse neighborhood can be extremely large: there is namely no algorithm to determine if a given CA is reversible, which means that the extent of the inverse neighborhood cannot be bounded by any computable function of the number of states [4]. In the one-dimensional case the reversibility question is decidable, and a trivial quadratic upper bound $O(n^2)$ exists [1], where n is the number of states and the neighborhood in the forward direction has been fixed to two consecutive cells.

We improve this bound to linear $n - 1$ where n is the number of states. This bound is tight as examples of one-dimensional reversible CA are known whose inverse neighborhoods reach this bound [3]. If the neighborhood in the forward direction consists of m consecutive cells rather than two cells, then the same argument provides an upper bound $n^{m-1} - 1$ for the inverse neighborhood. This is not known to be tight: [3] only provides examples of cellular automata with $2n$ states whose inverse neighborhoods reach this size.

2 Definitions and Basic Properties

In this section we present precise definitions and some basic properties of reversible cellular automata, and Welch sets and indices. Our proofs are based on elementary linear algebra, so we also recall some linear algebra concepts.

2.1 Cellular Automata

Formally, a one-dimensional cellular automaton, CA for short, is a 3-tuple system

$$\mathcal{A} = (S, N, f),$$

where $S = \{1, 2, \dots, n\}$ is a finite *state set*, N is a *neighborhood vector*

$$N = (x_1, \dots, x_m) \in \mathbb{Z}^m$$

of m distinct integers, and f is a mapping from S^m to S representing the *local update rule* of the CA. The *cells* are laid on an infinite line and are indexed by \mathbb{Z} , the set of integers. The neighbors of a cell situated on position $x \in \mathbb{Z}$ are all the cells on positions $x + x_i, i = 1, \dots, m$. The local update rule f determines the future state of a cell according to the states of its neighbors.

A *configuration* c of a CA \mathcal{A} is a mapping

$$c : \mathbb{Z} \rightarrow S$$

which specifies the states of all the cells. We are denoting by \mathcal{C} the set of all configurations. The *global transition function*

$$G : \mathcal{C} \rightarrow \mathcal{C}$$

describes the evolution of the CA and is obtained by a simultaneous application of the local update rule f on all cells:

$$G(c)(x) = f(c(x + x_1), \dots, c(x + x_m)),$$

for all $x \in \mathbb{Z}$. It is common to identify a cellular automaton with its global transition function G , and talk about cellular automaton function G or, when there is no risk of confusion, simply cellular automaton G .

If the neighborhood vector is $(-r, \dots, r)$ then the CA is called *radius- r* automaton. The special case $r = 1$ is the nearest neighbor neighborhood. In this work we mainly consider CA whose neighborhood is even smaller and consists of just two consecutive integers. If $N = (0, 1)$ we say that we have a *radius- $\frac{1}{2}$* CA. Figure 1 shows the trellis whose rows are consecutive configurations of a radius- $\frac{1}{2}$ cellular automaton, and the rows are shifted to make the neighborhood look symmetric. Note that any CA can be viewed as a radius- $\frac{1}{2}$ CA over a larger state set if we divide the configurations into sufficiently long blocks and use the blocks as "super cells". The partitioning may shift in time, but the computation is essentially the same.

Two CA are called equivalent if their global functions are identical. The following facts are easy to see: If two cellular automata are equivalent then there is a third equivalent CA whose neighborhood is the intersection of the neighborhoods of the first two CA. Hence, each CA function G has a minimal neighborhood, that is, a neighborhood that is contained in the neighborhoods of all CA that specify G . We call it the neighborhood of G . The interval from the smallest to the largest element of the minimal neighborhood is the neighborhood range for G . It is the smallest contiguous segment that can be used as the neighborhood to specify G .

A CA \mathcal{A} with global function G is called *reversible*, for short RCA, if there exists another CA, called the *inverse automaton* of \mathcal{A} , whose global transition function is G^{-1} , the inverse of G . The minimal neighborhood of G^{-1} is called the

Fig. 1. Dependencies in a radius- $\frac{1}{2}$ cellular automaton

inverse neighborhood of \mathcal{A} or G . Each cell can uniquely determine its previous state by looking only at the states contained in the inverse neighborhood.

A CA \mathcal{A} is called *injective* (*surjective*, *bijective*) if its global transition rule $G : \mathcal{C} \rightarrow \mathcal{C}$ is an injective (surjective, bijective, respectively) function. It has been known since the early 60's that injective cellular automata are automatically also surjective [6, 8], while the converse is not necessarily true. It is also known that all bijective CA are reversible [2, 9]. We have

Property 1 ([2, 6, 8, 9]). *In cellular automata, reversibility, bijectivity and injectivity are equivalent. They imply surjectivity.*

2.2 Welch Sets and Indices

From now on we consider radius- $\frac{1}{2}$ RCA only. We frequently need to apply the CA on partial configuration where we only know the states on some contiguous interval. Since the exact location of the interval on the line is irrelevant, we specify such configurations as finite or infinite words. For the state set S we denote by S^* the set of all words over alphabet S , by S^k the set of words of length k , by S^ω the set of one-way infinite words that are infinite to the right, and by ${}^\omega S$ the set of words that are infinite to the left. CA $\mathcal{A} = (S, (0, 1), f)$ specifies the functions $G : S^* \rightarrow S^*$, $G : S^\omega \rightarrow S^\omega$ and $G : {}^\omega S \rightarrow {}^\omega S$ (all denoted by the same symbol G) defined by

- $G(a_1 a_2 \dots a_k) = b_1 b_2 \dots b_{k-1}$ where each $b_i = f(a_i, a_{i+1})$,
- $G(a_1 a_2 \dots) = b_1 b_2 \dots$ where each $b_i = f(a_i, a_{i+1})$,
- $G(\dots a_2 a_1) = \dots b_2 b_1$ where each $b_i = f(a_{i+1}, a_i)$.

For each $w \in S^\omega$ we set

$$L(w) = \{a \in S \mid G(au) = w \text{ for some } u \in S^\omega \}$$

and call it the *left Welch set* of w . It contains all the states that were possible one time step earlier at the leftmost cell that affects w , see Figure 2. Analogously, for any $w \in {}^\omega S$ we define the *right Welch set* as

$$R(w) = \{a \in S \mid G(ua) = w \text{ for some } u \in {}^\omega S \}.$$

Fig. 2. The left Welch set $L(w)$ of the infinite word w consists of all possible states in the indicated cell

These sets were introduced already in [2], and have since been reinvented independently by many authors. The Welch sets have the following nice properties [2]:

Property 2. Let $\mathcal{A} = (S, (0, 1), f)$ be reversible and let $n = |S|$ be the number of states. Then for every $w \in S^\omega$ and $v \in {}^\omega S$ we have

$$|L(w)| \cdot |R(v)| = n.$$

Consequently, the cardinalities $|L(w)|$ and $|R(v)|$ are independent of the choice of w and v .

We denote by n_L the size of left Welch sets and by n_R the size of the right Welch sets, and call them the *left* and the *right Welch index*. Then $n_L \cdot n_R = n$.

The following result is another useful property of the Welch sets [2]:

Property 3. Let $\mathcal{A} = (S, (0, 1), f)$ be reversible. Then for every $w \in S^\omega$ and $v \in {}^\omega S$ we have

$$|L(w) \cap R(v)| = 1,$$

i.e. the intersection of any left Welch set with any right Welch set is a singleton.

The following proposition relates the Welch sets to the minimal inverse neighborhood of the CA:

Proposition 1. Let $\mathcal{A} = (S, (0, 1), f)$ be reversible. Then the inverse neighborhood of G is included in the interval

$$\{-r, \dots, l - 1\}$$

if and only if

- $L(uw) = L(uv)$ for all $u \in S^l$ and $w, v \in S^\omega$, and
- $R(wu) = R(vu)$ for all $u \in S^r$ and $w, v \in {}^\omega S$.

Proof. First, notice that even though the given interval does not at first appear symmetric, it in fact contains l positions to the right of the cell and r positions to the left of the cell, if the cells are shifted to the right as in Figure 1.

(\implies) Suppose that $\{-r, \dots, l - 1\}$ contains the inverse neighborhood of G and let $u \in S^l$ and $w, v \in S^\omega$ be arbitrary. Let us prove that $L(uw) \subseteq L(uv)$. Then by symmetry we have $L(uw) = L(uv)$.

Fig. 3. Configurations γuw and γwv agree in all the positions up to $l - 1$

If $a \in L(uw)$ then there exists some $\alpha \in S^\omega$ such that $G(a\alpha) = uw$. Pick an arbitrary $\beta \in {}^\omega S$ and let $\gamma = G(\beta a)$. Then $G(\beta a \alpha) = \gamma uw$, where letter a and the first letter of u are in the position 0 of the cellular array. Consider then the configuration γwv , where the first letter of u is still in position 0, see Figure 3. It agrees with γuw in positions up to $l - 1$. By applying the inverse cellular automata to γwv we must therefore get state a in position 0, which means that $a \in L(uv)$.

Analogously we get the claim concerning the right Welch sets.

(\Leftarrow) Suppose l and r are such that for all $v \in S^l$ and $\alpha_1, \alpha_2 \in S^\omega$ we have $L(v\alpha_1) = L(v\alpha_2)$, and that for all $u \in S^r$ and $\beta_1, \beta_2 \in {}^\omega S$ we have $R(\beta_1 u) = R(\beta_2 u)$. Then the inverse function G^{-1} is computed by the cellular automaton that uses the neighborhood $(-r, \dots, l - 1)$ and has the local update rule

$$g(uv) = R(\beta u) \cap L(v\alpha)$$

for $u \in S^r, v \in S^l$ and all $\alpha \in S^\omega$ and $\beta \in {}^\omega S$. The above intersection always contains a unique element, due to Property 3. □

2.3 Vector Interpretation of Sets

In our proofs we take advantage of dimension arguments on vector spaces. Any subset X of the state set $S = \{1, 2, \dots, n\}$ is interpreted as the 0-1 vector \vec{X} in \mathbb{R}^n whose i 'th coordinate is 1 if $i \in X$ and 0 if $i \notin X$. The single element sets $\{a\}$ then correspond to the unit coordinate vectors of \mathbb{R}^n and they form a basis of the vector space \mathbb{R}^n . Notice that for any $X, Y \subseteq S$ the inner product $\vec{X} \cdot \vec{Y}$ is the cardinality of their intersection $X \cap Y$. The vectors \vec{L} and \vec{R} corresponding to left and right Welch sets L and R will be called left and right Welch vectors, respectively.

Let us denote by Θ the null space $\{(0, 0, \dots, 0)\}$ and by I the one-dimensional space generated by vector $(1, 1, \dots, 1)$. For any $U \subseteq \mathbb{R}^n$ the subspace of \mathbb{R}^n generated by U is denoted as $\langle U \rangle$.

Let $\mathcal{A} = (S, (0, 1), f)$ be reversible. For any $c \in S$ we define a linear function $h_c : \mathbb{R}^n \rightarrow \mathbb{R}^n$ as follows. For every $b \in S$ we have $h_c(\vec{b}) = \vec{H}$ where \vec{b} is the basis vector corresponding to b and $H = \{a \mid f(a, b) = c\}$. This uniquely specifies the linear function h_c . Vector \vec{X} , corresponding to a set $X \subseteq S$ of states, is mapped according to $h_c(\vec{X}) = \sum_{b \in X} h_c(\vec{b})$. Note that $h_c(\vec{X})$ is not always a 0-1 vector, so it does not necessarily represent a set. However, the next proposition states that if L is a left Welch set then $h_c(\vec{L})$ is a 0-1 vector representing a left Welch set:

Proposition 2. *Let $\mathcal{A} = (S, (0, 1), f)$ be reversible, and let $c \in S$ be arbitrary. For every $w \in S^\omega$ we have $h_c(\vec{L}(w)) = \vec{L}(cw)$.*

Proof. It is enough to show that (i) for every $a \in L(cw)$ there is a unique $b \in L(w)$ such that $f(a, b) = c$, and (ii) for any $a \notin L(cw)$ there is no $b \in L(w)$ such that $f(a, b) = c$. Parts (i) and (ii) imply then that the vector $h_c(\vec{L}(w))$ has 1 and 0 in coordinates i for all $i \in L(cw)$ and $i \notin L(cw)$, respectively.

Claim (ii) is trivial, as if there would exist $b \in L(w)$ such that $f(a, b) = c$ then $G(ab\alpha) = cw$ where $\alpha \in S^\omega$ is such that $G(b\alpha) = w$. This contradicts the assumption $a \notin L(cw)$.

Consider then claim (i). Since $a \in L(cw)$ there is some $b\alpha \in S^\omega$ such that $G(ab\alpha) = cw$. This b satisfies the condition in (i). If $b' \in L(w)$ is another state with the property $f(a, b') = c$ then $G(ab'\beta) = cw$ for some $\beta \in S^\omega$. But then $G(\gamma ab\alpha) = G(\gamma ab'\beta)$ for any $\gamma \in {}^\omega S$ which, by injectivity, implies that $b = b'$. \square

Analogously, let us define linear functions $g_c(\vec{a}) = \vec{H}$ where $H = \{b \mid f(a, b) = c\}$. They naturally have the similar property concerning the right Welch sets:

Proposition 3. *Let $\mathcal{A} = (S, (0, 1), f)$ be reversible, and let $c \in S$ be arbitrary. For every $w \in {}^\omega S$ we have $g_c(\vec{R}(w)) = \vec{R}(wc)$. \square*

3 The Inverse Neighborhood Range

In this section we prove that the size of the inverse neighborhood range of a radius- $\frac{1}{2}$ RCA $\mathcal{A} = (S, (0, 1), f)$ is less than or equal to $n - 1$, where n is the number of states. We do this by creating two decreasing chains of linear subspaces of \mathbb{R}^n based on the Welch sets. The first elements of the chains are the subspaces

$$\begin{aligned} \mathcal{L}_0 &= \langle \vec{L}(w) - \vec{L}(v) \mid w, v \in S^\omega \rangle, \text{ and} \\ \mathcal{R}_0 &= \langle \vec{R}(w) - \vec{R}(v) \mid w, v \in {}^\omega S \rangle, \end{aligned}$$

that is, the spaces generated by the differences between any two left Welch vectors and any two right Welch vectors, respectively. The goal is to prove the following theorem:

Theorem 1. *Let $\mathcal{A} = (S, (0, 1), f)$ be reversible, and let \mathcal{L}_0 and \mathcal{R}_0 be the subspaces defined above. Then the inverse neighborhood range of G contains at most $\dim \mathcal{L}_0 + \dim \mathcal{R}_0$ elements. More precisely, the inverse neighborhood of G is included in the interval*

$$\{-\dim \mathcal{R}_0, \dots, \dim \mathcal{L}_0 - 1\}.$$

Proof. For every $k = 0, 1, 2, \dots$ define the following subspaces of \mathbb{R}^n :

$$\begin{aligned} \mathcal{L}_k &= \langle \vec{L}(uw) - \vec{L}(vw) \mid u \in S^k, w, v \in S^\omega \rangle, \text{ and} \\ \mathcal{R}_k &= \langle \vec{R}(wu) - \vec{R}(vu) \mid u \in S^k, w, v \in {}^\omega S \rangle. \end{aligned}$$

We make the following observations:

- There is l such that $\mathcal{L}_l = \Theta$, the null space,
- $\mathcal{L}_{k+1} \subseteq \mathcal{L}_k$ for every $k = 0, 1, 2, \dots$, and
- if $\mathcal{L}_{k+1} = \mathcal{L}_k$ then $\mathcal{L}_j = \mathcal{L}_k$ for every $j \geq k$.

To prove the first fact, choose l and r such that the inverse neighborhood of G is included in the interval $\{-r, \dots, l - 1\}$. According to Proposition 1, $L(uw) = L(uv)$ for every $u \in S^l$ and $w, v \in S^\omega$. But then all generators of \mathcal{L}_l are zero vectors, hence $\mathcal{L}_l = \Theta$.

The second fact is trivial since all the generators of \mathcal{L}_{k+1} are among the generators of \mathcal{L}_k .

For the third fact, notice that $\vec{L}(cuw) - \vec{L}(cuv) = h_c(\vec{L}(uw) - \vec{L}(uv))$. This means that, for every $k = 0, 1, 2, \dots$, the generators of \mathcal{L}_{k+1} are obtained from the generators of \mathcal{L}_k by applying the homomorphisms h_c with all $c \in S$. Consequently,

$$\begin{aligned} \mathcal{L}_{k+1} &= \langle h_c(\vec{X}) \mid c \in S, \vec{X} \text{ is a generator of } \mathcal{L}_k \rangle \\ &= \langle h_c(\vec{X}) \mid c \in S, \vec{X} \in \mathcal{L}_k \rangle. \end{aligned}$$

In other words, \mathcal{L}_{k+1} is determined by \mathcal{L}_k . It follows that if $\mathcal{L}_{k+1} = \mathcal{L}_k$ then $\mathcal{L}_{k+2} = \mathcal{L}_{k+1}$, and therefore $\mathcal{L}_j = \mathcal{L}_k$ for all $j \geq k$.

Our three facts imply that

$$\mathcal{L}_0 \supseteq \mathcal{L}_1 \supseteq \mathcal{L}_2 \supseteq \dots \supseteq \mathcal{L}_l = \Theta$$

for some l . Since the dimension of the subspaces decreases at every step, we must have $l \leq \dim \mathcal{L}_0$.

The analogous reasoning can be done on the right Welch sets. We conclude that there are numbers $l \leq \dim \mathcal{L}_0$ and $r \leq \dim \mathcal{R}_0$ such that $\mathcal{L}_l = \mathcal{R}_r = \Theta$. Then l has the property that $L(uw) = L(uv)$ for every $u \in S^l$ and $w, v \in S^\omega$, and r has the property that $L(wu) = L(vu)$ for every $u \in S^r$ and $w, v \in {}^\omega S$. According to Proposition 1, the inverse neighborhood of G is included in the interval $\{-r, \dots, l - 1\}$ and hence also in the interval $\{-\dim \mathcal{R}_0, \dots, \dim \mathcal{L}_0 - 1\}$. □

Upper bounds on the dimensions of the spaces \mathcal{L}_0 and \mathcal{R}_0 provide nice limits on the inverse neighborhood:

Corollary 1. *Let $A = (S, (0, 1), f)$ be reversible. Then $\dim \mathcal{L}_0 + \dim \mathcal{R}_0 \leq n - 1$ where n is the number of states. Hence the inverse neighborhood range of G has at most size $n - 1$*

Proof. This follows from the facts that vector spaces \mathcal{L}_0 and \mathcal{R}_0 are orthogonal to each other and also to the one-dimensional space I generated by the vector $(1, 1, \dots, 1)$. Let $\vec{L}_1 - \vec{L}_2$ and $\vec{R}_1 - \vec{R}_2$ be two arbitrary generators of \mathcal{L}_0 and \mathcal{R}_0 , respectively. Their inner product is

$$(\vec{L}_1 - \vec{L}_2) \cdot (\vec{R}_1 - \vec{R}_2) = \vec{L}_1 \cdot \vec{R}_1 - \vec{L}_1 \cdot \vec{R}_2 - \vec{L}_2 \cdot \vec{R}_1 + \vec{L}_2 \cdot \vec{R}_2 = 1 - 1 - 1 + 1 = 0,$$

where we have used Property 3 of the Welch sets. So spaces \mathcal{L}_0 and \mathcal{R}_0 are orthogonal to each other. With $(1, 1, \dots, 1)$ we get the inner product

$$(\vec{L}_1 - \vec{L}_2) \cdot (1, 1, \dots, 1) = n_L - n_L = 0,$$

where n_L is the left Welch index. Here we used Property 2 of the Welch sets. Analogously \mathcal{R}_0 is seen orthogonal to I .

Now we can reason as follows: Since the three spaces are orthogonal, we have

$$\dim \mathcal{L}_0 + \dim \mathcal{R}_0 + \dim I = \dim(\mathcal{L}_0 \oplus \mathcal{R}_0 \oplus I) \leq \dim \mathbb{R}^n = n,$$

so

$$\dim \mathcal{L}_0 + \dim \mathcal{R}_0 \leq n - 1.$$

□

We can also use our theorem to bound the inverse neighborhood from either side separately:

Corollary 2. *Let $\mathcal{A} = (S, (0, 1), f)$ be reversible, and let n_L and n_R be its left and right Welch indices, respectively. Then $\dim \mathcal{L}_0 \leq n - n_L$ and $\dim \mathcal{R}_0 \leq n - n_R$ where n is the number of states. Hence the inverse neighborhood of G is contained in the interval*

$$\{n_R - n, \dots, n - n_L - 1\}.$$

Proof. Consider the left Welch vectors $\vec{L}(u)$, $u \in S^\omega$. Each is a 0-1 vector with n_L ones. Every state belongs to some left Welch set, so each position has one in some of the vectors. Out of all this vectors, we can extract a set of linearly independent ones as follows. First, extract an arbitrarily vector. Then, for any state $a \in S$ such that the corresponding position is zero in all the vectors already selected, extract a left Welch vector having one in position a , and add it to the set of linearly independent vectors. Repeat the process until each position is covered by at least one selected vector. It is clear that the extracted vectors are linearly independent, and since each vector covers n_L positions there are at least $\frac{n}{n_L}$ vectors selected. Since $\frac{n}{n_L} = n_R$, it follows easily that there are at least n_R linearly independent left Welch vectors.

Next we use the following well known property: if $\vec{v}_1, \vec{v}_2, \dots, \vec{v}_k$ are k linearly independent vectors, then $\vec{v}_2 - \vec{v}_1, \vec{v}_3 - \vec{v}_1, \dots, \vec{v}_k - \vec{v}_1$ are $k - 1$ linearly independent vectors. We apply this to the n_R linearly independent left Welch vectors and obtain the result that the generators of \mathcal{L}_0 contain at least $n_R - 1$ linearly independent vectors, so $\dim \mathcal{L}_0 \geq n_R - 1$. On the other hand we know by Corollary 1 that $\dim \mathcal{L}_0 + \dim \mathcal{R}_0 \leq n - 1$, so

$$\dim \mathcal{R}_0 \leq (n - 1) - \dim \mathcal{L}_0 \leq (n - 1) - (n_R - 1) = n - n_R.$$

Analogously we can prove that $\dim \mathcal{L}_0 \leq n - n_L$.

□

The previous corollaries were proved in [3] in the special case that one of the Welch indices is 1. This constraint simplifies the proofs very much. The techniques used in [3] were quite different. Examples were also provided in [3] of reversible CA with n states and Welch index 1 whose inverse neighborhood reached the size $n - 1$. Hence the bound of Corollary 1 is tight. We do not know if there are such examples for other values of the Welch indices, and also we do not know if the bounds in Corollary 2 are tight.

4 Larger Neighborhoods

So far we have been concerned with radius- $\frac{1}{2}$ cellular automata. With larger forward neighborhoods larger inverse neighborhoods are possible. The notions of the Welch sets and indices can be generalized to such settings. Let m be the size of the neighborhood range in the forward direction, that is, m consecutive positions can be used as the forward neighborhood. Then the elements of the Welch sets are words of length $m - 1$ over alphabet S , and the Welch indices n_L and n_R satisfy the relation $n_L \cdot n_R = n^{m-1}$. By a straightforward generalization of the proofs in the previous section we obtain the following results:

Theorem 2. *Let $\mathcal{A} = (S, (0, \dots, m - 1), f)$ be a reversible CA with n states and forward neighborhood range m . Then the inverse range has size at most $n^{m-1} - 1$. Moreover, the size of the left inverse neighborhood is less than or equal to $n^{m-1} - n_R$ while the size of the right inverse neighborhood is less than or equal to $n^{m-1} - n_L$, where n_L and n_R are the left and right Welch indices.*

The bound in Theorem 2 is not known to be tight. The best known examples are automata with $2n$ states whose inverse neighborhood have range n^{m-1} [3].

5 Final Remarks

We have shown that the inverse neighborhood of a one-dimensional reversible cellular automaton of size n is at most $n - 1$ when the neighborhood in the forward direction consists of only two consecutive cells. We have also generalized this result for the case when the forward neighborhood is wider, i.e., if it contains m consecutive cells, then the size of the inverse neighborhood is bounded by $n^{m-1} - 1$. The proof uses several properties of the Welch sets, as well as some algebraic results concerning dimension of vector spaces.

The present paper gives rise to several open problems. E.g., we do not know if the generalized bound $n^{m-1} - 1$ for the size of the inverse neighborhood is tight. This is indeed the case if $m = 2$: see [3] for an example of a reversible cellular automaton with left and right Welch indexes equal to 1 and n respectively, and with inverse neighborhood size equal to $n - 1$. Also, for any $n_L, n_R \in \mathbb{N}$, it remains open to find examples of reversible cellular automata with left and right Welch indexes equal to n_L and n_R respectively, such that the size of the inverse neighborhood is maximal, i.e., equal to $n - 1 = n_L \cdot n_R - 1$.

There are quadratic time algorithms in the literature testing for surjectivity and injectivity of a given cellular automaton, see [1] and [10]. Although it is improbable that a linear algorithm exists, some improvements may be possible. For example, Lemma 3 from [1] can now be improved from quadratic to linear, although the time complexity of the injectivity algorithm, based on that result, does not change.

1 Introduction

Finite semigroups, i.e. finites sets equipped with a binary associative operation, have played a role in theoretical computer science for fifty years. They were first observed to be closely related to finite automata, hence, by the famous theorem of Kleene, to regular languages. It was later understood that this association is very deep and the theory of pseudo-varieties of Schützenberger and Eilenberg [5] became the accepted framework in which to discuss computations realized by finite-state machines. It is today fair to say that semigroups and automata are so tightly intertwined that it makes little sense to study one without the other.

In recent years, the usage of semigroups in the theory of computation has increased substantially; for example, it has proved useful in the study of shallow boolean circuits [1]. Word problems in finite semigroups provide instances of complete problems for the well-known circuit class \mathbf{NC}^1 , i.e. circuits of logarithmic depth constructed with binary gates; moreover, several interesting subclasses of \mathbf{NC}^1 can also be characterized by word problems, by restricting appropriately the semigroups under consideration. Recently [12], new separation results have been proved within the realm of constant-depth circuits, largely based on an algebraic point of view. Other areas of theory of computation where semigroups have proved to be interesting include communication complexity [16] and computational learning theory [6].

When the axiom of associativity is dropped, we obtain algebraic structures known as groupoids. These also play a role in formal languages and there is an analog to Kleene's theorem relating groupoids to push-down automata and to context-free languages [10]. On the computational complexity side, these structures are now known to be of interest as well. Non-associativity can be seen as an algebraic form of non-determinism that has been used, for example, as an important ingredient in the separation of the monotone \mathbf{NC} hierarchy [9]. On

the other hand, word problems over groupoids provide instances of complete problems for the circuit class SAC^1 , i.e. circuits of logarithmic depth and polynomial size constructed with binary AND gates and unbounded OR gates, and also for interesting subclasses like L and NL.

It is clear that groupoids have been much less studied than semigroups and moreover much of what has been done is of little help to understand computations. It seems important to develop a deeper knowledge of these algebras, in a form that is useful in theory of computation. The apparent absence of structure in the non-associative world should not be seen as an absolute barrier to comprehension. Meaningful results can be obtained; for example, the fact that loops (i.e. groupoids with an identity that obey the cancellation law) recognize exactly the regular open languages [3] provide a surprising link to the topology of the free monoid.

In this paper, we directly address what appears to us to be the most basic question. What differentiates a “weak” groupoid from a “powerful” one in a computing power perspective? For example, when can it be guaranteed that a groupoid recognizes only regular languages? We provide an algebraic sufficient condition on the groupoid for this property to hold. We also show that any regular language can be recognized by a groupoid that satisfies this condition. Finally, we concentrate on loops, which form a proper subclass of this family and have been studied at greater length. We show that the syntactic monoid of any regular open languages has interesting connection with the loops that recognize it. We introduce the notion of the *derived monoid* of a loop and establish the computational significance of this concept. All these results provide further evidence that non-associative structures can be analyzed in a way that sheds light on computational issues.

2 Preliminaries

A groupoid is a set closed under a binary operation. A semigroup S is a groupoid that satisfies the *associative law*: $(xy)z = x(yz)$ for all $x, y, z \in S$. A monoid is a semigroup in which there exists an identity element, i.e. an element $e \in S$ such that $ex = x = xe$ for all $x \in S$. A group is a semigroup G that satisfies the *cancellation laws*, i.e. for all $a, b \in G$ the equations $ax = b$ and $ya = b$ have exactly one solution. Observe that in the finite case, satisfaction of the cancellation and associative laws guarantees the presence of an identity. The *free* semigroup over an alphabet A is the set of all non empty words over A where the operation is the concatenation. It is denoted A^+ . The free monoid A^* is obtained by adjoining an identity (the empty word) to A^+ . We say that a semigroup S *divides* a semigroup T (written $S \prec T$) if S is a morphic image of a subgroup of T . All groupoids considered in this paper are finite, except for the free semigroup and the free monoid.

An important key to understand the structure of semigroups has been developed by Green in 1951 and consists of four equivalence relations denoted \mathcal{R} , \mathcal{L} , \mathcal{H} and \mathcal{J} . Let S be a semigroup and let S^1 be the smallest monoid that contains S . The Green relations are defined as follows:

1. $a\mathcal{R}b$ iff $aS^1 = bS^1$
2. $a\mathcal{L}b$ iff $S^1a = S^1b$
3. $a\mathcal{H}b$ iff $a\mathcal{R}b$ and $a\mathcal{L}b$
4. $a\mathcal{J}b$ iff $S^1aS^1 = S^1bS^1$

The relation \mathcal{J} is the coarsest among the four. Each \mathcal{J} -class (i.e. each equivalent class of the relation \mathcal{J}) can be visualized as a two-dimensional array where each row is an \mathcal{R} -class, each column is an \mathcal{L} -class and each cell is an \mathcal{H} -class.

An element $x \in S$ is an *idempotent* if $xx = x$. Idempotents play a fundamental role in semigroup theory. A \mathcal{J} -class that contains an idempotent is said to be *regular*. Any regular \mathcal{J} -class has the property that each row and each column contains at least one idempotent. An \mathcal{H} -class that contains an idempotent forms a subsemigroup which is a maximal group in S . A necessary and sufficient condition for a \mathcal{J} -class to be a subsemigroup is that each of its \mathcal{H} -classes contains an idempotent. We define **DS** to be the class of all semigroups for which each regular \mathcal{J} -class is a subsemigroup.

Some other classes of semigroups have to be mentioned here. A semigroup that contains no nontrivial group is said to be *aperiodic*. A semigroup is aperiodic if and only if each of its regular \mathcal{H} -classes is trivial (i.e. contains only one element). The class of aperiodic semigroups contained in **DS** is denoted **DA**. A semigroup is called *orthodox* if the set of its idempotents forms a subsemigroup. The class **DO** consists of those semigroups in **DS** for which each regular \mathcal{J} -class is orthodox. A semigroup is \mathcal{J} -trivial if each of its \mathcal{J} -classes is trivial. We define similarly \mathcal{R} -trivial semigroups. We denote with **J** and **R** the classes of \mathcal{J} -trivial and \mathcal{R} -trivial semigroups, respectively. Finally, the class **J₁** contains all commutative semigroups in which all elements are idempotent. From these definitions we have the inclusions:

$$\mathbf{J}_1 \subset \mathbf{J} \subset \mathbf{R} \subset \mathbf{DA} \subset \mathbf{DO} \subset \mathbf{DS}$$

Every semigroup S can be seen as a language recognizer in the following way. Given a finite alphabet A and a language $L \subseteq A^+$ we say that L is *recognized* by S if there exists a subset $F \subseteq S$ and a morphism $h : A^+ \rightarrow S$ such that $L = \{w \in A^+ \mid h(w) \in F\}$. A variant of Kleene's theorem asserts that a subset of A^+ is regular iff it can be recognized by a finite semigroup. The theorem also holds in the case of monoids recognizing subsets of A^* .

One fascinating aspect of this theory is the strong correspondence that exists between subclasses of regular languages satisfying certain combinatorial properties and subclasses of semigroups satisfying some algebraic properties. A classical example is the result of Schützenberger [13] stating that a language is recognized by a finite aperiodic monoid if and only if it is star-free.

The following more complex example is of particular interest for our work. Let \mathcal{C} be a class of semigroups. The *polynomial closure* of \mathcal{C} (denoted $\text{Pol}(\mathcal{C})$) is the set of languages which are finite unions of languages of the form $K = L_0a_1L_1 \cdots a_nL_n$, where each a_i is a letter and each L_i is a language recognized by some semigroup in \mathcal{C} . We say that the product defining K is unambiguous if every word w in K can have at most one factorization $w = w_0a_1w_1 \cdots a_nw_n$ with

w_i in L_i . The subset of $\text{Pol}(\mathcal{C})$ obtained by restricting to unambiguous products is denoted $\text{UPol}(\mathcal{C})$. Let $\mathbf{J}_1 \vee \mathbf{G}$ be the class of all semigroups that divides a direct product of a semigroup in \mathbf{J}_1 and a group. Then, a theorem of Schützenberger [14] states that a language is recognized by a semigroup in \mathbf{DO} if and only if it is in $\text{UPol}(\mathbf{J}_1 \vee \mathbf{G})$.

Associativity is not essential in the previous definition of recognition and it has been known for a long time [10, 7] that every groupoid can be seen as a pushdown automaton. Let us formalize this idea. Let G be a groupoid, $\mathcal{P}(G)$ its power set, and let G^+ denotes the free semigroup generated by the set of elements in G . Observe that evaluating a word in G^+ to an element in G depends on the evaluation tree since G is in general non-associative. We define the function $\text{eval} : G^+ \rightarrow \mathcal{P}(G)$ by requesting that for each $w \in G^+$, $\text{eval}(w)$ is equal to the set of elements that can be obtained by evaluating w with all possible evaluation trees. Given an alphabet A and a language $L \subseteq A^+$, we say that a groupoid G recognizes L if there exist a subset $F \subseteq G$ and a length-preserving morphism $h : A^+ \rightarrow G^+$ such that $L = \{w \in A^+ \mid \text{eval}(h(w)) \cap F \neq \emptyset\}$. The analog of Kleene’s theorem now states that a language is recognized by a finite groupoid if and only if it is context-free.

The structure of the groupoid being used as a recognizer must necessarily determine the combinatorial properties of the languages being recognized. One would hope that this relationship can be made explicit for interesting cases. One positive example of this happening has to do with quasigroups. A *quasigroup* is a groupoid that satisfies the cancellation law. A quasigroup with identity is called a *loop*. In [3], it is proved that a language is recognized by a finite quasigroup (or loop) if and only if it is in $\text{Pol}(\mathbf{G})$, where \mathbf{G} is the class of all finite groups.

Loops and quasigroups are “weak” in the sense that they can only recognize regular languages. It is natural to ask what are the groupoids with this property. Our first result gives a sufficient condition for a groupoid to be “weak”.

Let G be a groupoid. With any element $a \in G$ we define the mapping $R(a) : G \rightarrow G$ called the *right multiplication by a* which is defined by $xR(a) = xa$ and the mapping $L : G \rightarrow G$ called the *left multiplication by a* which is defined by $xL(a) = ax$. The *multiplication semigroup*¹ of G (denoted $\mathcal{M}(G)$) is the closure under composition of all left and right multiplications. When G is a quasigroup then $\mathcal{M}(G)$ is a group called the *multiplication group* of G .

Theorem 1. *Let G be a groupoid such that $\mathcal{M}(G) \in \mathbf{DO}$. Then, G recognizes only regular languages.*

Two particular cases of this theorem were already known : when $\mathcal{M}(G)$ belongs to \mathbf{DA} (see [2]) and when G is a quasigroup (see [4]). We conjecture that this result is optimal in the sense that for any pseudovariety \mathbf{V} not contained in \mathbf{DO} , there exists a groupoid whose multiplication semigroup is in \mathbf{V} that can recognize a non-regular language.

¹ This terminology is standard in loop theory. A similar notion exists in universal algebra where this is called *translation semigroup*.

Now, what regular languages can be recognized by groupoids with multiplication semigroup in **DO**? The answer is given by our second result.

Theorem 2. *Any regular language is recognized by a groupoid whose multiplication semigroup is in **R** (which is a proper subclass of **DO**).*

In this context where “simple” groupoids are used to recognize “complicated” regular languages, it is not so clear what is the relation between the combinatorial structure of the language and the algebraic structure of the groupoid. As an example, consider the language PARITY over the alphabet $\{0, 1\}$ that contains all words with an even number of 1. Any semigroup that recognizes this language must contain the cyclic group of order two. However, PARITY can be recognized by a groupoid of four elements ($00 = 0, 01 = 10 = 1, 11 = 22 = 2$, all other products gives 3) and neither this groupoid nor its multiplication semigroup contains any group. Our third result states that this situation does not arise with loops.

Recall that the syntactic congruence of a language $L \subseteq A^*$ is defined by $x \sim_L y$ whenever $uxv \in L \Leftrightarrow uyv \in L$ for all $u, v \in A^*$. The syntactic monoid of L is the quotient monoid $M(L) = A^*/\sim_L$. It can be shown that $M(L)$ divides any monoid that recognizes L .

Theorem 3. *Let $L \in A^*$ be recognized by a loop B and let $M(L)$ be its syntactic monoid. Then, any group that divides $M(L)$ also divides B .*

The proof of the previous theorem relies upon an algebraic tool which is introduced in this paper. For any groupoid G we define a congruence over G^+ by defining $x \sim y$ if and only if $\text{eval}(sxt) = \text{eval}(syt)$, for all $s, t \in G^*$. The *derived monoid* of G is the quotient monoid $D(G) = G^*/\sim$. It is easy to see that $D(G)$ is finite if and only if G recognizes only regular languages.

In the case of a loop B , we show that any language recognized by B is also recognized by $D(B)$. Moreover, a group divides B if and only if it divides $D(B)$. We show that there exists a relational morphism $\tau : D(B) \rightarrow \mathcal{M}(B)$ such that $D_1(B) = \tau^{-1}(1)$ is a \mathcal{J} -trivial submonoid of $D(B)$. Finally, denoting the wreath product by \circ , we prove the following noticeable identity:

Theorem 4. $D(B) \prec D_1(B) \circ \mathcal{M}(B)$

Theorems 1 to 4 are proved in Sections 3 to 6, respectively. Conclusion and open problems are given in Section 7.

3 Recognizing Only Regular Languages

Theorem 1 is proved in this section. Let G be a groupoid, $F \subseteq G$ and $L = \{w \in G^+ \mid \text{eval}(w) \cap F \neq \emptyset\}$. Define $K_F = \{W \in \mathcal{M}(G)^+ \mid 1W \in F\}$.

Proposition 1. *If $K_F \in \text{Pol}(J_1 \vee G)$ then L is regular.*

Proof. Let $w \in G^+$ be any word and consider some fixed evaluation tree of w . Each node n has a value $v(n) \in G$ that is the value of the subtree rooted at n . We associate to any path from a node n to a leaf a a word $p(n, a) \in \mathcal{M}(G)^+$ as follows. If n is a leaf then $p(n, a) = R(v(n))$. Otherwise, let n_l and n_r be, respectively, the left and right children of n . Then, $p(n, a) = p(n_l, a)R(v(n_r))$ if n_l lies on the path, otherwise $p(n, a) = p(n_r, a)L(v(n_l))$. A simple inductive argument shows that $v(n) = 1p(n, a)$. In particular, for any leaf a we have $v(r) = 1p(r, a)$, where r is the root of the evaluation tree.

Let an *angle* along a path be a pair of consecutive edges with exactly one right edge and one left edge. In [2], it is shown that L is recognized by a PDA whose stack never needs to be higher than the maximal number of angles along any path in the tree. We will show that any evaluation tree is equivalent to a tree whose maximal number of angles is bounded by a constant. This will prove that L is regular.

Each angle along a path from a leaf a to the root r corresponds in $p(r, a)$ to two consecutive elements of the form $R(x)L(y)$ or $L(x)R(y)$. Let $p(r, a)$ contains a factor of the form $L(a)R(b_1) \cdots R(b_i)L(c_1) \cdots L(c_j)R(d)$ and replace this factor with $L(a)L(c_1) \cdots L(c_j)R(b_1) \cdots R(b_i)R(d)$. This keeps intact the ordering of the leaves and corresponds to a transformation of the evaluation tree that reduces the number of angles along the path from a to r without increasing that number on the other paths. However, nothing guarantees that the two trees evaluate to the same element.

In order to solve this problem, assume $w \in L$. Thus, $1p(r, a) \in F$ and $p(r, a) = x_0a_1x_1 \cdots a_nx_n$ where $a_i \in \mathcal{M}(G)$ and $x_i \in L_i$ which is recognized by some semigroup $M \in \mathbf{J}_1 \vee \mathbf{G}$. Without loss of generality we can suppose that M is the same for all $0 \leq i \leq n$ and that $|M| = t$. If $p(r, a)$ contains more than $3nt$ angles then there must exist $0 \leq c \leq n$ such that x_c contains more than $3t$ angles. Let $x_c = u_0B_1u_1B_2u_2 \cdots B_tu_t$ be a factorization such that each B_m has the form $L(a)R(b_1) \cdots R(b_i)L(c_1) \cdots L(c_j)R(d)$. For each such B_m , define $B'_m = L(a)L(c_1) \cdots L(c_j)R(b_1) \cdots R(b_i)R(d)$. For each $0 \leq i \leq t$ define $y_i = u_0B'_1u_1 \cdots B'_iu_iB_{i+1}u_{i+1} \cdots B_tu_t$.

Let $\varphi : \mathcal{M}(G) \rightarrow M$ be the syntactic morphism of L_c . By the pigeon hole principle, there is $0 \leq i < j \leq t$ such that $\varphi(y_i) = \varphi(y_j)$. This implies that $\varphi(B_{i+1}u_{i+1} \cdots B_ju_j) = \varphi(B'_{i+1}u_{i+1} \cdots B'_ju_j)$ since $M \in \mathbf{J}_1 \vee \mathbf{G}$. Hence, $\varphi(x_c) = \varphi(u_0B_1u_1 \cdots B_iu_iB'_{i+1}u_{i+1} \cdots B'_ju_jB_{j+1}u_{j+1} \cdots B_tu_t)$. This shows that if an evaluation tree contains a path with more than $3tn$ angles then we can find an equivalent tree that contains less angles along that path and no more angles along the other paths. Hence, if $w \in L$, there exists an evaluation tree with no more than $3tn$ angles along any path. We conclude that L is regular.

Theorem 1 is a simple corollary of the above proposition since, as it was mentioned in the preliminaries, monoids in \mathbf{DO} recognize only languages in $\text{UPol}(\mathbf{J}_1 \vee \mathbf{G})$ which is a subclass of $\text{Pol}(\mathbf{J}_1 \vee \mathbf{G})$.

4 Recognizing all Regular Languages

In this section we prove that any regular language is recognized by a finite groupoid whose multiplication semigroup is in \mathbf{R} . Let M be a finite monoid and $\{a_1, a_2, \dots, a_k\}$ an enumeration of the elements of M . Let S_0 be the empty set and for $1 \leq i \leq k$ let $S_i = \{a_1, \dots, a_i\}$. We write $v < w$ to mean that v is a strict non empty prefix of w . We define the following language:

$$D(a_i, a_j, t) = \{w \in M^+ \mid a_i w = a_j \text{ and } v < w \Rightarrow a_i v \notin S_t\}$$

We only have to show that Theorem 2 applies for languages of the form $D(a_i, a_j, 0) = \{w \in M^+ \mid a_i w = a_j\}$ which can be defined using the well known recurrence:

$$D(a_i, a_j, t) = D(a_i, a_j, t + 1) \cup D(a_i, a_t, t + 1) D(a_t, a_t, t + 1)^* D(a_t, a_j, t + 1)$$

if $0 \leq t < k$ and

$$D(a_i, a_j, k) = \{b \in M \mid a_i b = a_j\}$$

We define a groupoid G on the set $\{0\} \cup \{[a_i, a_j, t] \mid 1 \leq i, j \leq k, 0 \leq t \leq k\}$ with $[a_i, a_j, s][a_j, a_i, t] = [a_i, a_i, j - 1]$ if $s \geq j - 1$ and $t \geq j$ (these inequalities are crucial for the proof). In all other cases the product is defined to be 0. The absorbing element of G is $R(0) = L(0)$. Observe also that a necessary condition to evaluate $w = [a_{i_1}, a_{j_1}, t_1] \cdots [a_{i_n}, a_{j_n}, t_n]$ to a non zero element is that $a_j = a_{i_{s+1}}$ for all $1 \leq s < n$. Moreover, if $t_i = k$ for all i then there exists a way to evaluate w to $[a_{i_1}, a_j, m]$ where $m = \min \{i_2, \dots, i_n\} - 1$. It is a simple exercise to prove:

Lemma 1. *The only idempotents in $\mathcal{M}(G)$ are $R(0)$ and the elements of the form $R([a_j, a_j, k])$, where $0 \leq j \leq k$. Moreover, if $W \in \mathcal{M}(G)^+$ can be evaluated to a nonzero element, then it contains at most $2k$ occurrences of non idempotent elements. Furthermore, two occurrences of the same idempotent must be adjacent.*

Let $\mathcal{P}(G)$ be the power groupoid of G and let $H \subseteq \mathcal{P}(G)$ be the subgroupoid generated by the sets $U_b = \{[a_i, a_i b, k] \mid 1 \leq i \leq k\}$ for all $b \in M$. It is easy to see that, for any $1 \leq i, j \leq k$, $D(a_i, a_j, 0)$ is recognized by H using the morphism which maps each $b \in M$ to the element U_b of H . We want to show that the multiplication semigroup of H belongs to \mathbf{R} .

There is an embedding from $\mathcal{M}(H)$ to $\mathcal{P}(\mathcal{M}(G))$. As in the next lemma, it will sometime be useful to see $\mathcal{M}(H)$ as a subsemigroup of $\mathcal{P}(\mathcal{M}(G))$. Due to lack of space, the proof of the following lemma is omitted.

Lemma 2. *$X \in \mathcal{M}(H)$ is an idempotent if and only if for all $A \in X$ there exists an idempotent $E \in X$ such that $A = AE$.*

Lemma 3. *$\mathcal{M}(H)$ is aperiodic.*

Proof. Let S be an element in $\mathcal{M}(H)$. We must show that there exists $m > 0$ such that $S^m = S^{m+1}$. By Lemma 1, for large m there exists a position i such

that all elements $X_1X_2 \cdots X_{m+1} \in S^{m+1}$ which evaluate to a nonzero element are such that X_i is an idempotent that occurs at least twice in X . Thus, we have $X = X_1 \cdots X_{i-1}X_{i+1} \cdots X_{m+1} \in S^m$. This shows that $S^{m+1} \subseteq S^m$. For the other direction, let S^m be an idempotent. By Lemma 2, for all $A \in S^m$ there exists an idempotent $E \in S^m$ such that $A = AE$. Now, if $E = R([a, a, k]) \in S^m$ then $E \in S$ as well. Hence, $A = AE \in S^{m+1}$ and $S^m \subseteq S^{m+1}$.

Lemma 4. *Let $X, Y \in \mathcal{M}(H)$ be two idempotents. Then, X and Y are \mathcal{J} -equivalent if and only if they contain the same idempotents in $\mathcal{M}(G)$. Moreover, if X and Y are \mathcal{J} -equivalent idempotents then they are \mathcal{L} -equivalent.*

Proof. Let $X, Y \in \mathcal{M}(H)$ be two \mathcal{J} -equivalent idempotents. Let $U, V \in \mathcal{M}(H^1)$ be such that $UXV = Y$. Then, for each $R([a, a, k]) \in Y$, there exist $u \in U$, $v \in V$ and $x \in X$ such that $uxv = R([a, a, k])$ and this is only possible if $x = R([a, a, k])$. This shows that $R([a, a, k]) \in X$ if and only if $R([a, a, k]) \in Y$.

Suppose now that X and Y are idempotents in $\mathcal{M}(H)$ containing the same idempotents in $\mathcal{M}(G)$. By Lemma 2 there exists an idempotent $e \in Y$ such that $y = ye$. By the definition of H , there is at most one $x \in X$ such that $yx \neq 0$. Since e also belongs to X then we have $YX = Y$. Similarly, we show that $X = XY$ proving that X and Y are \mathcal{L} -equivalent.

Proposition 2. $\mathcal{M}(H)$ belongs to \mathbf{R} .

Proof. The proof of Lemma 4 shows that the product of two \mathcal{J} -equivalent idempotents is an idempotent in the same \mathcal{L} -class. Hence, each regular \mathcal{J} -class contains only one \mathcal{L} -class. Moreover, by lemma 3, $\mathcal{M}(H)$ is aperiodic. We conclude that $\mathcal{M}(H)$ is \mathcal{R} -trivial since it satisfies the equation $(xy)^\omega x = (xy)^\omega$.

5 Groups in Loops

This section is devoted to the proof of Theorem 3 which makes extensive use of the derived monoid of a loop defined earlier. It is easy to see that any language L recognized by a loop B is also recognized by $D(B) = B^+ / \sim$. We denote by $[w]$ the element of $D(B)$ that contains $w \in B^+$. Before proving Theorem 3, we give some simple properties of the derived monoid. Let B be a loop with identity e . The set of elements $[w] \in D(B)$ such that $e \in \text{eval}(w)$ forms a submonoid of $D(B)$ that we denote $D_1(B)$.

Lemma 5. *If $[w]$ is an idempotent of $D(B)$ then $[w] \in D_1(B)$ and $\text{eval}(w)$ is a subloop of B .*

Proof. By the cancellation law, there exists $k > 0$ such that $e \in \text{eval}(a^k)$ for all $a \in B$. In particular we have $e \in \text{eval}(w^k)$ for all $w \in B^+$. Since $[w]$ is an idempotent then $[w^k] = [w]^k = [w]$, and so, $e \in \text{eval}(w)^k = \text{eval}(w)$.

Lemma 6. $D_1(B)$ is \mathcal{J} -trivial.

Proof. Let $X, Y \in D_1(B)$ such that XJY . Hence, there exists $A, B \in D_1(B)$ such that $AXB = Y$. This means that for all $s, t \in B^*$ we have $\text{eval}(sAXBt) = \text{eval}(sYt)$. Since both $\text{eval}(A)$ and $\text{eval}(B)$ contain the identity, then we must have $\text{eval}(sXt) \subseteq \text{eval}(sYt)$. Similarly, we show that $\text{eval}(sYt) \subseteq \text{eval}(sXt)$ for all $s, t \in B^*$. This proves that $X = Y$.

Proposition 3. If H is a group that divides B , then H divides $D(B)$.

Proof. We first show that if H is a loop that divides B then $D(H)$ divides $D(B)$. Let K be a subloop of B and let $\psi : K \rightarrow H$ be a morphism. Let $\varphi : D(K) \rightarrow D(H)$ be the morphism defined by $\varphi([w]) = [\psi(w)]$. Ideed, we have that $\varphi([u][v]) = \varphi([uv]) = [\psi(uv)] = [\psi(u)\psi(v)] = [\psi(u)][\psi(v)] = \varphi([u])\varphi([v])$, proving that φ is a morphism. The conclusion follows from the observation that $D(K) \prec D(B)$ and that if H is a group then $D(H) = H$.

The converse of this proposition needs a few lemmas. Let $H = \{[w_1], \dots, [w_n]\}$ be a subgroup of $D(B)$ where $[w_1]$ is the identity.

Lemma 7. For all $[u], [v] \in H$ we have that $|\text{eval}(u)| = |\text{eval}(v)|$.

Proof. Since H is a group, there exists $[w] \in H$ such that $[u][w] = [v]$. Hence, $\text{eval}(uw) = \text{eval}(v)$ and by the cancellation law $|\text{eval}(u)| \leq |\text{eval}(v)|$. Similarly, we show that $|\text{eval}(u)| \geq |\text{eval}(v)|$.

Lemma 8. For all i, j , either $\text{eval}(w_i) = \text{eval}(w_j)$ or $\text{eval}(w_i) \cap \text{eval}(w_j) = \emptyset$.

Proof. Let $a \in \text{eval}(w_i) \cap \text{eval}(w_j)$. Since $[w_1]$ is the identity, then $\text{eval}(w_i) = \text{eval}(w_1)\text{eval}(w_i) = \text{eval}(w_1)a = \text{eval}(w_1)\text{eval}(w_j) = \text{eval}(w_j)$, where the first and the last equality are given by Lemma 7.

Lemma 9. For all $1 \leq i \leq n$, the set $N_i = \{[u] \in H : \text{eval}(u) = \text{eval}(w_i)\}$ is a singleton.

Proof. We first show that for all i, j , we have $|N_i| = |N_j|$. Let $[u_i] \in N_i$ and $[u_j] \in N_j$. There exists N_k and $[u_k] \in N_k$ such that $[u_i][u_k] = [u_j]$. It follows from Lemma 7 that $\text{eval}(u_i)\text{eval}(u_k) = \text{eval}(u_j)$. This shows that $N_iN_k \subseteq N_j$ and that $|N_i| \leq |N_j|$. Similarly, we show that $|N_j| \leq |N_i|$. We conclude that $|N_i| = |N_j|$. Now, let N_1 contains the identity $[w_1] \in H$. Then, N_1 is a group that is a submonoid of $D_1(B)$, and since $D_1(B)$ is \mathcal{J} -trivial then N_1 must be trivial.

We are now ready to prove the converse of Proposition 3.

Proposition 4. If H be a group that divides $D(B)$, then H divides B .

Proof. It is known (see [5] Chap.3, prop. 4.5) that if a group G divides $D(B)$ then there exists a group H which is a submonoid of $D(B)$ and such that G divides H . Hence, we only have to consider the case where H is a group which is a submonoid of $D(B)$.

From the previous lemma, if $H = \{[w_1], [w_2], \dots, [w_n]\}$ is a group that is a submonoid of $D(B)$ then $\text{eval}(w_i) \cap \text{eval}(w_j) \neq \emptyset$ implies that $i = j$. In other words, $\text{eval}(w_1), \text{eval}(w_2), \dots, \text{eval}(w_n)$ is a partition of $D = \{g \in B : \exists [w] \in H \text{ s.t. } g \in \text{eval}(w)\}$ which is a subloop of B . Moreover, $\text{eval}(w_1)$ is a normal subloop of D , and $D/\text{eval}(w_1)$ is a group isomorphic to H .

Proof of Theorem 3: If L is recognized by B then it is also recognized by $D(B)$. This means that $M(L)$ divides $D(B)$. Hence, any group that divides $M(L)$ also divides B by the previous proposition.

6 Other Properties of the Derived Monoid

This section is devoted to the proof of Theorem 4. We first show the existence of a relational morphism from the derived monoid $D(B)$ to the multiplication group $\mathcal{M}(B)$. Recall that a relational morphism between two monoids N and M is a relation $\tau : M \rightarrow N$ satisfying: (1) $1 \in \tau(1)$; (2) $\tau(s) \neq \emptyset$; (3) $\tau(s)\tau(t) \subseteq \tau(st)$, for all $s, t \in M$.

Proposition 5. *Let B be a loop, $\mathcal{M}(B)$ its multiplication group, and $R(1) = L(1)$ the identity of $\mathcal{M}(B)$. There exists a relational morphism $\tau : D(B) \rightarrow \mathcal{M}(B)$ such that $D_1(B) = \tau^{-1}(R(1))$*

Proof. We actually only need the subgroup $\mathcal{M}_R(B) \subseteq \mathcal{M}(B)$ that is generated by the right multiplications of B . Given $S \subseteq \mathcal{M}_R(B)$ and $a \in B$ let $aS = \{aW : W \in S\} \subseteq B$. Given a word $v \in B^+$ let $R(v) = \{R(a) : a \in \text{eval}(v)\}$. We first define the relational morphism $\eta : B^* \rightarrow \mathcal{M}_R(B)$ as follows: $\eta(\epsilon) = \{R(1)\}$, $\eta(a) = \{R(a)\}$ for all $a \in G$, and $\eta(w) = \bigcup_{w=uv} \eta(u)R(v)$, where $u \in B^*, v \in B^+$. It should be clear that $\text{eval}(w) = 1\eta(w)$ for all $w \in B^+$.

To prove that η is a relational morphism we need to show that $\eta(u)\eta(v) \subseteq \eta(uv)$ for all $u, v \in B^+$. We proceed by induction on the length of v . If $v = a \in B$ then $\eta(u)\eta(a) = \eta(u)R(a) \subseteq \eta(ua)$. Suppose now that v contains more than one letters and let $X \in \eta(v)$. Then, there exist $v_1 \in B^*, v_2 \in B^+$ such that $v = v_1v_2$ and such that $X \in \eta(v_1)R(v_2)$. By the induction hypothesis we have $\eta(u)\eta(v_1) \subseteq \eta(uv_1)$. Putting everything together we have: $\eta(u)X \subseteq \eta(u)\eta(v_1)R(v_2) \subseteq \eta(uv_1)R(v_2) \subseteq \eta(uv_1v_2) = \eta(uv)$. Let $h : B^* \rightarrow D(B)$ be the natural morphism. Then, $\tau = \eta h^{-1}$ is a relational morphism with the desired property.

To prove Theorem 4 we need some classical result from category theory. A *multigraph* C is a set of *objets* $\text{Obj}(C)$ and, for each pair $a_1, a_2 \in \text{Obj}(C)$, a set of *arrows* denoted $C(a_1, a_2)$. A *category* C is a multigraph with an associative composition rule that assign to every consecutive pair of arrows $s : a_1 \rightarrow a_2$

and $t : a_2 \rightarrow a_3$ an arrow $st : a_1 \rightarrow a_3$. Moreover, for each $a \in \text{Obj}(C)$ there is a unique *identity arrow* $1_a : a \rightarrow a$ satisfying $1_a t = t$ and $s 1_a = s$ for all $s \in C(a', a)$ and $t \in C(a, a'')$ such that $a', a'' \in \text{Obj}(C)$.

Given a category C , a *subcategory* S is a sub-multigraph of C which is a category under the composition rule of C . If $S \subseteq \text{Obj}(C)$ then $C(S)$ denote the full subcategory whose set of objects is S . In particular, for each $a \in \text{Obj}(C)$, the subcategory $C(a)$ forms a monoid called the *local monoid* of C at a .

Let C and D be categories. A *relational morphism* $\tau : C \rightarrow D$ is an object function $\tau_1 : \text{Obj}(C) \rightarrow \text{Obj}(D)$ and, for each $a, b \in \text{Obj}(C)$, a relation $\tau_2 : C(a, b) \rightarrow D(\tau_1(a), \tau_1(b))$ such that for each pair of arrows s, t we have $\varphi_2(s)\varphi_2(t) \subseteq \varphi_2(st)$. Also, for all $a \in \text{Obj}(C)$ we have $1_{\varphi_1(a)} \in \varphi_2(1_a)$. Moreover, if $\tau_2 : C(a, b) \rightarrow D(\tau_1(a), \tau_1(b))$ is *injective* (i.e. $s \neq t$ implies $\tau_2(s) \cap \tau_2(t) = \emptyset$), then τ is called a *division*.

A category C *divides* a category D (denoted $C \prec D$) if there exists a division $C \rightarrow D$. If moreover $D \prec C$ then we say that C is *equivalent* to D and we write $C \sim D$.

Let $a, b \in \text{Obj}(C)$. We say a is a *retract* of b if there exists arrows $s \in C(a, b)$ and $t \in C(b, a)$ such that $st = 1_a$. The following three results are from [17]:

Lemma 10 (Tilson). *Let C be a category, and let $S \subseteq \text{Obj}(C)$. If every object of C is a retract of some object in S , then $C \sim C(S)$.*

Let $\tau : S \rightarrow T$ be a relational morphism of monoids. The *derived category* D_τ of τ is the category whose objects set is $\text{Obj}(D_\tau) = \tau(S)$ and $D_\tau(t, tt') = \{[t, (s, t'), tt'] : s \in \tau^{-1}(t)\}$. The composition rule is given by

$$[t, (s, t'), tt'] [tt', (s', t''), tt't''] = [t, (ss', t't''), tt't'']$$

Lemma 11 (Tilson). *Let $\tau : S \rightarrow T$ be a relational morphism of monoids. Then, $D_\tau(1) = \tau^{-1}(1)$.*

Theorem 5 (Derived Category Theorem). *Let $\tau : S \rightarrow T$ be a relational morphism of monoids, and let M be a monoid satisfying $D_\tau \prec M$. Then, $S \prec M \circ T$.*

Proof of Theorem 4: Let $\tau : D(B) \rightarrow \mathcal{M}(B)$ be the relational morphism defined in Proposition 5. By Lemma 11 we have that $D_\tau(1)$ is equivalent to $\tau^{-1}(1) = D_1(B)$. Now, let $a \in \text{Obj}(D_\tau)$ and consider the arrows $s = [1, (1, a), a]$ and $t = [a, (1, a^{-1}), 1]$. Then, we have $st = [1, (1, a), a][a, (1, a^{-1}), 1] = [1, (1, 1), 1] = 1_1$ which is the identity arrow of the object 1. Hence, every object is a retract of 1 and, by Lemma 10, D_τ is equivalent to $D_\tau(1) \sim D_1(B)$. The conclusion follows from the Derived Category Theorem.

7 Conclusion

In this work we have investigated groupoids that can recognize only regular languages. We prove that if the multiplication semigroup of a groupoid G belongs

to **DO** then G can only recognize regular languages. On the other hand, it is known from [2] that if the multiplication semigroup belongs to any pseudovariety which is not contained in **DS**, then G can recognize a language that is not regular. The case of **DS** is more obscure and its investigation is complicated by the fact that it is difficult to build non-trivial examples of groupoids whose multiplication semigroup is in **DS** but not in **DO**.

Groupoids who recognize only regular languages could be called “weak” since their Word Problems is always in \mathbf{NC}^1 . However, there exist groupoids with this property that can recognize non-regular languages. For example, a groupoid that recognizes the non-regular language MAJORITY (set of words over $\{0, 1\}$ that contain a majority of 1) is given in [9]. Moreover, all the Word Problems of this groupoid belong to \mathbf{TC}^0 a class that lies inside \mathbf{NC}^1 . Knowledge of algebraic conditions that would force the Word problem of a groupoid to be in \mathbf{TC}^0 could be very useful for the important question of whether the inclusion $\mathbf{TC}^0 \subseteq \mathbf{NC}^1$ is strict or not.

Generally, given a groupoid G and a set $F \subseteq G$, it is undecidable to determine if the set $\{w \in G^+ \mid \text{eval}(w) \cap F \neq \emptyset\}$ is regular. However, it is not clear if it is decidable to determine if a groupoid recognizes only regular languages. This is equivalent to the question of deciding if the derived semigroup of a groupoid is finite or not. An important related question is to decide whether a groupoid has its word problem in \mathbf{NC}^1 or not. Again, this could have interesting consequences on the study of small complexity classes.

Abstract. We present a new primitive – Append-only Signatures (AOS) – with the property that any party given an AOS signature $\text{Sig}[M_1]$ on message M_1 can compute $\text{Sig}[M_1\|M_2]$ for any message M_2 , where $M_1\|M_2$ is the concatenation of M_1 and M_2 . We define the security of AOS, present concrete AOS schemes, and prove their security under standard assumptions. In addition, we find that despite its simple definition, AOS is equivalent to Hierarchical Identity-based Signatures (HIBS) through efficient and security-preserving reductions. Finally, we show direct applications of AOS to problems in network security. Our investigations indicate that AOS is both useful in practical applications and worthy of further study as a cryptographic primitive.

Keywords: Algebraic Signatures, Append-only Signatures, Hierarchical Identity-based Signatures.

1 Introduction

In many real-world applications, users and programs alike require notions of delegation to model the flow of information. It is often required that delegation from one party to another enables the delegatee to “append” to the information it received but to do nothing more. For example, in wide-area Internet routing, each network passes a routing path advertisement to its neighboring networks, which then append to it information about themselves and forward the updated advertisement to their neighbors. For security, the route advertisements must be authenticated; intermediate networks must be incapable of modifying routes except according to the protocol (that is, by appending their names to already-received advertisements). Likewise, in the context of secure resource delegation for distributed systems, users need to delegate their share of resources to other users, who may then re-delegate to other users by including their own resources in

the pool. In many of these applications, it is desirable that delegation is possible without parties having to share any cryptographic keys and that the authenticity of any information received through a series of delegations is verifiable based only on the identity of the first party in the chain.

To directly address these needs, we present a new cryptographic primitive called Append-Only Signatures (AOS). An AOS scheme enables the extension of signed messages and update of the corresponding signatures, without requiring possession of the signing key. That is, any party given an AOS signature $\text{Sig}[M_1]$ on message M_1 can compute $\text{Sig}[M_1\|M_2]$ for any message M_2 , where $M_1\|M_2$ is the concatenation of M_1 and M_2 . The verifier of the final signature needs the initial signer’s public key but does not need to know the public keys or any other information from intermediate signers except the message data appended. Clearly, such a scheme cannot be secure according to the standard notion of security for signatures. Instead, we define an AOS scheme to be secure if it is infeasible to forge signatures of messages that are not obtained by extending already-signed messages. A formal definition appears in Section 2.

In Section 3 we present several provably secure AOS schemes, offering different tradeoffs of flexibility and efficiency. Our first construction shows a generic approach to building AOS schemes from any standard digital signature scheme using certificate chains. The construction works as follows: The secret and public keys for the AOS scheme are obtained by running the key generator for \mathcal{SIG} . For any message $M = M_1\|M_2\|\dots\|M_n$, each M_i being a symbol in some predetermined message space, the AOS signature of M is defined as a sequence of n public keys pk_1, pk_2, \dots, pk_n (generated using the key generator for \mathcal{SIG}) and a sequence of n certificates binding the message symbols to these public keys. The i th certificate in the chain binds the message symbol M_i to the corresponding public key pk_i and is signed using the secret key, sk_{i-1} , corresponding to pk_{i-1} . The secret key, sk_0 , of the AOS scheme signs the first certificate in the chain while the secret key sk_n (corresponding to the last public key), is revealed as part of the AOS signature and is used for appending new symbols to M . We observe that if the message space is small enough, we can make use of “weaker”, and more efficient, signature schemes without compromising the security of the resulting AOS scheme. Using aggregation techniques of [2, 10] one can reduce the length of the signature by a factor of two.

We also present a more efficient construction of AOS for applications in which the message space is constant size and the total number of append operations performed is also constant. This construction is based on a seemingly stronger assumption (than that of the existence of signature schemes) and makes use of pseudorandom generators and collision-resistant hash functions (CRHFs).

RELATION TO HIERARCHICAL IDENTITY-BASED SIGNATURES. Identity-Based Signature (IBS) schemes, due to Shamir [14], are signature schemes in which the identity of the signer (for example, her email address) plays the role of his public key. Such schemes assume the existence of a trusted authority that holds a master public-private key pair that is used to assign secret keys to users based

on their identities. Anyone can verify signatures on messages signed by a user knowing only the master public key and the identity of that user. Hierarchical IBS (HIBS) schemes, proposed by Gentry and Silverberg [4], are identity-based signature schemes in which users are arranged in a hierarchy and a user at any level in this hierarchy can delegate secret keys to her descendants based on their identities and her own secret key. To verify the signature created by any user, one needs to know only the identity of the user (and her position in the hierarchy) and the public key of the root user.

HIBS can be implemented using certificate chains (as suggested in [4]) and the resulting construction bears a strong resemblance to the certificate-based construction of AOS we give in this paper. Upon closer examination, we find that the similarity between the two constructions is not accidental: it is an artifact of the close relationship between the two primitives themselves—AOS and HIBS are, in fact, tightly equivalent. This means that (a) there exist generic transformations from any HIBS scheme into a corresponding AOS scheme and, likewise, from any AOS scheme into a corresponding HIBS scheme; and (b) these transformations are extremely efficient (the derived scheme is as efficient as the scheme being derived from) and highly security-preserving (an adversary attacking the derived scheme can be transformed into an adversary attacking the original one, losing only a constant factor in efficiency and query complexity). Section 4 gives details.

A benefit of this equivalence is that it considerably simplifies the notion of HIBS and makes security analysis for HIBS schemes less onerous: AOS is simpler than HIBS, and, for any HIBS scheme, it is typically easy to find an equivalent AOS scheme whose security properties carry over to the corresponding HIBS scheme. For example, our security proof for certificate-based AOS translates to a security proof for certificate-based HIBS (originally proposed in [4]). Although this construction of HIBS was known prior to our work, it was never analyzed in the literature, and, to the best of our knowledge, we give the first proof of security for it. Furthermore, our construction of AOS based on pseudorandom generators and CRHFs yields a novel approach to designing HIBS and can be useful for some restricted scenarios (for example, in a constant-depth hierarchy wherein each user signs messages from a constant-size message space). We remark that both these constructions yield HIBS schemes in the standard model and neither involves the use of computationally intensive bilinear maps (this is in contrast with some recent results on HIBS [3]).

APPLICATION TO SECURE ROUTING. In Section 5 we discuss an important real-life application of AOS in internet routing security.

RELATED WORK. Append-only signatures belong to a general class of primitives called *algebraic signatures*. Informally, an algebraic signature scheme allows the creation of signatures on a message M using the signatures on some known messages, M_1, M_2, \dots, M_n , and the public key, provided M can be obtained from the known messages using some prespecified set of (n -ary) operations, say $\mathcal{O} = \{f_1, f_2, \dots, f_m\}$. That is, given the signatures, $\text{sig}[M_1], \dots, \text{sig}[M_n]$ and

the public key, it is easy to compute $\text{sig}[f_i(M_1, \dots, M_n)]$ for any $f_i \in \mathcal{O}$. In our setting, each f_i has arity 1 and appends some fixed message symbol M_i to an input message M . Security for algebraic signatures is defined in a manner similar to our approach to security of AOS (that is, it should be hard to forge signatures of messages that cannot be obtained by applying the operations in \mathcal{O} to already-signed messages). Examples of algebraic signatures studied in the literature include transitive signatures by Micali and Rivest [12], homomorphic signatures by Johnson, Molnar, Song and Wagner [7], and graph-based algebraic signatures by Hevia and Micciancio [5].

Although no obvious relation exists between our primitive and any of the previously studied algebraic signature primitives, we do note that some of the techniques we use in our constructions parallel prior techniques. For example, our construction of AOS schemes using CRHFs can be viewed as a special instance of graph-based algebraic signature schemes studied in [5] (although the set of update operations considered there are different from the `append` operation that we consider).

2 Append-Only Signatures

Informally, append-only signatures (AOS) are signatures that enable the public extension of existing signatures. That is, any party given an AOS signature `Sig` on a message (M_1, \dots, M_n) can compute an AOS signature on any message $(M_1, \dots, M_n, M_{n+1})$. (As in the introduction, one could represent the message (M_1, \dots, M_n) as the string $M_1 \parallel \dots \parallel M_n$ which better captures the idea of appending. However, since we want to differentiate between the message “A” \parallel “B” and the message symbol “AB”, we prefer to think of messages as n -tuples. That is, in our example, we have the two different tuples (A, B) and (AB)). Besides the append operation, AOS is the same as ordinary signatures. That is, given only an AOS signature on the message (M_1, \dots, M_n) it should be infeasible to forge an AOS signature on any message not having (M_1, \dots, M_n) as a prefix.

Let `AOS.MSpace` be any set of symbols (for example, $\{0, 1\}$ or $\{0, 1\}^*$). A *message of length n* is an n tuple of symbols written as $M[1..n] = (M_1, M_2, \dots, M_n)$. The special case of $n = 0$ is the empty message, denoted ε . We use the symbol \sqsubseteq to denote the prefix relation over the messages. An append-only signature (AOS) scheme with respect to the message space `AOS.MSpace` is a collection of three polynomial-time algorithms: a setup algorithm (`AOS.Setup`), an append algorithm (`AOS.Append`), and a verify algorithm (`AOS.Vfy`), defined as follows:

- `AOS.Setup` takes the security parameter as input and outputs a pair of keys: the public key `AOS.pk` and the secret key `Sig[ε]`, which is the signature on the empty message ε .
- `AOS.Append` takes the public key `AOS.pk`, a signature on a message $M[1..n-1] = (M_1, \dots, M_{n-1})$, of length $n-1$, and a symbol $M_n \in \text{AOS.MSpace}$ and produces a signature on the message $M[1..n] = (M_1, \dots, M_n)$.
- `AOS.Vfy` takes the public key `AOS.pk`, a message $M[1..n]$, and a signature `sig`, and returns either `true` or `false`.

All algorithms can be randomized. Additionally, the scheme should have the property that for any pair $(\text{AOS.pk}, \text{Sig}[\varepsilon])$ and any message $M[1..n]$, the signature \mathbf{sig} obtained by iteratively appending M_1, \dots, M_n to $\text{Sig}[\varepsilon]$ should be accepted by AOS.Vfy . Appending the symbols one-by-one should be the only way of generating a signatures on the message $M[1..n]$. This fact ensures history independence of AOS: that is, no party, given an AOS signature, can tell whether the signature was created by the owner of the secret key or whether it passed through multiple parties that appended symbols at every step. History independence is a useful property to have in most applications, as already highlighted in previous work on algebraic signatures [7].

Definition 1. Let $\mathcal{AOS} = (\text{AOS.Setup}, \text{AOS.Append}, \text{AOS.Vfy})$ be an AOS scheme, let k be the security parameter, and let \mathcal{A} be an adversary. We consider the experiment:

<p>Experiment $\text{Exp}_{\mathcal{AOS}, \mathcal{A}}^{\text{aos-uf-cma}}(k)$</p> <p>$MSGSet \leftarrow \emptyset$; $(\text{AOS.pk}, \text{Sig}[\varepsilon]) \xleftarrow{\\$} \text{AOS.Setup}(1^k)$</p> <p>$(M[1..n], \mathbf{sig}) \xleftarrow{\\$} \mathcal{A}^{\text{AOSSIGN}(\cdot)}(\text{AOS.pk})$</p> <p>if $\text{AOS.Vfy}(\text{AOS.pk}, M[1..n], \mathbf{sig}) = \text{true}$</p> <p style="padding-left: 20px;">and $\forall J[1..j] \sqsubseteq M[1..n] : J[1..j] \notin MSGSet$</p> <p style="padding-left: 20px;">then return 1 else return 0</p>	<p>Oracle $\text{AOSSIGN}(M[1..n])$</p> <p style="padding-left: 20px;">Add $M[1..n]$ to $MSGSet$</p> <p style="padding-left: 20px;">return $\text{EXTRACT}(M[1..n])$</p>
--	--

Oracle $\text{EXTRACT}(M[1..i])$ // defined recursively

if $i = 0$ **then return** $\text{Sig}[\varepsilon]$

else if $\text{Sig}[M[1..i]] = \text{defined}$

then return $\text{Sig}[M[1..i]]$

else $\text{Sig}[M[1..i]] \xleftarrow{\$} \text{AOS.Append}(\text{AOS.pk}, M[1..i-1], \text{EXTRACT}(M[1..i-1]), M_i)$

return $\text{Sig}[M[1..i]]$

The aos-uf-cma-advantage of an adversary \mathcal{A} in breaking the security of the scheme \mathcal{AOS} is defined as $\text{Adv}_{\mathcal{AOS}, \mathcal{A}}^{\text{aos-uf-cma}}(k) = \Pr[\text{Exp}_{\mathcal{AOS}, \mathcal{A}}^{\text{aos-uf-cma}}(k) = 1]$, and \mathcal{AOS} is said to be *unforgeable under chosen message attacks* (aos-uf-cma secure) if the above advantage is a negligible function in k for all polynomial-time adversaries \mathcal{A} .

Note that \mathcal{A} is given access to the oracle $\text{AOSSIGN}(\cdot)$, not to the oracle $\text{EXTRACT}(\cdot)$ (the latter is used internally by $\text{AOSSIGN}(\cdot)$ to create intermediate signatures).

3 Efficient AOS Constructions

We briefly sketch our constructions for AOS in this section. More details (including proofs of all theorems) can be found in [9].

CERTIFICATE-BASED APPEND-ONLY SIGNATURES. We present an efficient construction of a provably-secure AOS scheme based on a public-key signature scheme. Let $\mathcal{SGN} = (\text{SGN.G}, \text{SGN.S}, \text{SGN.V})$ be a signature scheme with a space of public keys SGN.PKSpace and message space $\text{SGN.MSpace} = \text{AOS.MSpace} \times$

SGN.PKSpace. That is, messages to be signed by \mathcal{SGN} are tuples of the form (M, pk) , where $M \in \text{AOS.MSpace}$ and $pk \in \text{SGN.PKSpace}$. An AOS signature Sig of $M[1..n]$ is a tuple $(pk_1, sig_1, \dots, pk_n, sig_n, sk_n)$, where for $1 \leq i \leq n$, (pk_i, sk_i) are random public/secret key pairs of the public-key signature scheme \mathcal{SGN} and sig_i is a signature on the tuple (M_i, pk_i) under the secret key sk_{i-1} . The signature sig_0 is signed with the secret key sk_0 , which is the signature of ε (the master secret key). Our AOS scheme $\mathcal{AOS1}$ with message space AOS.MSpace is specified as follows:

- **AOS.Setup**(1^k): Run $\text{SGN.G}(1^k)$ to generate a pair (pk_0, sk_0) and returns it as AOS public/secret key pair.
- **AOS.Append**($\text{AOS.pk}, \text{Sig}[M[1..n]], M_{n+1}$): Parse Sig as $(pk_1, sig_1, \dots, pk_n, sig_n, sk_n)$. Run $\text{SGN.G}(1^k)$ to generate a pair (sk_{n+1}, pk_{n+1}) . Compute $sig_{n+1} \leftarrow \text{SGN.S}_{sk_n}(M_{n+1}, pk_{n+1})$. Return $(pk_1, sig_1, \dots, pk_{n+1}, sig_{n+1}, sk_{n+1})$.
- **AOS.Vfy**($\text{AOS.pk}, M[1..n], \text{Sig}$): Parse Sig as $(pk_1, sig_1, \dots, pk_n, sig_n, sk_n)$. Set pk_0 to be the master public key AOS.pk . For $i = 1..n - 1$ verify that $\text{SGN.V}(pk_{i-1}, sig_i, (M_i, pk_i)) = \text{true}$. If any of the verifications fail, return **false**. If all the verifications succeed, verify that (sk_n, pk_n) is a valid secret key/public key pair (by signing and verifying a signature on a random message under sk_n).

Theorem 2. The AOS scheme $\mathcal{AOS1}$ is aos-uf-cma secure assuming that the public-key signature scheme \mathcal{SGN} is *unforgeable under chosen message attacks*.

SHORTER SIGNATURES VIA AGGREGATION. An aggregate signature scheme, $\mathcal{ASGN} = (\text{ASGN.G}, \text{ASGN.S}, \text{ASGN.AG}, \text{ASGN.V})$, allows the aggregation of n signatures on n distinct messages from n distinct users into a single signature. Its verification algorithm, $\text{ASGN.V}(n, \cdot)$, takes an aggregated signature, n messages, and n public keys and verifies that the n users signed the n messages. When using the certificate-based construction of AOS from Section 3, we can use sequential signature aggregation to shrink the size of the signature (without significantly decreasing security or efficiency). To be more precise, the length of an AOS signature of a message of length n can be condensed to one signature of \mathcal{ASGN} , n public keys of \mathcal{ASGN} , and one secret key of \mathcal{ASGN} . We note that there are two known signature aggregation techniques. The first scheme, given in [2], is based on bilinear maps. The second scheme (only supporting sequential aggregation) is from [10] and can be based on homomorphic trapdoor permutations (such as RSA). Both aggregation schemes are in the random oracle model.

AOS VIA HASH TREES. If the number of symbols in the alphabet AOS.MSpace is small, AOS can be efficiently implemented using hash trees [11]. This approach suffers from dramatic complexity blowup as the size of the message space increases, but uses only secret-key primitives and provides good security guarantees. We believe that this construction is useful in computationally

constrained applications. Here we show how to construct an AOS scheme $\mathcal{AOS2}$ with message space $\text{AOS.MSpace} = \{0, 1\}$ and message length restricted to d . The construction uses a pseudorandom generator $G : \{0, 1\}^k \rightarrow \{0, 1\}^{2k}$ and a collision-resistant hash function $H : \{0, 1\}^k \times \{0, 1\}^k \rightarrow \{0, 1\}^k$. We denote by $G_i : \{0, 1\}^k \rightarrow \{0, 1\}^k$ the i -th k -bit component of G for $i \in \{0, 1\}$.

Consider the graph T depicted in the left part of Figure 1, whose nodes are denoted as shown on the figure (the upper part (UT) in round brackets and the lower part (LT) in square brackets). In general, the graph T has d levels in both upper and lower parts. For any node $u = \langle v_1, \dots, v_j \rangle$ from the upper part of the graph, we define the complement of u , denoted $\text{Comp}(u)$, to be the minimal set of nodes in $LT - \{\tilde{\varepsilon}\}$ such that every path from ε to $\tilde{\varepsilon}$ passes through exactly one node from $\{u\} \cup \text{Comp}(u)$. An example of a complement set is given on the right half of Figure 1.

Fig. 1. Structure of the hash-tree construction for $d = 2$. The diagram on the left depicts the hash tree. The diagram on the right highlights the node $u = \langle 0, 1 \rangle$ (shown in black) and the set of its complements, $\text{Comp}(u)$ (shown in gray)

In $\mathcal{AOS2}$, a message $M = (M_1, \dots, M_n)$ is associated with a node $u = \langle M_1, \dots, M_n \rangle$ from the upper part of the graph. Each node u is associated with a k -bit value $\text{key}(u)$, which is called the “key” of the message. The setup algorithm assigns these values in a top-down manner, starting from the root node ε . Initially, the root key $\text{key}(\varepsilon)$ is chosen at random from $\{0, 1\}^k$. Keys of all the other nodes in the upper part of T are obtained by repeated application of G : keys of left and right children of a node u are $G_0(\text{key}(u))$ and $G_1(\text{key}(u))$, respectively. Keys of the nodes on the highest lower level are obtained by applying G_0 to their parents’ keys; keys of the other nodes in the lower part are obtained by applying H to their parents’ keys. The setup algorithm outputs $\text{key}(\tilde{\varepsilon})$ as the public key and $\text{key}(\varepsilon)$ as the secret key of AOS.

The signature of a node u consists of the keys in the set $\{u\} \cup \text{Comp}(u)$. Note that given a signature of u , one can compute the keys of all the descendants

of u including the last node $\tilde{\varepsilon}$. Verification of a signature is done by computing the keys of all the descendants of u and comparing the obtained key($\tilde{\varepsilon}$) with the public key. The append algorithm, given a signature of $u = \langle M_1, \dots, M_n \rangle$ and a bit M_{n+1} , computes the key of $u' = \langle M_1, \dots, M_{n+1} \rangle$ (which is a child of u) and the keys of all the nodes in $\text{Comp}(u')$ (which are descendants of u and $\text{Comp}(u)$). It returns these keys as a signature on (M_1, \dots, M_{n+1}) .

Theorem 3. If $G(\cdot)$ is a secure pseudorandom generator, $G_0(\cdot)$, $G_1(\cdot)$, are secure one-way functions and $H(\cdot, \cdot)$, $G_0(\cdot)$, and $G_1(\cdot)$ are all collision-resistant hash functions, then $\mathcal{AOS2}$ is aos-uf-cma secure.

AOS VIA ONE-TIME SIGNATURES. We observe that we can combine the ideas of the certificate-based AOS and the hash-tree AOS to gain a more efficient append-only signature scheme when the message space is small. Assume the message space AOS.MSpace consists of m elements, where m is a constant. Then we can use our certificate-based construction $\mathcal{AOS1}$ instantiated with an m -time signature scheme. m -time signatures can be efficiently constructed using hash-trees (see [5, 13] for the definition and efficient constructions of one-time and m -time signatures). In addition, the security proof of $\mathcal{AOS1}$ guarantees unforgeability if \mathcal{SGN} is at least an $|\text{AOS.MSpace}|$ -time signature scheme.

COMPACT AOS. In the full version of the paper [9] we show how to use a recent technique of Boneh, Boyen and Goh [1] to get an AOS scheme in which the signature size is proportional to the square root of the length of the message.

4 Relations Between HIBS and AOS

In this section, we show that the concepts of AOS and Hierarchical Identity-based Signatures (HIBS) are in fact equivalent.

We start with a formal definition of HIBS. Let HIBS.IDSpace be any set of identities (typically $\{0, 1\}^*$). A *hierarchical identity of length n* is an n -tuple of identities from HIBS.IDSpace , written as $I[1..n] = (I_1, I_2, \dots, I_n)$. The *root identity* is denoted as $I[1..0]$ or ε . Again we use the symbol \sqsubseteq to denote the prefix relation over the set of hierarchical identities.

A HIBS scheme over identity space HIBS.IDSpace is made up of four (possibly randomized) algorithms: a setup algorithm HIBS.Setup , a key delegation algorithm HIBS.KeyDel , a signing algorithm HIBS.Sign and a verification algorithm HIBS.Vfy .

Definition 4. Given a HIBS scheme $\mathcal{HIBS} = (\text{HIBS.Setup}, \text{HIBS.KeyDel}, \text{HIBS.Sign}, \text{HIBS.Vfy})$, security parameter k and adversary \mathcal{A} consider the following experiment:

Experiment $\text{Exp}_{\mathcal{HIBS}, \mathcal{A}}^{\text{hibs-uf-cma}}(k)$

```

IDSet  $\leftarrow \emptyset$ 
(HIBS.pk, HIBS.SK[ $\varepsilon$ ])  $\leftarrow$  HIBS.Setup( $1^k$ )
( $I[1..n]$ ,  $M$ , sig)
 $\leftarrow \mathcal{A}^{\text{CORRUPT}(\cdot), \text{SIGN}(\cdot, \cdot)}(\text{HIBS.pk})$ 
if HIBS.Vfy( $I[1..n]$ ,  $M$ , sig) = true
  and  $\forall j \leq n$   $I[1..j] \notin \text{IDSet}$ 
  and ( $I[1..n]$ ,  $M$ )  $\notin \text{MSGSet}$ 
then return 1 else return 0

```

Oracle CORRUPT($I[1..n]$)

```

IDSet  $\leftarrow \text{IDSet} \cup \{I[1..n]\}$ 
return EXTRACT( $I[1..n]$ )

```

Oracle SIGN($I[1..n]$, M)

```

MSGSet  $\leftarrow \text{MSGSet} \cup \{(I[1..n], M)\}$ 
sk  $\leftarrow$  EXTRACT( $I[1..n]$ )
return HIBS.Sign(sk,  $I[1..n]$ ,  $M$ )

```

Oracle EXTRACT($I[1..i]$) // defined recursively

```

if  $i = 0$  return HIBS.SK[ $\varepsilon$ ]
else if HIBS.SK[ $I[1..i]$ ] = defined
  then return HIBS.SK[ $I[1..i]$ ]
else sk  $\leftarrow$  HIBS.KeyDel(HIBS.pk,  $I[1..i - 1]$ , EXTRACT( $I[1..i - 1]$ ),  $I_i$ )
  return sk

```

The *hibs-uf-cma-advantage* of an adversary \mathcal{A} in breaking the security of the scheme \mathcal{HIBS} is defined as $\text{Adv}_{\mathcal{HIBS}, \mathcal{A}}^{\text{hibs-uf-cma}}(k) = \Pr[\text{Exp}_{\mathcal{HIBS}, \mathcal{A}}^{\text{hibs-uf-cma}}(k) = 1]$, and \mathcal{HIBS} is said to be *existentially unforgeable under chosen message attacks* (hibs-uf-cma secure) if the above advantage is a negligible function in k for all polynomial time adversaries \mathcal{A} .

CONSTRUCTING AOS FROM HIBS. We set $\text{AOS.MSpace} = \text{HIBS.IDSpace}$ and associate an AOS message (M_1, \dots, M_n) of length n with the hierarchical identity $I[1..n] = (M_1, \dots, M_n)$ of depth n . We then define the signature of this message as the secret key $\text{HIBS.SK}[I[1..n]]$ of $I[1..n]$. Given the above analogy between signatures of messages and secret keys of hierarchical identities, we construct an AOS scheme given a HIBS scheme as follows. Appending to a given signature in \mathcal{AOS} is done using key delegation in \mathcal{HIBS} . The verification of an AOS signature $\text{HIBS.SK}[I[1..n]]$ is done by signing a random message $M \in \text{HIBS.MSpace}$ under the secret key $\text{HIBS.SK}[I[1..n]]$ and verifying that the resulting signature is valid. A formal construction is given in the full version [9].

Theorem 5. If the HIBS scheme $\mathcal{HIBS} = (\text{HIBS.Setup}, \text{HIBS.KeyDel}, \text{HIBS.Sign}, \text{HIBS.Vfy})$ is *hibs-uf-cma* secure, then the above AOS scheme is *aos-uf-cma* secure.

CONSTRUCTING HIBS FROM AOS. A naive approach to building a HIBS scheme from an AOS scheme would be as follows: for any hierarchical identity $I[1..n]$, define $\text{HIBS.SK}[\square I[1..n]]$ as the AOS signature on $I[1..n]$ and the HIBS signature created with $\text{HIBS.SK}[\square I[1..n]]$ on message M as the AOS signature formed by appending M to $\text{HIBS.SK}[\square I[1..n]]$. However, it can be shown that such a scheme is insecure. Our tweak is to insert a unique identifier to separate identities and messages. Let $\mathcal{AOS} = (\text{AOS.Setup}, \text{AOS.Append}, \text{AOS.Vfy})$ be an AOS scheme with message space AOS.MSpace . Let HIBS.IDSpace and HIBS.MSpace be subsets of AOS.MSpace such that there is some symbol Δ from the AOS message space which is not a valid identity for the HIBS scheme (Δ can still be in the

HIBS message space). Then we can construct a HIBS scheme with identity space HIBS.IDSpace and message space HIBS.MSpace as follows:

Construction 6. $\mathcal{HIBS} = (\text{HIBS.Setup}, \text{HIBS.KeyDel}, \text{HIBS.Sign}, \text{HIBS.Vfy})$:

- $\text{HIBS.Setup}(1^k)$: Run the $\text{AOS.Setup}(1^k)$ to generate a pair $(\text{AOS.pk}, \text{Sig}[\varepsilon])$; output it as the master public/private key pair for \mathcal{HIBS} .
- $\text{HIBS.KeyDel}(\text{HIBS.pk}, \text{HIBS.SK}[I[1..n]], I_{n+1})$: The delegation algorithm interprets $\text{HIBS.SK}[I[1..n]]$ as an \mathcal{AOS} signature of $I[1..n]$. It appends to the signature a symbol I_{n+1} and outputs the resulting signature as the secret key of $I[1..n+1]$.
- $\text{HIBS.Sign}(\text{HIBS.pk}, \text{HIBS.SK}[I_n], M)$: The signing algorithm for \mathcal{HIBS} interprets $\text{HIBS.SK}[I[1..n]]$ as an \mathcal{AOS} signature of $I[1..n]$. It appends a symbol Δ to $\text{HIBS.SK}[I[1..n]]$ and then appends the message M to the resulting \mathcal{AOS} signature to get the final signature \mathbf{sig} .
- $\text{HIBS.Vfy}(\text{HIBS.pk}, I[1..n], M, \mathbf{sig})$: The verification algorithm for \mathcal{HIBS} verifies if \mathbf{sig} is a valid \mathcal{AOS} signature of $(I_1, \dots, I_n, \Delta, M)$.

The following theorem is proven in the version [9]:

Theorem 7. If the \mathcal{AOS} scheme $\mathcal{AOS} = (\text{AOS.Setup}, \text{AOS.Append}, \text{AOS.Vfy})$ is aos-uf-cma secure, then the HIBS scheme \mathcal{HIBS} from Construction 6 is hibs-uf-cma secure.

5 Applications

An important application of \mathcal{AOS} is in the construction of secure routing protocols for the Internet. The Border Gateway Protocol (BGP), which is the primary routing protocol used today in the Internet, has some well-known security weaknesses which require cryptographic solutions. While there have been many proposals for securing BGP in the past [8, 6], each must develop its own cryptographic constructions due to the lack of any primitive designed specifically for this application. In the discussion below, we briefly describe Internet routing and explain how our primitive is useful for ensuring important security requirements in BGP.

The Internet is composed of various autonomous systems (ASes), each having control over some portion of the IP address space. BGP is the protocol used to spread information about the routes to all IP addresses in this network of ASes. Initially, all ASes advertise the IP addresses they own to their neighboring ASes. Upon receipt of such advertisements, each neighbor records this information, appends itself to the advertized route and sends the new information further down. The process repeats with the next AS in the chain and eventually, all ASes learn a route to the originating AS (In case an AS receives two or more routes to the same IP address, it selects one of them based on some local policy). Authenticity of route announcements is essential for ensuring the correct behaviour of BGP for otherwise, malicious ASes can play havoc with the Internet traffic. For example, if an AS truncates the route in some advertisement or modifies it selectively,

it could convince its neighbors to forward all their traffic to it, which it could then modify or drop at will (incidents of this nature have indeed occurred in the recent past [6]).

Append-only Signatures are a useful tool in addressing this problem. Suppose that an AS R_0 wishes to announce routes for some IP prefix it owns. It first generates an AOS public-private key pair, distributes the public key AOS.pk throughout the network (this can be done through a PKI as in [8, 6]) and to every neighboring AS R_{i_1} , sends the usual BGP information along with the AOS signature $\text{AOS.Append}(\text{AOS.pk}, \text{Sig}[\varepsilon], R_{i_1})$. In order to continue the advertisement process, R_{i_1} sends to each of its own neighbors R_{i_2} a BGP announcement containing the route (R_0, R_{i_1}) and the signature $\text{AOS.Append}(\text{AOS.pk}, \text{Sig}[R_{i_1}], R_{i_2})$. In other words, R_0 appends the label of its neighbor R_{i_1} into the AOS signature chain and R_{i_1} further appends the label of R_{i_2} into it. The advertisement process continues in this manner until all ASes in the network receive information about a route to R_0 . Each recipient can verify the validity of the announced route using the public key AOS.pk . If the AOS scheme is secure, then all that a malicious AS can do now is to append one of its neighbors into the AOS signature chain (since each R_i can check that the AS it receives a route from was the last to be appended before R_i). In practice, the number of path advertisements received by an AS from any given source AS is extremely small: as observed in real routing data [6], the odds that an AS receives more than 15 path advertisements coming from the same source are about 1 in a 1000. This enables us to use m -time signature schemes (with $m = 15$) for an efficient AOS with reasonable security guarantee. For more details and other applications of AOS, see [9].

6 Final Remarks and Open Problems

FINALIZATION OF AOS SIGNATURE. A property of append-only signature schemes which might be needed by some applications is the ability to “finalize” the signature, that is, to modify the signature of a message in a way that prohibits any further appending. The general solution to this problem is to use a special symbol Θ (from the message space) to denote the end of the message. When one wants to finalize the signature of some message, he should append Θ to the signature. Messages that contain symbol Θ in the middle of the message (not as the last symbol) are therefore considered to be invalid.

RESTRICTED AOS. In AOS, anyone can append and verify signatures. In certain scenarios, however, one may want to restrict the ability to append messages to a limited group of users. Still, anyone should be able to verify the signatures. We call this extension of AOS *Restricted Append-Only Signatures* (RAOS). Using a symmetric encryption scheme we show in the full version [9] how to modify a given AOS scheme to get an RAOS scheme.

SHORTER AOS SIGNATURES. Given that wide-area routing protocols propagate a large number of messages, compact signatures are desirable. Thus we raise an

open problem of whether it is possible to build an AOS scheme with constant signature length (in both message length and maximal message length). This problem is equivalent to building a HIBS scheme where secret keys of the users have constant length (in the depth of the given user in the hierarchy and in the maximal depth of the hierarchy).

Acknowledgments

We thank Mihir Bellare (for suggesting an improvement to the proof of Theorem 2) and Daniele Micciancio (for useful insight about the definition of AOS). Thanks also to the anonymous reviewers for helpful comments.

Hierarchical Group Signatures

Abstract. We introduce the notion of *hierarchical group signatures*. This is a proper generalization of group signatures, which allows multiple group managers organized in a tree with the signers as leaves. When opening a signature a group manager only learns to which of its subtrees, if any, the signer belongs.

We provide definitions for the new notion and construct a scheme that is provably secure given the existence of a family of trapdoor permutations. We also present a construction which is relatively practical, and prove its security in the random oracle model under the strong RSA assumption and the DDH assumption.

1 Introduction

Consider the notion of group signatures introduced by Chaum and van Heyst [13]. A group member can compute a signature that reveals nothing about the signer's identity except that he is a member of the group. On the other hand the group manager can always reveal the identity of the signer.

An application for group signatures is anonymous credit cards. The cardholder wishes to preserve his privacy when he pays a merchant for goods, i.e., he is interested in unlinkability of payments. The bank must obviously be able to extract the identity of a cardholder from a payment or at least an identifier for an account, to be able to debit the account. To avoid fraud, the bank, the merchant, and the cardholder all require that a cardholder cannot pay for goods without holding a valid card. To solve the problem using group signatures we let the bank be the group manager and the cardholders be signers. A cardholder signs a transaction and hands it to the merchant. The merchant then hands the signed transaction to the bank, which debits the cardholder and credits the merchant. Since signatures are unlinkable, the merchant learns nothing about the cardholder's identity. The bank on the other hand can always extract the cardholder's identity from a valid signature and debit the correct account.

The above scenario is somewhat simplified since normally there are many banks that issue cards of the same brand which are processed through the same payment network. The payment network normally works as an administrator and routes transactions to several independent banks. Thus, the merchant hands a payment to the payment network which hands the payment to the issuing bank. We could apply group signatures here as well by making the payment network act

as the group manager. The network would then send the extracted identity to the issuing bank. Another option is to set up several independent group signatures schemes, one for each issuer. In the first approach, the payment network learns the identity of the customer, and in the second approach the merchant learns which bank issued the customer's card. A better solution would reveal nothing except what is absolutely necessary to each party. The merchant needs to be convinced that the credit card is valid, the payment network must be able to route the payment to the correct card issuer, and the issuer must be able to determine the identity of the cardholder.

In this extended abstract we introduce and investigate the notion of *hierarchical group signatures*. These can be employed to solve the above problem. When using a hierarchical group signature scheme there is not one single group manager. Instead there are several group managers organized in a tree, i.e., each group manager either manages a group of signers or a group of group managers. In the original notion the group manager can always identify the signer of a message, but nobody else can distinguish between signatures by different signers. The corresponding property for hierarchical group signatures is more complicated. When opening a signature from a signer in its subtree, a group manager learns to which of the subtrees directly below it the signer belongs. Signatures from other signers are indistinguishable. Hence a group manager on the level directly above the signers can identify its signers, whereas group managers higher in the hierarchy only learn to which subtree the signer belongs.

When we use hierarchical group signatures to construct anonymous credit cards for the more realistic setting we let the payment network be the root manager that manages a set of group managers, i.e., the issuing banks, and we let the cardholders be signers. The credit card application also demonstrates what kind of responsibility model is likely to be used with a hierarchical group signature scheme. With a valid signature on a transaction, the merchant has a valid demand on the payment network. If the payment network has a signature that can be shown to belong to a certain bank, the network has a valid demand on that bank. Thus, it is in the network's interest to open the signatures it receives from merchants, and it is in the issuing banks' interest to open the signatures they receive from the network.

1.1 Previous Work

The concept of group signatures was first introduced by Chaum and van Heyst [13] in 1991. This and the group signature schemes that followed [14, 7] all have the property that the complexity of the scheme grows with the number of participants. In [11] Camenisch and Stadler presented a system where the key does not grow with the number of participants. This system, however, relies on a non-standard number-theoretic assumption. The assumption was actually found to be incorrect and modified in [2]. An efficient system whose security rests on the strong RSA assumption and the Diffie-Hellman decision assumption was presented by Camenisch and Michels in 1998 [10]. This system was improved in [1]. The currently most efficient scheme that is secure under standard assumptions

is [8]. More efficient schemes do exist [6, 9], but they are based on bilinear maps and thus relies on less well-studied assumptions for security.

A related notion is *traceable signatures* introduced by Kiayias et al. [19], where signatures belonging to a member can be opened, or traced, in a distributed way without revealing the group secret.

Bellare et al. [4] give a definitional framework for group signatures for static groups, i.e., when the set of members cannot be changed after the initial setup. The paper also contains a scheme based on general methods in this setting. Kiayias and Yung [20] define security for dynamic groups and prove that a modification of [1] is secure under these definitions. Independently, Bellare et al. [5] extend the definitions of [4] in a similar way to handle dynamic groups, and present a scheme that is secure under general assumptions.

In [2] the concepts of *multi-group signatures* and *subgroup signatures* are described, and in [21] a system for hierarchical multi-groups is given. It may be worthwhile to consider the differences between these concepts and hierarchical signatures introduced here. Subgroup signatures make it possible for an arbitrary number i of signers to produce a joint signature which can be verified to stem from i distinct group members. Multi-group signature schemes allow a signer who is a member of two groups to produce a signature that shows membership of either both groups or just one of them. In hierarchical multi-groups a signer who is a member of a supergroup with subgroups can produce a signature that reveals membership either of the supergroup or of a subgroup of his choice. However, the opening procedure is not hierarchical, i.e., there are no group managers for the subgroups.

1.2 Notation

Throughout the text, κ denotes a security parameter. A function $f : \mathbb{N} \rightarrow [0, 1]$ is said to be negligible if for each $c > 0$ there exists a $\kappa_0 \in \mathbb{N}$ such that $f(\kappa) < \kappa^{-c}$ for $\kappa_0 < \kappa \in \mathbb{N}$. We write \emptyset to denote both the empty set and the empty string. If T is a tree we denote by $\mathcal{L}(T)$ its set of leaves and by $\mathcal{V}(T)$ the set of all vertices. We write G_q for the unique subgroup of order q of \mathbb{Z}_p^* for a prime $p = 2q + 1$. In the ElGamal cryptosystem a secret key is a randomly generated $x \in \mathbb{Z}_q$ and the public key is $y = g^x$. To encrypt message $m \in G_q$, $r \in \mathbb{Z}_q$ is chosen randomly and the cryptotext is given by $(u, v) = E_y(m, r) = (g^r, y^r m)$. To decrypt a cryptotext $D_x(u, v) = u^{-x} v = m$ is computed. We denote by $N = PQ$ an RSA module for two strong primes P and Q , and let QR_N be the subgroup of squares in \mathbb{Z}_N^* with generators \mathbf{g} and \mathbf{h} . The adversaries in this paper are modeled as polynomial time Turing machines with *non-uniform* auxiliary advice string. We denote the set of such adversaries by PPT^* .

2 Hierarchical Group Signatures

In this section we discuss the notion of hierarchical group signatures. We begin by describing the parties of a hierarchical group signature system. Then we proceed by giving formal definitions.

Fig. 1. A tree of group managers and signers, where $\rho = \{\beta_1, \beta_2, \beta_3\}$, $\beta_1 = \{\alpha_1, \alpha_2\}$, $\beta_2 = \{\alpha_3, \alpha_4, \alpha_5, \alpha_6\}$, and $\beta_3 = \{\alpha_7, \alpha_8, \alpha_9\}$

There are two types of parties: signers denoted S_α for α in some index set \mathcal{I} , and group managers denoted M_α for indices α described below. The parties form a tree T , where the signers are leaves and the group managers are inner nodes. The indices of the group managers are formed as follows. If a group manager manages a set of signers $\beta \subset \mathcal{I}$ we denote it by M_β . This corresponds to M_β having S_α for $\alpha \in \beta$ as children. If a group manager M_γ manages a set of group managers $\{M_{\beta_1}, \dots, M_{\beta_l}\}$ we denote it by M_γ where $\gamma = \{\beta_1, \dots, \beta_l\}$. This corresponds to M_γ having M_{β_i} for $i = 1, \dots, l$ as children. Let M_ρ denote the root group manager. We define the root group manager to be at depth 0 and assume that all leaves in the tree are at the same depth δ . Figure 1 illustrates a tree of parties.

Note that standard group signatures correspond to having a single group manager $M_{\{1, \dots, l\}}$ that manages all signers S_1, \dots, S_l .

2.1 Definition of Security

Bellare et al. [4] give a definition of a group signature scheme, but more importantly they argue that two properties of group signatures, full anonymity and full traceability, imply any reasonable security requirements one can expect from a group signature scheme. We follow their definitional approach closely.

Definition 1 (Hierarchical Group Signature). A hierarchical group signature scheme $\mathcal{HGS} = (\text{HKg}, \text{HSig}, \text{HVf}, \text{HOpen})$ consists of four polynomial-time algorithms

1. The randomized key generation algorithm HKg takes as input $(1^\kappa, T)$, where T is a tree of size polynomially bounded in the security parameter κ with all leaves at the same depth, and outputs a pair of maps $\text{hpk}, \text{hsk} : \mathcal{V}(T) \rightarrow \{0, 1\}^*$. For each node (or leaf) α , $\text{hpk}(\alpha)$ is the public key and $\text{hsk}(\alpha)$ is the secret key.
2. The randomized signature algorithm HSig takes as input a message m , a tree T , a public key hpk , and a secret signing key $\text{hsk}(\alpha)$, and returns a signature of m .
3. The deterministic signature verification algorithm HVf takes as input a tree T , a public key hpk , a message m and a candidate signature σ of m and returns either 1 or 0.

Fig. 2. Nodes in black represent group managers able to distinguish between signatures by $S_{\alpha^{(0)}}$ and $S_{\alpha^{(1)}}$, the two marked leaves

4. The deterministic opening algorithm HOpen takes as input a tree T , a public key hpk , a secret opening key $\text{hsk}(\beta)$, a message m , and a candidate signature σ . It outputs an index $\alpha \in \beta$ or \perp .

We need to define what we mean by security for a hierarchical group signature scheme. We begin with anonymity. Consider Figure 2, where two signers $S_{\alpha^{(0)}}$ and $S_{\alpha^{(1)}}$ are marked. Assume that it is known that a message has been signed by one of them. Then any group manager on the path leading from $S_{\alpha^{(0)}}$ or $S_{\alpha^{(1)}}$ to their first common ancestor can determine which of them signed the message. In the figure those group managers are marked with black. In the definition of anonymity we capture the property that unless the adversary corrupts one of these group managers, it cannot determine whether $S_{\alpha^{(0)}}$ or $S_{\alpha^{(1)}}$ signed the message, even if the adversary is given the private keys of all signers and is allowed to select $\alpha^{(0)}$, $\alpha^{(1)}$ and the message itself.

We define Experiment 1 to formalize these ideas. Throughout the experiment the adversary has access to an $\text{HOpen}(T, \text{hpk}, \text{hsk}(\cdot), \cdot, \cdot)$ oracle. At the start of the experiment the adversary is given the public keys of all parties and the private keys of all signers. Then it can adaptively ask for the private keys of the group managers. At some point it outputs the indices $\alpha^{(0)}$ and $\alpha^{(1)}$ of two leaves and a message m . The $\text{HSig}(\cdot, T, \text{hpk}, \text{hsk}(\cdot))$ oracle computes the signature of m using the private key $\text{hsk}(\alpha^{(b)})$ and hands it to the adversary. The adversary finally outputs a guess d of the value of b . If the scheme is anonymous the probability that $b = d$ should be negligibly close to $1/2$ when b is a randomly chosen bit. The labels *corrupt*, *choose* and *guess* below distinguish between the phases of the experiment.

Experiment 1 (Hierarchical Anonymity, $\text{Exp}_{\text{HGS}, A}^{\text{anon}-b}(\kappa, T)$).

$(\text{hpk}, \text{hsk}) \leftarrow \text{HKg}(1^\kappa, T); s_{\text{state}} \leftarrow (\text{hpk}, \text{hsk}(\mathcal{L}(T))); \mathcal{C} \leftarrow \emptyset; \alpha \leftarrow \emptyset;$
 Do
 $\mathcal{C} \leftarrow \mathcal{C} \cup \{\alpha\}$
 $(s_{\text{state}}, \alpha) \leftarrow A^{\text{HOpen}(T, \text{hpk}, \text{hsk}(\cdot), \cdot, \cdot)}(\text{corrupt}, s_{\text{state}}, \text{hsk}(\alpha))$
 While $(\alpha \in \mathcal{V}(T) \setminus \mathcal{C})$
 $(s_{\text{state}}, \alpha^{(0)}, \alpha^{(1)}, m) \leftarrow A^{\text{HOpen}(T, \text{hpk}, \text{hsk}(\cdot), \cdot, \cdot)}(\text{choose}, s_{\text{state}})$
 $\sigma \leftarrow \text{HSig}(m, T, \text{hpk}, \text{hsk}(\alpha^{(b)}))$
 $d \leftarrow A^{\text{HOpen}(T, \text{hpk}, \text{hsk}(\cdot), \cdot, \cdot)}(\text{guess}, s_{\text{state}}, \sigma)$

Let B be the set of nodes on the paths from $\alpha^{(0)}$ and $\alpha^{(1)}$ up to their first common ancestor α_t excluding $\alpha^{(0)}$ and $\alpha^{(1)}$ but including α_t , i.e., the set of nodes $\alpha_l^{(0)}, \alpha_l^{(1)}, l = t, \dots, \delta - 1$, such that

$$\alpha^{(0)} \in \alpha_{\delta-1}^{(0)} \in \alpha_{\delta-2}^{(0)} \in \dots \in \alpha_{t+1}^{(0)} \in \alpha_t \ni \alpha_{t+1}^{(1)} \ni \dots \ni \alpha_{\delta-2}^{(1)} \ni \alpha_{\delta-1}^{(1)} \ni \alpha^{(1)} .$$

If $B \cap \mathcal{C} \neq \emptyset$ or if A asked its $\text{HOpen}(T, \text{hpk}, \text{hsk}(\cdot), \cdot, \cdot)$ oracle a question $(\alpha_l^{(0)}, m, \sigma)$ or $(\alpha_l^{(1)}, m, \sigma)$ return 0. Otherwise return d .

Consider the above experiment with a depth one tree T and root ρ . In that case we may assume that $\text{hsk}(\rho)$ is never handed to the adversary, since the adversary fails in that case anyway. Similarly the $\text{HOpen}(T, \text{hpk}, \text{hsk}(\cdot), \cdot, \cdot)$ oracle reduces to the Open oracle in [4]. Thus, our experiment reduces to the experiment for full anonymity given in [4] where the adversary gets the secret keys of all signers, but only the public key of the group manager.

Next we consider how the notion of full traceability can be defined in our setting. Full traceability as defined in [4] is similar to security against chosen message attacks (CMA-security) as defined by Goldwasser, Micali and Rivest [18] for signatures. The only essential difference is that the group manager must always be able to open a signature and identify the signer. In our setting this amounts to the following. Given a signature deemed valid by the HVf algorithm, the root should always be able to identify the child directly below it of which the signer is a descendent. The child should have the same ability for the subtree of which it is a root and so on until the child itself is a signer.

Again we define an experiment consisting of two phases. The adversary is given the secret keys of all group managers. Then the adversary adaptively chooses a set of signers to corrupt. Then in a second phase the adversary outputs a message and a signature. If the output amounts to a signature deemed valid by HVf and the signer cannot be traced, or if the signature is traced to a non-corrupted signer, the adversary has succeeded and the experiment outputs 1. Otherwise it outputs 0. Thus, the distribution of the experiment should be negligibly close to 0 for all adversaries if the scheme is secure.

Experiment 2 (Hierarchical Traceability, $\text{Exp}_{\text{HGSA}}^{\text{trace}}(\kappa, T)$).

$(\text{hpk}, \text{hsk}) \leftarrow \text{HKg}(1^\kappa, T); s_{\text{state}} \leftarrow (\text{hpk}, \text{hsk}(\mathcal{V}(T) \setminus \mathcal{L}(T))); \mathcal{C} \leftarrow \emptyset; \alpha \leftarrow \emptyset;$
 Do
 $\mathcal{C} \leftarrow \mathcal{C} \cup \{\alpha\}$
 $(s_{\text{state}}, \alpha) \leftarrow A^{\text{HSig}(\cdot, T, \text{hpk}, \text{hsk}(\cdot))}(\text{corrupt}, s_{\text{state}}, \text{hsk}(\alpha))$
 While $(\alpha \in \mathcal{V}(T) \setminus \mathcal{C})$
 $(m, \sigma) \leftarrow A^{\text{HSig}(\cdot, T, \text{hpk}, \text{hsk}(\cdot))}(\text{guess}, s_{\text{state}})$

If $\text{HVf}(T, \text{hpk}, m, \sigma) = 0$ return 0. Define $\alpha_0 = \rho$ and $\alpha_l = \text{HOpen}(T, \text{hpk}, \text{hsk}(\alpha_{l-1}), m, \sigma)$ for $l = 1, \dots, \delta$. If $\alpha_l = \perp$ for some $0 < l \leq \delta$ return 1. If $\alpha_\delta \notin \mathcal{C}$ and the $\text{HSig}(\cdot, T, \text{hpk}, \text{hsk}(\cdot))$ oracle did not get a question (m, α_δ) return 1. Otherwise return 0.

Consider the experiment above with a depth one tree. This corresponds to giving the adversary the secret key of the group manager, and letting it adaptively choose additional signing keys. This is precisely the setting of [4].

The advantage of the adversary is defined in the natural way by setting $\text{Adv}_{\mathcal{HGS},A}^{\text{anon}}(\kappa, T) = |\Pr[\text{Exp}_{\mathcal{HGS},A}^{\text{anon}-0}(\kappa, T) = 1] - \Pr[\text{Exp}_{\mathcal{HGS},A}^{\text{anon}-1}(\kappa, T) = 1]|$ and $\text{Adv}_{\mathcal{HGS},A}^{\text{trace}}(\kappa, T) = \text{Exp}_{\mathcal{HGS},A}^{\text{trace}}(\kappa, T)$.

Definition 2 (Security of Hierarchical Group Signatures). *A hierarchical group signature scheme $\mathcal{HGS} = (\text{HKg}, \text{HSig}, \text{Hvf}, \text{HOpen})$ is secure if for all trees T of polynomial size in κ with all leaves at the same depth, and all $A \in \text{PPT}^*$, $\text{Adv}_{\mathcal{HGS},A}^{\text{trace}}(\kappa, T) + \text{Adv}_{\mathcal{HGS},A}^{\text{anon}}(\kappa, T)$ is negligible.*

3 Our Constructions

We construct two hierarchical group signature schemes, one under general assumptions, and one under standard assumptions in the random oracle model. Both require a trusted key generator at the start of the protocol. The two constructions are different, but based on similar ideas. In this extended abstract we only give the main ideas behind our constructions. Detailed descriptions and proofs of our claims are given in the full paper [26].

3.1 Our Approach

All known group signatures are based on the idea that the signer encrypts a secret of some sort using the group manager’s public key, and then proves that the resulting cryptotext is on this special form. The security of the cryptosystem used implies anonymity, since no adversary can distinguish cryptotexts of two distinct messages if they are encrypted using the *same* public key. We generalize this approach.

First we consider the problem of forwarding partial information on the identity of the signer to group managers without leaking information. Each group manager M_β is given a secret key sk_β and a public key pk_β of a cryptosystem. We also give each signer S_α a public key pk_α that is used to identify the signer. Each signer is associated in the natural way with the path $\alpha_0, \alpha_1, \dots, \alpha_\delta$ from the root $\rho = \alpha_0$ to the leaf $\alpha = \alpha_\delta$ in the tree T of group managers and signers. To compute a signature, the signer computes as part of the signature a chain

$$(C_0, C_1, \dots, C_{\delta-1}) = (E_{\text{pk}_{\alpha_0}}(\text{pk}_{\alpha_1}), E_{\text{pk}_{\alpha_1}}(\text{pk}_{\alpha_2}), \dots, E_{\text{pk}_{\alpha_{\delta-1}}}(\text{pk}_{\alpha_\delta})) .$$

Note that each cryptotext C_l in the list encrypts the public key $\text{pk}_{\alpha_{l+1}}$ used to form the following cryptotext. The particular structure of the chain and the fact that all leaves are on the same depth in the tree ensures that a group manager M_β on depth l can try to open a signature by decrypting C_l , i.e., it computes $\text{pk} = D_{\text{sk}_\beta}(C_l)$. If $\alpha_l = \beta$, then $\text{pk} = \text{pk}_{\alpha_{l+1}}$. Thus, if M_β manages signers, it

learns the identity of the signer S_α , and if it manages other group managers it learns the identity of the group manager below it in the tree which (perhaps indirectly) manages the signer S_α .

Now suppose that $\alpha_l \neq \beta$, so $\text{pk} \neq \text{pk}_{\alpha_{l+1}}$. What does M_β , or indeed any outsider, learn about the identity of the signer S_α ? It clearly does not learn anything from a cryptotext C_l about the encrypted cleartext, as long as the cryptosystem is semantically secure. However, if the cryptotext C_{l+1} somehow indicates which public key was used to form it, M_β , or any outsider, can simply look at C_{l+1} and recover the cleartext of C_l . This means that it can look at the chain of cryptotexts and extract information on the identity of the signer. We conclude that using the approach above, we need a cryptosystem which not only hides the cleartext, but also hides the public key used to form the cryptotext. Such a cryptosystem is called an *anonymous* cryptosystem [3].

Next we consider the problem of ensuring hierarchical traceability. This problem consists of two parts. We must ensure chosen message security to avoid that an illegitimate signer is able to compute a valid signature at all. However, the more difficult problem is to ensure that the signer S_α not only formed $(C_0, \dots, C_{\delta-1})$ as described above for some public keys $\text{pk}_{\alpha_0}, \dots, \text{pk}_{\alpha_\delta}$, but also that the public keys used correspond to the unique path $\alpha_0, \alpha_1, \dots, \alpha_\delta$ from the root $\rho = \alpha_0$ to the leaf $\alpha = \alpha_\delta$ corresponding to the signer S_α . This is the main obstacle to construct an efficient hierarchical group signature scheme.

3.2 A Construction Under General Assumptions

We sketch the construction under general assumptions. To achieve hierarchical anonymity we employ the cryptosystem of Goldwasser and Micali [17] and prove that this cryptosystem is anonymous. To achieve traceability we use the group signature scheme of Bellare et al. [4] and a non-interactive adaptive zero-knowledge unbounded simulation sound proof (NIZK) as defined and constructed for any language in NP in Feige, Lapidot and Shamir [16], Sahai [23], and De Santis [24]. Both constructions are provably secure under the existence of a trapdoor permutation family.

The signer proves using the NIZK that the chain of cryptotexts is formed correctly, and the group signature scheme ensures that only legitimate signers can form a signature, without losing anonymity. The group signature also allows us to use a semantically secure cryptosystem for the chain (cf. [4, 8]), since any query to the HOpen oracle obviously can be answered correctly by the simulator if we know the full identity of the signer, i.e., we use a variant of the double-cryptotext trick of Naor and Yung [22]. The following theorem is proved in the full version [26].

Theorem 1. *If there exists a family of trapdoor permutations, then there exists a secure hierarchical group signature scheme.*

3.3 A Construction Under the DDH Assumption and the Strong RSA Assumption

To achieve hierarchical anonymity in the practical construction we employ the ElGamal cryptosystem, which is semantically secure under the DDH assumption. It is easy to see that ElGamal is also anonymous, as long as a fixed group is used for each security parameter. Thus, each group manager M_β holds a secret key x_β and a public key $y_\beta = g^{x_\beta}$, and the chain of cryptotexts is on the form

$$((u_0, v_0), \dots, (u_{\delta-1}, v_{\delta-1})) = (E_{y_{\alpha_0}}(y_{\alpha_1}), \dots, E_{y_{\alpha_{\delta-1}}}(y_{\alpha_\delta})) .$$

To achieve chosen message security we employ the Fiat-Shamir heuristic to turn an identification scheme into a signature scheme. The secret key of a signer S_α is a Cramer-Shoup [15] signature $\sigma_\alpha = \text{Sig}^{\text{CS}}(y_{\alpha_1}, \dots, y_{\alpha_{\delta-1}})$ of the public keys corresponding to the path $\alpha_0, \alpha_1, \dots, \alpha_\delta$ from the root $\rho = \alpha_0$ to the leaf $\alpha = \alpha_\delta$. The Cramer-Shoup scheme is provably secure under the strong RSA assumption.

To form a signature of a message m the signer first computes a commitment $C(\sigma_\alpha)$ of the signature σ_α . Then it computes an honest verifier zero-knowledge public coin proof $\pi(m)$ that the cryptotexts $((u_0, v_0), \dots, (u_{\delta-1}, v_{\delta-1}))$ form a chain and that $C(\sigma_\alpha)$ hides a signature of the list $(y_{\alpha_1}, \dots, y_{\alpha_{\delta-1}})$ of public keys used to form the chain of cryptotexts. The proof is given in the random oracle model and the message m to be signed is given as a prefix to every query to the random oracle. Thus, the complete signature is given by

$$(E_{y_{\alpha_0}}(y_{\alpha_1}), \dots, E_{y_{\alpha_{\delta-1}}}(y_{\alpha_\delta}), C(\sigma_\alpha), \pi(m)) .$$

Intuitively, this means that if a signer S_α can produce a valid signature, we can by rewinding extract a signature of the list of public keys corresponding to the path from the root to the signer. Thus, a signature can only be formed if the signer is legitimate and if it has formed the chain correctly. Denote the hierarchical group signature scheme sketched above by \mathcal{HGS} . We prove the following theorem in the full version [26].

Theorem 2. *The hierarchical signature scheme \mathcal{HGS} is secure under the DDH assumption and the strong RSA assumption in the random oracle model.*

Efficiency Analysis. The complexity of the protocol is largely determined by the proof sketched in the next subsection. This protocol has soundness $1 - O(\delta 2^{-\kappa'})$, where κ' is a secondary security parameter. Using standard computational tricks we estimate the complexity of the protocol to correspond to roughly $\kappa'(\delta + 3)$ general exponentiations modulo a κ -bit integer. If we set $\delta = 3$ and $\kappa' = 160$ this corresponds to less than 1000 general exponentiations. The size of a signature is about 1 Mb. The full version [26] contains a more detailed analysis.

Construction of the Proof of Knowledge. The main obstacle to find an efficient hierarchical group signature scheme following our approach is how to

prove efficiently that $C(\sigma_\alpha)$ is a commitment of a signature σ_α of the list of public keys $(y_{\alpha_1}, \dots, y_{\alpha_{\delta-1}})$ used to form the chain $((u_0, v_0), \dots, (u_{\delta-1}, v_{\delta-1}))$. We construct a reasonably practical honest verifier zero-knowledge public coin proof for this relation by carefully selecting and combining a variety of cryptographic primitives and techniques. Due to the complexity of this protocol we can only sketch the main ideas of this protocol in this extended abstract. Details are given in the full version [26].

Let q_0, \dots, q_3 be primes such that $q_i = 2q_{i+1} + 1$ for $i = 0, 1, 2$. A list of such primes is called a Cunningham chain and exists under mild assumptions on the distribution of primes. There is a subgroup $G_{q_{i+1}} \subset \mathbb{Z}_{q_i}^*$ of order q_{i+1} for $i = 0, 1, 2$. Denote by g_i and y_i fixed and independently chosen generators of G_{q_i} for $i = 1, 2, 3$, i.e., $\log_{g_i} y_i$ is not known to any party in the protocol. Thus, we can form a commitment of a value $y_\alpha \in G_{q_3}$ in three ways, as

$$(y_3^{t'''} g_3^{s'''} , y_3^{s'''} y_\alpha) , \quad (y_2^{t''} g_2^{s''} , y_2^{s''} g_2^{y_\alpha}) , \quad \text{and} \quad (y_1^{t'} g_1^{s'} , y_1^{s'} g_1^{y_\alpha}) ,$$

where $t''', s''' \in \mathbb{Z}_{q_3}$, $t'', s'' \in \mathbb{Z}_{q_2}$, and $t', s' \in \mathbb{Z}_{q_1}$ are randomly chosen. By extending the ideas of Stadler [25] we can give a reasonably practical cut-and-choose proof that the elements hidden in two such commitments are identical.

Recall that the collision-free Chaum-Heijst-Pfitzmann [12] hash function is defined by $H^{\text{CHP}} : \mathbb{Z}_{q_2}^\delta \rightarrow G_{q_2}$, $H^{\text{CHP}} : (z_1, \dots, z_\delta) \mapsto \prod_{i=1}^\delta h_i^{z_i}$, where the bases $h_1, \dots, h_\delta \in G_{q_2}$ are randomly chosen, i.e., no party knows a non-trivial representation of $1 \in G_{q_2}$ in these elements.

We employ ElGamal over G_{q_3} . This means that the public keys $y_{\alpha_1}, \dots, y_{\alpha_\delta}$ belong to G_{q_3} . Although it is not trivial, the reader should not find it too hard to imagine that Stadler-techniques can be used to prove that the public keys used for encryption are identical to values hidden in a list of commitments formed as

$$((\mu_0, \nu_0), \dots, (\mu_{\delta-1}, \nu_{\delta-1})) = ((y_2^{t''_0} g_2^{s''_0} , y_2^{s''_0} h_1^{y_{\alpha_1}}), \dots, (y_2^{t''_{\delta-1}} g_2^{s''_{\delta-1}} , y_2^{s''_{\delta-1}} h_\delta^{y_{\alpha_\delta}})) .$$

The importance of this is that if we take the product of the commitments we get a commitment of $H^{\text{CHP}}(y_{\alpha_1}, \dots, y_{\alpha_\delta})$, i.e.,

$$\left(\prod_{i=0}^{\delta-1} \mu_i , \prod_{i=0}^{\delta-1} \nu_i \right) = \left(y_2^{t''} g_2^{s''} , y_2^{s''} \prod_{i=1}^\delta h_i^{y_{\alpha_i}} \right) , \tag{1}$$

for some $t'', s'' \in \mathbb{Z}_{q_2}$. Thus, at this point we have devised a way for the signer to verifiably commit to the hash value of the keys it used to form the chain of cryptotexts. This is a key step in the construction.

Recall that the signer commits to a Cramer-Shoup signature σ_α of the list of public keys it uses to form the chain of cryptotexts. This signature scheme uses an RSA-modulus N and elements from the subgroup QR_N of squares in \mathbb{Z}_N^* , and it is parameterized by two collision-free hash functions. The first hash function is used to compute a message digest of the message to be signed, i.e.,

the list $(y_{\alpha_1}, \dots, y_{\alpha_\delta})$ of public keys. Above we have sketched how the signer can verifiably form a commitment of the H^{CHP} hash value of this message, so it is only natural that we let this be the first of the two hash functions in the signature scheme. However, in the signature scheme the message digest lives in the exponent of an element in QR_N in the signature scheme. To move the hash value up in the exponent and to change group from G_{q_1} to QR_N , the signer forms two commitments

$$(y_1^{t'} g_1^{s'}, y_1^{s'} g_1^{H^{\text{CHP}}(y_{\alpha_1}, \dots, y_{\alpha_\delta})}) \quad \text{and} \quad \mathbf{h}^t \mathbf{g}^{H^{\text{CHP}}(y_{\alpha_1}, \dots, y_{\alpha_\delta})} .$$

Then it gives a cut-and-choose proof that the exponent in the left commitment equals the value committed to in the product (1). It also proves that the exponents in the two commitments are equal. Thus, at this point the signer has proved that it holds a commitment over QR_N of the hash value of the public keys it used to form the chain of cryptotexts.

The second hash function used in the Cramer-Shoup signature scheme is applied to a single element in QR_N . Since H^{CHP} is not collision-free on such inputs, we use the Shamir hash function $H_{(\mathbf{g}, N)}^{\text{Sh}} : \mathbb{Z} \rightarrow \text{QR}_N, x \mapsto \mathbf{g}^x \bmod N$ instead. Using similar techniques as explained above the signer evaluates the hash function and moves the result into the exponent, by two Stadler-like cut-and-choose proofs.

Given the two hash values in the exponents of two commitments, standard techniques can be used to prove that the commitment $C(\sigma_\alpha)$ is a commitment of the Cramer-Shoup signature σ_α of the list of public keys used to form the chain of cryptotexts.

4 Conclusion

We have introduced and formalized the notion of hierarchical group signatures and given two constructions. The first is provably secure under general assumptions, whereas the second is provably secure under the DDH assumption and the strong RSA assumption in the random oracle model. The latter is practical, i.e., it can be implemented and run on modern workstations, but it is still slow. Both require a trusted key generator. Thus, an interesting open problem is to eliminate these deficiencies.

Acknowledgments

We thank Johan Håstad for excellent advice. We also thank Torsten Ekedahl for explaining the heuristic view on the existence of Cunningham chains. We thank Ronald Cramer for providing us with references. We had valuable discussions on anonymity of cryptosystems with Gustav Hast.

Designated Verifier Signature Schemes: Attacks, New Security Notions and a New Construction

Helger Lipmaa¹, Guilin Wang², and Feng Bao²

¹ Cybernetica AS and University of Tartu, Estonia

² Institute for Infocomm Research (I²R), Singapore

Abstract. We show that the signer can abuse the disavowal protocol in the Jakobsson-Sako-Impagliazzo designated-verifier signature scheme. In addition, we identify a new security property—non-delegatability—that is essential for designated-verifier signatures, and show that several previously proposed designated-verifier schemes are delegatable. We give a rigorous formalisation of the security for designated-verifier signature schemes, and propose a new and efficient designated-verifier signature scheme that is provably unforgeable under a tight reduction to the Decisional Diffie-Hellman problem in the non-programmable random oracle model, and non-delegatable under a loose reduction in the programmable random oracle model. As a direct corollary, we also get a new efficient conventional signature scheme that is provably unforgeable under a tight reduction to the Decisional Diffie-Hellman problem in the non-programmable random oracle plus common reference string model.

Keywords: Designated verifier signature scheme, non-delegatability, non-programmable random oracle model, signature scheme.

1 Introduction

In 1996, Jakobsson, Sako and Impagliazzo introduced the concept of designated-verifier signature (DVS) schemes [JSI96]. A DVS scheme makes it possible for a prover Signy to convince a designated verifier Desmond that she has signed a statement so that Desmond cannot transfer the signature to a third party Trevor. This is achieved since Desmond himself can efficiently simulate signatures that are indistinguishable from Signy's signatures. Moreover, in a disavowable DVS scheme, Signy can prove to Trevor that a simulated signature was not created by Desmond, while she can not disavow her own signatures. This is possible only when Signy's and Desmond's signatures are computationally but not perfectly indistinguishable.

We point out weaknesses in the designated-verifier signature schemes of [JSI96, SKM03, SBWP03, SWP04, LV04]. Of these schemes, the JSI scheme from [JSI96] is the only disavowable DVS scheme. However, we show that in the JSI scheme, a malicious Signy can generate signatures exactly from the same distribution as Desmond and thus the JSI scheme is perfectly non-transferable and thus also not disavowable. Our attack against the DVS schemes from [SKM03, SBWP03, SWP04, LV04] is not an attack according to the definitions of the designated verifier signatures in these papers,

although it is an attack according to the original informal definition of [JSI96]: namely, we show that Signy can delegate her signing ability—with respect to a fixed designated verifier Desmond—to a third party Trevor, without revealing her secret key or making it possible for Trevor to sign with respect to other designated verifiers. This delegation property, while desirable in some settings (e.g., proxy DVS schemes), is extremely undesirable in many other settings and must therefore be considered as a serious weakness of a DVS scheme.

By pointing out the described flaws in these designated verifier signature scheme, we arrive to a stronger security notion for DVS that includes two novel requirements: (a) most importantly, *non-delegatability*: there exists an efficient knowledge extractor that can extract either Signy’s secret key or Desmond’s secret key, when given oracle access to an adversary who can create valid signatures with a high probability (this property is not shared by the DVS schemes from [SKM03, SBWP03, SWP04, LV04]), and (b) secure disavowability: if the DVS scheme has a disavowal protocol, it must be the case that Signy cannot disavow signatures, given by herself (this property is not shared by the DVS scheme from [JSI96]).

Non-delegatability of a DVS means that a valid designated-verifier signature constitutes a proof of knowledge of either Signy’s or Desmond’s secret key. Now, for conventional signatures, ability to sign is conceptually equal to the knowledge of the secret key. Therefore, a valid signature does not be a proof of knowledge. Now, as it is known from [KW03], one can construct conventional signature schemes whose unforgeability is proven by giving a tight reduction to an underlying cryptographic problem; this is achieved by specially avoiding the use of proofs of knowledge. However, in the case of a DVS scheme, we can also avoid proofs of knowledge in the proof of unforgeability, but not in the proof of non-delegatability. Therefore, even if we have a proof that a DVS scheme is unforgeable (w.r.t. any verifier), we cannot directly derive from that that this scheme is also non-delegatable. Therefore, in some sense, a (non-delegatable) DVS is a more “complex” notion than a conventional signature scheme.

It is not difficult to show that the DVS scheme from [JSI96] is secure—more precisely, unforgeable, non-delegatable, computationally non-transferable and securely disavowable—after a trivial fix of just adding some additional variables under the used hash value, by following the usual proof of knowledge methodology. We do not present these proofs in this paper: while it is straightforward to prove these results, the corresponding proofs do not really give an insight to the just pointed out difference between unforgeability and non-delegatability.

Instead, we propose a new DVS scheme, DVS-KW, based on the provably secure signature scheme of Katz and Wang [KW03], where the signer presents a designated-verifier proof that his public key is a Decisional Diffie-Hellman (DDH) tuple. We prove that DVS-KW is unforgeable by providing a tight reduction to the underlying cryptographic problem (DDH) in the non-programmable random oracle (NPRO) model. The NPRO model is known to be strictly weaker than the random oracle (RO) model [Nie02] and thus the unforgeability of DVS-KW in the NPRO model is interesting by itself, especially since the unforgeability proof of the original Katz-Wang signature scheme relies heavily on the programmability of the random oracle. We also prove non-delegatability of DVS-KW, though this proof is in the programmable random ora-

cle model and has a larger security degradation due to the involved proof-of-knowledge property. More precisely, we show that if some forger can create valid signatures with probability $\varepsilon > \kappa$ where κ is the knowledge error, then there exists a knowledge extractor that extracts one of the two secret keys in time, dominated by $56/\kappa$ oracle queries to the forger.

DVS-KW can be seen as a proof of concept, showing how to design DVS schemes that have a tight reduction in the unforgeability proof and are still non-delegatable. Moreover, DVS-KW is more efficient than the JSI scheme from [JSI96], and DVS-KW does not allow the signer to disavow simulated signatures; the latter property makes DVS-KW attractive in many applications. (Recall also that we broke the disavowability of the JSI scheme.) At this moment, the most efficient secure disavowable designated-verifier signature scheme seems to be the corrected JSI DVS scheme, while the most efficient secure designated-verifier signature scheme seems to be the DVS-KW scheme.

We also show the existence of an efficient conventional signature scheme that is unforgeable under a tight reduction to the Decisional Diffie-Hellman problem in the NPRO+CRS (common reference string) model. In this model, all parties will additionally have access to the common reference string that corresponds to Desmond's public key in DVS-KW. The importance of this result is that signature schemes, secure in the plain model, are considerably slower than this scheme and/or are secure under incompatible and often less studied assumptions. Therefore, if one wants to avoid the programmable random oracle model—where one can construct very efficient signature schemes—one might want to use the new scheme.

2 Preliminaries

Let \mathcal{G}_q be a finite, cyclic group of prime order q in which the group operation is represented multiplicatively; furthermore, let g be a generator of \mathcal{G} . The most common setting is as follows: let p, q be two large primes such that $q|(p-1)$, then \mathcal{G}_q a multiplicative subgroup of \mathbb{Z}_p^* of order q , and g a generator of \mathcal{G}_q . Other settings (e.g., using elliptic curves) are possible. A distinguishing algorithm \mathcal{A} is said to (τ, ε) -break DDH (Decisional Diffie-Hellman) in group \mathcal{G}_q if \mathcal{A} runs in time at most τ and furthermore $\text{Adv}_{\mathcal{G}}^{\text{ddh}}(\mathcal{A}) := |\Pr[x, y, z \leftarrow_r \mathbb{Z}_q : \mathcal{A}(g, g^x, g^y, g^z) = 1] - \Pr[x, y \leftarrow_r \mathbb{Z}_q : \mathcal{A}(g, g^x, g^y, g^{xy}) = 1]| \geq \varepsilon$, where the probability is taken over the choice of random variables and the coin tosses of \mathcal{A} . We say that \mathcal{G} is a (τ, ε) -DDH group if no algorithm (τ, ε) -breaks DDH in \mathcal{G} .

A *designated-verifier signature scheme* [JSI96] is a tuple of probabilistic algorithms (Gen, Sign, Simul, Vrfy) over a message space \mathcal{M} , such that: (a) The key-generation algorithm Gen outputs a public key pk and a secret key sk ; (b) The signing algorithm Sign takes as input signer's secret key sk_S , designated verifier's public key pk_D and a message $m \in \mathcal{M}$ and returns signature σ ; (c) The simulation algorithm Simul takes as input signer's public key pk_S , designated verifier's secret key sk_D and a message $m \in \mathcal{M}$ and returns signature σ ; (d) Verification algorithm Vrfy takes as input signer's public key pk_S , designated verifier's public key pk_D , a message $m \in \mathcal{M}$, and a signature σ and returns accept or reject. In some of the existing designated verifier schemes, the verification algorithm must have access to the designated verifier's secret key sk_D . We

call such a designated-verifier signature scheme *privately verifiable*. We make the standard correctness requirement: for all $(\text{sk}_S, \text{pk}_S)$ and $(\text{sk}_D, \text{pk}_D)$ output by Gen and for all $m \in \mathcal{M}$ we have $\text{Vrfy}_{\text{pk}_S, \text{pk}_S}(\text{Sign}_{\text{sk}_S, \text{pk}_S}(m)) = \text{Vrfy}_{\text{pk}_D, \text{pk}_D}(\text{Sign}_{\text{sk}_S, \text{pk}_S}(m)) = \text{accept}$. We say that a signature σ is *valid* if $\text{Vrfy}_{\text{pk}_D, \text{pk}_D}(\sigma) = \text{accept}$.

3 Previous DVS Schemes and Their Security

Jakobsson-Sako-Impagliazzo Disavowable DVS Scheme [JSI96]. Let p, q and \mathcal{G}_q be as described in Sect. 2. Assume that Signy and Desmond have the Diffie-Hellman key pairs $(x_S, y_S = g^x \bmod p)$ and $(x_D, y_D = g^x \bmod p)$, respectively. Assume that H_q is a random oracle mapping to \mathbb{Z}_q . (Note: If $m \notin \mathbb{Z}_p$ then m must be hashed by using a full-domain hash, modelled by a random oracle. We will ignore this issue throughout this paper.) In $\text{Sign}_{\text{sk}_S, \text{pk}_S}(m)$, Signy sets $s \leftarrow m^x \bmod p$, selects three random numbers $w, t, r \leftarrow_r \mathbb{Z}_q$, and computes $G \leftarrow g^r \bmod p$, $M \leftarrow m^r \bmod p$, $h \leftarrow H_q(g^w y_D^t \bmod p, G, M)$ and $z \leftarrow r + (h + w)x_S \bmod q$. Then, Signy sends the signature $\sigma := (s, P)$, where $P = (w, t, G, M, z)$, to the designated verifier, Desmond. In $\text{Simul}_{\text{sk}_S, \text{pk}_S}(m, s)$, by selecting three random numbers $z, \alpha, \beta \leftarrow_r \mathbb{Z}_q$, Desmond creates $P = (w, t, G, M, z)$, for any message m and any $s \leftarrow \mathcal{G}_q$, as follows: $(G, M) \leftarrow (g^z y_S^{-\beta} \bmod p, m^z s^{-\beta} \bmod p)$, $h \leftarrow H_q(g^\alpha \bmod p, G, M)$, $w \leftarrow \beta - h \bmod q$, $t \leftarrow (\alpha - w)x_D^{-1} \bmod q$. He sets $\sigma \leftarrow (s, P)$. In $\text{Vrfy}_{\text{pk}_S, \text{pk}_S}(m; s, w, t, G, M, z)$, the verifier computes $h \leftarrow H_q(g^w y_D^t \bmod p, G, M)$ and checks whether $G = g^z y_S^{-(h+w)} \bmod p$ and $M = m^z s^{-(h+w)} \bmod p$. The JSI scheme can be made more communication-efficient by transferring h (instead of G and M) to Desmond. Then the verifier must check that $h = H_q(g^w y_D^t \bmod p, g^z \cdot y_S^{-(h+w)} \bmod p, m^z \cdot s^{-(h+w)} \bmod p)$. This version is security-wise equivalent to the original scheme but somewhat more efficient.

Our Attack: First, a honest Signy generates valid signatures only for $s = m^x$ while Desmond can generate valid signatures for any $s \in \mathbb{Z}_p^*$. That is, knowing x_S , a honest Signy generates valid designated-verifier proof P only for $s = m^x$, while knowing x_D , Desmond generates valid designated-verifier proofs P for any $s \in \mathbb{Z}_p^*$. Thus it suffices to have a disavowal where Signy proves in non-interactive zero-knowledge that $s \neq m^x$. Next, we show that Signy can also compute valid signatures for any $\bar{s} \in \mathbb{Z}_p^*$, therefore, Signy can create signatures from the same distribution as Desmond and thus, the JSI scheme is perfectly non-transferable. This means that there exists no disavowal protocol for the JSI scheme at all.

Here is how Signy does it. Signy computes a signature $(\bar{s}; w, t, G, \bar{M}, z)$ for a message m , with $\bar{s} \neq m^x$, as follows. She selects four random numbers $w, t, r, \bar{r} \leftarrow_r \mathbb{Z}_q$ and then sets $c \leftarrow g^w y_D^t \bmod p$, $G \leftarrow g^r \bmod p$, $\bar{M} \leftarrow m^{\bar{r}} \bmod p$, $h \leftarrow H_q(c, G, \bar{M})$, $z \leftarrow r + (h + w)x_S \bmod q$ and $\bar{s} \leftarrow m^{(r-\bar{r})/(h+w)} \bmod q$ mod p . After that, Signy sends the message-signature pair (m, \bar{s}) with $\bar{\sigma} = (\bar{s}, P = (w, t, G, \bar{M}, z))$, to Desmond. Clearly, $\text{Vrfy}_{\text{pk}_S, \text{pk}_S}(m, \bar{\sigma}) = \text{accept}$ so Desmond will believe that \bar{s} is Signy's signature for message m . In later disputes, however, Signy can convince a third party (e.g., a judge) that \bar{s} was simulated by Desmond, by using a stan-

dard disavowal protocol to show that $\log_g y_S \neq \log_m \bar{s}$. This attack does not result in a signature forgery, it just shows that the JSI scheme is not disavowable.

There are two intuitive countermeasures to avoid this attack. First, Signy provides an additional proof of knowledge that $\log_m M = \log_g G$. However, this increases the signature length. Second, include s (together with pk_S and pk_D) to the input of the hash function. This turns out to be sufficient, related discussion can be found in Sect. 6.

Saeednia-Kremer-Markowitch Privately Verifiable DVS Scheme [SKM03]. Let p , q and \mathcal{G}_q be as defined in Sect. 2. In the SKM scheme, Signy and Desmond have the Diffie-Hellman key pairs $(x_S, y_S = g^x \pmod p)$ and $(x_D, y_D = g^x \pmod p)$, respectively. Assume that $H_q(\cdot)$ is a random oracle mapping to \mathbb{Z}_q . In $\text{Sign}_{\text{sk}, \text{VK}}(m)$, Signy selects two random numbers $k \leftarrow_r \mathbb{Z}_q$, $t \leftarrow_r \mathbb{Z}_q^*$, and then computes the signature $\sigma = (h, d, t)$ by setting $c \leftarrow y_D^k \pmod p$, $h \leftarrow H_q(m, c)$ and $d \leftarrow kt^{-1} - h \cdot x_S \pmod q$. In $\text{Simul}_{\text{sk}, \text{pk}}(m)$, Desmond picks two random numbers $\bar{d} \leftarrow_r \mathbb{Z}_q$, $\bar{r} \leftarrow_r \mathbb{Z}_q^*$, and then computes $\sigma = (h, d, t)$ as follows: for $c \leftarrow g^{\bar{d}} y_S^{\bar{r}} \pmod p$, set $h \leftarrow H_q(m, c)$, $d \leftarrow h \cdot \bar{d} \cdot \bar{r}^{-1} \pmod q$ and $t \leftarrow \bar{r} \cdot (x_D \cdot h)^{-1} \pmod q$. In $\text{Vrfy}_{\text{pk}, \text{sk}}(m; h, d, t)$, the verifier accepts iff $h = H_q(m, (g^d y_S^h)^{tx} \pmod p)$.

Our attack: We show that the knowledge of $y_{SD} := g^{x \cdot x} \pmod p$ is sufficient to generate both a valid signature and to verify it, and therefore, this scheme is delegatable (both in the sense of signing and verifying). On the one hand, given y_{SD} , one can verify whether a message-signature pair (m, h, d, t) is valid for the designated verifier Desmond by checking whether $h = H_q(m, (y_D^d y_{SD}^h)^t \pmod p)$. On the other hand, given y_{SD} , anybody can produce a valid designated-verifier signature $\sigma = (h, d, t)$ for any message m by selecting two random numbers $\bar{d} \leftarrow_r \mathbb{Z}_q$, $\bar{r} \leftarrow_r \mathbb{Z}_q^*$, and then setting $c \leftarrow y_D^{\bar{d}} y_{SD}^{\bar{r}} \pmod p$, $h \leftarrow H_q(m, c)$, $d \leftarrow h \cdot \bar{d} \cdot \bar{r}^{-1} \pmod q$ and $t \leftarrow \bar{r} h^{-1} \pmod q$. The resulting signature $\sigma = (h, d, t)$ is accepted by the verifier, since $(g^d y_S^h)^{tx} \pmod p = (g^{h \cdot \bar{d} \cdot \bar{r}^{-1}} y_S^h)^{\bar{r} \cdot h^{-1} x} = y_D^{\bar{d}} y_{SD}^{\bar{r}} \pmod p = c$. In particular, this means that this scheme is perfectly non-transferable. (The authors of [SKM03] get the same result by a complicated analysis of probability theory.) It might again seem that one can remedy this situation by including t under the hash. However, in the simulation, Desmond needs to choose t after fixing h , and therefore this fix does not work.

Steinfeld-Wang-Pieprzyk DVS. Assume again that p , q and \mathcal{G}_q are as defined in Sect. 2. At least the first privately-verifiable DVS scheme, SchUDVS₁, from [SWP04] is also delegatable. Recall that there, a designated-verifier signature of message m is equal to (r, u, K) , for $r \leftarrow H_q(m, u)$, and the verifier accepts only when $K = (u \cdot y_S^r)^x \pmod p$. But if Signy publishes $y_{SD} \leftarrow y_D^x$, anybody can produce valid signatures by setting $u \leftarrow g^k \pmod p$ and $K \leftarrow y_D^k \cdot y_{SD} \pmod p$ for random $k \leftarrow_r \mathbb{Z}_q$. Thus, also this scheme is delegatable.

Steinfeld-Bull-Wang-Pieprzyk and Laguillaumie-Vergnaud DVS. The SBWP designated-verifier signature scheme from [SBWP03] is based on a group pair $(\mathcal{G}_1, \mathcal{G}_2)$ with bilinear pairing $\langle \cdot, \cdot \rangle$ from \mathcal{G}_1^2 , with $\text{ord } \mathcal{G}_1 = q$, to \mathcal{G}_2 . (See [SBWP03] for more details.) Let m be the message to be signed, $H_{\mathcal{G}_1}$ —a random oracle with outputs from \mathcal{G}_1 , and let g be a generator of \mathcal{G}_1 . Assume that Signy's key-pair is $(x_S, y_S = g^x)$

and that Desmond’s key-pair is $(x_D, y_D = g^x)$ for randomly chosen $x_S, x_D \leftarrow \mathbb{Z}_q$. Signy’s designated-verifier signature on a message m is $\sigma \leftarrow \langle H_{\mathcal{G}_1}(m)^x, y_D \rangle$. Desmond simulates the signature by setting $\sigma \leftarrow \langle H_{\mathcal{G}_1}(m)^x, y_S \rangle$. The signature is verified by checking that $\sigma = \langle H_{\mathcal{G}_1}(m)^x, y_S \rangle$. Again, if the value of $y_{SD} = g^{x \cdot x \bmod q}$ is compromised, any entity who gets to know y_{SD} can also produce a valid σ by computing $\sigma \leftarrow \langle H_{\mathcal{G}_1}(m), y_{SD} \rangle$. Therefore, this scheme is also delegatable. The Laguillaumie-Vernaud [LV04] DVS scheme is delegatable for the same reason.

4 DVS Security Definitions

In the original paper [JSI96], a designated-verifier signature was required to convince the designated verifier Desmond that the signer Signy has signed the message, in a way that Desmond is able to simulate signature that is indistinguishable from the real signatures, even by a verifier who has access to the designated verifier’s private key. A more formal definition was given in say [SBWP03]. We will first repeat formal definitions of unforgeability and non-transferability and then give a definition of the new notion, non-delegatability.

A designated-verifier signature scheme must satisfy at least the next two conditions: (a) Unforgeability: signatures are verifiable by the designated verifier Desmond who rejects it when the signature was not signed by himself or Signy, and (b) Non-transferability: given a message-signature pair (m, σ) , that is accepted by the designated-verifier, and without access to the secret key of the signer, it is computationally infeasible to determine whether the message was signed by the signer, or the signature was simulated by the designated verifier.

In the following, Ω denotes the space from which the random oracle H is selected; definition without a random oracle is analogous. Depending on the situation, we will have either $\Omega = \Omega_{\text{npro}}$ to be the set of all non-programmable random oracles [Nie02] or $\Omega = \Omega_{\text{ro}}$ to be the set of all random oracles with proper input and output domains.

Let $\Delta = (\text{Gen}, \text{Sign}, \text{Simul}, \text{Vrfy})$ be a designated-verifier signature scheme with the message space \mathcal{M} . We say that Δ is *perfectly non-transferable* if $\text{Sign}_{\text{sk}_S, \text{pk}_S}(m) = \text{Simul}_{\text{sk}_S, \text{pk}_S}(m)$ as distributions for every $(\text{pk}_S, \text{sk}_S) \leftarrow \text{Gen}, (\text{pk}_D, \text{sk}_D) \leftarrow \text{Gen}, H_q \leftarrow \Omega$ and $m \leftarrow \mathcal{M}$. Analogously, one can define statistically non-transferable and computationally non-transferable schemes. An adversarial forging algorithm \mathcal{F} is said to $(\tau, q_h, q_s, \varepsilon)$ -forge Δ if \mathcal{F} runs in time at most τ , makes at most q_h hash queries and in total at most q_s signing and simulation queries, and furthermore

$$\text{Adv}_{\Delta}^{\text{forge}}(\mathcal{F}) := \Pr \left[\begin{array}{l} (\text{pk}_S, \text{sk}_S) \leftarrow \text{Gen}; (\text{pk}_D, \text{sk}_D) \leftarrow \text{Gen}; H \leftarrow \Omega; \\ (m, \sigma) \leftarrow \mathcal{F}^{\text{Sign}_{\text{sk}_S, \text{pk}_S}(\cdot), \text{Simul}_{\text{sk}_S, \text{pk}_S}(\cdot), H(\cdot)}(\text{pk}_S, \text{pk}_D) : \\ \sigma \notin \Sigma(m) \wedge \text{Vrfy}_{\text{pk}_S, \text{pk}_D}(m, \sigma) \neq \text{reject} \end{array} \right] \geq \varepsilon,$$

where $\Sigma(m)$ is the set of signatures received either from $\text{Sign}_{\text{sk}_S, \text{pk}_S}(m)$ or from $\text{Simul}_{\text{sk}_S, \text{pk}_S}(m)$. A designated-verifier signature scheme is $(\tau, q_h, q_s, \varepsilon)$ -unforgeable if no forger can $(\tau, q_h, q_s, \varepsilon)$ -forge it. In the case a DVS scheme is only computationally non-transferable, it is important that $\Sigma(m)$ also includes signatures received from

$\text{Simul}_{\text{sk}_S, \text{pk}_D}^{\text{pk}_S}(m)$. If a scheme is perfectly non-transferable then an access to the Simul oracle will not help the forger.

Delegatability. The definition of unforgeability does not cover the case when the signer, without disclosing her secret key sk_S , delegates her signing rights (w.r.t. to a concrete designated verifier Desmond) to \mathcal{F} by disclosing some side information $y_{SD} := f_S(\text{sk}_S, \text{pk}_D)$, that helps the latter to produce valid signatures. Analogously, the designated verifier might delegate his signature simulating capability by disclosing some—potentially different—side information $y'_{SD} := f_D(\text{sk}_D, \text{pk}_S)$. This implies that when Desmond sees a valid signature σ that is not generated by himself, he can only conclude that σ is generated by somebody who knows either y_{SD} or y'_{SD} . In some scenarios, Signy may reveal or be forced to reveal the value of y_{SD} to a third party Trevor so that Trevor can generate valid Signy's signatures for Desmond. Such a delegation is essentially different from the situation where Signy reveals her secret key x_S to Trevor, since knowledge of y_{SD} allows Trevor to sign messages designated only to Desmond, and not to anybody else. Therefore, Signy might be more willing to give out the value y_{SD} than her secret key sk_S . This is not an issue in the case of conventional signature schemes where non-delegatability follows from unforgeability.

We will next give a longer explanation why delegatability is bad. First of all, in the original definition of designated-verifier proofs [JSI96], it was said that a proof of the truth of some statement Φ is a designated-verifier proof if it is a proof that either Φ is true or the signer knows Desmond's secret key. This intuitive requirement is clearly not satisfied by delegatable DVS schemes, where a signer proves that either Φ is true or she knows y_{SD} or she knows y'_{SD} .

Moreover, delegatability is undesirable in many applications of the designated-verifier signature scheme. We will give two examples. First, in an hypothetical e-voting protocol where voters sign messages by using a designated-verifier signature scheme (with the tallier being the designated verifier Desmond), knowing that this information can only be used to vote in this concrete election, a voter Signy could be motivated to give a copy of y_{SD} to the coercer for a moderate sum of money. On the other hand, since Signy might use sk_S in many other applications, she might not be willing to send sk_S to the coercer for any imaginable “moderate” amount of money. Second, assume that Signy is a subscriber to an e-library, maintained by Desmond, and that she identifies herself by using a designated-verifier signature scheme so that Desmond could not sell Signy's access history to third parties. If the DVS scheme is delegatable, Signy could however send y_{SD} to a non-subscriber who could then also start enjoying Desmond's service. Since y_{SD} is used only in this application, Signy could be happily willing to do that. On the other hand, if the DVS were not delegatable, Signy would have to reveal her secret key. Finally, it may happen that Signy and Desmond also participate in some other protocols where y_{SD} or y'_{SD} is revealed legitimately and thus the attacker can gain access to either of these values. Note also that a DVS scheme with delegatability is somewhat similar to the proxy signatures, except that in the case of proxy signatures, (a) the verifier can distinguish between messages, signed by Signy and a proxy, and (b) the signatures are universally verifiable.

The preceding discussion motivates the next definition. It basically says that a non-delegatable DVS scheme is a non-interactive system of proofs of knowledge of either

sk_S or sk_D . Here, \mathcal{F}_m denotes \mathcal{F} with m as its input, and oracle calls are counted as one step. More precisely, let $\kappa \in [0, 1]$ be the knowledge error. We say that Δ is (τ, κ) -non-delegatable if there exists a black-box knowledge extractor \mathcal{K} that, for every algorithm \mathcal{F} and for every valid signature σ , satisfies the following condition: For every $(pk_S, sk_S) \leftarrow \text{Gen}$, $(pk_D, sk_D) \leftarrow \text{Gen}$ and message m , if \mathcal{F} produces a valid signature on m with probability $\varepsilon > \kappa$ then, on input m and on access to the oracle \mathcal{F}_m , \mathcal{K} produces either sk_S or sk_D in expected time $\frac{\tau}{\varepsilon - \kappa}$ (without counting the time to make the oracle queries). (Here, \mathcal{F} 's probability is taken over the choice of her random coins and over the choice of $H_q \leftarrow \Omega$.)

5 New DVS Scheme with Tight Reduction to DDH in NPRO

Let p, q and \mathcal{G}_q be as defined in Sect. 2. Let $g_1, g_2 \in \mathcal{G}_q$ be two elements such that nobody knows the mutual discrete logarithms of g_1 and g_2 . Following the ideas from [KW03], in the next DVS-KW DVS scheme, we let Signy to prove Desmond that $(g_1, g_2, y_{1S}, y_{2S})$ is a Decisional Diffie-Hellman tuple, where $x_i \leftarrow_r \mathbb{Z}_q$ is i 's private key and $pk_i := (g_1, g_2, y_{1i}, y_{2i})$ is i 's public key with $y_{1i} = g_1^{x_i}$ and $y_{2i} = g_2^{x_i}$. This proof is made designated-verifier by using the same trick as in the JSI scheme [JSI96], and non-interactive by using a non-programmable random oracle [Nie02] H_q with outputs from \mathbb{Z}_q . In particular, the random oracle H_q can be chosen at the same stage as other system parameters, g_1 and g_2 . This is an interesting result by itself since in [KW03], H_q had to be a programmable random oracle for their security proof to go through. The description of the full DVS-KW scheme follows:

- Sign_{sk_S, pk_S}(m): Signy generates random $r, w, t \leftarrow \mathbb{Z}_q$, and sets $a_1 \leftarrow g_1^r \pmod p$, $a_2 \leftarrow g_2^r \pmod p$, $c \leftarrow g_1^w y_{1D}^t \pmod p$, $h \leftarrow H_q(pk_S, pk_D, a_1, a_2, c, m)$ and $z \leftarrow r + (h + w)x_S \pmod q$. She outputs the signature $\sigma \leftarrow (w, t, h, z)$.
- Simul_{sk_S, pk_S}(m): By selecting three random numbers $z, \alpha, \beta \leftarrow_r \mathbb{Z}_q$, Desmond creates $\sigma = (w, t, h, z)$ for any message m as follows: $(a_1, a_2) \leftarrow (g_1^z y_{1S}^{-\beta} \pmod p, g_2^z y_{2S}^{-\beta} \pmod p)$, $h \leftarrow H_q(pk_S, pk_D, a_1, a_2, g_1^\alpha \pmod p, m)$, $w \leftarrow \beta - h \pmod q$, $t \leftarrow (\alpha - w)x_D^{-1} \pmod q$.
- Vrfy_{pk_S, pk_S}($m; w, t, h, z$): The verifier checks whether $h = H_q(pk_S, pk_D, g_1^z y_{1S}^{-(h+w)} \pmod p, g_2^z y_{2S}^{-(h+w)} \pmod p, g_1^w y_{1D}^t \pmod p, m)$.

Security: First, clearly this scheme is correct and perfectly non-transferable. Second, we can prove the next result that is a generalisation of a proof from [KW03]:

Theorem 1. *Let \mathcal{G} be a (τ', ε') -DDH group with $|\mathcal{G}| = q$ such that exponentiation in \mathcal{G} takes time t_{exp} . Then the above designated-verifier signature scheme is $(\tau, q_h, q_s, \varepsilon)$ -unforgeable in the non-programmable random oracle model, where $\tau \leq \tau' - (3.2q_s + 5.6)t_{\text{exp}}$ and $\varepsilon \geq \varepsilon' + q_s q_h q^{-2} + q^{-1} + q_h q^{-2}$.*

Proof. Assume that we have an algorithm \mathcal{F} , running in time at most τ and making at most q_h hash queries and in total at most q_s signing and simulation queries, which forges

a new message/signature or a new message/simulated signature pair with probability at least ε . We use \mathcal{F} to construct an algorithm \mathcal{A} running in time τ' which solves the DDH problem with probability ε' . The stated result follows.

Algorithm \mathcal{A} is given as input a tuple $(g_1, g_2, y_{1D}, y_{2D})$; its goal is to determine whether this represents a “random tuple” or a “DDH tuple”. To this end, it sets $\text{pk}_D = (g_1, g_2, y_{1D}, y_{2D})$, sets Signy’s public key pk_S to be equal to a random DDH tuple $\text{pk}_S = (g_1, g_2, y_{1S} = g_1^x, y_{2S} = g_2^x)$ for which she chooses the corresponding secret key $x_S \leftarrow \mathbb{Z}_q$, and runs \mathcal{F} on input $(\text{pk}_S, \text{pk}_D)$. Algorithm \mathcal{A} simulates the signing oracle and the random oracle for \mathcal{F} as follows:

Hash queries. In response to a query $H_q(\text{pk}_S, \text{pk}_D, a_1, a_2, c, m)$, algorithm \mathcal{A} responds with $h \leftarrow H_q(\text{pk}_S, \text{pk}_D, a_1, a_2, c, m)$. Additionally, if this query was not made before, \mathcal{A} stores the tuple $(\text{pk}_S, \text{pk}_D, a_1, a_2, c, m)$.

Signing and simulation queries. If \mathcal{F} asks either for a signature or a simulation on message m , then \mathcal{A} attempts to sign pk_S . That is, \mathcal{A} chooses random $r, w, t \leftarrow \mathbb{Z}_q$, sets $a_1 \leftarrow g_1^r \pmod p$, $a_2 \leftarrow g_2^r \pmod p$ and $c \leftarrow g_1^w y_{1D}^t \pmod p$. If H_q had previously been queried on input $H_q(\text{pk}_S, \text{pk}_D, a_1, a_2, c, m)$ then \mathcal{A} aborts (with output 0); otherwise, \mathcal{A} sets $h \leftarrow H_q(\text{pk}_S, \text{pk}_D, a_1, a_2, c, m)$ and outputs the signature (w, t, h, z) , where $z \leftarrow r + (h + w)x_S \pmod q$.

At some point, \mathcal{F} outputs its forgery $(\bar{m}, \bar{\sigma} = (\bar{w}, \bar{t}, \bar{h}, \bar{z}))$, where we assume that $\bar{\sigma}$ was not previously the response to a query $\text{Sign}_{\text{sk}}(\bar{m})$ or $\text{Simul}_{\text{sk}}(\bar{m})$. Set $\bar{a}_1 \leftarrow g_1^{\bar{w}} y_{1S}^{-(\bar{h} + \bar{w})} \pmod p$, $\bar{a}_2 \leftarrow g_2^{\bar{w}} y_{2S}^{-(\bar{h} + \bar{w})} \pmod p$, $\bar{c} \leftarrow g_1^{\bar{w}} y_{1D}^{\bar{t}} \pmod p$. Now, if $H_q(\text{pk}_S, \text{pk}_D, \bar{a}_1, \bar{a}_2, \bar{c}, \bar{m}) = \bar{h}$ (i.e., $\text{Vrfy}_{\text{pk}}(\bar{m}, \bar{\sigma}) = 1$), then \mathcal{A} outputs 1; otherwise, \mathcal{A} outputs 0.

We now analyse the probability that \mathcal{A} outputs 1. If $(g_1, g_2, y_{1D}, y_{2D})$ is a Diffie-Hellman tuple, then \mathcal{A} provides a perfect simulation for \mathcal{F} except for the possibility of an abort. An abort can occur during \mathcal{A} ’s simulation of any of the signing queries; in the simulation of any particular signing query, it is not hard to see that the probability of abort is at most q_h/q^2 . Thus the overall probability that \mathcal{A} aborts is at most $q_s q_h/q^2$. This means that \mathcal{A} outputs a forgery (and hence \mathcal{A} outputs 1) with probability at least $\varepsilon - q_s q_h/q^2$. On the other hand, if $(g_1, g_2, y_{1D}, y_{2D})$ is a random tuple then with probability $1 - q^{-1}$ it is not a Diffie-Hellman tuple. In this case, for any query $H_q(\text{pk}_S, \text{pk}_D, a_1, a_2, c, m)$ made by \mathcal{F} there is at most q possible values of (w, t, z) such that the verification succeeds. Thus, \mathcal{F} outputs a forgery (and hence \mathcal{A} outputs 1) with probability at most $q^{-1} + q_h q^{-2}$. Putting everything together, we see that $\text{Adv}_{\mathcal{G}}^{\text{ddh}}(\mathcal{A}) \geq \varepsilon - q_s q_h q^{-2} - q^{-1} - q_h q^{-2} = \varepsilon'$. The running time of \mathcal{A} includes the running time of \mathcal{F} and is otherwise dominated by two exponentiations and one multi-exponentiation that are performed for each query to the signing oracle plus those done in generating Signy’s key and verifying the output of \mathcal{F} . Assuming as in [KW03] that a two-exponent multi-exponentiation takes time $1.2t_{\text{exp}}$ gives the result of the theorem. \square

On NPRO Versus RO Model. The non-programmable random oracle model is known to be strictly weaker than the random oracle model [Nie02]. This is not surprising looking at the corresponding security proofs, e.g., at the security proof in [KW03] and at the proof of Thm. 1. In the former, the adversary does not know the secret key, and therefore is forced to program the random oracle to be able to answer successfully to

the signature queries. In the latter, the adversary knows Signy’s secret key, and knowing this, can answer successfully to the signature and simulation queries without a need to program the random oracle. A conceptual difference between the two models is that proofs in the RO model work for the “best case” (showing that for every forger, there exists a function H_q such that the signature scheme is unforgeable), while proofs in the NPRO model work for the “average case” (showing that the signature scheme is unforgeable for a randomly chosen function $H_q \leftarrow \Omega_{\text{npro}}$, independent of the forger). Given such arguments, we think that unforgeability in the NPRO model is an important property of DVS-KW.

Conventional Signature Scheme with Tight Reduction to DDH in the NPRO+CRS Model. From DVS-KW, one can build a conventional signature scheme with the same properties (tight reduction to the DDH problem in the non-programmable random oracle model) if one additionally assumes the common reference string (CRS) model. More precisely, in this case, the CRS is equal to a pair (y_{1D}, y_{2D}) , drawn randomly from the set $\{(g_1^x, g_2^x) : x_D \in \mathbb{Z}_q\}$. It is assumed that nobody will use the corresponding secret key to simulate a DVS; in our case, this is easily achieved since CRS can be a random DDH tuple. On the other hand, for the proof to go through, \mathcal{A} is allowed to generate the CRS herself. This scheme is about twice less efficient than the Katz-Wang scheme, but its security does not rely on programmable random oracles. On the other hand, this scheme is more efficient than the currently known signature schemes that are unforgeable in the plain model, and/or has a more standard underlying assumption.

Non-delegatability of DVS-KW. Next, we will give a proof of the non-delegatability of DVS-KW. Because of the structure of our proof, we expect that an arbitrary DVS scheme would have a similar time bound in its security proof.

Theorem 2. *Assume that for some $m \in \mathcal{M}$, \mathcal{F} can produce valid signatures in time τ and with probability ε . Then DVS-KW is $(56\tau/\varepsilon, \frac{1}{q})$ -non-delegatable in the programmable random oracle model.*

Proof. Assume that $\varepsilon > \kappa = 1/q$. We must show there exists a knowledge extractor \mathcal{K} that on input σ and on black-box oracle access to \mathcal{F} can produce either sk_S or sk_D in expected time $\tau' \leq 56\tau/\varepsilon$ and with probability 1.

Let \mathcal{F}_m be a forger with input m . Consider two executions of \mathcal{F}_m by \mathcal{K} on the same random input of \mathcal{F}_m . In both cases, \mathcal{K} executes \mathcal{F}_m step-by-step, except that \mathcal{K} returns different random values (h versus h') as the answer to the hash query $H_q(\text{pk}_S, \text{pk}_D, a_1, a_2, c, m)$. Since (a_1, a_2, c) are under the hash, their values must be equal in both runs. If both signatures are valid, one must have $z - (h + w)x_S \equiv z' - (h' + w')x_S \pmod q$ and $w + tx_D \equiv w' + t'x_D \pmod q$, where (w, t, h, z) is the first signature and (w', t', h', z') , $h \neq h'$, is the second signature. Now we have two cases. If $w \not\equiv w' \pmod q$ then one can find $x_D \leftarrow (w - w')/(t' - t) \pmod q$. If $w \equiv w' \pmod q$ then $h + w \not\equiv h' + w' \pmod q$ and thus one can find $x_S \leftarrow (z - z')/(h - h' + w - w') \pmod q$. Now, assume Rewind is an algorithm that, given an oracle access to \mathcal{F}_m , in time τ_R , for some τ_R , produces two different valid signatures (w, t, h, z) and (w', t', h', z') on m , such that $h \neq h'$ but $(a_1, a_2, c) = (a'_1, a'_2, c')$. Then one can compute either x_S

or x_D with probability 1. Thus, given that algorithm Rewind runs in expected time $56/\varepsilon$ (counting every access to \mathcal{F}_m as one step), we have proven the theorem.

Next, let us describe the algorithm Rewind. We are given a forger \mathcal{F}_m who returns a signature (w, t, h, z) that may or may not be correct. We are given that the probability of a correct answer taken over \mathcal{F}_m coins and the choice of h is at least ε . We want to find correct answers to two different h -values for a given (a_1, a_2, c, m) as efficiently as possible. The idea is to run the prover, and use rewinding to try to make him answer two different challenges correctly. But to run him, we need to supply random coins. Although we know that the average success probability is ε , we do not know that \mathcal{F}_m is equally successful with any random input. To get a better view of this, let H be a matrix with a row for each possible set of random coins for \mathcal{F}_m , and one column for each possible challenge value. Write 1 in an entry if \mathcal{F}_m answers correctly with the corresponding random choices and challenge, and 0 otherwise. Using \mathcal{F}_m as black-box, we can probe any entry we want in H , and our goal can be rephrased to: find two 1's in the same row. What we know is that ε equals the fraction of 1-entries in H . Now, Rewind uses an algorithm from [DF02] to find such 1 entries in time $56/\varepsilon$. \square

6 On Disavowability

In a few proposed designated-verifier signature schemes [JSI96], given a pair (m, σ) , Signy and Desmond cannot prove to a third party, even when they join their forces, which one of them generated σ . In some other schemes—that we call *disavowable*—Signy can prove that (a) she signed messages that she really signed, and (b) she has not signed signatures, simulated by Desmond. This is achieved by decomposing the signature σ of a message m in two non-empty parts, s (“undeniable signature”) and P (“designated-verifier proof”), where for every message m and for every possibly incorrect \bar{s} , the designated verifier can produce a simulated proof \bar{P} such that the distribution of (\bar{s}, \bar{P}) is computationally indistinguishable from the distribution of the real signature (s, P) . Therefore, in this case, Simul takes an additional argument \bar{s} , and one requires also the existence of four additional protocols, Confirm, ConfirmVrfy, Disavowal and DisavowalVrfy. To model our attack on the JSI scheme we must also define “secure disavowability”. The idea behind such definition is to prove that if $\text{Vrfy}_{\text{pk}, \text{pk}}(m, s) = \text{accept}$ and on input (m, s) , an oracle machine \mathcal{F} can, with high probability, produce a δ such that $\text{DisavowalVrfy}_{\text{pk}, \text{pk}}(m; \sigma, \delta) = \text{success}$ then there exists a knowledge extractor that can use \mathcal{F} to recover sk_D .

The JSI scheme [JSI96] was claimed to be disavowable—although, as shown earlier in this paper, it is not—while most of the subsequent DVS schemes provide perfect non-transferability and thus are not disavowable. (If a DVS scheme is perfectly non-transferable then there is no trapdoor information that Signy might use to prove that a message was or was not signed by her. Thus, to make it able for Signy to disavow a signature, a DVS scheme must be computationally but not perfectly non-transferable.) However, even in [JSI96], disavowability was not seen as a feature of the DVS schemes and disavowability was never formally defined; their scheme, being based on Chaum’s undeniable signature, just happens to have this property.

Corrected JSI Scheme: JSI+. As mentioned before, the original JSI scheme, is secure including pk_S , pk_D and $s = m^x$ under the hash. Since we want this scheme to be disavowable, $\text{Simul}_{\text{sk}, \text{pk}}$ also gets an additional input $s \in \mathbb{Z}_p$. Clearly, JSI+ is computationally but not perfectly non-transferable. Unforgeability, non-delegatability and secure disavowability of this scheme can be proven by using standard cryptographic tools, although most probably either in the RO model or with looser reductions. One of the reasons is that since DVS-KW is *perfectly* non-transferable, in its unforgeability proof \mathcal{A} could answer signing and simulation queries in the same manner. Therefore, it was sufficient for \mathcal{A} to know only one of sk_S and sk_D to simulate both kind of queries without using a programmable random oracle. It is not a priori clear how to achieve the same in the case of JSI+.

Further Work and Acknowledgments. We feel that this paper raises interesting questions about the relationship between different non-standard security models; it is an interesting open question to study the necessity of these models in any concrete case. We would like to thank anonymous referees for useful comments. The first author was partially supported by the Estonian Science Foundation.

Abstract. We investigate a general paradigm for constructing arbitrary-input-length (AIL) MACs from fixed-input-length (FIL) MACs, define the waste as the relevant efficiency parameter of such constructions, and give a simple and general security proof technique applicable to very general constructions. We propose concrete, essentially optimal constructions for practical use, Chain-Shift (CS) and Chain-Rotate (CR), and prove their security. They are superior to the best previously known construction, the NI-construction proposed by An and Bellare: Only one rather than two secret keys are required, the efficiency is improved, and the message space is truly AIL, i.e., there is no upper bound on the message length. The generality of our proof technique is also illustrated by giving a simple security proof of the NI-construction and several improvements thereof.

Keywords: Message authentication code (MAC), arbitrary-input-length (AIL), variable-input-length (VIL), fixed-input-length (FIL).

1 Introduction

1.1 Message Authentication Codes (MACs)

Authenticity is a fundamental security requirement for data transmissions. A well-known technique for authenticating messages is to use a so-called *message authentication code* (MAC), an important symmetric-key cryptographic primitive with widespread use in many practical applications. A MAC is a function family $H := \{h_k : \mathcal{M} \rightarrow \mathcal{T}\}_{k \in \mathcal{K}}$, where \mathcal{M} is the message space, \mathcal{T} the tag space, and \mathcal{K} the key space. Two communicating parties who share a secret key k can authenticate a message m , sent over an insecure channel, by computing a tag $\tau = h_k(m)$, which is sent together with the message. The message need not be encrypted. The receiver accepts the message if and only if the received pair (m', τ') satisfies $\tau' = h_k(m')$. We refer to h_k as an *instantiation* of H .

The message space is an important parameter of a MAC scheme. In most applications one needs to authenticate messages of potentially *arbitrary-input-length* (AIL), i.e., $\mathcal{M} = \{0, 1\}^*$. Many proposed MACs are not AIL-MACs since there is an upper bound on the message length, i.e., the message space is the set $\mathcal{M} = \{0, 1\}^{\leq N}$ of all bit strings of length at most N . We refer to such MACs

as having *variable-input-length* (VIL). The constant N is typically large enough to be of little practical concern. A MAC which has $\mathcal{M} = \{0, 1\}^L$ for a constant L is referred to as having *fixed-input-length* (FIL). In this paper we address the problem of constructing (VIL- and) AIL-MACs from any FIL-MAC.

1.2 Previous Work

Constructing VIL- or AIL-primitives from FIL-primitives have been addressed in many papers. A well-known example is the Merkle-Damgård [5, 7] iteration method for constructing AIL collision-resistant functions from FIL collision-resistant functions. The question of constructing VIL- or AIL- pseudo random functions (PRFs) based on any FIL-PRF has received substantial attention, see for example the CBC-MAC [4, 6, 10] and the XOR-MAC [3] (which are PRFs and thus trivially also MACs). Other examples of AIL-MAC constructions are the hash function-based MACs like NMAC and HMAC [2].

A central goal in cryptography is to prove the security of cryptographic schemes under as weak assumptions as possible. In the context of constructing VIL- or AIL-MACs, a natural assumption (much weaker than the PRF assumption) is that the underlying FIL-primitive is a secure FIL-MAC. In 1997 Naor and Reingold [8] constructed a FIL-PRF from any FIL-MAC, but with high cost. While this FIL-PRF could in principle be used in some well-known construction of an AIL-MAC from any FIL-PRF (e.g. the CBC-MAC), it would be impractical. Their question whether a FIL-PRF can be obtained from any FIL-MAC at low cost is still open to date. In 1999 the problem of constructing VIL-MACs from FIL-MACs was proposed and investigated by An and Bellare [1]. They showed that the CBC-MAC is insecure under this weaker assumption for the FIL-primitive. They also presented the *nested iterated* (NI) construction, the first practical construction of a VIL-MAC based on any FIL-MAC (see Fig. 3). As we will see, the NI-construction leaves room for improvements.

1.3 MAC Constructions and Important Design Criteria

Throughout this paper, let $G := \{g_k : \{0, 1\}^L \rightarrow \{0, 1\}^\ell\}_{k \in \{0, 1\}}$ denote a FIL-MAC, with *compression* $b := L - \ell > 0$. We consider a general type of construction C , which uses G to construct a MAC $C^G := \{C^g : \mathcal{M} \rightarrow \{0, 1\}^\ell\}_{k \in \{0, 1\}}$, where \mathcal{M} is either AIL (i.e., $\{0, 1\}^*$) or VIL (i.e., $\{0, 1\}^{\leq N}$). The instantiation C^g is constructed by invoking g_k several times in a black-box manner. To be more precise, let us describe the computation of the tag $\tau = C^g(m)$ for an n -bit message m . In a pre-processing step m is encoded into a bit string m' of length (denoted by) $\lambda(n)$, for instance by padding m and appending information about its length. The processing step is best described with a buffer initialized with m' , where each call to g_k fetches (and deletes) some L bits and writes back the ℓ -bit result to the buffer. This reduces the number of bits in the buffer (by b bits) with each call to g_k . As soon as the number of bits is less than L , the content of the buffer is returned as the tag τ . To obtain an ℓ -bit output, an appropriate

encoding is used such that $\lambda(n) = t(n) \cdot b + \ell$ for some $t(n)$. Note that $t(n)$ is exactly the number of calls to g_k required to compute τ , and that τ is the last output of g_k . The function $t(\cdot)$ is referred to as the *application* function of C . A particular construction can thus be described by the encoding function mapping m to m' and by the scheme by which the L -bit blocks are fetched.

In a more general variant of such a construction, several (say 2) instantiations g_{k_1} and g_{k_2} of G can be used to build an instantiation C^{g_1, g_2} of the MAC $C^{G, G} := \{C^{g_1, g_2} : \mathcal{M} \rightarrow \{0, 1\}^\ell\}_{k_1, k_2 \in \{0, 1\}^\kappa}$ (with key space $(\{0, 1\}^\kappa)^2$). The only difference in the computation of the tag, described above, is that for each L -bit block that is fetched, the instantiation to be invoked needs to be specified. For such schemes $t^i(n)$ (with $i \in \{1, 2\}$) denotes the number of calls needed to g_k in order to compute the tag of an n -bit message, and $t(n) := t^1(n) + t^2(n)$.

Note that the key space of $C^{G, G}$ is twice the size of the key space of C^G . We refer to C as a single-key construction and to C^{g_1, g_2} as a 2-key construction. We now discuss the main design criteria for the constructions:

Number of Keys: We will propose single-key constructions (like C) for practical use and see that there is essentially no reason for considering multiple-key constructions (like C^{g_1, g_2}).

Efficiency: The efficiency can be measured in the number of *applications* $t(n)$ of the FIL-MAC, or equivalently in terms of the *waste* $w(n) := \lambda(n) - n = t(n) \cdot b + \ell - n$, i.e., the amount by which pre-processing expands the message.

Type of Processing: It is desirable that a message can be processed *on-line*, i.e., as the message bits arrive, without knowing the message length in advance. Moreover, it is desirable that the computation of the tag τ can be *parallelized*, i.e., sped up by a factor of roughly c (over the construction using one processor) when c processors are available.

Message Space: As we will see, it turns out that no bound on the message length is necessary, and therefore our focus is on AIL-MAC constructions.

1.4 Contributions of This Paper

The purpose of this paper is to investigate systematically a natural and general paradigm for constructing (VIL- or) AIL-MACs from FIL-MACs, a problem introduced by An and Bellare [1]. Our proof technique, applicable to a very general type of construction, turns out to be insightful for constructing (VIL- and) AIL-MACs from FIL-MACs. We propose concrete, essentially optimal AIL-MAC constructions for practical use, Chain-Shift (CS) and Chain-Rotate (CR) (see Fig. 1 and Fig. 2), and prove their security. They use a single key, have constant waste, allow for on-line and parallel processing of the messages, and their security reduction is essentially tight.

The only previously known (practical) VIL-MAC construction, the NI-construction (see Fig. 3), uses two keys, has an upper bound of 2^b on the message length, and is not optimal in terms of the number of applications to the FIL-MAC (especially not for short messages). In Sect. 4.2 we give a simple security proof (using our proof technique) and several improvements of the NI-construction.

2 Preliminaries

2.1 Notation and Definitions

Let $\{0, 1\}^L$ denote the set of all bit strings of length L , $\{0, 1\}^{\leq N}$ the set of all bit strings of length at most N , $\{0, 1\}^*$ the set of all bit strings, and $[n] := \{1, \dots, n\}$ (with $[0] := \emptyset$). If M is a set, $\#M$ denotes its cardinality. For $x, y \in \{0, 1\}^*$, let $|x|$ denote the length of x (in bits), $x\|y$ the concatenation of x and y , $\langle n \rangle_b$ a b -bit encoding of a positive integer $n \leq 2^b$, $x[i]$ the i^{th} bit of x , and $x[i, j] := x[i]\|x[i+1]\|\dots\|x[j]$ for $1 \leq i < j \leq |x|$. Furthermore, let $\text{RR}(\cdot)$ denote the operator on bit strings that rotates the input by one position to the right, i.e., $\text{RR}(x) := x[L]\|x[1, L-1]$. For a sequence S of elements, $|S|$ denotes its length, and S_i the sequence of the first $i \leq |S|$ elements of S . An encoding $\sigma : \{0, 1\}^* \rightarrow \{0, 1\}^*$ is called *prefix-free* if there are no three strings $x, x', y \in \{0, 1\}^*$ such that $x \neq x'$, $|y| \geq 1$, and $\sigma(x)\|y = \sigma(x')$. A *suffix-free* encoding is an encoding which becomes prefix-free if the bit-order of the output is reversed. A *non-trivial* collision for a function f is a pair $x \neq x'$ of inputs for which $f(x) = f(x')$. If \mathcal{E} denotes an event, $\bar{\mathcal{E}}$ denotes the complementary event.

2.2 Security Definition for MACs

A forger F for a MAC $H := \{h_k : \mathcal{M} \rightarrow \mathcal{T}\}_{k \in \mathcal{K}}$ has oracle access to $h_k(\cdot)$ (for which k is chosen uniformly at random from \mathcal{K}) and can thus learn the tag values for some adaptively chosen messages m_1, m_2, \dots . It then returns a *forgery* (m, τ) , i.e., a message m together with a tag τ . The forger F is considered successful if $h_k(m) = \tau$. The only constraint on m is that it must be *new*, i.e., different from all previous messages m_1, m_2, \dots . We refer to a forger F of this kind as a $(\dot{t}, q, \mu, \varepsilon)$ -forger, where \dot{t} , q , and μ are upper bounds on the running time, the number of messages (or oracle queries), respectively the total length (in bits) of the oracle queries including the forgery message m , and ε is a lower bound on the success probability. Informally, a MAC is considered secure against *existential forgery* under an *adaptive chosen-message attack*, if there is no $(\dot{t}, q, \mu, \varepsilon)$ -forger, even for very high values of \dot{t} , q , and μ , and a very small value of ε . A forger for a FIL-MAC will be denoted simply as a $(\dot{t}, q, \varepsilon)$ -forger, since the parameter μ is determined by q and the message-input-length L , i.e., $\mu = (q + 1)L$.

To prove the security of a MAC based on a FIL-MAC one shows that the existence of a $(\dot{t}, q, \mu, \varepsilon)$ -forger F for the MAC implies the existence of a $(\dot{t}', q', \varepsilon')$ -forger F' for the FIL-MAC, where \dot{t}' , q' , and ε' are functions of \dot{t} , q , μ , and ε . In all our security proofs F is called only once by F' . Therefore, the running time of F' is essentially that of F , i.e., $\dot{t}' \approx \dot{t}$, with some small overhead that is obvious from the construction of F' . We will therefore not bother to explicitly compute the running time of forgers, as this complicates the analysis unnecessarily without providing more insight. Therefore we drop the time parameter \dot{t} in the sequel.

3 Single-Key AIL-MACs Based on Any FIL-MAC

3.1 FIL-MAC Forgers Based on an AIL-MAC Forger (Single Key)

Let F be a (q, μ, ε) -forger for a MAC C^G , i.e., if k is chosen uniformly at random from $\{0, 1\}^\kappa$, and F is allowed at most q oracle queries to C^g of total length at most μ (including the length of the forgery message), then F returns a valid forgery (m, τ) with probability at least ε . We refer to $F \circ C^g$ as the process in which F 's queries to C^g are computed and returned to F , and where F 's forgery (m, τ) is verified by computing $C^g(m)$. Let us consider the random variables occurring at the interface to g_k (in the process $F \circ C^g$). Let z_i denote the i^{th} input to g_k and let $y_i := g_k(z_i)$. The sequences $\mathbf{Z} := (z_1, z_2, \dots)$ and $\mathbf{Y} := (y_1, y_2, \dots)$ are thus naturally defined. Note that as soon as the key k and the random coins of F are fixed, all values in \mathbf{Z} and \mathbf{Y} are determined, and also whether F is successful or not. Let \mathcal{E} denote the event that F is successful. Without loss of generality we assume that F 's forgery message m is distinct from F 's oracle queries. Thus \mathcal{E} occurs if and only if $C^g(m) = \tau$.

A FIL-MAC forger F' for G simulates $F \circ C^g$ with the help of F and its oracle access to g_k . At some query z_i to g_k it stops the simulation and returns a forgery (z', τ') for g_k (without making any other oracle queries to g_k). Such a forger is characterized by the moment it stops (i.e., i) and the way it produces its forgery. We refer to this as the *strategy* s of F' and let F'_s denote the corresponding forger.

The most simple strategy is the *naïve* strategy s_{na} . $F'_{s_{\text{na}}}$ stops the simulation of $F \circ C^g$ at the very last query \mathbf{z} to g_k (i.e., \mathbf{z} is the last entry in \mathbf{Z}). Then it returns (\mathbf{z}, τ) as a forgery, where τ is the forgery tag of F 's forgery (m, τ) for C^g . $F'_{s_{\text{na}}}$ is successful if the following two conditions hold. First, \mathcal{E} occurs, i.e., $C^g(m) = \tau$ (and thus $g_k(\mathbf{z}) = \tau$ by definition of C), and second \mathbf{z} is new, i.e., \mathbf{z} is only the last entry in \mathbf{Z} . Let \mathcal{E}_{new} denote the event that \mathbf{z} is new. Thus $F'_{s_{\text{na}}}$ is successful whenever $\mathcal{E} \wedge \mathcal{E}_{\text{new}}$ occurs.

Imagine that there is a set \mathcal{S} of strategies, such that whenever $\bar{\mathcal{E}}_{\text{new}}$ occurs there exists at least one strategy $s \in \mathcal{S}$ for which F'_s is successful. We refer to such a set \mathcal{S} as *complete* for the construction. Obviously, the set $\mathcal{S} \cup \{s_{\text{na}}\}$ has the property that whenever \mathcal{E} occurs, there is at least one strategy $s \in \mathcal{S} \cup \{s_{\text{na}}\}$ for which F'_s is successful. Thus an overall strategy of F' is to pick its strategy uniformly at random from $\mathcal{S} \cup \{s_{\text{na}}\}$. Its success probability is at least the probability that \mathcal{E} occurs divided by $\#\mathcal{S} + 1$, since the choice of strategy is independent of \mathcal{E} . As F' 's number of oracle queries is $|\mathbf{Z}|$, which is a random variable, it is convenient to introduce the following function.

Definition 1. *The expansion function e of a construction C is defined as*

$$e(\tilde{q}, \tilde{\mu}) := \max \left\{ \sum_{i=1}^{\tilde{q}} t(n_i) : n_1, \dots, n_{\tilde{q}} \in \mathbb{N}_0, n_1 + \dots + n_{\tilde{q}} \leq \tilde{\mu} \right\},$$

where $t(\cdot)$ is the application function of C .

It follows that $|\mathbf{Z}| \leq e(q + 1, \mu)$, since there are at most $q + 1$ queries of total length at most μ to C^g in $F \circ C^g$. In general $\#\mathcal{S}$ is a function of $e(q + 1, \mu)$.

Proposition 1. *The existence of a complete set \mathcal{S} for a construction C and a (q, μ, ε) -forger F for C^G implies the existence of a (q', ε') -forger F' for G , where $q' = e(q + 1, \mu)$ and $\varepsilon' = \frac{\varepsilon}{\#\mathcal{S} + 1}$.*

Proof. F' picks its strategy s uniformly at random from $\mathcal{S} \cup \{s_{\text{na}}\}$. Let \mathcal{E}' denote the event that F' is successful, and let \mathcal{E} and \mathcal{E}_{new} be defined as above.

$$\underbrace{\Pr[\mathcal{E}']}_{=: \varepsilon'} \geq \underbrace{\Pr[\mathcal{E}' | \mathcal{E} \wedge \mathcal{E}_{\text{new}}]}_{\geq 1/(\#\mathcal{S} + 1)} \cdot \Pr[\mathcal{E} \wedge \mathcal{E}_{\text{new}}] + \underbrace{\Pr[\mathcal{E}' | \bar{\mathcal{E}}_{\text{new}}]}_{\geq 1/(\#\mathcal{S} + 1)} \cdot \underbrace{\Pr[\bar{\mathcal{E}}_{\text{new}}]}_{\geq \Pr[\mathcal{E} \wedge \bar{\mathcal{E}}_{\text{new}}]} \geq \underbrace{\frac{\Pr[\mathcal{E}]}{\#\mathcal{S} + 1}}_{=: \varepsilon/(\#\mathcal{S} + 1)}$$

□

3.2 Deterministic Strategies

An important class of strategies for F' are the deterministic strategies. A deterministic strategy s is characterized by a pair (i, f) , where $i \in [e(q + 1, \mu)]$ is an index and f a function mapping $(\mathbf{Z}_i, \mathbf{Y}_{i-1})$ to some value $\hat{y}_i \in \{0, 1\}^\ell$ (which can be seen as a prediction of y_i). To be more precise, the corresponding forger F'_s stops (the simulation of $F \circ C^g$) at query z_i and returns (z_i, \hat{y}_i) as a forgery.¹ The forger is successful if $\hat{y}_i = y_i$ and if z_i is new, i.e., not contained in the sequence \mathbf{Z}_{i-1} . Next follow three particular sets of strategies, which will be used in the sequel:

- Let $s_{i,y}$ (with $y \in \{0, 1\}^\ell$) denote the strategy of stopping at query z_i and returning (z_i, y) as a forgery. Note that whenever the event occurs that g_k outputs y , i.e., when y is an entry in \mathbf{Y} , then there is at least one strategy $s \in \mathcal{S}_y := \{s_{i,y} | i \in [e(q + 1, \mu)]\}$ for which F'_s is successful. We have

$$\#\mathcal{S}_y = e(q + 1, \mu). \quad (1)$$

- Let $s_{\text{coll},i,j}$ (with $i > j$) denote the strategy of stopping at query z_i and returning (z_i, y_j) as a forgery. Note that whenever a non-trivial collision for g_k occurs, i.e., $\alpha, \beta \in [|\mathbf{Z}|]$ satisfying $z_\alpha \neq z_\beta$ and $y_\alpha = y_\beta$, then there is at least one strategy $s \in \mathcal{S}_{\text{coll}} := \{s_{\text{coll},i,j} | i, j \in [e(q + 1, \mu)], i > j\}$ for which F'_s is successful. The cardinality of $\mathcal{S}_{\text{coll}}$ is

$$\#\mathcal{S}_{\text{coll}} = e(q + 1, \mu)^2 / 2 - e(q + 1, \mu) / 2. \quad (2)$$

- Let $s_{\text{coll}2,i,j,a,\text{left}}$ (with $a \in \{0, 1\}$ and $i > j$) denote the strategy of stopping at input z_i and returning $(z_i, a || y_j[1, \ell - 1])$ as a forgery, and let $s_{\text{coll}2,i,j,a,\text{right}}$ denote the strategy of stopping at input z_i and returning $(z_i, y_j[2, \ell] || a)$ as a forgery. Note that whenever the event occurs that there are $\alpha, \beta \in [|\mathbf{Z}|]$ satisfying $z_\alpha \neq z_\beta$ and $g_k(z_\alpha)[2, \ell] = g_k(z_\beta)[1, \ell - 1]$, then there is a strategy $s \in \mathcal{S}_{\text{coll}2} := \{s_{\text{coll}2,i,j,a,d} | i, j \in [e(q + 1, \mu)], i > j, a \in \{0, 1\}, d \in \{\text{left}, \text{right}\}\}$ for which F'_s is successful. The cardinality of $\mathcal{S}_{\text{coll}2}$ is

$$\#\mathcal{S}_{\text{coll}2} = 2 \cdot e(q + 1, \mu)^2 - 2 \cdot e(q + 1, \mu). \quad (3)$$

¹ If $i > |\mathbf{Z}|$ the forger aborts.

3.3 The Chain-Shift (CS) Construction

The CS-construction uses any FIL-MAC $G := \{g_k : \{0, 1\}^{b+\ell} \rightarrow \{0, 1\}^\ell\}_{k \in \{0, 1\}}$ with compression $b \geq \ell$, to construct an AIL-MAC $CS^G := \{CS^g : \{0, 1\}^* \rightarrow \{0, 1\}^\ell\}_{k \in \{0, 1\}}$. For a message $m \in \{0, 1\}^*$ of length $n := |m|$, the tag $\tau = CS^g(m)$ is computed according to the following recursion (as depicted in Fig. 1). Parse m into a sequence of b -bit blocks m_1, \dots, m_{t-1} and a $(b - \ell)$ -bit block m_t , such that $m_1 \parallel \dots \parallel m_t = m \parallel 10^\nu$ for some $\nu \in \{0, \dots, b - 1\}$:

$$y_0 := 0^\ell, y_i := g_k(y_{i-1} \parallel m_i) \text{ for } i \in [t - 1], \text{ and } \tau := g_k(1^\ell \parallel y_{t-1} \parallel m_t).$$

The waste $w(n) = t(n) \cdot b + \ell - n = \lceil (n + 1 + \ell) / b \rceil \cdot b + \ell - n \leq L + \ell$ is upper bounded by a constant, and on-line processing is possible.

Fig. 1. The Chain-Shift (CS) construction

Theorem 1.2 *A (q, μ, ε) -forger F for CS^G implies a (q', ε') -forger F' for G , where $q' = \lfloor \frac{\mu}{b} \rfloor + 2(q + 1)$ and $\varepsilon' = \frac{\varepsilon}{q'^2/2 + 3q'/2 + 1}$.*

Proof. We apply Proposition 1 and show that $\mathcal{S} := \mathcal{S}_{\text{coll}} \cup \mathcal{S}_0 \cup \mathcal{S}_1$ is complete for CS by proving that whenever the last entry \mathbf{z} in \mathbf{Z} is not new, then there is a non-trivial collision in g_k , or an output from g_k that equals 0^ℓ or 1^ℓ .

Assume that \mathbf{z} is not new. Let $\tilde{z}_1, \dots, \tilde{z}_t$ denote the sequence of queries to g_k resulting from the last query m_β to CS^g . Note that m_β is the forgery message of F and thus new. Since $\tilde{z}_t = \mathbf{z}$ is not new, \tilde{z}_t must have been an earlier query to g_k , resulting from some query m_α (with $\alpha \leq \beta$) to CS^g . Let $\tilde{z}'_1, \dots, \tilde{z}'_{t'}$ denote the sequence of queries to g_k in the computation of $CS^g(m_\alpha)$. There are three cases to distinguish, depending on the index $i \in [t']$ for which $\tilde{z}_t = \tilde{z}'_i$.

At the end of the chain ($\tilde{z}_t = \tilde{z}'_{t'}$): First, we note that this can not be the case if $\alpha = \beta$, since in that case $\tilde{z}'_{t'}$ is not an earlier occurring query. Thus we have (the non-trivial collision) $m_\alpha \neq m_\beta$ satisfying $CS^g(m_\alpha) = CS^g(m_\beta)$. Without loss of generality assume that $t' \geq t$. Now, either there exist an index $j \in [t - 1]$ such that $\tilde{z}_{t-j} \neq \tilde{z}'_{t'-j}$ and $\tilde{z}_{t-j+1} = \tilde{z}'_{t'-j+1}$, i.e., a non-trivial collision in g_k occurs (since $\tilde{z}_{t-j+1} = \tilde{z}'_{t'-j+1}$ implies $g_k(\tilde{z}_{t-j}) = g_k(\tilde{z}'_{t'-j})$) or $\tilde{z}'_{t'-t+1} = \tilde{z}_1 = 0^\ell \parallel v$ for some $v \in \{0, 1\}^b$, which implies $g_k(\tilde{z}'_{t'-t}) = 0^\ell$ (with $t' - t \geq 1$ since $m_\alpha \neq m_\beta$).

² An and Bellare point out in [1] that the security loss of roughly $(\mu/b)^2$ is unavoidable for iterative constructions of this nature. It is shown using birthday attacks illustrated by Preneel and Van Oorschot [11].

In the middle of the chain ($\tilde{z}_t = \tilde{z}'_i$ with $1 < i < t'$): We have $1^\ell \|v = \tilde{z}_t = \tilde{z}'_i = g_k(\tilde{z}'_{i-1}) \|v$, for some $v \in \{0, 1\}^b$. Thus g_k outputs 1^ℓ .

At the beginning of the chain ($\tilde{z}_t = \tilde{z}'_1$ and $t' > 1$): This case is obviously impossible, since $\tilde{z}_t = 1^\ell \|v \neq 0^\ell \|v' = \tilde{z}'_1$ for any $v, v' \in \{0, 1\}^b$.

By definition of $e(q+1, \mu)$, there is a sequence $n_1, \dots, n_{q+1} \in \mathbb{N}_0$ such that:

$$e(q+1, \mu) = \sum_{i=1}^{q+1} t(n_i) \leq \left\lfloor \frac{\mu + (q+1)L}{b} \right\rfloor \leq \left\lfloor \frac{\mu}{b} + 2(q+1) \right\rfloor =: q'.$$

Thus $\#\mathcal{S} + 1 \leq (q'^2/2 - q'/2) + q' + q' + 1 \leq q'^2/2 + 3q'/2 + 1$ by (1) and (2). \square

Improving the Waste for Short Messages. We improve the efficiency of the CS-construction for $n := |m| < rb$, where $r \in \mathbb{N}_0$ is a design parameter. This is relevant (see for example [9]). The computation of the tag τ is redefined for messages m of length shorter than rb as follows. Parse m into a sequence of b -bit blocks m_1, \dots, m_t such that $m_1 \| \dots \| m_t = m \| 10^\nu$ where $\nu \in \{0, \dots, b-1\}$:

$$y_0 := \langle t \rangle_\ell, y_i := g_k(y_{i-1} \| m_i) \text{ for } i \in [t], \text{ and } \tau := y_t.$$

Now, $t(n) = \lceil (n+1)/b \rceil$ if $n < rb$ (and $t(n) = \lceil (n+1+\ell)/b \rceil$ if $n \geq rb$). The proof that $\mathcal{S}_{\text{coll}} \cup \mathcal{S}_0 \cup \mathcal{S}_1 \cup (\cup_{i=1}^r \mathcal{S}_{(i)})$ is complete for the construction is omitted. The only modification of Theorem 2 is thus that $\epsilon' = \frac{\epsilon}{q'^2/2 + (3/2+r)q'+1}$, i.e., the reduction is essentially as tight (as for $r=0$) for reasonable r 's.

Parallelizing the CS-Construction. We modify the CS-construction to allow $c \geq 1$ processors to compute the tag in parallel, achieving a speed up by a factor of roughly c for long messages. The tag τ of an n -bit message m is computed according to the following recursion:

1. If $c \leq \lceil (n+1)/b \rceil$ then set $c' := c$, and else set $c' := \lceil (n+1)/b \rceil$.
2. Parse m into $m_1 \| \dots \| m_{c't} = m \| 10^\nu$, where $m_1, \dots, m_{c't}$ are b -bit blocks and $\nu \in \{0, \dots, c'b-1\}$. Set $m_{i,j} := m_{i+(j-1)c'}$ for $i \in [c']$ and $j \in [t]$.
3. Set $y_{i,0} := 0^\ell$, and compute $y_{i,j} := g_k(y_{i,j-1} \| m_{i,j})$ for $i \in [c']$ and $j \in [t]$.
4. Return $\tau := \text{CS}^g(y_{1,t} \| \dots \| y_{c',t})$.³

³ The construction can be further parallelized by replacing step 4 as follows. For simplicity assume $b = \ell$ (the generalization to $b \geq \ell$ is straight forward). Apply g_k to every pair of adjacent blocks in $(y_{1,t}, \dots, y_{c',t})$, resulting in a new sequence of $\lceil c'/2 \rceil$ blocks, and repeat this until a single block y is obtained. Then set $\tau := g_k(1^\ell \| y)$.

By setting $c := \infty$ this construction is *fully* parallelized (FP) (here meaning that the computation time is in $\Theta(\log(n))$ when arbitrary many processors are available) with $w(n) \in \Theta(n)$. From a theoretical viewpoint it would be interesting to see whether FP single-key AIL-MAC constructions with $w(n) \in \Theta(1)$ exists. There are FP single-key AIL-MAC constructions with $w(n) \in \Theta(\log(n))$ and FP 2-key AIL-MAC constructions with $w(n) \in \Theta(1)$.

The waste remains constant and the on-line property is preserved. We omit the proof that $\mathcal{S} = \mathcal{S}_{\text{coll}} \cup \mathcal{S}_0 \cup \mathcal{S}_1$ is complete for the construction, as it is similar to the proof that \mathcal{S} is complete for the CS-construction.

3.4 The Chain-Rotate (CR) Construction

The purpose of presenting this single-key AIL-MAC construction is twofold. First, it shows that constant waste and on-line processing is possible (even) with compression $b < \ell$. Second, it demonstrates the generality of our proof technique.

The CR-construction transforms any FIL-MAC $G := \{g_k : \{0, 1\}^{b+\ell} \rightarrow \{0, 1\}^\ell\}_{k \in \{0,1\}}$ into an AIL-MAC $\text{CS}^G := \{\text{CS}^g : \{0, 1\}^* \rightarrow \{0, 1\}^\ell\}_{k \in \{0,1\}}$. The tag $\tau = \text{CR}^g(m)$ of an n -bit message m is computed as follows (see Fig. 2). Parse m into a sequence of b -bit blocks m_1, \dots, m_t such that $m_1 \parallel \dots \parallel m_t = m \parallel 10^\nu$ with $\nu \in \{0, \dots, b-1\}$. If $t > 1$, set $y_0 := 0^\ell$ and else set $y_0 := 1^\ell$:

$$y_i := g_k(y_{i-1} \parallel m_i) \text{ for } i \in [t-1] \text{ and } \tau := g_k(\text{RR}(y_{t-1} \parallel m_t)).$$

The waste is $w(n) = \lceil (n+1)/b \rceil \cdot b + \ell - n \leq L$, and on-line processing is possible.

Fig. 2. The Chain-Rotate (CR) construction

Theorem 2. *A (q, μ, ε) -forger F for CR^G implies a (q', ε') -forger F' for G , where $q' = \lfloor \frac{\mu}{b} \rfloor + q + 1$ and $\varepsilon' = \frac{\varepsilon}{5q'^2/2 + 3q'/2 + 1}$.*

Proof (Sketch). We apply Proposition 1. With a case study similar to that for the CS (here omitted), one shows that $\mathcal{S} := \mathcal{S}_{\text{coll}} \cup \mathcal{S}_{\text{coll}2} \cup \mathcal{S}_0 \cup \mathcal{S}_1 \cup \mathcal{S}_{0-1} \cup \mathcal{S}_{01-1}$ is complete for CR. There exist $n_1, \dots, n_{q+1} \in \mathbb{N}_0$ such that:

$$e(q+1, \mu) = \sum_{i=1}^{q+1} t(n_i) \leq \sum_{i=1}^{q+1} \left\lceil \frac{n_i + 1}{b} \right\rceil \leq \left\lceil \sum_{i=1}^{q+1} \frac{n_i + b}{b} \right\rceil \leq \left\lfloor \frac{\mu}{b} \right\rfloor + q + 1 =: q'.$$

As a consequence, $\#\mathcal{S} + 1 \leq 5q'^2/2 + 3q'/2 + 1$ by (1), (2), and (3). □

Parallelizing the CR-Construction. The CR-construction can be parallelized in a similar way as the CS-construction. Just replace CS by CR in step 4 of the corresponding paragraph of Sect. 3.3. As for the CR-construction the set $\mathcal{S} := \mathcal{S}_{\text{coll}} \cup \mathcal{S}_{\text{coll}2} \cup \mathcal{S}_0 \cup \mathcal{S}_1 \cup \mathcal{S}_{0-1} \cup \mathcal{S}_{01-1}$ is complete for the construction.

4 Comparison with the NI-Construction and Variations

The security analysis described in Sect. 3.1 can be generalized to multiple-key constructions. Motivated by the NI-construction (see Fig. 3), we consider constructions C^{\cdot} (using two instantiations g_{k_1} and g_{k_2} of G to construct an instantiation $C^{g_{k_1}, g_{k_2}}$ of the MAC $C^{G,G}$), where one of the instantiations (say g_{k_2} without loss of generality) is invoked at the end of the computation. We prove the security of the NI-construction and give several improvements thereof.

4.1 FIL-MAC Forgers Based on an AIL-MAC Forger (2 Keys)

Let F denote a (q, μ, ε) -forger for the MAC $C^{G,G}$. As before let $F \circ C^{g_{k_1}, g_{k_2}}$ denote the process in which for each query \tilde{m} issued by F , the corresponding tag $C^{g_{k_1}, g_{k_2}}(\tilde{m})$ is computed and returned to F , and once F returns a forgery (m, τ) , the forgery is verified by computing $C^{g_{k_1}, g_{k_2}}(m)$. Let $\mathbf{Z}^i := (z_1^i, z_2^i, \dots)$ and $\mathbf{Y}^i := (y_1^i, y_2^i, \dots)$ be the sequence of inputs respectively outputs occurring at the interface to instantiation g_k (for $i \in \{1, 2\}$).

The FIL-MAC forger F' simulates $F \circ C^{g_{k_1}, g_{k_2}}$ by letting its own oracle simulate one of the instantiations g_k (say the instantiation *under attack*) and by choosing a random key for the other, but stops the simulation at some query z_j^i to its oracle and returns a forgery (without making any further query to any FIL-MAC instantiation). This is equivalent to first instantiating g_{k_1} and g_{k_2} (by choosing the keys k_1, k_2 uniformly at random) and then letting F' specify which instantiation to attack, i.e., consider as its own oracle, after which the key to the other instantiation is revealed to F' . We adopt this view. Any such forger is characterized by its *strategy*, i.e., which instantiation it attacks (i.e., i), the moment it stops (i.e., j), and the way it produces its forgery.

Let s_{na} denote the naïve strategy described in Sect. 3.1, with the only modification that the second instantiation, g_{k_2} is put under attack (recall that the tag τ is an output of g_{k_2}). $F'_{s_{\text{na}}}$ stops at the very last query \mathbf{z} to g_{k_2} and returns (\mathbf{z}, τ) as a forgery. Of course F' is successful if the following two conditions hold. First, \mathcal{E} occurs, i.e., $C^{g_{k_1}, g_{k_2}}(m) = \tau$ (and thus $g_{k_2}(\mathbf{z}) = \tau$),⁴ and second \mathcal{E}_{new} holds, i.e., \mathbf{z} is new for g_{k_2} or equivalently \mathbf{z} is only the last entry in \mathbf{Z}^2 .

Imagine as before, that a *complete* set of strategies \mathcal{S} exists, i.e., a set for which whenever $\bar{\mathcal{E}}_{\text{new}}$ occurs, there exists a strategy $s \in \mathcal{S}$ for which F'_s is successful. Then an overall strategy of F' is to pick its strategy uniformly at random from $\mathcal{S} \cup \{s_{\text{na}}\}$. Its success probability is at least the probability that \mathcal{E} occurs (i.e., ε) divided by the number $\#\mathcal{S} + 1$ of strategies, since the choice of strategy is independent of the event \mathcal{E} . Since F' 's number of queries to its oracle is upper bounded by $\max\{|\mathbf{Z}^1|, |\mathbf{Z}^2|\}$, which is a random variable, it is convenient to introduce the expansion function for each instantiation, i.e., for $i \in \{1, 2\}$, let $e^i(\tilde{q}, \tilde{\mu}) := \max\{\sum_{j=1}^{\tilde{q}} t^i(n_j) : n_1, \dots, n_{\tilde{q}} \in \mathbb{N}_0, n_1 + \dots + n_{\tilde{q}} \leq \tilde{\mu}\}$. Thus $|\mathbf{Z}^i| \leq e^i(q + 1, \mu)$. Proposition 1 generalizes as follows.

⁴ We assume w.l.o.g. that F' 's forgery message m is distinct from its oracle queries.

Proposition 2. *The existence of a complete set \mathcal{S} for a construction C^\cdot and a (q, μ, ε) -forger F for $C^{G,G}$ implies a (q', ε') -forger F' for G , where $q' = \max(e^1(q + 1, \mu), e^2(q + 1, \mu))$ and $\varepsilon' = \frac{\varepsilon}{\#\mathcal{S}+1}$.*

A deterministic strategy s is now characterized by a triple of values (i, j, f) , where i denotes the instantiation to attack, z_j^i the moment to stop, and f a function mapping $(\mathbf{Z}_j^i, \mathbf{Y}_{j-1}^i)$ to some value $\hat{y}_j^i \in \{0, 1\}^\ell$. The pair (z_j^i, \hat{y}_j^i) is the forgery of F'_s . The sets of deterministic strategies introduced in Sect. 3.2 is naturally defined for each instantiation. Let \mathcal{S}_y^i , $\mathcal{S}_{\text{coll}}^i$, and $\mathcal{S}_{\text{coll}2}^i$ denote the corresponding sets for the i^{th} instantiation.

4.2 The NI-Construction

The NI-construction [1] transforms any FIL-MAC G into a VIL-MAC $\text{NI}^{G,G} := \{\text{NI}^{g_1, g_2} : \{0, 1\}^{\leq 2} \rightarrow \{0, 1\}^\ell\}_{k_1, k_2 \in \{0, 1\}}$. For a message $m \in \{0, 1\}^{\leq 2}$ of length $n := |m|$, the tag $\tau = \text{NI}^{g_1, g_2}(m)$ is computed according to the following recursion (as illustrated in Fig. 3). Break m into $t - 1 = \lceil n/b \rceil$ blocks $\{m_i\}_{i=1}^{t-1}$ of length b , where m_{t-1} is padded with zeroes if necessary, and set $m_t := \langle n \rangle_b$:

$$y_0 := 0^\ell, y_i := g_{k_1}(y_{i-1} \| m_i) \text{ for } i \in [t - 1], \text{ and } \tau := g_{k_2}(y_{t-1} \| m_t). \tag{4}$$

The waste is $w(n) = t(n) \cdot b + \ell - n = \lceil \frac{n}{b} + 1 \rceil \cdot b + \ell - n \leq L + b$, and on-line processing is possible. Note that the message space is VIL, due to $m_t := \langle n \rangle_b$.

Fig. 3. The nested iterated (NI) construction

Theorem 3. *A (q, μ, ε) -forger F for $\text{NI}^{G,G}$ implies a (q', ε') -forger F' for G , where $q' = \lfloor \frac{\mu}{b} \rfloor + q + 1$ and $\varepsilon' = \frac{\varepsilon}{q^2/2 - q'/2 + 1}$.*

Proof. We show that $\mathcal{S}_{\text{coll}}^1$ is complete for NI^\cdot by proving that whenever the last entry \mathbf{z} in \mathbf{Z}^2 is not new, then a non-trivial collision in g_{k_1} occurs. Let m_β denote the forgery message of F . Since \mathbf{z} is not new, there is a query m_α (issued by F and different from m_β) with same input to g_{k_2} . Thus we have $|m_\alpha| = |m_\beta|$, and (the non-trivial collision) $m_\alpha \neq m_\beta$ satisfying $\text{NI}^{g_1, g_2}(m_\alpha) = \text{NI}^{g_1, g_2}(m_\beta)$. Since $m_\alpha \neq m_\beta$, all corresponding intermediate values in the computation chains can not be the same. As a consequence a non-trivial collision in g_{k_1} occurs.

By definition of $e^1(q + 1, \mu)$, there is a sequence $n_1, \dots, n_{q+1} \in \mathbb{N}_0$ such that:

$$e^2(q + 1, \mu) \leq e^1(q + 1, \mu) = \sum_{i=1}^{q+1} t^1(n_i) \leq \left\lfloor \sum_{i=1}^{q+1} \frac{n_i + b - 1}{b} \right\rfloor \leq \left\lfloor \frac{\mu}{b} + q + 1 \right\rfloor =: q'.$$

Thus $\#\mathcal{S}_{\text{coll}}^1 + 1 \leq q^2/2 - q'/2 + 1$ by (2). Proposition 2 concludes the proof. \square

Improvements on the NI-Construction

1. By replacing $y_0 := 0^\ell$ with a message block, the waste decreases by ℓ bits, the security reduction is slightly tighter, and the on-line property is of course preserved. The security proof is identical to that of the NI-construction.
2. The block $m_t := \langle n \rangle_b$, encoding the message length, is superfluous. It can be replaced by a message block with appropriate padding. This decreases the waste of the construction, improves the tightness of the reduction, lifts the message space to AIL, and preserves the on-line property. To be more precise the message m is parsed into a sequence of b -bit blocks m_1, \dots, m_t such that $m_1 \| \dots \| m_t = m \| 10^\nu$ with $\nu \in \{0, \dots, b-1\}$ and processed according to (4). It is straight forward to see that $\mathcal{S}_{\text{coll}}^1 \cup \mathcal{S}_0^1$ is complete for the construction.
3. If the block encoding the message length is used as the first block instead of the last or if any other prefix-free encoding of the message into blocks is used, the two keys can actually be replaced by a single key. By choosing an appropriate prefix-free encoding (for example the one on page 126 in [6]) the message space can be lifted to AIL, at the cost of having $w(n) \in \Theta(\log(n))$. We conjecture that linear waste, i.e., $w(n) \in \Theta(n)$ is needed for the on-line property. It is easy to verify that $\mathcal{S}_{\text{coll}} \cup \mathcal{S}_0$ is complete for the construction.

5 Conclusions

A general paradigm for constructing VIL- and AIL-MACs from any FIL-MAC was presented. The design goals were minimal key-length, optimal waste, as well as suitability for on-line and parallel processing of the messages. Our single-key AIL-MAC constructions, CS and CR, have constant waste, allow for on-line and parallel processing of the message, and have essentially tight security reductions.

The Efficiency and Fairness of a Fixed Budget Resource Allocation Game

Li Zhang

Hewlett-Packard Labs, 1501 Page Mill Road,

l.zhang@hp.com

Abstract. We study the resource allocation game in which price anticipating players compete for multiple divisible resources. In the scheme, each player submits a bid to a resource and receives a share of the resource according to the proportion of his bid to the total bids. Unlike the previous study (e.g. [5]), we consider the case when the players have budget constraints, i.e. each player's total bids is fixed. We show that there always exists a Nash equilibrium when the players' utility functions are strongly competitive. We study the efficiency and fairness at the Nash equilibrium. We show the tight efficiency bound of $\Theta(1/\sqrt{m})$ for the m player balanced game. For the special cases when there is only one resource or when there are two players with linear utility functions, the efficiency is $3/4$. We extend the classical notion of envy-freeness to measure fairness. We show that despite a possibly large utility gap, any Nash equilibrium is 0.828-approximately envy-free in this game.

1 Introduction

We study the performance of a mechanism for allocating multiple *divisible* resources to strategic and selfish players. We consider the price anticipating allocation scheme in which each player submits a bid to a resource and receives a fraction of his bid to the total bids submitted to that resource. Compared to, for example, auction based schemes [4, 19, 14], such commodity based scheme is simple to implement and is highly responsive to the player's need. It has been implemented for allocating computing resources in several distributed systems [2, 9] and analyzed in [10, 5, 3]. One important constraint we consider in this paper is that each player has a budget constraint, i.e. a player's total bids is fixed. As we explain later, the natural condition on the budget adds difficulty for applying the existing technique. We also consider general utility functions instead of restricting to network game as considered in [17, 5].

Similar to the previous work, we analyze the scheme as a noncooperative game and focus on the game's Nash equilibrium, the stable state at which no player has incentive to change his behavior. We first answer the question about the existence of Nash equilibrium in such a game. It is easy to construct an example to show that even when the utility functions satisfy the standard assumptions, there may still not exist an equilibrium. We show that an additional requirement of

strong competitiveness can guarantee the existence of Nash equilibria. Informally, the players are strongly competitive if for each resource, there are at least two players who always desire it. However, unlike some similar game without budget constraint, the Nash equilibria are no longer unique.

For the performance at the Nash equilibrium, we first consider the efficiency, or price of anarchy according to [13], of the Nash equilibrium, defined as the ratio of the social welfare at the worst equilibrium to the social optimum. We show that with the budget constraint, the efficiency can be unfortunately low, at $\Theta(1/\sqrt{m})$ for m players. For the two special cases when there is only one resource and when there are only two players with linear utility functions, we show the tight efficiency bound of $3/4$. Interestingly, in both cases, the efficiency is $3/4$ although the proofs are completely different. In particular, the bound of $3/4$ in one resource case is a property of concave functions, which is probably interesting in its own right.

Another important criterion for evaluating a mechanism is its fairness. However, unlike the common agreement on the importance of efficiency metric, there are multiple definitions on fairness, such as max-min fairness [8] and proportional fairness [6, 7]. In this paper, we evaluate the fairness by extending the notion of envy-freeness commonly used in the study of fair division [18, 1]. An allocation is called *envy-free* if no one feels someone else gets a share more than he does. We extend this notion to approximately envy-free. Roughly speaking, an allocation is called c -approximately envy-free if everyone feels he gets at least c times of others share. We are able to show that if the players have the same budget, then any allocation at the Nash equilibrium is $2\sqrt{2} - 2 \approx 0.828$ approximately envy-free. This shows that while the utility gap between two players at an equilibrium might be big, the gap is bounded by a constant if we evaluate the player's utility from any single player's view.

In the previous work, there is usually no constraint on the budget so one can bid as much as one can as long as the marginal profit gain is positive. Such assumption about infinite supply of money is not realistic in practice. It is often the case that the player receives a limited endowment. The fixed budget can also be a result of multi-stage decision process in which the fund is reserved to cope the future need. The budget constraint has been considered in [10] with only empirical results.

The budget constraint, however, adds difficulty to analyzing those games. One typical technique used in analyzing Nash equilibria is to relate the equilibrium condition to the optimality condition of some potential function [16, 12, 11] or some convex program [17, 5]. Intuitively, such connection is established by that at a Nash equilibrium, the marginal profit for each player on each resource is equally 0 and is therefore equivalent to the first order condition at the solution of some optimization problem. However, this is no longer true with budget constraint as the Lagrangian multiplier condition only stipulates that each player has equal margin on the resources he bids on but those margins may vary from player to player. Actually, there may exist multiple Nash equilibria when adding budget constraints, which is different from its counterpart without budget constraint.

2 Definitions

Price Anticipating Allocation Scheme. Suppose that there are m players (or users) and n resources (or machines) where each resource is continuously divisible. An *allocation scheme* $\omega = (\mathbf{r}_1, \dots, \mathbf{r}_m)$, where $\mathbf{r}_i = (r_{i1}, \dots, r_{in})$ with r_{ij} representing player i 's share of resource j , satisfies that for any $1 \leq i \leq m$ and $1 \leq j \leq n$, $r_{ij} \geq 0$ and $\sum_{i=1}^m r_{ij} \leq 1$. Let Ω denote the set of all the allocation schemes.

Each player i has a finite budget $X_i > 0$. Let $X = \sum_i X_i$ be the total budget. In the *price anticipating allocation mechanism*, the resources are allocated as follows: a player submits a bid to each resource under the constraint that the total bids sum to the player's budget. Let x_{ij} denote the bid of player i on resource j , where $x_{ij} \geq 0$ and $\sum_{j=1}^n x_{ij} = X_i$. The bidding vector of player i is $\mathbf{x}_i = (x_{i1}, \dots, x_{in})$. Let $Y_j = \sum_{i=1}^m x_{ij}$ be the total bids on resource j . Then, the fraction of player i gets from resource j is $r_{ij} = \frac{x_{ij}}{Y_j}$ if $Y_j > 0$ and 0 otherwise.

Utility function. The player's utility $U_i(r_{i1}, \dots, r_{in}) : [0, 1]^n \rightarrow R$ is a function of the fraction of each resource assigned to the player. We assume common properties about the utility functions: for each i , U_i is non-negative, differentiable, non-decreasing, and concave. One special family is *linear utility function*: $U_i(r_{i1}, \dots, r_{in}) = w_{i1}r_{i1} + \dots + w_{in}r_{in}$ for $w_{ij} \geq 0$. For linear utility functions, we also call w_{ij} the *weight* of resource j to the player i . We sometimes abuse the notation and let $U_i(\mathbf{x}_1, \dots, \mathbf{x}_m)$ denote the utility of player i under the bidding vectors \mathbf{x}_i for player i . Note that while $U_i(\mathbf{r})$ is differentiable and concave, $U_i(\mathbf{x})$ may not — in fact, it is not even continuous at the points where $x_{ij} = 0$ for some j and for all $1 \leq i \leq m$.

Let U_{ij} denote the partial derivative of U_i with respect to the j -th variable¹. We say a resource j is *non-satiated* to player i if for any \mathbf{r} , $U_{ij}(\mathbf{r}) > 0$. Denote by Γ_j the set of players to whom the resource j is non-satiated. For example, for linear utility function, $\Gamma_j = \{i \mid w_{ij} > 0\}$. A game is called *strongly competitive* if for any j , $|\Gamma_j| > 1$. For linear utility functions, a game is strongly competitive if for any j , there exist $i \neq k$ such that $w_{ij}, w_{kj} > 0$.

Nash equilibrium. The bidding vectors $\mathbf{x}_1, \dots, \mathbf{x}_m$ is a *Nash equilibrium* if for any $1 \leq i \leq m$ and for any legitimate bidding vector \mathbf{x}'_i , $U_i(\mathbf{x}_1, \dots, \mathbf{x}_i, \dots, \mathbf{x}_m) \geq U_i(\mathbf{x}_1, \dots, \mathbf{x}'_i, \dots, \mathbf{x}_m)$. At a Nash equilibrium, each player's bidding vector is the best response to the other's biddings. It represents a stable state at which no player has incentive to change his strategy. Denote by Ω_0 the set of all the allocation schemes at the Nash equilibria.

For an allocation scheme $\omega \in \Omega$, denote by $U(\omega) = \sum_i U_i(\mathbf{r}_i)$ the social welfare under ω . Let $U^* = \max_{\omega \in \Omega} U(\omega)$ denote the maximal social welfare. The efficiency at ω is defined as $\pi(\omega) = \frac{U(\omega)}{U^*}$. When $\Omega_0 \neq \emptyset$, the *efficiency* of a game Q is defined to be $\pi(Q) = \min_{\omega \in \Omega_0} \pi(\omega)$. While the definition of

¹ At the boundary, the derivative is understood as from one side.

efficiency is standard, there are multiple ways to define fairness. We extend the concept of envy-freeness [18] and measure the fairness of an allocation scheme ω by $\rho(\omega) = \min_{i \neq j} \frac{U_i(\mathbf{r})}{U_j(\mathbf{r})}$. When $\rho(\omega) \geq 1$, the scheme is known as an envy-free allocation scheme. We call a game *c-approximately envy-free* if for any $\omega \in \Omega_0$, $\rho(\omega) \geq c$. This shall be contrasted to the definition of utility gap $\min_{i \neq j} \frac{U_i(\mathbf{r})}{U_j(\mathbf{r})}$.

3 The Existence of Nash Equilibrium

The differentiability and concavity alone are not sufficient to guarantee the existence of the Nash equilibrium. This can be shown by a simple example of two players and two resources. For example, let $U_1(r_1, r_2) = r_1$ and $U_2(r_1, r_2) = r_1 + r_2$. Then player 1 should never bid on resource 2 because it has no value to him. Now, player 2 has to put a positive bid on resource 2 in order to claim the resource, but there is no lower limit, resulting the non-existence of the Nash equilibrium.² Clearly, this happens whenever there is a resource that is “wanted” by exactly one player, or when the game is not strongly competitive. As we shall show, this is the only case when the Nash equilibrium may not exist.

We use Rosen’s theorem, a generalization of Nash’s theorem, for proving the existence of Nash equilibrium. According to [15], a *concave game* is a game in which each player’s strategy domain is a compact convex set, and each user’s utility function is a concave function for any fixed choice of the other player’s strategies. In [15], it is shown that

Theorem 1 (Rosen [15]). *An equilibrium exists for any concave game.*

Our game is almost a concave game except at the domain boundary where there is some j , $x_{ij} = 0$ for all $1 \leq i \leq m$. As noted before, the utility function is discontinuous at those points. This discontinuity causes the problem in the above example and prevents us from applying Rosen’s theorem. To overcome this difficulty, by a similar technique used in [5], we perturb the game to fix the discontinuity and then argue that the limiting point is a Nash equilibrium of the original game, with the help of the additional assumption that the game is strongly competitive.

Now consider a perturbed game Q^ε in which each player’s payoff function is $U_i^\varepsilon(\mathbf{x}) = U_i\left(\frac{x_1}{\varepsilon+Y_1}, \dots, \frac{x_n}{\varepsilon+Y}\right)$. It is easily verified that U_i^ε is differentiable, concave, and non-decreasing in x_{ij} ’s, for $1 \leq j \leq n$. The domain of player i ’s strategy is the set $\Omega_i = \{(x_{i1}, \dots, x_{in}) \mid \sum_{j=1}^n x_{ij} = X_i, x_{ij} \geq 0\}$, which is clearly a compact convex set. Therefore, by Rosen’s theorem, there exists a Nash equilibrium of game Q^ε . Let $\omega^\varepsilon = (x_{ij}^\varepsilon)$ be any equilibrium of Q^ε . Now let $\varepsilon \rightarrow 0$. Since the strategy space is compact, there exist an infinite sequence that converge to a limiting point. Suppose the limiting point is ω , i.e. there is a sequence $\varepsilon_k \rightarrow 0$ and $\omega^\varepsilon \rightarrow \omega$. Clearly, ω is a legitimate strategy. We shall show that ω is a Nash equilibrium of the original game $Q = Q^0$.

² In fact, there does not even exist mixed strategy Nash equilibrium in this case.

Let us consider only those ε 's in the converging sequence. In what follows, a constant means a number that is solely determined by the system parameters, m, n, U_i 's, and is independent of ε . Let $Y_j^\varepsilon = \sum_{i=1}^m x_{ij}^\varepsilon$, and $z_{ij}^\varepsilon = Y_j^\varepsilon - x_{ij}^\varepsilon$. Then, $\frac{\partial U}{\partial x}(\omega^\varepsilon) = U_{ij} \left(\frac{x}{\varepsilon+Y} \right) \frac{\varepsilon+z}{(\varepsilon+Y)^2}$.

By definition, the bidding vectors $\mathbf{x}_1, \dots, \mathbf{x}_m$ is a Nash equilibrium if and only if each player's strategy is the best response to the group's bids. Since U_i is differentiable and concave, and Ω_i is convex, the optimality condition is that there exists $\lambda_i^\varepsilon > 0$ such that

$$\frac{\partial U_i^\varepsilon}{\partial x_{ij}^\varepsilon} \begin{cases} = \lambda_i^\varepsilon & \text{if } x_{ij}^\varepsilon > 0, \text{ and} \\ < \lambda_i^\varepsilon & \text{if } x_{ij}^\varepsilon = 0. \end{cases} \tag{1}$$

It is easy to see, from our condition on U_i and by the compactness of the domain, that

Lemma 1. *Let $\mathbf{r} = (r_1, \dots, r_n)$. For any $\varepsilon > 0$, there exists a constant $C > 0$, such that $U_{ij}(\mathbf{r}) < C$ for any $r_j \geq \varepsilon$; and for any $1 \leq i \leq m$, there exists a constant $D_i > 0$ such that for $i \in \Gamma_j$, $U_{ij}(\mathbf{r}) > D_i$.*

For an n -tuple (r_1, r_2, \dots, r_n) , let $(\mathbf{r}_{-j}; s)$ denote the n -tuple where r_j is replaced by s . In addition, let $\mathbf{0}$ and $\mathbf{1}$ denote the n -tuple with all 0's and all 1's, respectively. For $\varepsilon > 0$ and $\delta < 1$, set $C_\varepsilon = \max(\max_{i,j} U_{ij}(\mathbf{0}_{-j}; \varepsilon), 1)$ and $D = \min_i D_i$. Clearly, $C_{\varepsilon_1} \geq C_{\varepsilon_2}$ for $\varepsilon_1 < \varepsilon_2$.

We first upper bound the marginal profit of ω^ε .

Lemma 2. *There exists a constant $M_1 > 0$ such that for sufficiently small ε , $\lambda_i^\varepsilon < M_1$ for any $1 \leq i \leq m$.*

Proof. At the equilibrium, the player i has to bid at least $\frac{X}{n}$ on some resource, say k . By optimality condition (1), $\lambda_i^\varepsilon = U_{ik}^\varepsilon(r_{i1}, \dots, r_{in}) \frac{\varepsilon+z}{(\varepsilon+Y)^2}$.

For any given x_{ik}^ε , $\frac{\varepsilon+z}{(\varepsilon+Y)^2} = \frac{\varepsilon+z}{(\varepsilon+z+x)^2}$ achieves maximum when $\varepsilon + z_{ik}^\varepsilon = x_{ik}^\varepsilon$. Thus, when $\varepsilon < X$,

$$\begin{aligned} \lambda_i^\varepsilon &\leq U_{ik}^\varepsilon(r_{i1}, \dots, r_{in}) \frac{1}{4x_{ik}^\varepsilon} \leq U_{ik}^\varepsilon(\mathbf{r}_{-k}; \frac{X_i}{n(\varepsilon+X)}) \frac{n}{4X_i} \\ &\leq U_{ik}^\varepsilon(\mathbf{r}_{-k}; \frac{X_i}{2nX}) \frac{n}{4X_i} \leq C_d / 2n \frac{n}{4X_i}. \end{aligned}$$

Let $d_{min} = \min_i \frac{X}{X} > 0$. Set $M_1 = C_d / 2n \frac{n}{4d} \frac{n}{X}$. By Lemma 1, we have that $\lambda_i^\varepsilon \leq M_1$. □

We then lower bound the total bids on each resource.

Lemma 3. *For a strongly competitive game, there exists a constant $c_0 > 0$ such that for sufficiently small ε and for any j , $Y_j^\varepsilon \geq c_0$.*

Proof. We first consider the case when there is some player $k \in \Gamma_j$ not bidding on resource j , i.e. $x_{kj}^\varepsilon = 0$. Then, $\lambda_k = U_{kj}(\mathbf{r}_k) \frac{\varepsilon+Y-x}{(\varepsilon+Y)^2} = \frac{U(\mathbf{r})}{\varepsilon+Y}$.

Since $\lambda_k \leq M_1$, we have that $Y_j^\varepsilon > \frac{U(\mathbf{r})}{M_1} - \varepsilon > \frac{D}{M_1} - \varepsilon$. Thus, if we set $c_0 = \frac{D}{4M_1}$, when $\varepsilon < c_0$, we have that $Y_j^\varepsilon > c_0$.

For the other case, we assume that for all $k \in \Gamma_j$, $x_{kj}^\varepsilon > 0$. Then,

$$\lambda_k = U_{kj}(\mathbf{r}_k) \frac{\varepsilon + Y_j^\varepsilon - x_{kj}^\varepsilon}{(\varepsilon + Y_j^\varepsilon)^2} \geq D \frac{\varepsilon + Y_j^\varepsilon - x_{kj}^\varepsilon}{(\varepsilon + Y_j^\varepsilon)^2}.$$

Let $\ell = |\Gamma_j|$. Then $\ell \geq 2$ by the assumption that the game is strongly competitive. Thus

$$\begin{aligned} \sum_{k \in \Gamma} \lambda_k &\geq D \sum_{k \in \Gamma} \frac{\varepsilon + Y_j^\varepsilon - x_{kj}^\varepsilon}{(\varepsilon + Y_j^\varepsilon)^2} = D \frac{\ell\varepsilon + \ell Y_j^\varepsilon - \sum_{k \in \Gamma} x_{kj}^\varepsilon}{(\varepsilon + Y_j^\varepsilon)^2} \\ &\geq D \frac{\ell\varepsilon + (\ell - 1)Y_j^\varepsilon}{(\varepsilon + Y_j^\varepsilon)^2} \geq D(\ell - 1) \frac{1}{\varepsilon + Y_j^\varepsilon}. \end{aligned}$$

By that $\lambda_k < M_1$, we have that $D(\ell - 1) \frac{1}{\varepsilon + Y_j^\varepsilon} < \ell M_1$. Thus $Y_j^\varepsilon > D(\ell - 1)/(\ell M_1) - \varepsilon \geq D/(2M_1) - \varepsilon$. Again, $Y_j^\varepsilon > c_0$ if $\varepsilon < c_0$. □

We are now ready for the main lemma.

Lemma 4. *If the game is strongly competitive, then for any $\delta > 0$, when ε is sufficiently small,*

$$\left| \frac{\partial U_i(x)}{\partial x_{ij}}(\omega) - \frac{\partial U_i^\varepsilon(x)}{\partial x_{ij}}(\omega^\varepsilon) \right| \leq \delta.$$

Proof. Clearly, $\frac{\partial U(x)}{\partial x}(\omega) = U_i(r_{ij}) \frac{z}{Y^2}$ and $\frac{\partial U(x)}{\partial x}(\omega^\varepsilon) = U_i(r_{ij}^\varepsilon) \frac{z}{(\varepsilon + Y) ^2}$.

The lemma follows immediately by $z_{ij}^\varepsilon \rightarrow z_{ij}$ and $Y_j^\varepsilon \rightarrow Y_j$, and that $Y_j^\varepsilon \geq c_0$, for some constant $c_0 > 0$. □

Thus, we have the following theorem.

Theorem 2. *ω is a Nash equilibrium if Q is strongly competitive.*

Proof. (By contradiction) Suppose it were not true, then the optimality condition (1) is violated for some player i . There are two possibilities.

1. There are j, k , where $j \neq k$, such that $x_{ij}, x_{ik} > 0$ and $\frac{\partial U}{\partial x} \neq \frac{\partial U}{\partial x}$. By Lemma 4, we know that for sufficiently small ε , the following holds: $x_{ij}^\varepsilon > 0, x_{ik}^\varepsilon > 0$, and $\frac{\partial U}{\partial x}(\omega^\varepsilon) \neq \frac{\partial U}{\partial x}(\omega^\varepsilon)$. This contradicts with that ω^ε is a Nash equilibrium of Q^ε . Now, we assume that $\lambda_i = \frac{\partial U}{\partial x}(\omega)$ for any $x_{ij} > 0$.
2. There is j where $x_{ij} = 0$ and $\frac{\partial U}{\partial x}(\omega) > \lambda_i$. By the same reasoning, we again derive contradiction.

Hence, ω is a Nash equilibrium of Q . □

We remark that there may exist multiple Nash equilibria. For example, consider the case with two players and two resources where $X_1 = X_2 = 1$, and $U_1 = \alpha r_1 + (1 - \alpha)r_2, U_2 = (1 - \alpha)r_1 + \alpha r_2$ for $0 < \alpha < 1$. As shown in [3], there exist three Nash equilibria whenever $\alpha > (2\sqrt{2} + 2)/4 \approx 0.854$.

4 Efficiency

In this section, we study the efficiency of Nash equilibria. If we allow arbitrary utility function and budget, the efficiency at Nash equilibria can be unboundedly low, for example, when there are players with high budget but very low utility. Therefore, we assume that the players' utilities are related with their budgets by requiring that $U_i(\mathbf{0}) = 0$ and $X_i/U_i(\mathbf{1}) = \delta$ for some constant δ and for $1 \leq i \leq n$. In other words, we assume that each player's utility is proportional to their budget if they can own the whole system. We refer to such game a *balanced* game. We first show asymptotic bounds for the general case and then present tight bounds for two special cases.

For large number of players, the efficiency can be unfortunately low, in the order of $\frac{1}{\sqrt{m}}$ for m players, as shown in the following theorem. Let $v_i = U_i(\mathbf{1})$ and $v = \sum_i v_i$.

Theorem 3. *For an m -player balanced game Q , $\pi(Q) \geq \max(\frac{v}{mU^*}, \frac{U^*}{2v}) \geq \frac{1}{\sqrt{2m}}$, and the bound is asymptotically tight as there exists an equilibrium w such that $\pi(w) = O(\frac{1}{\sqrt{m}})$.*

Proof. We first construct an upper bound. Consider a system with $m = n^2 + n$ players and n resources. In addition, each player has a linear utility function. Of m players, there are n^2 who have the same weights on all the resources, i.e. $1/n$ on each resource (recall the definition of weight in Section 2). The other n players have weight 1 on each different resource and 0 on all the other resources. Clearly $U^* = n$. It is easy to verify the following allocation is an equilibrium: the first n^2 players evenly distribute their bids among all the resources, the other n player put all the bid on their respective favorite resource. At this equilibrium, the total bids on each resource is $n+1$. Each of the first n^2 players receives $\frac{1}{n} \frac{1/n}{n+1} = \frac{1}{n^2(n+1)}$ on each resource, summing up to a total utility of $n^3 \cdot \frac{1}{n^2(n+1)} < 1$. The other n players each receives $\frac{1}{n+1}$ on their favorite resource, summing up to a total utility of $n \cdot \frac{1}{n+1} < 1$. Therefore, the total utility of the equilibrium is < 2 , while the social optimum is $n = \Theta(\sqrt{m})$.

Now we show the lower bound. Let $X = \sum_i X_i = \delta v$. First, we show that each player i gets at least $\frac{X}{m} v_i$. For any existing allocations, a player can distribute his bid proportional to the amount of total bids already allocated to the resources. Let y_j denote the total bids of the players other than i on resource j . We can then assign $x_{ij} = \frac{y_j X}{Y}$, where $Y = \sum_j y_j = X - X_i$. Under such scheme, player i 's share of resource j is $r_{ij} = \frac{x_{ij}}{x_{ij} + y_j} = X_i / (X_i + Y) = X_i / X$. Thus the utility of the player i is at least $U_i(X_i/X, X_i/X, \dots, X_i/X) \geq U_i(\mathbf{1}) X_i / X = X_i v_i / X$ by concavity of U_i . Therefore, $U \geq \sum_i X_i v_i / X = \sum_i v_i^2 / v \geq v / m$ by Cauchy-Schwarz inequality. Thus, $U/U^* \geq v / (mU^*)$.

Now we show that $U \geq (U^*)^2 / (2v)$. Let r_{ij}^* denote player i 's share of resource j at the social optimum, and $U^* = \sum_i U_i(r_{i1}^*, \dots, r_{in}^*)$. Let $Y_j = \sum_i x_{ij}$, the total bids on resource j at the Nash equilibrium. Let $B_i = \sum_j r_{ij}^* Y_j$ and $z_{ij} =$

$r_{ij}^* Y_j X_i / B_i$. Clearly, $\sum_j z_{ij} = X_i$. Consider the bidding where player i submits bid z_{ij} to resource j . Then $r_{ij} = \frac{z}{Y-x+z} \geq \frac{z}{Y+z} = \frac{r^* X}{B+X r^*} \geq \frac{r^* X}{X+B}$.

Since at the equilibrium, player i 's strategy is the best response to the group. We have that $U_i(\mathbf{x}) \geq U_i(\mathbf{z}) \geq U_i(r_{ij}^* X_i / (X_i + B_i)) \geq \frac{X}{X+B} U_i(r_{ij}^*)$. Therefore, $U = \sum_{i=1}^m U_i \geq \sum_{i=1}^m U_i(r_{ij}^*) \frac{X}{X+B}$. Further, $\sum_i B_i = \sum_i \sum_j r_{ij}^* Y_j = \sum_j Y_j \sum_i r_{ij}^* = \sum_j Y_j = X$.

Let $W_i = U_i(r_{ij}^*)$. We now minimize $\sum_{i=1}^m \frac{W_i X}{X+B}$ under the constraints that $\sum_{i=1}^m B_i = X$, and $B_i \geq 0$. Let $\zeta = \min_i \frac{\sqrt{X W_i}}{\sqrt{X} W_i} X$. We relax the above constraints to that $\sum_{i=1}^m B_i = X$, and $B_i \geq -X_i + \zeta$.

The domain remains a convex set and the minimization function is a convex function on the domain. By Lagrangian multiplier method, the minimum is achieved when setting $B_i = \frac{2X\sqrt{X}W_i}{\sum_{i=1}^m \sqrt{X}W_i} - X_i > -X_i + \zeta$. Thus

$$U \geq \sum_{i=1}^m \frac{\sqrt{X_i W_i} \sum_{j=1}^m \sqrt{X_j W_j}}{2X} = \frac{(\sum_{i=1}^m \sqrt{X_i W_i})^2}{2X}.$$

Since $X_i = \delta v_i \geq \delta W_i$, we have that $U \geq \frac{\delta(\sum_{i=1}^m W_i)^2}{2X} = \frac{(U^*)^2}{2v}$. Hence, $U/U^* \geq \frac{U^*}{2v}$. Combining with $U/U^* \geq v/(mU^*)$, we have that $U/U^* \geq 1/\sqrt{2m}$ as $\max(v/(mU^*), U^*/2v)$ is minimized when $U^* = v\sqrt{2/m}$. \square

In the following, we show tight bounds for two special cases.

One resource. In this case, the Nash equilibrium is the trivial one: everyone bids all of his budget on the resource, and player i receives the fraction of $X_i/X = v_i/v$. Recall that $v_i = U_i(1)$, $v = \sum_i v_i$, and $X_i/v_i = \delta$. At the equilibrium, $U = \sum_i U_i(v_i/v)$. On the other hand, $U^* = \max_r \sum_i U_i(r_i)$, where $r_i \geq 0$ and $\sum_i r_i = 1$. Surprisingly, the efficiency is at least $3/4$ under such a ‘‘dumb’’ allocation scheme.

Theorem 4. *Let $U_1, \dots, U_m : [0, 1] \rightarrow \mathbb{R}$ be non-negative, non-decreasing concave functions with $U_i(1) = v_i$. Let $v = \sum_i v_i$. Then for any $r_i \geq 0$ that satisfy $\sum_i r_i = 1$, $\sum_{i=1}^m U_i(v_i/v) \geq 3/4 \cdot \sum_{i=1}^m U_i(r_i)$.*

Proof. Write $a_i = U_i(r_i)$. Let f_i be the piecewise linear function with $f_i(0) = 0$, $f_i(r_i) = a_i$, and $f_i(1) = 1$. Clearly, $f_i(r_i) = U_i(r_i)$. Further $U_i(x) \geq f_i(x)$ for $x \in [0, 1]$ by concavity. Write $s_i = v_i/v$. Thus, it suffices to show that $\sum_{i=1}^m f_i(s_i) \geq 3/4 \cdot \sum_{i=1}^m a_i$.

If $r_i \leq s_i$, then $f_i(s_i) = a_i + \frac{v-a_i}{1-r_i}(s_i-r_i)$, and when $r_i > s_i$, $f_i(s_i) = \frac{s_i a_i}{r_i}$.

Let $r_i \leq s_i$ for $1 \leq i \leq k$ and $r_i > s_i$ for $k < i \leq m$. Then,

$$\begin{aligned} \sum_i f_i(s_i) &= \sum_{i=1}^k \left(a_i + \frac{v_i - a_i}{1 - r_i} (s_i - r_i) \right) + \sum_{i=k+1}^m \frac{a_i s_i}{r_i} \\ &= \sum_{i=1}^m a_i + \sum_{i=1}^k \frac{v_i - a_i}{1 - r_i} (s_i - r_i) + \sum_{i=k+1}^m \left(\frac{a_i s_i}{r_i} - a_i \right). \end{aligned}$$

Let $\Delta = (\sum_{i=1}^k \frac{v-a}{1-r}(s_i - r_i) + \sum_{i=k+1}^m (\frac{a}{r} - a_i))/\sum_i a_i$. We observe that Δ is minimized when $a_i = v_i$ for all $1 \leq i \leq m$: it is when the denominator is maximized, and every individual term in the numerator is minimized. Thus, Δ is at least

$$\sum_{i=k+1}^m (v_i s_i / r_i - v_i) / v = \sum_{i=k+1}^m (v_i^2 / (v r_i) - v_i) / v. \tag{2}$$

Write $w = \sum_{i=k+1}^m v_i$. (2) is minimized when $r_i = \frac{v}{w}$, and the minimum value is $\frac{w^2/v-w}{v} \geq -1/4$. Thus, $\sum_i f_i(s_i) / \sum_i a_i = 1 + \Delta \geq 3/4$. \square

The bound of 3/4 is tight even when $m = 2$ by setting $U_1(x) = 1$ and $U_2(x) = x$. As a special case, when $v_i = 1$ for all i , we have that for any m non-negative, non-decreasing concave functions $f_i(x)$ with $f_i(1) = 1$, $\sum_i f_i(1/m) \geq 3/4 \sum_i f_i(r_i)$, for any $r_i \geq 0$ and $\sum_i r_i = 1$,

Two player, linear utility function. In this case, we can obtain again the same efficiency of 3/4, but curiously with completely different proof.³ The proof is by reducing the problem further to when there are only two resources. The details will appear in the full version of the paper.

Theorem 5. *For any two player, two resource game with linear utility functions, $\pi(Q) \geq 3/4$, and the bound is tight in the worst case.*

5 Fairness

It is important for a resource allocation scheme to be “fair”. There are many standards to evaluate fairness [18, 1]. In one definition, one may consider whether any player gets a more than average share. According to Theorem 3, each player i ’s utility is at least $U_i(\mathbf{1})/m$, or in other words, each player gets at least $1/m$ -th of the maximum utility he can possibly get from the system. Thus, in this sense the scheme is fair.

Another possibility is to compare the utility between two players. We can easily construct an example so that one player has utility $1/m$ while some player has 1. Or $U_i(\mathbf{x}_i) \leq U_j(\mathbf{x}_j)/m$. In this standard, the scheme is highly unfair as it creates large utility gap.

Here, we consider fairness by extending the notion of envy-freeness [18], a concept central in the economical study of fair division. Different from the utility gap measure, envy-freeness, as defined in Section 2, measures how much each player likes (or envies) other’s share compared to his own. For a meaningful discussion, we assume that all the players have the same budget, or $X_i = 1$ for

³ The constant 3/4 also appears in [17] in analyzing the efficiency of selfish routing and in [5] when there is no budget constraint. The bound is tight in all the four cases, but all those proofs do not have apparent connection. We do not know if it is just a coincidence or there is a deeper connection.

all the i 's. Unlike the efficiency analysis, we do not require $U_i(\mathbf{1})$ proportional to the player's budget. In general, an equilibrium allocation is not envy-free. But it is not very far from being envy free according to the following theorem.

Theorem 6. *When $X_i = 1$ for all the i 's, any Nash equilibrium is at least c -approximately envy-free for $c = 2\sqrt{2} - 2 \approx 0.828$. The bound is tight in the worst case.*

Proof. Suppose that at the Nash equilibrium ω , x_1, \dots, x_n are the allocation of bids of a player A , and y_1, \dots, y_n are the total bids by the other players. Let $r_i = x_i/(x_i + y_i)$. We need to show that for all z_1, \dots, z_n with $0 \leq z_i \leq y_i$ and $\sum_i z_i = 1$, we have that $U_i(\mathbf{r}) \geq c \cdot U_i\left(\frac{z_1}{x_1+y_1}, \dots, \frac{z_n}{x_n+y_n}\right)$.

First, we show that we can assume A has a linear utility function. Otherwise, we consider the linear utility function $\bar{U}(s_1, \dots, s_n) = \sum_i U'_i(r_1, \dots, r_n) s_i$. Because $\frac{\partial \bar{U}}{\partial x}(\mathbf{r}) = U'_i(\mathbf{r}) \frac{y}{(x+y)^2} = \frac{\partial U}{\partial x}(\mathbf{r})$, the bids x_1, \dots, x_n is still A 's best response to the group bids y_1, \dots, y_n under the utility function \bar{U} . In addition, the change of A 's utility function does not affect the other players. Hence, ω remains a Nash equilibrium of the changed utility function. In addition, by concavity of U , we have that

$$U(\mathbf{s}) \leq U(\mathbf{r}) + \sum_i U'_i(r_1, \dots, r_n)(s_i - r_i) = U(\mathbf{r}) + \bar{U}(\mathbf{s}) - \bar{U}(\mathbf{r}). \tag{3}$$

Thus, if $\bar{U}(\mathbf{r}) \geq c \cdot \bar{U}(\mathbf{s})$, then

$$\begin{aligned} U(\mathbf{r}) &= \bar{U}(\mathbf{r}) + (U(\mathbf{r}) - \bar{U}(\mathbf{r})) \geq c \cdot \bar{U}(\mathbf{s}) + (U(\mathbf{r}) - \bar{U}(\mathbf{r})) \\ &\geq c(U(\mathbf{s}) - U(\mathbf{r}) + \bar{U}(\mathbf{r})) + (U(\mathbf{r}) - \bar{U}(\mathbf{r})) \\ &= c \cdot U(\mathbf{s}) + (1 - c)(U(\mathbf{r}) - \bar{U}(\mathbf{r})) \geq c \cdot U(\mathbf{s}). \end{aligned}$$

Therefore, without loss of generality, we assume that A has linear utility function $U(\mathbf{s}) = w_1 s_1 + \dots + w_n s_n$, and $U_A = U(\mathbf{r})$. Let λ_i be the margin on the resources i for A . By optimality condition, for any i, j , $\lambda_i \geq \lambda_j$ if $x_i > 0$ and the equality holds when $x_j > 0$. The price p_i of the resources $\frac{w}{x+y}$ on each resource. We first note that

$$\frac{\lambda_i}{p_i} = \frac{w_i y_i / (x_i + y_i)^2}{w_i / (x_i + y_i)} = \frac{y_i}{x_i + y_i} \leq 1. \tag{4}$$

Now suppose that $\mathbf{z} = (z_1, \dots, z_n)$ maximizes $V = \sum_i p_i z_i$ subject to that $0 \leq z_i \leq y_i$, and $\sum_i z_i = 1$. We now show that $U_A \geq (2\sqrt{2} - 2)V$. Intuitively, the proof is done by comparing the utility of A on each resource under two allocations. When $x_i > z_i$, we collect the "residual" utility to compensate those i 's where $x_i < z_i$. Formally, consider b_{ij} for $1 \leq i, j \leq n$ that satisfy

$$b_{ii} = \min(x_i, z_i), \quad \sum_j b_{ij} = x_i, \quad \sum_i b_{ij} = z_j, \quad b_{ij} \geq 0.$$

Since $\sum_i x_i = \sum_i z_i$, there always exist b_{ij} 's satisfying the above condition.

$$\begin{aligned}
 U_A &= \sum_i p_i x_i = \sum_i (p_i \sum_j b_{ij}) = \sum_i (p_i b_{ii} + \sum_{i \neq j} p_i b_{ij}) \\
 &\geq \sum_i (p_i b_{ii} + \sum_{i \neq j} \lambda_i b_{ij}), \text{ by (4).} \\
 &\geq \sum_i (p_i b_{ii} + \sum_{i \neq j} \lambda_j b_{ij}), \text{ since } b_{ij} > 0 \text{ implies } x_i > 0. \\
 &= \sum_j (\sum_{i \neq j} \lambda_j b_{ij} + p_j b_{jj}) = \sum_j (\lambda_j \sum_{i \neq j} b_{ij} + p_j b_{jj}).
 \end{aligned}$$

Let $u_j = \lambda_j \sum_{i \neq j} b_{ij} + p_j b_{jj}$, and $v_j = p_j z_j$. We distinguish two cases.

- When $z_j \leq x_j$, then $b_{jj} = z_j$ and for all $i \neq j$, $b_{ij} = 0$. Thus, $u_j = p_j z_j = v_j$.
- When $z_j > x_j$, then $b_{jj} = z_j$ and $\sum_{i \neq j} b_{ij} = z_j - x_j$. Thus $u_j = p_j x_j + \lambda_j (z_j - x_j)$. Therefore, $c_j = u_j / (p_j z_j) \geq (x_j + (z_j - x_j) \frac{y}{x+y}) / z_j = \frac{x^2}{z(x+y)} + \frac{y}{x+y}$. Clearly, c_j is minimized when z_j is maximized, i.e. $z_j = y_j$, and the minimum value is: $\frac{x^2}{y(x+y)} + \frac{y}{x+y} = \frac{x^2 + y^2}{y(x+y)}$. Now, fix y_j , c_j is minimized when $x_j = (\sqrt{2} - 1)y_j$ and the minimum value is $2\sqrt{2} - 2$.

In both cases, $u_j \geq (2\sqrt{2} - 2)v_j$. Thus, $\sum_i u_i \geq (2\sqrt{2} - 2) \sum_i p_i z_i$. Hence, the scheme is c -approximately envy-free for $c = 2\sqrt{2} - 2 \approx 0.828$.

For the upper bound, consider the case with $s + 2$ players and 2 resources. Let $\alpha = 2/(s + 1)$. Suppose that the utility functions are $U_1 = \alpha r_1 + (1 - \alpha)r_2$, $U_2 = r_1$, and for $3 \leq i \leq s + 2$, $U_i = r_2$. Clearly, at the equilibrium, player 2 bids $(1, 0)$, and the player 3 to $s + 2$ bid $(0, 1)$. By equalizing the margin on the two resources, we derive that the bids of player 1 are $\frac{2\beta - \alpha}{\alpha(1 + \beta)}$ and $\frac{2\alpha + \alpha\beta - 2\beta}{\alpha(1 + \beta)}$, where $\beta = \frac{\alpha}{\sqrt{(1 - \alpha)(2 - \alpha)}}$. When $s \rightarrow +\infty$, i.e. $\alpha \rightarrow 0$, the bids of player 1 approaches $(\sqrt{2} - 1, 2 - \sqrt{2})$, and $U_1(\mathbf{x}_1)/U_1(\mathbf{x}_2) \rightarrow 2\sqrt{2} - 2$. \square

6 Conclusion

In this paper, we study the existence and performance of Nash equilibrium of a price anticipating resource allocation game. We consider general utility functions with the budget constraint. We show the existence of Nash equilibrium for strongly competitive game and the bounds for efficiency and fairness of such a game. It would be interesting to design efficient algorithms to achieve the equilibrium and to study the specific utility functions that arise from practice, e.g. those discussed in [3].

Abstract. We give the first analyses in multicommodity networks of both the worst-case severity of Braess's Paradox and the price of anarchy of selfish routing with respect to the maximum latency. Our first main result is a construction of an infinite family of two-commodity networks, related to the Fibonacci numbers, in which both of these quantities grow exponentially with the size of the network. This construction has wide implications, and demonstrates that numerous existing analyses of selfish routing in single-commodity networks have no analogues in multicommodity networks, even in those with only two commodities. This dichotomy between single- and two-commodity networks is arguably quite unexpected, given the negligible dependence on the number of commodities of previous work on selfish routing.

Our second main result is an exponential upper bound on the worst-possible severity of Braess's Paradox and on the price of anarchy for the maximum latency, which essentially matches the lower bound when the number of commodities is constant.

Finally, we use our family of two-commodity networks to exhibit a natural network design problem with intrinsically exponential (in)approximability: while there is a polynomial-time algorithm with an exponential approximation ratio, subexponential approximation is unachievable in polynomial time (assuming $P \neq NP$).

1 Introduction

Selfish Routing and the Price of Anarchy. A recent trend in theoretical computer science is to analyze the extent to which equilibria in a noncooperative game approximate a social optimum. The most popular measure is the *price of anarchy* [15] (also called the *coordination ratio* [13]), defined as the worst-case ratio between the objective function value of a Nash equilibrium of a game and that of an optimal solution. The price of anarchy is thus defined relative to a game and to an objective function.

In this paper, we will study one of the most popular models for price of anarchy analyses, the so-called *selfish routing* model. Selfish routing is a mathematical model of how noncooperative agents route traffic in a network with congestion. Formally, the game takes place in a directed multicommodity flow network, where each edge possesses a continuous, nondecreasing latency function that models how the performance of an edge degrades as it becomes increasingly congested. The traffic in the network is assumed to comprise a large number of independent network users, so that each individual has negligible impact on the experience of others. Under this assumption, equilibria—*flows at Nash equilibrium*—are naturally defined as the multicommodity flows in which all traffic travels only on minimum-latency paths.

As in most noncooperative games, flows at Nash equilibrium are inefficient, in the sense that they need not optimize natural objective functions. One such objective function, the average latency incurred by traffic, has been extensively studied. Beginning with Roughgarden and Tardos [21] and continuing with studies of ever-increasing generality [4, 6, 16, 18, 22], exact worst-case bounds on the price of anarchy with respect to the average latency have been established under a wide variety of different assumptions.

The Maximum Latency Objective. As in many combinatorial optimization problems, permitting an objective function to average the cost of different users can be problematic from a fairness perspective. Specifically, to attain or approximate a flow that minimizes the average latency, some users may need to be sacrificed to very costly paths, in order to reduce the congestion encountered by others. This unfairness inherent in the average latency measure motivates modifying the objective function to be more attuned to those users on the most costly paths. Arguably, the most obvious way to accomplish this is to aspire toward minimizing the *maximum* latency incurred by any user.

Compared to the average latency objective, considerably less is known about the price of anarchy relative to the maximum latency. The first paper on the topic is by Weitz [25], whose results we will review below. Most relevant for us is a paper by Roughgarden [19], where only the special case of single-commodity networks, networks in which all traffic shares the same source and destination, were considered. The main result of [19] states that, if latency functions are allowed to be arbitrary continuous, nondecreasing functions, then the (worst-case) price of anarchy with respect to the maximum latency objective in single-commodity networks with at most n vertices is precisely $n - 1$.

Roughgarden [19] also made two conjectures about this price of anarchy in multicommodity networks. The *weak conjecture* of [19] asserts that in multicommodity networks, this price of anarchy can be bounded by a function of the number of vertices, edges, and commodities in the network. As a point of contrast, simple examples show

that no such bound is possible for the price of anarchy relative to the average latency, unless additional structure is imposed on the network latency functions [21]. The *strong conjecture* of [19] states that the price of anarchy with respect to the maximum latency remains $n - 1$ in multicommodity networks. This conjecture was motivated in part by the provable equivalence of single-commodity and multicommodity networks for the price of anarchy relative to the average latency [6, 18].

Braess's Paradox. Braess's Paradox is the following counterintuitive fact: adding additional edges to a network with selfish routing can make all of the traffic worse off. First discovered in 1968 [3], Braess's Paradox has since motivated a vast number of follow-up papers; see [17] for a survey. Almost all existing work on the paradox confines attention to close variations on or analogues of Braess's original example in a four-node network. Only recently have larger, more severe versions of Braess's Paradox been discovered. Specifically, Roughgarden [17] defined an infinite family of networks, beginning with Braess's original example, that shows that adding edges to a single-commodity network with n vertices can increase the latency experienced by all of the traffic (and hence the maximum latency) by a factor of $\lfloor n/2 \rfloor$. It was also shown in [19] that no greater increase is possible in single-commodity networks, but the proof of this crucially used the combinatorial structure of flows at Nash equilibrium in such networks. Once again the story was left incomplete: are the networks of [17] the worst examples possible, or are more severe versions of Braess's Paradox lurking in the richer landscape of multicommodity networks?

Our Results. In this paper, we establish nearly matching upper and lower bounds on both the price of anarchy with respect to the maximum latency and on the worst-possible severity of Braess's Paradox in multicommodity networks. Our results resolve both of the conjectures in [19]—one in the affirmative, one in the negative—and also give the first demonstration that Braess's Paradox is provably more severe in multicommodity networks than in single-commodity ones. Specifically, our two main results are the following.

- We give a parameterized construction, based on the Fibonacci numbers, that shows that adding one edge to a two-commodity network with n vertices can increase the latency of all traffic by a $2^{\Omega(n)}$ factor.
- We prove that the price of anarchy with respect to the maximum latency in networks with k commodities, n vertices, and m edges is $2^{O(\min\{kn, m \log n\})}$.

The construction used to prove the first result has wide implications. In particular, for all existing approximation-type analyses of selfish routing that were only known to hold for single-commodity networks [14, 17, 19], this construction rules out any reasonable extension to multicommodity networks, even those with only two commodities. For example, removing one edge from a single-commodity network can only decrease the maximum (or average) latency of a Nash flow by a factor of 2 [14], while our construction shows that a single edge removal can cause an exponential improvement in the average and the maximum latency (even with only two commodities). This dichotomy between single- and two-commodity networks is somewhat unexpected, given

the negligible role that the number of commodities has played in previous work in this area [6, 18, 21].

The first result easily implies a lower bound of $2^{\Omega(n)}$ on the price of anarchy for the maximum latency in multicommodity networks, as an optimal flow has the option of ignoring edges that are causing Braess's Paradox. By the same reasoning, the second result implies that adding any number of edges to a network with k commodities, n vertices, and m edges can only increase the maximum latency by a $2^{O(\min\{kn, m \log n\})}$ factor. Our upper and lower bounds on both the price of anarchy and on the worst-possible severity of Braess's Paradox are thus essentially tight for networks with a constant number of commodities.

Finally, we consider the following network design problem, motivated by the goal of detecting and avoiding Braess's Paradox: given a network, find the subnetwork with the smallest maximum latency. Using our family of two-commodity networks and ideas from the gap reductions of [17] that apply to the single-commodity version of the problem, we prove that there is no polynomial-time algorithm for this network design problem with subexponential approximation ratio (assuming $P \neq NP$). Since our upper bound on the price of anarchy trivially implies that an exponential performance guarantee is achievable, this network design problem is a rare example of a natural optimization problem with intrinsically exponential approximability.

Further Related Work. There have been numerous price of anarchy analyses in the past few years. Study of the original load-balancing model of Koutsoupias and Papadimitriou [13] continues unabated; see [7, 10] for surveys. A survey of the selfish routing model studied here, including results on the price of anarchy, can be found in [20]. Other noncooperative games have also been studied recently from a price of anarchy perspective, including facility location games [8, 24], network design games [1, 9], and resource allocation games [12].

As noted above, Weitz [25] was the first to study the price of anarchy of selfish routing under the maximum latency objective. Weitz [25] noted that, for single-commodity networks and classes of restricted latency functions, the price of anarchy for the maximum latency is no more than that for the average latency objective. For example, a theorem of Roughgarden and Tardos [21] bounding the price of anarchy with respect to the average latency objective then implies that the price of anarchy for the maximum latency in single-commodity networks with linear latency functions is at most $4/3$, and a matching lower bound is furnished by the original form of Braess's Paradox [3, 25]. However, upper bounds on the price of anarchy with respect to the maximum latency objective do not imply upper bounds on the price of anarchy with respect to the average latency objective: for example, the price of anarchy for the maximum latency objective is at most $n - 1$ in single-commodity networks with arbitrary latency functions [19], while the price of anarchy for the average latency can be arbitrarily large even in two-node, two-link networks [21].

Weitz [25] also gave a family of networks that shows that this price of anarchy is $\Omega(n)$ for multicommodity networks with n vertices and linear latency functions. Concurrently with Roughgarden [19], Correa, Schulz, and Stier Moses [5] studied the maximum latency objective from several different perspectives. The results of [5] mostly concern the computational complexity of computing an optimal solution and the extent

to which multiple objective functions can be simultaneously optimized, and are disjoint from those in [19] and in the present work.

2 Preliminaries

The Model. We now describe our model of selfish routing, following Roughgarden and Tardos [21]. We will study a multicommodity flow network, described by a directed graph $G = (V, E)$ and k source-destination vertex pairs $(s_1, t_1), \dots, (s_k, t_k)$. We denote by r_i the amount of traffic that wishes to travel from the source s_i to the destination t_i —the *traffic rate*. The graph G can contain parallel edges, but we can exclude self-loops. We will denote the s_i - t_i paths of G by \mathcal{P}_i . We assume that \mathcal{P}_i is non-empty for all i , and define $\mathcal{P} = \cup_{i=1}^k \mathcal{P}_i$.

A *flow* is a nonnegative vector indexed by \mathcal{P} . By f_e we mean the amount $\sum_{P \in \mathcal{P}: e \in P} f_P$ of flow that traverses edge e . With respect to a network G and a vector r of traffic rates, a flow is *feasible* if $\sum_{P \in \mathcal{P}} f_P = r_i$ for all commodities i .

We assume that the network G suffers from congestion effects, and to model this we give edge e a nonnegative, continuous, nondecreasing *latency function* ℓ_e that describes the time needed to traverse the edge as a function of the edge congestion f_e . Given a flow f , the latency ℓ_P of a path P is the sum of the latencies of the edges in the path: $\ell_P(f) = \sum_{e \in P} \ell_e(f_e)$. We will call a triple of the form (G, r, ℓ) an *instance*.

Our objective function is the maximum latency incurred by a flow, defined formally by $M(f) = \max_{P \in \mathcal{P}: f > 0} \ell_P(f)$. With respect to an instance (G, r, ℓ) , a flow that minimizes $M(\cdot)$ over all feasible flows will be called *optimal*. Since the feasible flows of an instance form a compact subset of Euclidean space and $M(\cdot)$ is a continuous function, every instance admits an optimal flow.

Flows at Nash Equilibrium. We next define the flows that we expect to arise from selfish routing. Assuming that all network users have negligible size and want to minimize the latency experienced, we expect all users to travel on paths with minimum-possible latency. We formalize this in the next definition.

Definition 1. A flow f feasible for (G, r, ℓ) is at Nash equilibrium, or is a Nash flow, if for every $i \in \{1, 2, \dots, k\}$ and two paths $P_1, P_2 \in \mathcal{P}_i$ with $f_{P_1} > 0$,

$$\ell_{P_1}(f) \leq \ell_{P_2}(f).$$

Happily, Nash flows always exist, and all Nash flows of an instance have equal maximum latency.

Proposition 1. Let (G, r, ℓ) be an instance.

- (a) There is at least one Nash flow for (G, r, ℓ) .
- (b) If f, \tilde{f} are Nash flows for (G, r, ℓ) , then $M(f) = M(\tilde{f})$.

Proposition 1 is classical; for example, it follows from arguments of Beckmann, McGuire, and Winsten [2].

Definition 1 implies that in a Nash flow, all of the traffic of a given commodity experiences a common latency. We will sometimes use the notation $L_i(G, r, \ell)$ to denote the

common latency of the i th commodity's traffic in a Nash flow for (G, r, ℓ) ; analogously to Proposition 1(b), this is well defined (i.e., independent of the particular Nash flow).

We will also benefit from the following alternative definition of a Nash flow, which was first noted by Smith [23]. It is an easy consequence of Definition 1.

Proposition 2. *A flow f feasible for (G, r, ℓ) is at Nash equilibrium if and only if*

$$\sum_{e \in E} \ell_e(f_e) f_e \leq \sum_{e \in E} \ell_e(f_e) \tilde{f}_e \quad (1)$$

for every flow \tilde{f} that is feasible for (G, r, ℓ) .

The Price of Anarchy. We now formalize what we mean by the price of anarchy. As noted in the introduction, it is the ratio of the objective function values of a flow at Nash equilibrium and an optimal flow. If (G, r, ℓ) is an instance, then the *price of anarchy* of (G, r, ℓ) , denoted $\rho(G, r, \ell)$, is the ratio $M(f)/M(f^*)$, where f is a Nash flow and f^* is an optimal flow. Proposition 1 ensures that the price of anarchy of an instance is well defined provided $M(f^*) > 0$. If $M(f^*) = 0$, then f^* is also a flow at Nash equilibrium and we define the price of anarchy of the instance to be 1.

Finally, the price of anarchy $\rho(\mathcal{I})$ of a collection \mathcal{I} of instances is defined in the obvious way:

$$\rho(\mathcal{I}) = \sup_{(G, r, \ell) \in \mathcal{I}} \rho(G, r, \ell).$$

3 Braess's Paradox in Multicommodity Networks

In this section, we prove that Braess's Paradox can be much more severe in multicommodity networks than in single-commodity networks. In fact, there will be a "phase transition" of sorts: the worst-case severity of Braess's Paradox is polynomial in single-commodity instances, but exponential in two-commodity instances. The family of instances that we construct in this section will also serve as a starting point for our inapproximability results in Section 5.

We will begin this section by formally stating the properties of our construction in Theorem 3 below. Prior to detailing this construction and proving Theorem 3, we will discuss its many consequences for multicommodity networks.

Our family of two-commodity instances is closely related to the *Fibonacci numbers*. Recall that for a nonnegative integer p , the p th Fibonacci number F_p is defined as follows: $F_0 = 0$, $F_1 = 1$, and $F_p = F_{p-2} + F_{p-1}$ for $p \geq 2$. It is well known that $F_p \approx c \cdot \phi^p$ as $p \rightarrow \infty$, where $c \approx 0.4472$ and $\phi \approx 1.618$ is the golden ratio.

We can now state the main result of this section.

Theorem 3. *There is an infinite family $\{(G^p, r^p, \ell^p)\}_{p=1}^{\infty}$ of instances with the following properties:*

- (a) (G^p, r^p, ℓ^p) has two commodities and $O(p)$ vertices and edges as $p \rightarrow \infty$;
- (b) for p odd, $L_1(G^p, r^p, \ell^p) = F_{p-1} + 1$ and $L_2(G^p, r^p, \ell^p) = F_p$;

- (c) for p even, $L_1(G^p, r^p, \ell^p) = F_p + 1$ and $L_2(G^p, r^p, \ell^p) = F_{p-1}$;
- (d) for all p , there is a subgraph H^p of G^p with one less edge than G^p that satisfies $L_1(H^p, r^p, \ell^p) = 1$ and $L_2(H^p, r^p, \ell^p) = 0$.

Theorem 3 has a number of implications. We begin by noting two immediate corollaries of the theorem.

Corollary 1. *Adding a single edge to an n -vertex two-commodity instance can increase the latency of all traffic by a $2^{\Omega(n)}$ factor as $n \rightarrow \infty$.*

Corollary 2. *If \mathcal{I}_n is the set of instances with at most n vertices, then $\rho(\mathcal{I}_n) = 2^{\Omega(n)}$ as $n \rightarrow \infty$.*

Furthermore, Corollary 1 trivially implies that for every $k \geq 2$, adding a single edge to an n -vertex k -commodity instance can increase the latency of all traffic by a $2^{\Omega(n)}$ factor as $n \rightarrow \infty$.

Theorem 3 and Corollaries 1 and 2 show that a number of previously established properties of single-commodity instances do not carry over to multicommodity networks. In particular, the following statements are known to hold in single-commodity instances.

- (1) Adding one edge to a single-commodity instance can only increase the maximum or average latency of a Nash flow by a factor of 2 [14].
- (2) Adding any number of edges to an n -vertex single-commodity instance can only increase the maximum or average latency of a Nash flow by a factor of $\lfloor n/2 \rfloor$ [17].
- (3) The price of anarchy with respect to maximum latency in an n -vertex single-commodity instance is at most $n - 1$ [19].

Theorem 3 and Corollaries 1 and 2 demonstrate that all of these statements utterly fail to extend to multicommodity networks, even to those with only two commodities. This dichotomy stands in contrast to other work on selfish routing, such as bounds on the price of anarchy with respect to the average latency objective function, where there is provably no separation between single-commodity and multicommodity instances [18, 6].

We now give the construction of the family of instances claimed in Theorem 3. We begin by defining the graph G^p for $p \geq 1$, see Figure 1. We will describe the construction only for p odd; the construction for even p is similar. We begin with two paths, which we will call P_1 and P_2 . The $(p + 3)$ -vertex path P_2 , drawn vertically in Figure 1, is $s_2 \rightarrow w_0 \rightarrow w_1 \rightarrow \dots \rightarrow w_p \rightarrow t_2$. The $(p + 4)$ -vertex path P_1 , drawn horizontally in Figure 1, is $s_1 \rightarrow a \rightarrow w_1 \rightarrow v_1 \rightarrow \dots \rightarrow v_p \rightarrow t_1$. We also add the following edges between the two paths:

- (a, w_i) for all positive even i ;
- (v_i, w_i) for all positive even i ;
- (s_2, v_i) for all odd i at most $p - 2$;
- (w_i, v_i) for all odd i .

Fig. 1. Construction of the instance (G^p, r^p, ℓ^p) when $p = 7$. Dotted edge (s_1, w_0) is the “extra edge”. Edges with non-constant latency functions are labelled

Finally, we complete G^p by adding what we will call an *extra edge*, defined as the edge (s_1, w_0) .

For all p , the traffic rate vector r^p will be $r_1^p = r_2^p = 1$. To complete the construction, we therefore need only describe the edge latency functions. All edges will either possess a constant latency function, or a latency function that approximates a step function. We next introduce notation for the latter function type. For a positive integer i and a positive real number δ , f_δ^i will denote a continuous, nondecreasing function satisfying $f_\delta^i(x) = 0$ for $x \leq 1$ and $f_\delta^i(x) = F_i$ for $x \geq 1 + \delta$. (The function f_δ^i can be defined arbitrarily on $(1, 1 + \delta)$, provided it is continuous and nondecreasing.)

For $i \in \{0, 1, \dots, p - 1\}$, we define the edge e_i to be (w_i, w_{i+1}) if i is even and (v_i, v_{i+1}) if i is odd. (See Figure 1.) We now define the latency functions ℓ^p for G^p as follows, where δ is sufficiently small (to be chosen later): for each $i > 0$, edge e_i receives the latency function $\ell^p(x) = f_\delta^i(x)$, edge e_0 receives the latency function $\ell^p(x) = f_\delta^1(x)$, edge (s_1, a) receives the latency function $\ell^p(x) = 1$, and all other edges receive the latency function $\ell^p(x) = 0$.

With the construction in hand, we now turn toward proving Theorem 3 for odd p (the arguments for even p are similar). Part (a) is obvious. Part (d) is easy to see: if H^p is obtained from G^p by removing the extra edge (s_1, w_0) and f is the flow that routes one unit of traffic on both P_1 and P_2 , then f is at Nash equilibrium for (G^p, r^p, ℓ^p) , showing that $L_1(H^p, r^p, \ell^p) = 1$ and $L_2(H^p, r^p, \ell^p) = 0$. (See Figure 2.)

To finish the proof of Theorem 3 (for p odd), we need only prove part (b). We will accomplish this via a sequence of lemmas, the first of which requires some further definitions. First, we will say that a flow f , feasible for (G^p, r^p, ℓ^p) , *floods* the instance if $f_e \geq 1 + \delta$ for all $i \in \{0, 1, \dots, p - 1\}$. Thus if f floods (G^p, r^p, ℓ^p) , all edge latencies are at their maximum, as in Figure 3. Second, we introduce notation for some of the paths of G^p . For i even, Q_i will denote the unique s_1 - t_1 path which traverses edge e_i before any odd labelled edges, and includes no other edge of P_2 . For i odd,

Fig. 2. Nash flow in (H^p, r^p, ℓ^p) , with $p = 7$, where H^p is G^p with the extra edge (s_1, w_0) removed. Solid edges carry flow, dotted edges do not. Edge latencies are with respect to the Nash flow. Unlabelled edges have zero latency

Fig. 3. Nash flow in (G^p, r^p, ℓ^p) , with $p = 7$. Solid edges carry flow, dotted edges do not. Edge latencies are with respect to the Nash flow. Unlabelled edges have zero latency

Q_i will denote the unique s_2 - t_2 path which traverses edge e_i before any even labelled edges, and includes no other edge of P_1 . We will call the paths Q_0, \dots, Q_{p-1} , together with the “axis-aligned” paths P_1 and P_2 , the *short paths*. The next lemma justifies this terminology, at least for flows that flood the instance (G^p, r^p, ℓ^p) .

Lemma 1. *If f floods (G^p, r^p, ℓ^p) with p odd, then:*

- (a) $\ell_P(f) \geq F_{p-1} + 1$ for every s_1-t_1 path P , and equality holds for short paths;
- (b) $\ell_P(f) \geq F_p$ for every s_2-t_2 path P , and equality holds for short paths.

We will only prove part (b) of Lemma 1, as the proof of part (a) is similar. In the proof, we will use the following lemma about Fibonacci numbers, which is easy to verify.

Lemma 2. *Let j and p be odd positive integers with $j < p$, and I the even numbers between j and p . Then, $F_j + \sum_{i \in I} F_i = F_p$.*

We now prove Lemma 1.

Proof of Lemma 1: Let P be an s_2-t_2 path. Let j be the largest odd number such that $e_j \in P$, or 0 if there is no such number. We only need to prove the case where $j > 0$, since the $j = 0$ and $j = 1$ cases are the same. If $j > 0$, then P contains e_j and also e_i for all even i between j and p . Since f floods (G^p, r^p, ℓ^p) , Lemma 2 implies that $\ell_P(f) \geq F_p$. Moreover, this inequality holds with equality for short paths. ■

Our final lemma states that routing flow on short paths suffices to flood the instance (G^p, r^p, ℓ^p) . For the statement of the lemma, recall that the parameter δ controls how rapidly the non-constant latency functions of (G^p, r^p, ℓ^p) increase as the amount of flow on the edge exceeds one.

Lemma 3. *For all p odd and δ sufficiently small, there is flow f , with $f_P > 0$ only for short paths P , that floods (G^p, r^p, ℓ^p) .*

Proof. Define the flow f as follows. First, for $i = 0, 1, \dots, p - 1$, route $2^{-(i+1)}$ units of flow (of the appropriate commodity) on the short path Q_i . This routes strictly less than one unit of flow of each commodity. The remaining flow is then routed on the short paths P_1 and P_2 .

To complete the proof, we need to show that f floods (G^p, r^p, ℓ^p) —that $f_e \geq 1 + \delta$ for all $p \in \{0, 1, \dots, p - 1\}$ provided δ is sufficiently small. We will prove this inequality only for i odd; the argument for even i is similar.

The second commodity uses edge e_i only in the short path Q_i , on which it routes $2^{-(i+1)}$ units of flow. The first commodity uses edge e_i in all of its flow paths except for the short paths Q_j for j even and greater than i . The total amount of flow on e_i is thus at least

$$2^{-(i+1)} + 1 - \sum_{j \geq 0} 2^{-(i+2+2j)} = 1 + 2^{-(i+1)} - \frac{4}{3} \cdot 2^{-(i+2)} > 1 + 2^{-(i+3)}.$$

Thus, provided $\delta \leq 2^{-(p+3)}$, f floods (G^p, r^p, ℓ^p) , and the proof is complete.

Theorem 3(b) now follows immediately from Definition 1, Lemma 1, and Lemma 3.

4 Upper Bounds on the Price of Anarchy

We now turn toward proving upper bounds on the price of anarchy and, as a consequence, on the worst-possible severity of Braess's Paradox. We will aim for an upper bound that matches the lower bound of Theorem 3, and will largely succeed in this goal.

We begin by proving a very weak bound on the price of anarchy, a bound that depends on parameters other than the size of the network. While not interesting in its own right, this bound will play a crucial role in later proofs in this section.

Lemma 4. *Let f be a Nash flow and f^* a feasible flow for an instance (G, r, ℓ) , where G has m edges. For every edge e of G with $f_e > f_e^*$,*

$$\ell_e(f_e) \leq \frac{m \sum_i r_i}{f_e - f_e^*} \cdot \max_e \ell_e(f_e^*). \tag{2}$$

Proof of Lemma 4: Let $F \subseteq E$ denote the edges e of G for which $f_e > f_e^*$. Using inequality (1) in Proposition 2 and the fact that $\ell_e(f_e^*) \leq M(f_e^*)$ whenever $f_e^* > 0$, we can derive the following crude bound:

$$\begin{aligned} \sum_{e \in F} \ell_e(f_e)(f_e - f_e^*) &\leq \sum_{e \in E \setminus F} \ell_e(f_e)(f_e^* - f_e) \\ &\leq \left(\max_e \ell_e(f_e^*) \right) \sum_{e \in E \setminus F} (f_e^* - f_e) \\ &\leq \max_e \ell_e(f_e^*) \cdot m \cdot \sum_i r_i. \end{aligned}$$

The lemma now follows easily. ■

We next use Lemma 4 as a bootstrap for deriving upper bounds on the price of anarchy that depend only on the size of the network. We will accomplish this as follows. For an arbitrary instance, we will set up a linear program, with edge latencies as variables, that maximizes the price of anarchy among instances that are “basically equivalent” to the given instance. We will define our notion of equivalence so that Lemma 4 ensures that the linear program has a bounded maximum, and will then analyze the vertices of the feasible region of the linear program to derive the following bound.

Theorem 4. *If (G, r, ℓ) is an instance with n vertices and m edges, then*

$$\rho(G, r, \ell) = 2^{O(m \log n)}.$$

Before implementing the proof approach outlined above, we state a proposition that bounds the maximum size of the optimal value of a linear program with a constraint matrix with entries in $\{-1, 0, 1\}$.

Proposition 5. *Let A be an $m \times n$ matrix with entries in $\{0, \pm 1\}$ and at most α non-zero entries in each row. Let b be a real-valued m -vector, and let the linear program $\max x_i$ subject to $Ax \leq b$ have a finite maximum. Then, this maximum is at most $n\alpha^n \|b\|_\infty$, where $\|b\|_\infty$ denotes $\max_j |b_j|$.*

Proposition 5 can be proved with Cramer’s rule and a simple bound on the determinant. We omit further details.

Proof of Theorem 4: Let (G, r, ℓ) be an instance with n vertices and m edges. Let f and f^* be Nash and optimal flows for (G, r, ℓ) , respectively. We aim to show that $\rho(G, r, \ell) = 2^{O(m \log n)}$.

We begin by performing some preprocessing on the instance (G, r, ℓ) . First, if $f_e = f_e^* = 0$ for some edge e , then that edge can be removed from the instance without affecting its ρ -value. We can therefore assume that $f_e^* > 0$ or $f_e > 0$ for every edge e . Second, we can assume that $\ell_e(0) = 0$ whenever $f_e^* = 0$. To see why, note that replacing the latency function $\ell_e(x)$ of such an edge by the function equal to (e.g.) $\min\{x/f_e, 1\} \cdot \ell_e(x)$ leaves the Nash flow unaffected while only decreasing the maximum latency of f^* and hence increasing the ρ -value of the instance. Combining these two assumptions, we can assume without loss of generality $\ell_e(f_e^*) \leq M(f^*)$ for every edge e of G .

We now set up a linear program that attempts to further transform the latency functions to make the ρ -value of the given instance as large as possible. In the linear program, the flow amounts $\{f_e\}$ and $\{f_e^*\}$, as well as the latencies $\{\ell_e(f_e^*)\}$ with respect to f^* , will be held fixed. There will be a nonnegative variable $\hat{\ell}_e(f_e)$ representing the latency of edge e with respect to the flow f . So that the new latency functions are nondecreasing, we impose the following linear constraints, which we call *monotonicity constraints*:

- For all edges e with $f_e = f_e^*$, $\hat{\ell}_e(f_e) = \ell_e(f_e^*)$.
- For all edges e with $f_e < f_e^*$, $\hat{\ell}_e(f_e) \leq \ell_e(f_e^*)$.
- For all edges e with $f_e > f_e^*$, $\hat{\ell}_e(f_e) \geq \ell_e(f_e^*)$.

Additionally, we will insist that the (fixed) flow f be at Nash equilibrium with respect to the (variable) latencies $\{\hat{\ell}_e(f_e)\}$. There are several ways that this requirement can be encoded with linear constraints. For this proof, we will be content with the following naive approach: for every commodity i , and every pair of paths $P, \tilde{P} \in \mathcal{P}_i$ for which $f_e^{(i)} > 0$ for all $e \in P$, we insist that $\sum_{e \in P} \hat{\ell}_e(f_e) \leq \sum_{e \in \tilde{P}} \hat{\ell}_e(f_e)$ in our linear program. Since this linear program has a small number of variables, we will not be hampered by its potentially massive number of constraints.

By construction, our constraints ensure the following: for every feasible solution $\{\hat{\ell}_e(f_e)\}$, there is an instance $(G, r, \hat{\ell})$ with continuous, nondecreasing latency functions $\hat{\ell}$, so that these latency functions interpolate their two prescribed values and f is a Nash flow for $(G, r, \hat{\ell})$. Consider the objective function $\max \hat{\ell}_e(f_e)$ for an edge e . Our key claim is that the resulting linear program is not unbounded. For edges e with $f_e \leq f_e^*$, the claim is obvious from the constraints. For edges e with $f_e > f_e^*$, the claim follows from Lemma 4 and the fact that all parameters on the right-hand side of the bound (2) are fixed in the linear program.

Since the maximum of the above linear program is bounded, we can apply Proposition 5. In our linear program, there are a total of m variables, of which each constraint contains at most $2n$. The right-hand side of each constraint is either a 0 or a term of the form $\ell_e(f_e^*)$. By our preprocessing step, $\ell_e(f_e^*) \leq M(f^*)$ for all edges e . Hence, Proposition 5 implies that the maximum of the linear program is at most

$mn^{O(m)} \cdot M(f^*)$. Hence, returning to the original instance (G, r, ℓ) , we must have $\ell_e(f_e) \leq mn^{O(m)} \cdot M(f^*)$ for all edges e . Since a flow path of f can contain only n edges, we can conclude that $\rho(G, r, \ell) \leq nm^{O(m)} = 2^{O(m \log n)}$. ■

When the number of commodities is small (e.g., a constant), we can improve the bound to $2^{O(kn)}$ using a different way to encode the constraint that f must be at Nash equilibrium with respect to $\{\hat{\ell}_e(f_e)\}$.

Theorem 6. *If (G, r, ℓ) is an instance with n vertices and k commodities, then*

$$\rho(G, r, \ell) = 2^{O(kn)}.$$

Proof. To prove our bound, we start with the linear program described in Theorem 4. We leave the objective and monotonicity constraints the same, but replace the constraints that ensure f is a Nash equilibrium for $\{\hat{\ell}_e(f_e)\}$. To ensure the latencies $\{\hat{\ell}_e(f_e)\}$ define a Nash equilibrium for f , we introduce an auxiliary variable $\hat{d}^i(v)$ for each commodity i and for every vertex $v \in V$ reachable from that commodity's source s_i , which will represent the length of the shortest path from s_i to v , with respect to the latencies $\{\hat{\ell}_e(f_e)\}$. Now, we define the following constraints:

- $\hat{d}_i(s_i) = 0$, for all commodities i .
- $\hat{d}_i(u) + \hat{\ell}_e(f_e) = \hat{d}_i(v)$, for all edges $e = (u, v)$ and commodities i with $f_e^{(i)} > 0$.
- $\hat{d}_i(u) + \hat{\ell}_e(f_e) \leq \hat{d}_i(v)$, for all edges $e = (u, v)$ and commodities i .

To complete the proof, we need to show:

- (a) A set of latencies $\{\hat{\ell}_e(f_e)\}$ is feasible for our linear program if and only if it defines a Nash equilibrium for f .
- (b) The latency variables can be removed, yielding a linear program with kn variables, that can be bounded by $2^{O(kn)}$.

To prove the forward direction of (a), it is easy to see that with our constraints, for every commodity i , each path $P \in \mathcal{P}_i$, with $f_e^{(i)} > 0$ for all $e \in P$, must have length precisely equal to $\hat{d}_i(t_i)$. Furthermore, no path in $P \in \mathcal{P}_i$ may have length strictly less than $\hat{d}_i(t_i)$. Therefore, for every commodity i and every $P, \tilde{P} \in \mathcal{P}_i$, with $f_e^{(i)} > 0$ for all $e \in P, \sum_{e \in P} \hat{\ell}_e(f_e) \leq \sum_{e \in \tilde{P}} \hat{\ell}_e(f_e)$, and our latencies define a Nash equilibrium for f . To prove the other direction of (a), note that for any set of latencies $\hat{\ell}_e(f_e)$ defining a Nash equilibrium for f , we can define $\hat{d}_i(v)$ to be the length of the shortest path from s_i to v , and we have a feasible solution for our linear program.

With (a) proven, we know that the maximum value of our linear program is precisely the maximum edge length that occurs in any Nash equilibrium for flow f . As before, note that Lemma 4 implies our linear program is bounded, and we can apply Proposition 5 to bound the maximum value of the linear program.

Before applying Proposition 5 however, we first eliminate the latency variables, which allows us to prove a better bound. Note that for any edge $e = (u, v)$ with $f_e^i > 0$ for some commodity i , $\hat{d}_i(u) + \hat{\ell}_e(f_e) = \hat{d}_i(v)$, so we can replace any occurrence

of $\hat{\ell}_e(f_e)$ in our linear program with $\hat{d}_i(v) - \hat{d}_i(u)$. Furthermore, for any other edges, $f_e = 0$, and it must be the case that $\hat{\ell}_e(f_e) \leq M(f^*)$. For these edges, an optimal solution must assign some value $x_e \leq M(f^*)$ to the latencies $\hat{\ell}_e(f_e)$, and thus for these edges, we can substitute the $\hat{\ell}_e(f_e)$ variable with the constant x_e value used in the optimal solution. With these substitutions, we have not changed the optimal value of our linear program, and we are only left with $O(kn)$ variables. Moreover, there are still a constant number of variables per constraint, and each entry of b is still bounded by $M(f^*)$. Therefore, applying Proposition 5 bounds the price of anarchy by $2^{O(kn)}$.

Corollary 2 shows that Theorem 6 is essentially tight for a constant number of commodities.

5 Exponential Inapproximability for Network Design

In this section, we will show that a network design problem that is naturally motivated by Braess's Paradox has intrinsically exponential approximability. The problem, which we call MULTICOMMODITY NETWORK DESIGN (MCND), is as follows.

Given a (multicommodity) instance (G, r, ℓ) , find a subgraph H of G that minimizes $M(H, r, \ell)$.

By $M(H, r, \ell)$, we mean the maximum latency of a Nash flow for (H, r, ℓ) (well defined by Proposition 1). MCND is tantamount to detecting and avoiding Braess's Paradox. For single-commodity instances, this problem was studied in [17].

The *trivial algorithm* is defined as the algorithm that always returns the entire graph G —the algorithm that always punts on trying to detect Braess's Paradox. The following was proved in [17]: the trivial algorithm is an $\lfloor n/2 \rfloor$ -approximation algorithm for the special case of single-commodity instances; and for every $\epsilon > 0$, no $(\lfloor n/2 \rfloor - \epsilon)$ -approximation algorithm exists (assuming $P \neq NP$). Here, we will succeed in proving analogues of these results for multicommodity networks, where the best-possible approximation ratio is inherently exponential.

First, we note that since Theorems 4 and 6 imply limits on the largest possible increase in the maximum latency due to Braess's Paradox, they also translate to an upper bound on the trivial algorithm.

Proposition 7. *The trivial algorithm is a $2^{O(\min\{kn, m \log n\})}$ -approximation algorithm for MCND.*

Much more interesting is the next result, which states that there is *no* polynomial-time algorithm with subexponential approximation ratio (assuming $P \neq NP$).

Theorem 8. *Assuming $P \neq NP$, there is no $2^{o(n)}$ -approximation algorithm for MCND.*

The proof of Theorem 8 combines ideas from the gap reductions of [17] for the single-commodity version of MCND with the family of two-commodity instances described in Section 3. Because of space constraints, we will content ourselves here with a high-level overview of the proof.

Recall that in an instance of the NP-complete problem PARTITION, we are given q positive integers $\{a_1, a_2, \dots, a_q\}$ and seek a subset $S \subseteq \{1, 2, \dots, q\}$ such that $\sum_{j \in S} a_j = \frac{1}{2} \sum_{j=1}^q a_j$ [11-SP12]. The idea of the reduction is to start with an instance (G^p, r^p, ℓ^p) of the form described in Section 3, and to replace the extra edge (s_1, w_0) with a collection of parallel edges representing an instance $\mathcal{I} = \{a_1, \dots, a_p\}$ of PARTITION. We will give these edges latency functions that simulate “capacities”, with an edge representing an integer a_j of \mathcal{I} receiving capacity proportional to a_j . The proof then break down into three parts. First, if too many of these parallel edges are removed from the network, there will be insufficient remaining capacity to send flow cheaply. To implement this, we must also augment the latency functions of the edges e_0, \dots, e_{p-1} of Section 3 to have effective capacities. Second, if too few of the parallel edges are removed, the excess of capacity results in a bad flow at Nash equilibrium similar to that of Figure 3. Finally, these two cases can be avoided if and only if \mathcal{I} is a “yes” instance of PARTITION, in which case removing the appropriate collection of parallel edges results in a network that admits a good Nash equilibrium similar to that of Figure 2.

Abstract. Weighted automata are used to describe quantitative properties in various areas such as probabilistic systems, image compression, speech-to-text processing. The behaviour of such an automaton is a mapping, called a formal power series, assigning to each word a weight in some semiring. We generalize Büchi's and Elgot's fundamental theorems to this quantitative setting. We introduce a weighted version of MSO logic and prove that, for commutative semirings, the behaviours of weighted automata are precisely the formal power series definable with our weighted logic. We also consider weighted first-order logic and show that aperiodic series coincide with the first-order definable ones, if the semiring is locally finite, commutative and has some aperiodicity property.

1 Introduction

Büchi's and Elgot's fundamental theorems [3, 9] established the coincidence of regular languages with languages definable in monadic second-order logic. At the same time, Schützenberger [22] investigated finite automata with weights and characterized their behaviours as rational formal power series. Both of these results have inspired a wealth of extensions and further research, cf. [24, 21, 15, 2] for surveys and monographs, and also led to recent practical applications, e.g. in verification of finite-state programs (model checking, [17, 1, 16]), in digital image compression [5, 11, 13, 12] and in speech-to-text processing [19, 20, 4].

It is the goal of this paper to introduce a logic with weights and to show that the behaviours of weighted finite automata are precisely the series definable in our weighted monadic second-order logic. This can be viewed as a quantitative version of Büchi's and Elgot's classical (qualitative) results.

The syntax of our weighted logics incorporates weights taken from a semiring K , just as done for weighted automata in order to model a variety of applications and situations. The semantics of a weighted logic formula will be a formal power

^{*} Work partly supported by the DAAD-PROCOPE project Temporal and Quantitative Analysis of Distributed Systems.

series with values in K . We restrict negation to atomic formulas since in general there is no natural complement operation in the semiring that would allow us to define the semantics of negation elementwise. In comparison to classical MSO-logic, this is not a restriction, since we include disjunction, conjunction, existential and universal quantifications in our syntax. Thus, we obtain the classical MSO-logics by letting $K = \mathbb{B}$, the 2-element Boolean algebra.

Even for the semiring of natural numbers or the tropical semiring it turns out that neither universal first-order nor universal second-order quantification of formulas preserve recognizability. Therefore, for the syntax of restricted MSO-logic we exclude universal second-order quantification, and we permit universal first-order quantification only for formulas whose semantics takes finitely many values in K . Moreover, if we allow existential set quantifications only to occur at the beginning of a formula, we arrive at restricted existential MSO-logic.

Now we give a summary of our results. First we show for any commutative semiring K that the behaviours of weighted automata with values in K are precisely the series definable by sentences of our restricted MSO-logic, or, equivalently, of our restricted existential MSO-logic. Second, if the semiring K is locally finite, we obtain that the semantics of all sentences of our full weighted MSO-logic are representable by weighted automata. Locally finite semirings were investigated in [6]; they form a large class of semirings including e.g. all finite semirings, the max-min-semiring employed for capacity problems of networks, and all Boolean algebras. Thus we obtain Büchi's and Elgot's theorems as a particular consequence. Moreover, if the semiring K is a field or locally finite and is given in some effective way, then the constructions in our proofs yield effective conversions of sentences of our weighted logics to weighted automata, and viceversa, and we obtain also decision procedures.

Finally, we investigate weighted first-order logic. As is well-known, the first-order definable languages are precisely the starfree languages which in turn coincide with the aperiodic ones [23, 18]. Aperiodic and starfree formal power series were introduced and investigated in [6]. Easy examples show that even if the semiring K is finite, series definable in our weighted first-order logic need not be aperiodic. However, we obtain that the aperiodic series coincide with the first-order definable ones, if the semiring is locally finite, commutative and both addition and multiplication satisfy a certain aperiodicity property. Such semirings include again all Boolean algebras, but also quite different ones like the truncated max-plus semiring.

We believe that the present paper opens a new research road. Obviously, one could try to extend our results to other structures such as trees or traces. One could also try to define weighted temporal logics and study not only expressiveness but also decidability and complexity of natural problems such as quantitative model checking.

Full proofs are available in the technical report [7].

2 Weighted Automata

We give basic definitions and properties of semirings, formal power series and weighted automata. For background, we refer the reader to [2, 15, 21].

A *semiring* is a structure $(K, +, \cdot, 0, 1)$ where $(K, +, 0)$ is a commutative monoid, $(K, \cdot, 1)$ is a monoid, multiplication distributes over addition, and $0 \cdot x = x \cdot 0 = 0$ for each $x \in K$. If the multiplication is commutative, we say that K is *commutative*. If the addition is idempotent, then the semiring is called *idempotent*. Important examples include

- the natural numbers $(\mathbb{N}, +, \cdot, 0, 1)$ with the usual addition and multiplication,
- the Boolean semiring $\mathbb{B} = (\{0, 1\}, \vee, \wedge, 0, 1)$,
- the tropical semiring $\text{Trop} = (\mathbb{N} \cup \{\infty\}, \min, +, \infty, 0)$ (also known as min-plus semiring), with \min and $+$ extended to $\mathbb{N} \cup \{\infty\}$ in the natural way,
- the arctical semiring $\text{Arc} = (\mathbb{N} \cup \{-\infty\}, \max, +, -\infty, 0)$,
- the semiring $([0, 1], \max, \cdot, 0, 1)$ which can be used to compute probabilities,
- the semiring of languages $(\mathcal{P}(A^*), \cup, \cap, \emptyset, A^*)$.

If K is a semiring and $n \in \mathbb{N}$, then $K^{n \times n}$ comprises all $(n \times n)$ -matrices over K . With usual matrix multiplication $(K^{n \times n}, \cdot)$ is a monoid.

A formal power series is a mapping $S : A^* \rightarrow K$. It is usual to write (S, w) for $S(w)$. The set $\text{Supp}(S) := \{w \in A^* \mid (S, w) \neq 0\}$ is called the *support* of S , and $\text{Im}(S) = \{(S, w) \mid w \in A^*\}$ is the *image* of S . The set of all formal power series over K and A is denoted by $K\langle\langle A^* \rangle\rangle$. Now let $S, T \in K\langle\langle A^* \rangle\rangle$. The *sum* $S + T$ and the *Hadamard product* $S \odot T$ are both defined pointwise:

$$(S + T, w) := (S, w) + (T, w) \text{ and } (S \odot T, w) := (S, w) \cdot (T, w) \quad (w \in A^*).$$

For $L \subseteq A^*$, we define the *characteristic series* $\mathbb{1}_L : A^* \rightarrow K$ by $(\mathbb{1}_L, w) = 1$ if $w \in L$, and $(\mathbb{1}_L, w) = 0$ otherwise.

Now we turn to weighted automata. We fix a semiring K and an alphabet A . A *weighted finite automaton* over K and A is a quadruple $\mathcal{A} = (Q, \lambda, \mu, \gamma)$ where Q is a finite set of states, $\mu : A \rightarrow K^{Q \times Q}$ is the transition weight function and $\lambda, \gamma : Q \rightarrow K$ are weight functions for entering and leaving a state, respectively. Here $\mu(a)$ is a $(Q \times Q)$ -matrix whose (p, q) -entry $\mu(a)_{p,q} \in K$ indicates the weight of the transition $p \xrightarrow{a} q$. Then μ extends uniquely to a monoid homomorphism (also denoted by μ) from A^* into $(K^{Q \times Q}, \cdot)$.

The *weight* of a path $P : q_0 \xrightarrow{a_1} q_1 \rightarrow \dots \rightarrow q_{n-1} \xrightarrow{a_n} q_n$ in \mathcal{A} is the product $\text{weight}(P) := \lambda(q_0) \cdot \mu(a_1)_{q_0, q_1} \cdots \mu(a_n)_{q_{n-1}, q_n} \cdot \gamma(q_n)$. This path has label $a_1 \dots a_n$. The *weight* of a word $w = a_1 \dots a_n \in A^*$ in \mathcal{A} , denoted $(\|\mathcal{A}\|, w)$, is the sum of $\text{weight}(P)$ over all paths P with label w . One can check that $(\|\mathcal{A}\|, w) = \lambda \cdot \mu(w) \cdot \gamma$ with usual matrix multiplication, considering λ as a row vector and γ as a column vector. If $w = \varepsilon$, we have $(\|\mathcal{A}\|, \varepsilon) = \lambda \cdot \gamma$. This defines a formal power series $\|\mathcal{A}\| : A^* \rightarrow K$ called the *behavior* of \mathcal{A} . A formal power series $S \in K\langle\langle A^* \rangle\rangle$ is called *recognizable*, if there exists a weighted finite automaton \mathcal{A} such that $S = \|\mathcal{A}\|$. Then we also call \mathcal{A} or (λ, μ, γ) a *representation* of S . We let $K^{\text{rec}}\langle\langle A^* \rangle\rangle$ be the collection of all recognizable formal power series over K and A .

Now let $h : A^* \rightarrow B^*$ be a homomorphism. If $T \in K\langle\langle B^* \rangle\rangle$, then $h^{-1}(T) := T \circ h \in K\langle\langle A^* \rangle\rangle$. That is, $(h^{-1}(T), w) = (T, h(w))$ for each $w \in A^*$. We say that h is *non-erasing*, if $h(a) \neq \varepsilon$ for any $a \in A$. In this case, for $S \in K\langle\langle A^* \rangle\rangle$, define $h(S) : B^* \rightarrow K$ by $(h(S), v) := \sum_{w \in h^{-1}(v)} (S, w)$ ($v \in B^*$), noting that the sum is finite since h is non-erasing. Recognizability is preserved by inverse morphisms and non-erasing morphisms [8, 2].

We say $S : A^* \rightarrow K$ is a *recognizable step function*, if $S = \sum_{i=1}^n k_i \cdot \mathbb{1}_L$ for some $n \in \mathbb{N}$, $k_i \in K$ and recognizable languages $L_i \subseteq A^*$ ($i = 1, \dots, n$). As is well-known, any recognizable step function is a recognizable power series.

3 Weighted Logics

In this section, we introduce our weighted logics and study its first properties. We fix a semiring K and an alphabet A . For each $a \in A$, P_a denotes a unary predicate symbol. The syntax of formulas of the *weighted MSO-logic* is given by

$$\begin{aligned} \varphi ::= & k \mid P_a(x) \mid \neg P_a(x) \mid x \leq y \mid \neg(x \leq y) \mid x \in X \mid \neg(x \in X) \\ & \mid \varphi \vee \psi \mid \varphi \wedge \psi \mid \exists x.\varphi \mid \exists X.\varphi \mid \forall x.\varphi \mid \forall X.\varphi \end{aligned}$$

where $k \in K$ and $a \in A$. We denote by $\text{MSO}(K, A)$ the collection of all such weighted MSO-formulas φ .

Now we turn to the definition of the semantics of formulas $\varphi \in \text{MSO}(K, A)$. We let $\text{Free}(\varphi)$ be the set of all free variables of φ . Let $w = a_1 \dots a_n \in A^*$ with $a_i \in A$. We also write $w(i) = a_i$ ($1 \leq i \leq n$). The length of w is $|w| = n$.

Let \mathcal{V} be a finite set of first-order and second-order variables. A (\mathcal{V}, w) -assignment σ is a function mapping first-order variables in \mathcal{V} to elements of $\{1, \dots, |w|\}$ and second-order variables in \mathcal{V} to subsets of $\{1, \dots, |w|\}$. If x is a first-order variable and $i \in \{1, \dots, |w|\}$ then $\sigma[x \rightarrow i]$ is the $(\mathcal{V} \cup \{x\}, w)$ -assignment which assigns x to i and acts like σ on all other variables. Similarly, $\sigma[X \rightarrow I]$ is defined for $I \subseteq \{1, \dots, |w|\}$.

As usual, a pair (w, σ) where σ is a (\mathcal{V}, w) -assignment will be encoded using an extended alphabet $A_{\mathcal{V}} = A \times \{0, 1\}^{\mathcal{V}}$. More precisely, we will write a word over $A_{\mathcal{V}}$ as a pair (w, σ) where w is the projection over A and σ is the projection over $\{0, 1\}^{\mathcal{V}}$. Now, σ represents a *valid* assignment over \mathcal{V} if for each first-order variable $x \in \mathcal{V}$, the x -row of σ contains exactly one 1. In this case, we identify σ with the (\mathcal{V}, w) -assignment such that for each first-order variable $x \in \mathcal{V}$, $\sigma(x)$ is the position of the 1 on the x -row, and for each second-order variable $X \in \mathcal{V}$, $\sigma(X)$ is the set of positions carrying a 1 on the X -row. Clearly, the language $N_{\mathcal{V}} = \{(w, \sigma) \in A_{\mathcal{V}}^* \mid \sigma \text{ is a valid } \mathcal{V}\text{-assignment}\}$ is recognizable. We simply write $A_{\varphi} = A_{\text{Free}(\varphi)}$ and $N_{\varphi} = N_{\text{Free}(\varphi)}$.

Definition 3.1. *Let $\varphi \in \text{MSO}(K, A)$ and \mathcal{V} be a finite set of variables containing $\text{Free}(\varphi)$. The semantics of φ is a formal power series $[\varphi]_{\mathcal{V}} \in K\langle\langle A_{\mathcal{V}}^* \rangle\rangle$. Let $(w, \sigma) \in A_{\mathcal{V}}^*$. If σ is not a valid \mathcal{V} -assignment, then we put $[\varphi]_{\mathcal{V}}(w, \sigma) = 0$. Otherwise, we define $[\varphi]_{\mathcal{V}}(w, \sigma) \in K$ inductively as follows:*

$$\begin{aligned}
 \llbracket k \rrbracket_{\mathcal{V}}(w, \sigma) &= k & \llbracket P_a(x) \rrbracket_{\mathcal{V}}(w, \sigma) &= \begin{cases} 1 & \text{if } w(\sigma(x)) = a \\ 0 & \text{otherwise} \end{cases} \\
 \llbracket x \leq y \rrbracket_{\mathcal{V}}(w, \sigma) &= \begin{cases} 1 & \text{if } \sigma(x) \leq \sigma(y) \\ 0 & \text{otherwise} \end{cases} & \llbracket x \in X \rrbracket_{\mathcal{V}}(w, \sigma) &= \begin{cases} 1 & \text{if } \sigma(x) \in \sigma(X) \\ 0 & \text{otherwise} \end{cases} \\
 \llbracket \neg\varphi \rrbracket_{\mathcal{V}}(w, \sigma) &= \begin{cases} 1 & \text{if } \llbracket \varphi \rrbracket_{\mathcal{V}}(w, \sigma) = 0 \\ 0 & \text{if } \llbracket \varphi \rrbracket_{\mathcal{V}}(w, \sigma) = 1 \end{cases} & & \text{if } \varphi \text{ is of the form } P_a(x), (x \leq y) \\
 & & & \text{or } (x \in X). \\
 \llbracket \varphi \vee \psi \rrbracket_{\mathcal{V}}(w, \sigma) &= \llbracket \varphi \rrbracket_{\mathcal{V}}(w, \sigma) + \llbracket \psi \rrbracket_{\mathcal{V}}(w, \sigma) \\
 \llbracket \varphi \wedge \psi \rrbracket_{\mathcal{V}}(w, \sigma) &= \llbracket \varphi \rrbracket_{\mathcal{V}}(w, \sigma) \cdot \llbracket \psi \rrbracket_{\mathcal{V}}(w, \sigma) \\
 \llbracket \exists x.\varphi \rrbracket_{\mathcal{V}}(w, \sigma) &= \sum_{1 \leq i \leq |w|} \llbracket \varphi \rrbracket_{\mathcal{V}_{\cup\{x\}}}(w, \sigma[x \rightarrow i]) \\
 \llbracket \exists X.\varphi \rrbracket_{\mathcal{V}}(w, \sigma) &= \sum_{I \subseteq \{1, \dots, |w|\}} \llbracket \varphi \rrbracket_{\mathcal{V}_{\cup\{X\}}}(w, \sigma[X \rightarrow I]) \\
 \llbracket \forall x.\varphi \rrbracket_{\mathcal{V}}(w, \sigma) &= \prod_{1 \leq i \leq |w|} \llbracket \varphi \rrbracket_{\mathcal{V}_{\cup\{x\}}}(w, \sigma[x \rightarrow i]) \\
 \llbracket \forall X.\varphi \rrbracket_{\mathcal{V}}(w, \sigma) &= \prod_{I \subseteq \{1, \dots, |w|\}} \llbracket \varphi \rrbracket_{\mathcal{V}_{\cup\{X\}}}(w, \sigma[X \rightarrow I])
 \end{aligned}$$

where we fix some order on the power set of $\{1, \dots, |w|\}$ so that the last product is defined even if K is not commutative. We simply write $\llbracket \varphi \rrbracket$ for $\llbracket \varphi \rrbracket_{\text{Free}(\varphi)}$.

Note that if φ is a sentence, i.e. has no free variables, then $\llbracket \varphi \rrbracket \in K \langle\langle A^* \rangle\rangle$. We give several examples of possible interpretations for weighted formulas:

- I. Let $K = (\mathbb{N}, +, \cdot, 0, 1)$ and assume φ does not contain constants $k \in \mathbb{N}$. We may interpret $\llbracket \varphi \rrbracket(w, \sigma)$ as the number of proofs we have that (w, σ) satisfies formula φ . Indeed, for atomic formulas the number of proofs is clearly 0 or 1, depending on whether φ holds for (w, σ) or not. Now if e.g. $\llbracket \varphi \rrbracket(w, \sigma) = m$ and $\llbracket \psi \rrbracket(w, \sigma) = n$, the number of proofs that (w, σ) satisfies $\varphi \vee \psi$ should be $m + n$ (since any proof suffices), and for $\varphi \wedge \psi$ it should be $m \cdot n$ (since we may pair the proofs of φ and ψ arbitrarily). Similarly, the semantics of the existential and universal quantifiers can be interpreted.
- II. The formula $\exists x.P_a(x)$ counts how often a occurs in the word. Here *how often* depends on the semiring: e.g. Boolean semiring, natural numbers, integers modulo 3, ...
- III. Consider the probability semiring $K = ([0, 1], \max, \cdot, 0, 1)$ and the alphabet $A = \{a_1, \dots, a_n\}$. Assume that each letter a_i has a reliability k_i . Then, the series assigning to a word its reliability can be given by the first-order formula $\forall x. \bigvee_{1 \leq i \leq n} (P_a(x) \wedge k_i)$.
- IV. Let K be an arbitrary Boolean algebra $(B, \vee, \wedge, \bar{}, 0, 1)$. In this case, sums correspond to suprema, and products to infima. Here we can define the semantics of $\neg\varphi$ for an arbitrary formula φ by $\llbracket \neg\varphi \rrbracket(w, \sigma) := \overline{\llbracket \varphi \rrbracket(w, \sigma)}$. Then clearly $\llbracket \varphi \wedge \psi \rrbracket = \llbracket \neg(\neg\varphi \vee \neg\psi) \rrbracket$, $\llbracket \forall x.\varphi \rrbracket = \llbracket \neg(\exists x.\neg\varphi) \rrbracket$ and $\llbracket \forall X.\varphi \rrbracket =$

$\llbracket \neg(\exists X.\neg\varphi) \rrbracket$. This may be interpreted as a multi-valued logics. In particular, if $K = \mathbb{B}$, the 2-valued Boolean algebra, our semantics coincides with the usual semantics of unweighted MSO-formulas, identifying characteristic series with their supports.

Let K be a semiring and A an alphabet. Observe that if $\varphi \in \text{MSO}(K, A)$, we have defined a semantics $\llbracket \varphi \rrbracket_{\mathcal{V}}$ for each finite set of variables \mathcal{V} containing $\text{Free}(\varphi)$. Now we show that these semantics' are consistent with each other.

Proposition 3.2. *Let $\varphi \in \text{MSO}(K, A)$ and \mathcal{V} a finite set of variables containing $\text{Free}(\varphi)$. Then $\llbracket \varphi \rrbracket_{\mathcal{V}}(w, \sigma) = \llbracket \varphi \rrbracket(w, \sigma|_{\text{Free}(\varphi)})$ for each $(w, \sigma) \in A_{\mathcal{V}}^*$ such that σ is a valid \mathcal{V} -assignment. In particular, $\llbracket \varphi \rrbracket$ is recognizable iff $\llbracket \varphi \rrbracket_{\mathcal{V}}$ is recognizable.*

Proof (sketch). The first claim can be shown by induction on φ . For the final claim, let $\llbracket \varphi \rrbracket$ be recognizable, and consider the projection $\pi : A_{\mathcal{V}} \rightarrow A_{\varphi}$. For $(w, \sigma) \in A_{\mathcal{V}}^*$, we have $\pi(w, \sigma) = (w, \sigma|_{\text{Free}(\varphi)})$. Hence, $\llbracket \varphi \rrbracket_{\mathcal{V}} = \pi^{-1}(\llbracket \varphi \rrbracket) \odot \mathbb{1}_{N_{\mathcal{V}}}$ is recognizable by standard preservation results, cf. [2]. The converse can be shown similarly. \square

Now let $Z \subseteq \text{MSO}(K, A)$. A series $S : A^* \rightarrow K$ is called *Z-definable*, if there is a sentence $\varphi \in Z$ such that $S = \llbracket \varphi \rrbracket$. The main goal of this paper is the comparison of Z-definable with recognizable series, for suitable fragments Z of $\text{MSO}(K, A)$. Crucial for this will be closure properties of recognizable series under the constructs of our weighted logic. However, first we will show that $K^{\text{rec}}\langle\langle A^* \rangle\rangle$ is in general not closed under universal quantification.

Example 3.3. Let $K = (\mathbb{N}, +, \cdot, 0, 1)$. Then $\llbracket \forall x.2 \rrbracket(w) = 2^{|w|}$ and $\llbracket \forall y \forall x.2 \rrbracket(w) = (2^{|w|})^{|w|} = 2^{|w|^2}$. Clearly, the series $\llbracket \forall x.2 \rrbracket$ is recognizable by the weighted automaton $(Q, \lambda, \mu, \gamma)$ with $Q = \{1\}$, $\lambda_1 = \gamma_1 = 1$ and $\mu_{1,1}(a) = 2$ for all $a \in A$. However, $\llbracket \forall y \forall x.2 \rrbracket$ is not recognizable. Suppose there was an automaton $\mathcal{A}' = (Q', \lambda', \mu', \gamma')$ with behavior $\llbracket \forall y \forall x.2 \rrbracket$. Let $M = \max\{|\lambda'_p|, |\gamma'_p|, |\mu'(a)_{p,q}| \mid p, q \in Q', a \in A\}$. Then $(\|\mathcal{A}'\|, w) \leq |Q'|^{|w|+1} \cdot M^{|w|+2}$ for any $w \in A^*$, a contradiction with $(\|\mathcal{A}'\|, w) = 2^{|w|^2}$.

A similar argument applies also for the tropical and the arctical semirings. Observe that in all these cases, $\llbracket \forall x.2 \rrbracket$ has infinite image.

Example 3.4. Let $K = (\mathbb{N}, +, \cdot, 0, 1)$. Then $\llbracket \forall X.2 \rrbracket(w) = 2^{2^{|w|}}$ for any $w \in A^*$, and as above $\llbracket \forall X.2 \rrbracket$ is not recognizable due to its growth. Again, this counterexample also works for the tropical and the arctical semirings.

The examples show that unrestricted universal quantification is too strong to preserve recognizability. This motivates the following definition. We will call a formula $\varphi \in \text{MSO}(K, A)$ *restricted*, if it contains no universal set quantification of the form $\forall X.\psi$, and whenever φ contains a universal first-order quantification $\forall x.\psi$, then $\llbracket \psi \rrbracket$ is a recognizable step function. We let $\text{RMSO}(K, A)$ comprise all restricted formulas of $\text{MSO}(K, A)$. Furthermore, let $\text{REMSO}(K, A)$ contain all restricted *existential* MSO-formulas φ , i.e. φ is of the form $\varphi = \exists X_1, \dots, X_n.\psi$ with $\psi \in \text{RMSO}(K, A)$ containing no set quantification.

We let $K^{\text{rmso}}\langle\langle A^* \rangle\rangle$ (resp. $K^{\text{remso}}\langle\langle A^* \rangle\rangle$) contain all series $S \in K\langle\langle A^* \rangle\rangle$ which are definable by some sentence in $\text{RMSO}(K, A)$ (resp. in $\text{REMSO}(K, A)$). The main result of this paper is the following theorem. It will be proved in sections 4 and 5.

Theorem 3.5. *Let K be a commutative semiring and A an alphabet. Then*

$$K^{\text{rec}}\langle\langle A^* \rangle\rangle = K^{\text{rmso}}\langle\langle A^* \rangle\rangle = K^{\text{remso}}\langle\langle A^* \rangle\rangle.$$

4 Definable Series Are Recognizable

In all of this section, let K be a semiring and A an alphabet. We wish to show that if K is commutative, then all RMSO-definable series $\llbracket \varphi \rrbracket$ over K and A are recognizable. We proceed by induction over the structure of RMSO-formulas.

Lemma 4.1. *Let $\varphi, \psi \in \text{MSO}(K, A)$.*

- (a) *If φ is atomic or the negation of an atomic formula, then $\llbracket \varphi \rrbracket$ is recognizable.*
- (b) *If $\llbracket \varphi \rrbracket$ and $\llbracket \psi \rrbracket$ are recognizable, then $\llbracket \varphi \vee \psi \rrbracket$ is recognizable. If in addition K is commutative, then $\llbracket \varphi \wedge \psi \rrbracket$ is also recognizable.*
- (c) *If $\llbracket \varphi \rrbracket$ is recognizable, then $\llbracket \exists x.\varphi \rrbracket$ and $\llbracket \exists X.\varphi \rrbracket$ are recognizable series.*

Proof (sketch). (a) Automata with behavior $\llbracket \varphi \rrbracket$ can easily be given explicitly.

(b) Let $\mathcal{V} = \text{Free}(\varphi) \cup \text{Free}(\psi)$. By definition, we have $\llbracket \varphi \vee \psi \rrbracket = \llbracket \varphi \rrbracket_{\mathcal{V}} + \llbracket \psi \rrbracket_{\mathcal{V}}$ and $\llbracket \varphi \wedge \psi \rrbracket = \llbracket \varphi \rrbracket_{\mathcal{V}} \odot \llbracket \psi \rrbracket_{\mathcal{V}}$. Hence the result follows from Proposition 3.2 and since sum and Hadamard product preserve recognizability of series [8, 2].

(c) Let $\mathcal{V} = \text{Free}(\exists X.\varphi)$ and consider the projection $\pi : A_{\mathcal{V} \cup \{X\}}^* \rightarrow A_{\mathcal{V}}^*$. We can show that $\llbracket \exists X.\varphi \rrbracket(w, \sigma) = \pi(\llbracket \varphi \rrbracket_{\mathcal{V} \cup \{X\}})(w, \sigma)$. Now, $\llbracket \varphi \rrbracket_{\mathcal{V} \cup \{X\}}$ is recognizable by Proposition 3.2 and since non-erasing projections preserve recognizability we get $\llbracket \exists X.\varphi \rrbracket$ recognizable. The case $\exists x.\varphi$ can be dealt with similarly. \square

The most interesting and new case here arises from universal quantification.

Lemma 4.2. *Let K be commutative and $\varphi \in \text{MSO}(K, A)$ such that $\llbracket \varphi \rrbracket$ is a recognizable step function. Then $\llbracket \forall x.\varphi \rrbracket$ is recognizable.*

Proof. Let $\mathcal{W} = \text{Free}(\varphi)$ and $\mathcal{V} = \text{Free}(\forall x.\varphi) = \mathcal{W} \setminus \{x\}$. We may write $\llbracket \varphi \rrbracket = \sum_{j=1, \dots, n} k_j \cdot \mathbf{1}_L$ with $n \in \mathbb{N}$, $k_j \in K$ and recognizable languages $L_j \subseteq A_{\mathcal{W}}^*$ ($j = 1, \dots, n$) forming a partition of $A_{\mathcal{W}}^*$.

First, we assume that $x \in \mathcal{W}$. Let $\tilde{A} = A \times \{1, \dots, n\}$. A word in $(\tilde{A}_{\mathcal{V}})^*$ will be written (w, ν, σ) where $(w, \sigma) \in A_{\mathcal{V}}^*$ and $\nu \in \{1, \dots, n\}^*$ is interpreted as a mapping from $\{1, \dots, |w|\}$ to $\{1, \dots, n\}$. Let \tilde{L} be the set of $(w, \nu, \sigma) \in (\tilde{A}_{\mathcal{V}})^*$ such that for all $i \in \{1, \dots, |w|\}$ and $j \in \{1, \dots, n\}$ we have $\nu(i) = j$ implies $(w, \sigma[x \rightarrow i]) \in L_j$. Observe that for each $(w, \sigma) \in A_{\mathcal{V}}^*$ there is a unique ν such that $(w, \nu, \sigma) \in \tilde{L}$ since the L_j form a partition of $A_{\mathcal{W}}^*$.

It can be shown that \tilde{L} is a recognizable word language. Hence there is a deterministic automaton $\tilde{\tilde{A}}$, with state set Q , say, recognizing \tilde{L} . Now we obtain

a weighted automaton \mathcal{A} with the same state set by adding weights to the transitions of $\tilde{\mathcal{A}}$ as follows: If $(p, (a, j, s), q)$ is a transition in $\tilde{\mathcal{A}}$ with $p, q \in Q$, $(a, s) \in A_{\mathcal{V}}$ and $1 \leq j \leq n$, we let this transition in \mathcal{A} have weight k_j , i.e. $\mu_{\mathcal{A}}(a, j, s)_{p,q} = k_j$. All triples which are not transitions in $\tilde{\mathcal{A}}$ get weight 0. Also, the initial state of $\tilde{\mathcal{A}}$ gets initial weight 1 in \mathcal{A} , all non-initial states of $\tilde{\mathcal{A}}$ get initial weight 0, and similarly for the final states and final weights.

Clearly, since $\tilde{\mathcal{A}}$ is deterministic and accepts \tilde{L} , the weight of $(w, \nu, \sigma) \in \tilde{L}$ in \mathcal{A} is $\prod_{1 \leq j \leq n} k_j^{|\nu^{-1}(j)|}$, and the weight of $(w, \nu, \sigma) \in \tilde{A}^* \setminus \tilde{L}$ in \mathcal{A} is 0. Now let $h : (\tilde{A}_{\mathcal{V}})^* \rightarrow A_{\mathcal{V}}^*$ be the projection mapping (w, ν, σ) to (w, σ) . Then for any $(w, \sigma) \in A_{\mathcal{V}}^*$ and the unique ν such that $(w, \nu, \sigma) \in \tilde{L}$ we obtain

$$h(\|\mathcal{A}\|)(w, \sigma) = \sum_{\rho} \|\mathcal{A}\|(w, \rho, \sigma) = \|\mathcal{A}\|(w, \nu, \sigma) = \prod_{1 \leq j \leq n} k_j^{|\nu^{-1}(j)|}.$$

Now we have

$$\llbracket \forall x. \varphi \rrbracket (w, \sigma) = \prod_{1 \leq i \leq |w|} \llbracket \varphi \rrbracket (w, \sigma[x \rightarrow i]) = \prod_{1 \leq j \leq n} k_j^{|\nu^{-1}(j)|}$$

where the last equality holds due to the form of φ . Hence $\llbracket \forall x. \varphi \rrbracket = h(\|\mathcal{A}\|)$ which is recognizable [8, 2].

Now assume that $x \notin \mathcal{W}$, so that $\mathcal{V} = \mathcal{W}$. Let $\varphi' = \varphi \wedge (x \leq x)$. So $\llbracket \varphi' \rrbracket$ is recognizable by Lemma 4.1, and clearly $\llbracket \varphi \rrbracket_{\mathcal{V} \cup \{x\}} = \llbracket \varphi' \rrbracket_{\mathcal{V} \cup \{x\}}$. Thus $\llbracket \forall x. \varphi \rrbracket_{\mathcal{V}} = \llbracket \forall x. \varphi' \rrbracket_{\mathcal{V}}$ which is recognizable by what we showed above. \square

Now the following result is immediate by Lemmata 4.1 and 4.2.

Theorem 4.3. *Let K be a commutative semiring, A an alphabet and $\varphi \in \text{RMSO}(K, A)$. Then $\llbracket \varphi \rrbracket \in K^{\text{rec}} \langle\langle A^* \rangle\rangle$ is recognizable.*

Next we turn to decidability questions. Employing decidability results from the theory of formal power series and our previous constructions, we can show:

Proposition 4.4. *Let K be a computable field, and let $\varphi \in \text{MSO}(K, A)$. It is decidable whether φ is restricted, and in this case one can effectively compute a weighted automaton \mathcal{A}_{φ} for $\llbracket \varphi \rrbracket$.*

Corollary 4.5. *Let K be a computable field, and let $\varphi, \psi \in \text{RMSO}(K, A)$. Then it is decidable whether $\llbracket \varphi \rrbracket = \llbracket \psi \rrbracket$. It is also decidable whether $\llbracket \varphi \rrbracket$ and $\llbracket \psi \rrbracket$ differ only for finitely many words.*

Proof. By Proposition 4.4, the series $\llbracket \varphi \rrbracket, \llbracket \psi \rrbracket$ and hence also $\llbracket \varphi \rrbracket - \llbracket \psi \rrbracket = \llbracket \varphi \rrbracket + (-1) \cdot \llbracket \psi \rrbracket$ are effectively recognizable. By [2–Propositions VI.1.1, VI.1.2], it is decidable whether such a series equals 0, or whether its support is finite. \square

5 Recognizable Series Are Definable

In all of this section let K be a semiring and A an alphabet. We wish to show that if K is commutative, then all recognizable series are REMSO-definable. For this, the concept of an unambiguous MSO-formula will be useful. The class of *unambiguous* formulas in $\text{MSO}(K, A)$ is defined inductively as follows: All atomic formulas of the form $P_a(x)$, $x \leq y$ or $(x \in X)$, and their negations are unambiguous. If φ, ψ are unambiguous, then $\varphi \wedge \psi$, $\forall x.\varphi$ and $\forall X.\varphi$ are also unambiguous. If φ, ψ are unambiguous and $\text{Supp}(\llbracket \varphi \rrbracket) \cap \text{Supp}(\llbracket \psi \rrbracket) = \emptyset$, then $\varphi \vee \psi$ is unambiguous. Let φ be unambiguous and $\mathcal{V} = \text{Free}(\varphi)$. If for any $(w, \sigma) \in A_{\mathcal{V}}^*$ there is at most one element $i \in \{1, \dots, |w|\}$ such that $\llbracket \varphi \rrbracket_{\mathcal{V} \cup \{x\}}(w, \sigma[x \rightarrow i]) \neq 0$, then $\exists x.\varphi$ is unambiguous. If for any $(w, \sigma) \in A_{\mathcal{V}}^*$, there is at most one subset $I \subseteq \{1, \dots, |w|\}$ such that $\llbracket \varphi \rrbracket_{\mathcal{V} \cup \{X\}}(w, \sigma[X \rightarrow I]) \neq 0$, then $\exists X.\varphi$ is unambiguous.

Proposition 5.1. *Let $\varphi \in \text{MSO}(K, A)$ be unambiguous. We may also regard φ as a classical MSO-formula defining the language $\mathcal{L}(\varphi) \subseteq A_{\varphi}^*$. Then, $\llbracket \varphi \rrbracket = \mathbf{1}_{\mathcal{L}(\varphi)}$ is a recognizable step function.*

Next we show that, conversely, classical MSO-formulas can be transformed into unambiguous formulas.

Lemma 5.2. *For each classical MSO-formula φ not containing set quantifications (but possibly including atomic formulas of the form $(x \in X)$) we can effectively construct two unambiguous MSO(K, A)-formula φ^+ and φ^- such that $\llbracket \varphi^+ \rrbracket = \mathbf{1}_{\mathcal{L}(\varphi)}$ and $\llbracket \varphi^- \rrbracket = \mathbf{1}_{\mathcal{L}(\neg\varphi)}$.*

Proof (sketch). We may assume (using also conjunction and universal quantification in our syntax or as abbreviations) that in φ negations are applied only to atomic formulas. Now we proceed by induction, giving only the formulas for some cases: $(\varphi \vee \psi)^- = \varphi^- \wedge \psi^-$, $(\varphi \vee \psi)^+ = \varphi^+ \vee (\varphi^- \wedge \psi^+)$, $(\exists x.\varphi)^- = \forall x.\varphi^-$ and $(\exists x.\varphi)^+ = \exists x.(\varphi^+(x) \wedge \forall y.((x \leq y) \vee (\neg(x \leq y) \wedge \varphi^-(y))))$. \square

Theorem 5.3. *Let K be commutative. Then $K^{\text{rec}}\langle\langle A^* \rangle\rangle \subseteq K^{\text{remso}}\langle\langle A^* \rangle\rangle$.*

Proof (sketch). Let $\mathcal{A} = (Q, \lambda, \mu, \gamma)$ be a weighted automaton over A . For each triple $(p, a, q) \in Q \times A \times Q$ choose a set variable $X_{p,a,q}$, and let $\mathcal{V} = \{X_{p,a,q} \mid p, q \in Q, a \in A\}$. We choose an enumeration X_1, \dots, X_m of \mathcal{V} with $m = |Q|^2 \cdot |A|$. In the formulas below we use classical macros such as $\text{partition}(X_1, \dots, X_m)$, $(y = x + 1)$, $\min(y)$ and $\max(y)$. Define the unambiguous formula

$$\begin{aligned} \psi(X_1, \dots, X_m) := & \text{partition}(X_1, \dots, X_m)^+ \wedge \bigwedge_{p,a,q} \forall x.((x \in X_{p,a,q}) \rightarrow P_a(x))^+ \\ & \wedge \forall x \forall y. \left((y = x + 1) \rightarrow \bigvee_{p,q,r \in Q, a,b \in A} (x \in X_{p,a,q}) \wedge (y \in X_{q,b,r}) \right)^+. \end{aligned}$$

Let $w = a_1 \dots a_n \in A^+$. One can show that there is a bijection between the set of paths in \mathcal{A} over w and the set of (w, \mathcal{V}) -assignments σ satisfying ψ . Consider now the formula $\varphi(X_1, \dots, X_m)$ defined by

$$\psi(X_1, \dots, X_m) \wedge \left(\bigwedge_{p,a,q} \forall x. (\neg(x \in X_{p,a,q}) \vee ((x \in X_{p,a,q}) \wedge \mu(a)_{p,q})) \right) \wedge \exists y. \left(\min(y) \wedge \bigvee_{p,a,q} (y \in X_{p,a,q}) \wedge \lambda_p \right) \wedge \exists z. \left(\max(z) \wedge \bigvee_{p,a,q} (z \in X_{p,a,q}) \wedge \gamma_q \right).$$

Let ρ be a path in \mathcal{A} over w and let σ_ρ be the associated (w, \mathcal{V}) -assignment. We can show that $\llbracket \varphi \rrbracket_{\mathcal{V}}(w, \sigma_\rho) = \text{weight}(\rho)$. Let $\xi = \exists X_1 \dots \exists X_m. \varphi(X_1, \dots, X_m)$. For $w \in A^+$ we can show that $(\llbracket \xi \rrbracket, w) = (\|\mathcal{A}\|, w)$. Let $\zeta = (\lambda \cdot \gamma) \wedge \forall x. \neg(x \leq x)$. Then, $\|\mathcal{A}\| = \llbracket \zeta \vee \xi \rrbracket \in K^{\text{remso}}\langle\langle A^* \rangle\rangle$. □

Now Theorem 3.5 is immediate by Theorems 4.3 and 5.3.

Observe that the proof of Theorem 5.3 is constructive, i.e. given a weighted automaton \mathcal{A} , we effectively obtain an REMSO(K, A)-sentence φ with $\llbracket \varphi \rrbracket = \|\mathcal{A}\|$. Using this, from the theory of formal power series (cf. [21, 15, 2]) we immediately obtain undecidability results for the semantics of weighted MSO-sentences. For instance, it is undecidable whether a given REMSO-sentence φ over \mathbb{Q} , the field of rational numbers, and an alphabet A , satisfies $\text{Supp}(\llbracket \varphi \rrbracket) = A^*$. Also, by a result of Krob [14], the equality of given recognizable series over the tropical semiring is undecidable. Hence, the equality of two given REMSO(Trop, A)-sentences is also undecidable.

6 Locally Finite Semirings

In section 3 we gave examples of semirings K showing that the results of Theorem 3.5 and 4.3 in general do not hold for arbitrary MSO(K, A)-sentences. In contrast, here we wish to show that for a large class of semirings K , all MSO(K, A)-formulas have a recognizable semantics.

A semiring K is called *locally finite*, if each finitely generated subsemiring of K is finite. For example, any Boolean algebra $(B, \vee, \wedge, 0, 1)$ is locally finite. The max-min semiring $\mathbb{R}_{\max, \min} = (\mathbb{R}_+ \cup \{\infty\}, \max, \min, 0, \infty)$ of positive reals, used in operations research for maximum capacity problems of networks, is locally finite. In fact, more generally, any distributive lattice $(L, \vee, \wedge, 0, 1)$ with smallest element 0 and largest element 1 is a locally finite semiring, cf. [6] for further basic properties. Examples of infinite but locally finite fields are provided by the algebraic closures of the finite fields $\mathbf{Z}/p\mathbf{Z}$ for any prime p . We can show (see [7]):

Theorem 6.1. *Let K be a locally finite commutative semiring and A an alphabet. Then $K^{\text{rec}}\langle\langle A^* \rangle\rangle = K^{\text{mso}}\langle\langle A^* \rangle\rangle$.*

Again, given an MSO(K, A)-formula φ , we can effectively construct a weighted automaton \mathcal{A} over K and A_φ such that $\|\mathcal{A}\| = \llbracket \varphi \rrbracket$. As a consequence of this and of corresponding decidability results given in the full version of [6] for recognizable series over locally finite semirings, we immediately obtain:

Corollary 6.2. *Let K be a locally finite commutative semiring and A an alphabet. It is decidable whether two given MSO(K, A)-formulas φ and ψ satisfy $\llbracket \varphi \rrbracket = \llbracket \psi \rrbracket$; whether a given MSO(K, A)-formula φ satisfies $\text{Supp}(\llbracket \varphi \rrbracket) = A_\varphi^*$.*

7 Weighted First-Order Logic

In this section, we investigate weighted first-order logic and the relationship to aperiodic series. Most of our results will require additional assumptions on the semiring K .

Let K be a semiring and A an alphabet. A formula $\varphi \in \text{MSO}(K, A)$ is called a (weighted) first-order formula, if φ does not contain any set variable. We let $\text{FO}(K, A)$ contain all first-order formulas and $\text{RFO}(K, A)$ all restricted first-order formulas over K and A . The collections of series definable by these formulas are denoted $K^{fo}\langle\langle A^* \rangle\rangle$ and $K^{rfo}\langle\langle A^* \rangle\rangle$, respectively.

As is well-known, the first-order definable languages are precisely the starfree languages which in turn coincide with the aperiodic ones [23, 18]. Aperiodic and starfree formal power series were introduced and investigated in [6]. Recall that a monoid M is said to be *aperiodic*, if there exists some $m \geq 0$ such that $x^m = x^{m+1}$ for all $x \in M$. We call a monoid M *weakly aperiodic*, if for each $x \in M$ there exists $m \geq 0$ such that $x^m = x^{m+1}$. Clearly, a finite monoid is aperiodic iff it is weakly aperiodic.

A series $S : A^* \rightarrow K$ is called *aperiodic*, if there exists a representation $S = (Q, \lambda, \mu, \gamma)$ with $\mu(A^*)$ aperiodic. Observe that then there exists some $m \geq 0$ such that for all $w \in A^*$ we have $\mu(w^m) = \mu(w^{m+1})$ and hence $(S, w^m) = (S, w^{m+1})$. The collection of all aperiodic series over K and A will be denoted $K^{aper}\langle\langle A^* \rangle\rangle$.

Now we turn to the relationship between aperiodic and FO-definable series. First we show that even if K is finite and commutative, in general we do not have $K^{aper}\langle\langle A^* \rangle\rangle = K^{fo}\langle\langle A^* \rangle\rangle$.

Example 7.1. Let $K = \mathbb{Z}/2\mathbb{Z}$, the field with two elements, and $S = [\exists x.1]$. Then $S(w) = |w| \pmod 2$ for any $w \in A^*$. Hence S is not aperiodic since otherwise we would obtain some $m \geq 1$ such that $S(a^m) = S(a^{m+1})$ ($a \in A$), a contradiction. Note that here the monoid (K, \cdot) is idempotent, and $(K, +)$ is not aperiodic.

Example 7.2. Let K be the tropical semiring and $T = [\forall x.1]$. Then $T(w) = |w|$ for all $w \in A^*$, so T is not aperiodic. Note that $(\mathbb{N} \cup \{-\infty\}, \max)$ is idempotent, but $(\mathbb{N} \cup \{-\infty\}, +)$ is not weakly aperiodic.

These examples indicate that in order to achieve the inclusion $K^{fo}\langle\langle A^* \rangle\rangle \subseteq K^{aper}\langle\langle A^* \rangle\rangle$, we need some aperiodicity assumption both for $(K, +)$ and (K, \cdot) .

We call a semiring K *weakly bi-aperiodic*, if both $(K, +)$ and (K, \cdot) are weakly aperiodic. If K is also commutative, then in particular K is locally finite. Clearly, any idempotent monoid is weakly aperiodic. Thus the weakly bi-aperiodic semirings include all semirings in which both addition and multiplication are idempotent, and this class of semirings properly contains (cf. [10]) the class of all distributive lattices $(L, \vee, \wedge, 0, 1)$ with smallest element 0 and greatest element 1. There are further examples:

Example 7.3. Let $0 < d \in \mathbb{R}$. We let \mathbb{R}_{\max}^d be the real max-plus semiring truncated at d , i.e. $\mathbb{R}_{\max}^d = ([0, d] \cup \{-\infty\}, \max, +_d, -\infty, 0)$ with $x +_d y := x + y$

if $x + y \leq d$, and $x +_d y := d$ if $x + y \geq d$. This semiring is weakly bi-aperiodic, and $(\mathbb{R}_{\max}^d, +_d)$ is weakly aperiodic but not aperiodic.

We can show (see [7]):

Theorem 7.4. *Let K be a commutative weakly bi-aperiodic semiring, and A an alphabet. Then $K^{aper}\langle\langle A^* \rangle\rangle = K^{fo}\langle\langle A^* \rangle\rangle = K^{rfo}\langle\langle A^* \rangle\rangle$.*

Abstract. We obtain a logical characterization of an important class of regular languages, denoted \mathcal{DO} , and of its most important subclasses in terms of two-variable sentences with ordinary and modular quantifiers but in which all modular quantifiers lie outside the scope of ordinary quantifiers. The result stems from a new decomposition of the variety of monoids \mathbf{DO} in terms of iterated block products.

This decomposition and the ensuing logical characterization allows us to shed new light on recent results on regular languages which are recognized by bounded-depth circuits with a linear number of wires and regular languages with small communication complexity.

1 Introduction

Descriptive complexity uses logical sentences to define languages. For instance, one can view the sentence

$$\exists x \exists y \exists z (x < y < z \wedge Q_a x \wedge Q_b y \wedge Q_c z)$$

as defining the set of words in which there are positions x, y, z with $x < y < z$ holding the letters a, b and c respectively, i.e. the set $\Sigma^* a \Sigma^* b \Sigma^* c \Sigma^*$. A large amount of research has sought to understand the expressive power of such sentences. In particular, the celebrated result of McNaughton and Papert [6] shows that languages definable by a first-order sentence which, as the one above, use only the order predicate $<$ are exactly the star-free regular languages. By a result of Schützenberger, these are also the regular languages recognizable by an aperiodic (or group-free) monoid and we can thus decide whether a language is **FO** definable. Kamp [4] further showed that these **FO** sentences could be restricted to use only three variables (provided that they can be reused). Much later, Thérien and Wilke characterized languages definable by **FO** formulas using only *two* variables (**FO**₂) [16] as languages recognized by monoids in **DA**.

* Part of this research took place while the author was at the University of Tübingen, supported by the von Humboldt Foundation.

** Research supported in part by NSERC, FQRNT and the von Humboldt Foundation.

When **FO** is augmented with modular quantifiers (checking whether a property holds for $i \pmod p$ of the positions in the string), all languages recognizable by solvable monoids can further be described. In this case too, three variables suffice to obtain full expressivity. The power of **FO + MOD** two-variable sentences was studied in [11, 12] and the results depended crucially on showing that every such sentence was equivalent to one where no ordinary quantifier occurs within the scope of a modular quantifier. In this paper, we handle the other extreme case, that is sentences in which no modular quantifier lies in the scope of an ordinary quantifier. This restriction is meaningful since we show that these are provably less expressive than general two-variable sentences and can provide a logical characterization for important subclasses of regular languages.

The key to our new results is a decomposition of the variety of monoids **DO** (precise definitions will be given in Section 2) in terms of weakly-iterated block products, an idea put forward in [12]. That result is interesting in its own right but our motivation comes from two recent results in complexity theory. We show that a regular language is definable by a two-variable sentence in which no modular quantifier lies in the scope of another quantifier iff it is recognized by a monoid in the class $\mathbf{DO} \cap \overline{\mathbf{Ab}}$. This happens to be *precisely* the class of regular languages that can be recognized by ACC^0 -circuits with a linear number of wires [5] and by $O(\log n)$ -cost communication protocols [15]. In contrast, languages defined by a two-variable sentence without this restriction can be computed by ACC^0 -circuits using a linear number of *gates* and we believe that they are the only regular languages with this property. The logical characterization of languages recognized by monoids in $\mathbf{DO} \cap \overline{\mathbf{Ab}}$ sheds new light on the circuit complexity and communication complexity upper bounds, highlighting the interplay between logic, algebra, complexity and formal languages in this context.

In Section 2, we introduce the algebraic tools needed for our discussion. In Section 3, we decompose subvarieties of **DO** using weakly iterated block-products and use this to obtain a logical characterization of the corresponding regular languages in Section 4. Finally, we discuss the applications of these results to circuit complexity and communication complexity in Section 5.

2 Finite Monoids and Regular Languages

We sketch here the algebraic background needed for our discussion. For a more thorough overview of algebraic automata theory, we refer the reader to e.g. [7]. A *monoid* M is a set with a binary associative operation (which we denote multiplicatively) and a distinguished identity element 1_M . For an alphabet Σ , the set of finite words Σ^* forms a monoid under concatenation and with identity element ϵ . For a finite monoid M and language $K \subseteq \Sigma^*$, we say that K is recognized by M if there exists a homomorphism $h : \Sigma^* \rightarrow M$ and a subset $T \subseteq M$ such that $K = h^{-1}(T)$. A simple variant of Kleene's Theorem states that a language is regular iff it can be recognized by some finite monoid. In fact, all monoids considered in this paper, with the exception of the free monoid Σ^* , will be finite. It is useful to point out that if K and K' are recognized by M and

M' respectively then K 's complement is recognized by M and both $K \cup K'$ and $K \cap K'$ are recognized by $M \times M'$.

A class of finite monoids is a *variety* if it is closed under direct product, homomorphic images and submonoids. In particular, we will deal with the variety of solvable groups \mathbf{G}_{sol} , p -groups \mathbf{G}_p , Abelian groups \mathbf{Ab} , Abelian p -groups \mathbf{Ab}_p , aperiodic or group-free monoids \mathbf{A} , semilattices \mathbf{SL} , i.e. monoids satisfying $x^2 = x$ and $xy = yx$, and the variety \mathbf{DO} of monoids M which satisfy the identity $(xy)^\omega(yx)^\omega(xy)^\omega = (xy)^\omega$ for all $x, y \in M$. In fact, ω can be chosen as the smallest integer such that $x^{2\omega} = x^\omega$ for all $x \in M$.

Furthermore, for any variety of groups \mathbf{H} , we denote as $\overline{\mathbf{H}}$ the variety of monoids whose subgroups all lie in \mathbf{H} . For any variety \mathbf{V} of monoids, we will denote as $L(\mathbf{V})$ the class of languages that can be recognized by a monoid of \mathbf{V} . These *varieties of languages* are fairly robust and in particular are closed under Boolean operations. We focus on varieties of the form $\mathbf{DO} \cap \overline{\mathbf{H}}$ and we give here a description of the corresponding regular languages.

We say that words $x, y \in \Sigma^*$ are M -equivalent if $h(x) = h(y)$ for any homomorphism $h : \Sigma^* \rightarrow M$. Let $\alpha(x) \subseteq \Sigma$ be the set of letters occurring in x . For $a \in \alpha(x)$, the *a-left decomposition* of x is the factorization $x = x_0ax_1$ with $a \notin \alpha(x_0)$. The *a-right decomposition* is defined symmetrically. For a finite group G we define the congruence $\sim_{n,k}^G$ on Σ^* with $|\Sigma| = n$ by induction on $n + k$. First, $x \sim_{n,0}^G y$ iff x, y are G -equivalent. Next, we let $x \sim_{n,k}^G y$ iff:

1. $x \sim_{n,k-1}^G y$;
2. $\alpha(x) = \alpha(y)$;
3. For any $a \in \alpha(x) = \alpha(y)$, if $x = x_0ax_1$ and $y = y_0ay_1$ are the a -left decompositions of x and y then $x_0 \sim_{n-1,k}^G y_0$ and $x_1 \sim_{n,k-1}^G y_1$;
4. For any $a \in \alpha(x) = \alpha(y)$, if $x = x_0ax_1$ and $y = y_0ay_1$ are the a -right decompositions of x and y then $x_0 \sim_{n,k-1}^G y_0$ and $x_1 \sim_{n-1,k}^G y_1$.

This equivalence relation is well-defined since $|\alpha(x_0)| < |\alpha(x)|$ in (3) and $|\alpha(x_1)| < |\alpha(x)|$ in (4). These congruences allow us to describe languages in $L(\mathbf{DO} \cap \overline{\mathbf{H}})$ and this will be crucial in the proof of Theorem 3.

Theorem 1 ([15]). *Let K be a language in Σ^* with $|\Sigma| = n$. Then K is in $L(\mathbf{DO} \cap \overline{\mathbf{H}})$ iff K is the union of $\sim_{n,k}^G$ -classes for some $k \in \mathbb{N}$ and $G \in \mathbf{H}$.*

The following simple fact will also prove useful for Theorem 3 and Lemma 4:

Lemma 1 (e.g. [7]). *A language $K \in \Sigma^*$ can be recognized by a semilattice iff it is in the Boolean algebra generated by the languages $\Sigma^*a\Sigma^*$. Furthermore, u, v are M -equivalent for any semilattice M iff $\alpha(u) = \alpha(v)$.*

Let M and N be finite monoids. As in [11] we denote the operation of M as $+$ and its identity element as 0 to distinguish it from the operation of N . A left-action of N on M is a function mapping pairs $(n, m) \in N \times M$ to $nm \in M$ and satisfying $n(m_1 + m_2) = nm_1 + nm_2$, $n_1(n_2m) = (n_1n_2)m$, $n0 = 0$ and $1m = m$. Right actions are defined symmetrically. If we have both a right and a left-action of N on M that further satisfy $n_1(mn_2) = (n_1m)n_2$, we can construct the

bilateral semidirect product $M ** N$ which we define as the monoid with elements in $M \times N$ and multiplication defined as $(m_1, n_1)(m_2, n_2) = (m_1 n_2 + n_1 m_2, n_1 n_2)$. This operation is associative and $(0, 1)$ acts as an identity for it.

For varieties \mathbf{V}, \mathbf{W} , we denote $\mathbf{V} \square \mathbf{W}$ the variety generated by all semidirect products $M * * N$ with $M \in \mathbf{V}$, $N \in \mathbf{W}$. For varieties $\mathbf{U}, \mathbf{V}, \mathbf{W}$ we always have $(\mathbf{U} \square \mathbf{V}) \square \mathbf{W} \subseteq \mathbf{U} \square (\mathbf{V} \square \mathbf{W})$ but the containment is strict in general. Block-product decompositions of varieties traditionally use the stronger bracketing but [11] showed the relevance of the weak bracketing, particularly in relation to two-variable logical sentences.

The languages recognized by $\mathbf{V} \square \mathbf{W}$ can be conveniently described in terms of languages recognized by \mathbf{V} and \mathbf{W} . For a monoid $N \in \mathbf{W}$, an N -transduction τ is a function determined by two homomorphisms $h_l, h_r : \Sigma^* \rightarrow N$ and mapping words in Σ^* to words in $(N \times \Sigma \times N)^*$. For a word $w = w_1 \dots w_n \in \Sigma^*$ we set $\tau(w) = \tau(w_1)\tau(w_2) \dots \tau(w_n)$ with $\tau(w_i) = (h_l(w_1 \dots w_{i-1}), w_i, h_r(w_{i+1} \dots w_n))$. For a language $K \subseteq (N \times \Sigma \times N)^*$, let $\tau^{-1}(K) = \{w \in \Sigma^* : \tau(w) \in K\}$.

Theorem 2. [9, 7] *A regular language lies in $L(\mathbf{V} \square \mathbf{W})$ iff it is the Boolean combination of languages in $L(\mathbf{W})$ and languages $\tau^{-1}(K)$ for some $K \in \mathbf{V}$ and N -transduction τ with $N \in \mathbf{W}$.*

A *pointed word* is a pair (w, p) consisting of a word $w \in \Sigma^*$ and a pointer p with $1 \leq p \leq |w|$. A *pointed language* \bar{K} is a set of such structures and, as in [17], we extend the notion of monoid recognizability to these languages: \bar{K} is recognized by M if there are homomorphisms $h_l, h_r : \Sigma^* \rightarrow M$ and a set of triples $T \subseteq (M \times \Sigma \times M)$ such that $\bar{K} = \{(w, p) : (h_l(w_1 \dots w_{p-1}), w_p, h_r(w_{p+1} \dots w_{|w|})) \in T\}$. For a variety \mathbf{V} we will denote as $P(\mathbf{V})$ the set of pointed languages recognized by a monoid in \mathbf{V} . Abusing our terminology, it will be convenient to think of ordinary words in Σ^* as pointed words with $p = 0$ and thus view $L(\mathbf{V})$ as a subset of $P(\mathbf{V})$.

3 A Weak Block Product Decomposition of DO

In this section, we characterize each variety $\mathbf{DO} \cap \bar{\mathbf{H}}$ for a variety of groups \mathbf{H} using weakly iterated block products. The idea is similar to that of [11] but we also need the combinatorial description of the corresponding regular languages.

Theorem 3. *Let \mathbf{H} be a variety of finite groups, and $\mathbf{V}_{\mathbf{H}}$ be the smallest variety such that $\mathbf{H} \subseteq \mathbf{V}_{\mathbf{H}}$ and $\mathbf{V}_{\mathbf{H}} \square \mathbf{SL} \subseteq \mathbf{V}_{\mathbf{H}}$, then $\mathbf{V}_{\mathbf{H}} = \mathbf{DO} \cap \bar{\mathbf{H}}$.*

Proof. Clearly, $\mathbf{DO} \cap \bar{\mathbf{H}}$ contains \mathbf{H} and we also need to show that it is closed under block product with \mathbf{SL} . First, we claim that $\mathbf{DO} \square \mathbf{SL} = \mathbf{DO}$. Let $M \in \mathbf{DO}$ and $N \in \mathbf{SL}$. As we did earlier, we denote the multiplication of M additively (even though M is not necessarily commutative). Since $M \in \mathbf{DO}$ there exists an integer k such that $k(v + w) + k(w + v) + k(v + w) = k(v + w)$ and $(2k)v = kv$ for all $v, w \in M$ and we prove that any bilateral semidirect product $M * * N$ satisfies the identity $(xy)^{2k}(yx)^{2k}(xy)^{2k} = (xy)^{2k}$.

Let $x = (m_1, n_1)$ and $y = (m_2, n_2)$ be arbitrary elements of $M * * N$. By definition of the bilateral semidirect product, we have $xy = (m_1n_2 + n_1m_2, n_1n_2)$ and so $(xy)^{2k} = (z, (n_1n_2)^{2k})$ where

$$z = m_1n_2(n_1n_2)^{2k-1} + n_1m_2(n_1n_2)^{2k-1} + \dots + (n_1n_2)^{2k-1}n_1m_2$$

Since N is commutative and idempotent ($n^2 = n$), this is simply:

$$\begin{aligned} z &= m_1(n_1n_2) + n_1m_2(n_1n_2) + \dots + (n_1n_2)m_2 \\ &= m_1(n_1n_2) + n_1m_2(n_1n_2) + (2k - 1) [(n_1n_2)m_1(n_1n_2) + (n_1n_2)m_2(n_1n_2)] \\ &\quad + (n_1n_2)m_2n_1 + (n_1n_2)m_2 \end{aligned}$$

By the same argument $(xy)^{2k}(yx)^{2k}(xy)^{2k}$ is the pair (z', n_1n_2) with

$$\begin{aligned} z' &= m_1(n_1n_2) + n_1m_2(n_1n_2) + (2k - 1) [(n_1n_2)m_1(n_1n_2) + (n_1n_2)m_2(n_1n_2)] \\ &\quad + (2k) [(n_1n_2)m_2(n_1n_2) + (n_1n_2)m_1(n_1n_2)] \\ &\quad + (2k - 1) [(n_1n_2)m_1(n_1n_2) + (n_1n_2)m_2(n_1n_2)] + (n_1n_2)m_2n_1 + (n_1n_2)m_2. \end{aligned}$$

If we let $v = (n_1n_2)m_1(n_1n_2)$ and $w = (n_1n_2)m_2(n_1n_2)$, then the middle part of the product is simply $(2k - 1)(v + w) + 2k(w + v) + (2k - 1)(v + w)$ and since M satisfies $k(v + w) + k(w + v) + k(v + w) = k(v + w)$ and $(2k)v = kv$, this sum is equal to $(k - 1)(v + w) + k(v + w) + (k - 1)(v + w) = (3k - 2)(v + w) = (2k - 2)(v + w)$. This gives

$$\begin{aligned} z' &= m_1(n_1n_2) + n_1m_2(n_1n_2) + (2k - 2) [(n_1n_2)m_1(n_1n_2) \\ &\quad + (n_1n_2)m_2(n_1n_2)] + (n_1n_2)m_2n_1 + (n_1n_2)m_2 \\ &= z \end{aligned}$$

and so $(xy)^{2k}(yx)^{2k}(xy)^{2k} = (xy)^{2k}$ as claimed.

Furthermore, folklore results show that if the variety \mathbf{W} is aperiodic (i.e. contains no non-trivial groups), then for any variety \mathbf{V} the groups lying in $\mathbf{V} \square \mathbf{W}$ are exactly those in \mathbf{V} . In particular, \mathbf{SL} is aperiodic so $(\mathbf{DO} \cap \overline{\mathbf{H}}) \square \mathbf{SL} \subseteq \overline{\mathbf{H}}$ and by the first part of our argument $(\mathbf{DO} \cap \overline{\mathbf{H}}) \square \mathbf{SL} \subseteq \mathbf{DO} \cap \overline{\mathbf{H}}$.

Let $\mathbf{V}_0 = \mathbf{H}$ and $\mathbf{V}_{i+1} = \mathbf{V}_i \square \mathbf{SL}$: to complete our proof we now show that $\mathbf{DO} \cap \overline{\mathbf{H}}$ is contained in any variety containing \mathbf{H} and closed under block product with \mathbf{SL} . We do so by proving that any monoid of $\mathbf{DO} \cap \overline{\mathbf{H}}$ lies in some \mathbf{V}_i . We use the family $\sim^{\mathbf{H}}$ of congruences for $\mathbf{DO} \cap \overline{\mathbf{H}}$ and show that for each alphabet Σ with $|\Sigma| = n$, any $k \geq 0$, any group G and any word $w \in \Sigma^*$, the language $L_{n,k}^{(w)} = \{v \in \Sigma^* : v \sim_{n,k}^G w\}$ is recognized by some M in \mathbf{V}_{n+k} . We argue by induction on $n + k$: if $n = 0$ the claim is trivial. If $k = 0$ then L_w is the set of words that are G -equivalent to w and this can be recognized by a direct product of t copies of G where t is the number of homomorphisms from Σ^* to G .

Suppose $n, k > 0$: to check if $v \sim_{n,k}^G w$, we need to first verify that $\alpha(v) = \alpha(w)$ and, as stated in Lemma 1, this can be done using some monoid in \mathbf{SL} . Now, let $w = w_l a w_r$ and $v = v_l a v_r$ be the a -left-decompositions of w and v .

We claim that there is an **SL**-transduction τ and a language $K' \in L(\mathbf{V}_{n+k-1})$ such that $\tau^{-1}(K')$ is the set of words v such that $v_l \sim_{n-1,k}^G w_l$. Consider the two-element monoid $U_1 = \{0, 1\}$ in **SL** with multiplication given by $0 \cdot x = x \cdot 0 = 0$ and $1 \cdot x = x \cdot 1 = x$. Let $h_l = h_r : \Sigma^* \rightarrow U_1$ be the homomorphism mapping a to 0 and every other letter to the identity 1. Thus, $h_l(v) = 0$ iff $a \in \alpha(v)$ and the transduction τ defined by h_l and h_r maps v to the sequence of triples

$$(1, v_1, 0) \dots (1, v_i, 0)(0, v_{i+1}, 0) \dots (0, v_j, 0)(0, v_{j+1}, 1) \dots (0, v_n, 1)$$

where v_i and v_j are the first and last occurrence of a in v (if any such occurrence exists). We are trying to check if $v_l \sim_{n-1,k}^G w_l$ and we know by induction that the language $L_{n-1,k}^{(w)}$ is in $L(\mathbf{V}_{n+k-1})$, i.e. there exists $M \in \mathbf{V}_{n+k-1}$, a homomorphism $h : \Sigma^* \rightarrow M$ and a subset $T \subseteq M$ with $L_{n,k-1}^{(w)} = h^{-1}(T)$. Let $h' : (U_1 \times \Sigma \times U_1)^* \rightarrow M$ be the homomorphism which maps triples $(t, b, t') \in (U_1 \times \Sigma \times U_1)$ to $h'(t, b, t') = \begin{cases} h(b) & \text{if } t = 1 \text{ and } b \neq a; \\ 1_M & \text{otherwise.} \end{cases}$

One can verify that for any $v \in \Sigma^*$ with the a -left decomposition $v_l a v_r$ we now get $h'(\tau(v)) = h'(\tau(v_l)) = h(v_l)$ because all the triples of $\tau(v)$ beyond that prefix are mapped to 1_M . Let $K' = h'^{-1}(T)$: we have $K' \in L(\mathbf{V}_{n+k-1})$ and $\tau^{-1}(K') = \{v \in \Sigma^* : v_l \in L_{n-1,k}^{(w)}\}$ as we had required.

Similarly, we can recognize words such that $w_r \sim_{n,k-1}^G v_r$ with the help of a U_1 -transduction. We argue symmetrically about the right-decompositions and conclude that $L_{n,k}^{(w)} \in L(\mathbf{V}_{n+k})$.

4 An Application to Two-Variable Sentences

We refer the reader to e.g. [9] for a thorough overview of logical descriptions of regular languages and their relation to algebraic automata theory and circuit complexity. As we suggested in our introduction, we view finite words over the finite alphabet Σ as logical structures. We construct logical formulas using the order predicate $<$, the “content” predicates $\{Q_a | a \in \Sigma\}$, constants **t** (true) and **f** (false), Boolean connectives, a set of variables $\{x_1, \dots, x_n\}$, existential and universal quantifiers as well as modular quantifiers $\exists^{i \bmod m} x$. The atomic formulas are either **t**, **f**, $x_i < x_j$ or $Q_a x_i$. A *word structure* over alphabet Σ and variable set $\mathcal{V} \subseteq \{x_1, \dots, x_n\}$ is a pair (w, \mathbf{p}) consisting of a word $w \in \Sigma^*$ and a set of pointers $\mathbf{p} = (p_{i_1}, \dots, p_{i_n})$ with $1 \leq p_i \leq |w|$ which associate each variable $x_i \in \mathcal{V}$ with a position p_i in the string. A *simple extension* of a word structure (w, \mathbf{p}) over Σ, \mathcal{V} is a word structure (w, \mathbf{p}') over $\Sigma, (\mathcal{V} \cup \{x_{i+1}\})$ such that $x_{i+1} \notin \mathcal{V}$ and $p_j = p'_j$ for $1 \leq j \leq k$. We can now formally define the semantics of our formulas in a natural way. If $w = w_1 \dots w_t$ is a word, we have

$$\begin{aligned}
 (w, \mathbf{p}) \models Q_a x_i & \quad \text{if } w_p = a; \\
 (w, \mathbf{p}) \models x_i < x_j & \quad \text{if } p_i < p_j; \\
 (w, \mathbf{p}) \models \exists x(\phi(x_k)) & \quad \text{if there exists an extension } (w, \mathbf{p}') \text{ of } (w, \mathbf{p}) \text{ such} \\
 & \quad \text{that } (w, \mathbf{p}') \models \phi(x_k); \\
 (w, \mathbf{p}) \models \exists^{i \bmod m} x_k(\phi(x_k)) & \quad \text{if there exists } i \text{ modulo } m \text{ extensions } (w, \mathbf{p}') \text{ of} \\
 & \quad (w, \mathbf{p}) \text{ such that } (w, \mathbf{p}') \models \phi(x_k);
 \end{aligned}$$

We omit for space the obvious definition of the semantics of the Boolean connectives and of the universal quantifiers.

If ϕ is a sentence, i.e. a formula with no free variable, we denote as $L_\phi \subseteq \Sigma^*$ the language $L_\phi = \{w : (w, \emptyset) \models \phi\}$. Similarly, it will be useful for our purposes to consider the special case of formulas with a single free variable. Such a formula naturally defines a set of word structures (w, p) with $1 \leq p \leq |w|$, i.e. a *pointed language*. For any formula ϕ having a single free variable and Φ a class of such formulas, we will denote as P_ϕ the pointed language $P_\phi = \{(w, p) : (w, p) \models \phi\}$ and $P(\Phi)$ the class of all P_ϕ with $\phi \in \Phi$.

We will denote as **FO**, **MOD**, **MOD^p**, **FO + MOD** and **FO + MOD^p** the class of respectively first-order sentences (no modular quantifier), modular sentences (no existential or universal quantifier), modular sentences with only mod p quantifiers and so on. The expressive power of such sentences has been investigated thoroughly and all existing results are algebraic in nature: languages definable by sentences of the fragment Γ are exactly those in $L(\mathbf{V}_\Gamma)$ for some appropriate variety \mathbf{V}_Γ . (see [10] for elements of a meta-explanation). In particular, we have $L(\mathbf{FO}) = L(\mathbf{A})$ [6, 8], $L(\mathbf{MOD}) = L(\mathbf{G}_{\text{sol}})$, $L(\mathbf{MOD}^p) = L(\mathbf{G}_p)$, $L(\mathbf{FO} + \mathbf{MOD}) = L(\mathbf{G}_{\text{sol}})$ [13].

While it is natural to construct logical sentences using a new variable for each quantifier, one can just as well write sentences that reuse variables. For instance, we gave earlier a three-variable sentence defining the language $\Sigma^* a \Sigma^* b \Sigma^* c \Sigma^*$. It is also definable by the two-variable sentence $\exists x(Q_a x \wedge \exists y(Q_b y \wedge x < y \wedge \exists x(Q_c x \wedge y < x)))$. The semantics of the sentence are perfectly unambiguous (see [12] for a formal discussion). We denote **FO_k**, **FO + MOD_k** and so on the class of sentences using only k variables. Surprisingly, three variables suffice to describe any language in $L(\mathbf{FO} + \mathbf{MOD})$ [4, 3, 12]. If only one variable is allowed, it is easy to show that our expressive power is dramatically reduced and, for instance, that $L(\mathbf{FO}_1) = L(\mathbf{SL})$ and $L(\mathbf{MOD}_1) = L(\mathbf{Ab})$. The expressiveness of **FO₂** or **FO + MOD₂** is trickier to understand [16, 12] but also admits algebraic characterizations. In order to study **FO + MOD₂**, [12] show that every such sentence can be rewritten so that no existential or universal quantifier appears in the scope of a modular quantifier. We will show that this is not just an artefact of the proof: at the other end of the spectrum, two-variable sentences in which no modular quantifier appears in the scope of an ordinary quantifier are provably less expressive than general **FO + MOD₂** sentences.

Definition 1. Let Σ be an alphabet and $\Phi = \{\phi_1, \dots, \phi_k\}$ be a set formulas over Σ with one free variable, say x , and a single bound variable y (possibly bound

by more than one quantifier). A recycling Φ -substitution σ over Σ is a function mapping two-variable sentences over the alphabet 2^Φ (the power set of Φ) to two-variable sentences over Σ as follows: each occurrence of the predicate Q_Sx with $S \subseteq \Phi$ is replaced by the conjunction $\bigwedge_{\phi \in S} \phi_i$ and each occurrence of Q_Sy is replaced by the similar formula in which the roles of x and y are interchanged.

Note that recycling substitutions preserve the two-variable property. If Γ is a class of two-variable sentences and Λ is a class of formulas with one bound and at most one free variable we will denote by $\Gamma \circ \Lambda$ the class of sentences which are Boolean combinations of sentences in Λ and of sentences obtained by applying to a sentence ψ of Γ a recycling substitution in which all formulas in Φ lie in Λ .

Lemma 2. *Let σ be a substitution and for any $w = w_1 \dots w_n$ in Σ^* let $\sigma^{-1}(w)$ be the word $u_1 \dots u_n$ over the alphabet 2^Φ with $u_i = \{\phi_j : (w, i) \models \phi_j\}$. Then $w \models \sigma(\psi)$ iff $\sigma^{-1}(w) \models \psi$.*

The proof is omitted but is straightforward. The function mapping w to $\sigma^{-1}(w)$ is of course quite similar to the notion of transduction which we introduced in Section 2 and we now prove an equivalent of the “block product/substitution principle” of [17] which formalizes the idea:

Lemma 3. *Let Γ be a class of $\mathbf{FO} + \mathbf{MOD}_2$ sentences and Λ a class of $\mathbf{FO} + \mathbf{MOD}_2$ formulas with one free variable. If \mathbf{V}, \mathbf{W} are monoid varieties such that $L(\Gamma) = L(\mathbf{V})$ and $P(\Lambda) = P(\mathbf{W})$, then $L(\Gamma \circ \Lambda) = L(\mathbf{V} \square \mathbf{W})$.*

Proof. Since $L(\mathbf{V} \square \mathbf{W})$ is closed under Boolean combinations, the left-to-right containment follows if we show that for any $\psi \in \Gamma$ and any Λ -substitution σ we have $L(\sigma(\psi)) \in L(\mathbf{V} \square \mathbf{W})$. Let w be some word in Σ^* and $\Phi = \{\phi_1, \dots, \phi_k\}$ be the formulas used by σ . Since $P(\mathbf{W}) = P(\Lambda)$, the pointed languages $P_\phi : \{(w, i) : (w, i) \models \phi_j\}$ can be recognized by monoids M_1, \dots, M_k in \mathbf{W} and $M = M_1 \times \dots \times M_k$ recognizes any Boolean combination of them. We can therefore construct an M -transduction τ such that $\tau(w_i)$ completely determines the set $\{\phi_j : (w, i) \models \phi_j\}$. Since we assume that $L(\psi)$ is recognized by a monoid N in \mathbf{V} , we get that $L(\sigma(\psi)) = \tau^{-1}(K)$ for some $K \subseteq (M \times \Sigma \times M)^*$ also recognized by N . Hence, $L(\sigma(\psi)) \in L(\mathbf{V} \square \mathbf{W})$.

For the right-to-left containment, we need to show that any language of $L(\mathbf{V} \square \mathbf{W})$ can be described by a sentence of $\Gamma \circ \Lambda$ and we proceed similarly. If τ is an M -transduction for some $M \in \mathbf{W}$ then for any triple $(m_1, a, m_2) \in M \times \Sigma \times M$, the pointed language $T_{(m_1, a, m_2)} = \{(w, i) : \tau(w_i) = (m_1, a, m_2)\}$ is in $P(\mathbf{W})$ and is thus definable by some formula $\phi_{(m_1, a, m_2)}$ in $P(\Lambda)$. Any language $K \subseteq (M \times \Sigma \times M)^*$ in $L(\mathbf{V})$ is definable by some sentence $\psi_K \in \Gamma$. Now the set of words such that $\tau(w) \in K$ is defined by the sentence obtained from ψ_K by a recycling substitution using the formulas¹ $\phi_{(m_1, a, m_2)}$.

Let \mathbf{FF}_1 be the class of \mathbf{FO} formulas with one free and one quantified variable.

¹ Note that at any position i , exactly one of the $\phi_{(m_1, a, m_2)}$ is true and we can thus identify the domain of $\sigma^{-1}(w_i)$ with the set $M \times \Sigma \times M$.

Lemma 4. $P(\mathbf{FF}_1) = P(\mathbf{SL})$.

Proof (sketch). Each \mathbf{FF}_1 formula can be rewritten as a Boolean combination of formulas of the form $\exists y((x * y) \wedge Q_a y)$ with $*$ $\in \{<, >, =\}$. By Lemma 1, the pointed language defined by such a formula is recognized by some $M \in \mathbf{SL}$ since we are simply asking whether the letter a occurs somewhere before x (if $*$ is $>$), at x (if $*$ is $=$) or after x (if $*$ is $<$). Conversely, if a pointed language K is recognized by some $M \in \mathbf{SL}$ then by Lemma 1 membership of (w, p) in K depends on the letter w_p and on the set of letters occurring before and after the pointer. Thus, K can be defined by an \mathbf{FF}_1 formula.

Theorem 4. *Let Σ be a finite alphabet. A language $L \subseteq \Sigma^*$ is*

- (1) *definable by a $\mathbf{FO} + \mathbf{MOD}_2$ sentence in which no modular quantifier appears in the scope of an ordinary quantifier iff $M(L) \in \mathbf{DO} \cap \overline{\mathbf{G}_{\mathbf{sol}}}$;*
- (2) *definable by a $\mathbf{FO} + \mathbf{MOD}_2$ sentence in which no modular quantifier appears in the scope of another quantifier iff $M(L) \in \mathbf{DO} \cap \overline{\mathbf{Ab}}$;*
- (3) *definable by a $\mathbf{FO} + \mathbf{MOD}_2$ sentence in which all modular quantifiers have prime moduli and no Mod_p -quantifier appears in the scope of an ordinary quantifier or of a Mod_q quantifier for p, q distinct primes iff $M(L) \in \mathbf{DO} \cap \mathbf{G}_{\mathbf{nil}}$;*

Proof. The proofs are applications of Lemma 3. By [11], we have $L(\mathbf{MOD}_2) = L(\mathbf{G}_{\mathbf{sol}})$. Let \mathbf{D}_k be the class $\mathbf{FO} + \mathbf{MOD}_2$ sentences in which no modular quantifier appears in the scope of an ordinary quantifier and in which the nesting depth of ordinary quantifiers is k . To complete our argument, it suffices to note that sentences in \mathbf{D}_k are exactly those which can be obtained from \mathbf{MOD}_2 sentences by applying successively k \mathbf{FF}_1 substitutions. By applying the block-product substitution principle and Lemma 4 we get that $L(\mathbf{D}_k) = L(\dots(\mathbf{G}_{\mathbf{sol}} \square \mathbf{SL}) \dots \square \mathbf{SL})$ (where the product has length k) and by Theorem 3 the union of the varieties on the right is exactly $\mathbf{DO} \cap \overline{\mathbf{G}_{\mathbf{sol}}}$.

To obtain, the second and third parts of our theorem we simply need to recall that $L(\mathbf{MOD}_1) = L(\mathbf{Ab})$ and that $L(\mathbf{G}_{\mathbf{nil}})$ is the class of languages definable by \mathbf{MOD}_2 sentences satisfying the restriction given in (3) [11, 13].

The regular language $K = (b * ab * a)^* b \Sigma^*$ is defined by the sentence $\exists x(Q_b x \wedge \exists^{0 \bmod 2} y(x < y \wedge Q_a x))$. We claim that K cannot be recognized by some M in \mathbf{DO} and, thus defined by a $\mathbf{FO} + \mathbf{MOD}_2$ sentence in which the modular quantifiers lie outside the scope of the ordinary quantifiers. Indeed, let h be the recognizing morphism and consider $x = h(ab)$ and $y = h(a)$: we have for some ω that $h[(aba)^\omega (baa)^\omega (aba)^\omega] = h[(aba)^\omega]$ in M but this is impossible since $(aba)^\omega (baa)^\omega (aba)^\omega$ is in K while $(aba)^\omega$ is not.

The variety \mathbf{DO} is decidable since it is defined by a simple identity and it is also easy to decide whether the subgroups of such a monoid lie in \mathbf{Ab} , \mathbf{G}_p , $\mathbf{G}_{\mathbf{nil}}$ or $\mathbf{G}_{\mathbf{sol}}$. Moreover the proof of Theorem 4 actually shows a tight correspondence between the depth of ordinary quantifiers in the $\mathbf{FO} + \mathbf{MOD}_2$ formulas with the depth of the product $(\dots(\mathbf{H} \square \mathbf{SL}) \square \mathbf{SL}) \dots \square \mathbf{SL}$ and each of these varieties is also decidable, as long as \mathbf{H} is. The argument requires machinery beyond the scope of this paper but the key ideas can be found in [17].

5 A New Perspective on Communication Complexity and Circuit Complexity Upper Bounds

Our decomposition of $\mathbf{DO} \cap \overline{\mathbf{AB}}$ in terms of block products and the ensuing logical characterization of the corresponding languages allow us to shed new light on two complexity problems recently resolved in [5, 15].

In [5], one considers Boolean circuits of bounded depth. A circuit C_n is an acyclic digraph: the nodes of in-degree 0 are *input* nodes labeled with a Boolean variable x_i with $1 \leq i \leq n$ or a Boolean constant, the other nodes are labeled by one of the Boolean functions $\{\wedge, \vee, \text{Mod}_m\}$. We also assume that there is a single *output* node, i.e. a node of out-degree 0. A circuit C_n with n inputs computes a function $C_n : \{0, 1\}^n \rightarrow \{0, 1\}$ in the obvious way (note that the output of a Mod_m gate is 1 if the sum of its inputs is 0 modulo m). The *depth* of C_n is the longest path from an input to the output node. The wire-size and the gate-size of C_n are, respectively, the number of edges and nodes in the graph. By extension a family of circuits $C = (C_n)_{n \geq 0}$ computes a function $C : \{0, 1\}^* \rightarrow \{0, 1\}$ (i.e. defines a language of $\{0, 1\}^*$) and we then think of the depth and size of C as a function of n . The class of languages which can be recognized by such circuits in polynomial-size and bounded-depth is denoted ACC^0 .

To process a non-Boolean input $w \in \Sigma^*$ with such circuits we can for instance require that the circuit be given a simple Boolean encoding of each letter w_i . In [5], it was shown that the regular languages definable by an ACC^0 circuit using only a linear number of wires are exactly those recognized by monoids in $\mathbf{DO} \cap \overline{\mathbf{AB}}$. The result relies on a communication complexity result: suppose Alice and Bob are given a word $w = w_1 w_2 \dots w_{2n}$ where Alice knows only the odd-indexed w_i and Bob only the even-indexed ones. What is then the minimal number of bits that Alice and Bob need to exchange in the worst case to determine whether w lies in some regular language L ? If L is recognized by some M in $\mathbf{DO} \cap \overline{\mathbf{AB}}$ this can be done with $O(\log n)$ bits of communication but requires $\Theta(n)$ bits otherwise [15]. It is interesting to note that the circuit complexity and communication complexity upper bounds follow simply from the block-product decomposition of this variety:

Theorem 5. *If every $K \in L(\mathbf{V})$ has a circuit with a linear number of wires then so does any $K' \in L(\mathbf{V} \square \mathbf{SL})$. Similarly, if each $K \in L(\mathbf{V})$ has communication complexity $O(\log n)$ then so does any $K' \in L(\mathbf{V} \square \mathbf{SL})$.*

Proof (sketch). Bilardi and Preparata show in [2] that there exists a linear-size circuit computing Prefix-Suffix-OR i.e. a circuit with n Boolean inputs x_1, \dots, x_n and $2n$ outputs $p_1, \dots, p_n, s_1, \dots, s_n$ with $p_i = \bigvee_{j=1}^{i-1} x_j$ and $s_i = \bigvee_{j=i+1}^n x_j$.

It suffices to show that for any language K recognized by a monoid of \mathbf{V} and any M -transduction τ with $M \in \mathbf{SL}$, the language $\tau^{-1}(K)$ has a linear size circuit. By Lemma 1, the value of $\tau(w_i)$ is determined entirely by the letter w_i and the sets $\alpha(w_1 \dots w_{i-1})$ and $\alpha(w_{i+1} \dots w_n)$ of letters occurring in the prefix and suffix around w_i . By using $|\Sigma|$ copies of the Prefix-Suffix-OR circuit, we can therefore build a circuit with a linear number of wires which on input $w_1 \dots w_n$

produces n blocks of $k = \log(|M|^2 \cdot |\Sigma|)$ outputs such that the i th block encodes the value of $\tau(w_i)$. These values can now simply be fed into a circuit recognizing K which, by assumption, uses only a linear number of wires.

For the communication complexity problem, Alice and Bob begin by exchanging the location of the first and last occurrence of a letter that they have access to. This requires $O(\log n)$ bits of communication and this information is enough for each player to privately compute $\tau(w_i)$ for any w_i he has access to.

In fact, the result in [2] is more general: for a regular language L , there exists a circuit which computes Prefix-Suffix- L iff L is piecewise-testable, i.e. recognized by a monoid in the variety \mathbf{J} . This well known variety contains \mathbf{SL} and is in fact the largest variety of aperiodics satisfying the equality $\mathbf{DO} \square \mathbf{V} = \mathbf{DO}$ [1].

Corollary 1. *Every language in $L(\mathbf{DO} \cap \overline{\mathbf{Ab}})$ can be defined by a linear-wire-size family of ACC^0 circuits and has two-party communication complexity $O(\log n)$.*

Proof. For any $K \in L(\mathbf{Ab})$, membership of $w \in K$ depends solely on the number $|w|_a$ of occurrences of each letter a in w modulo some integer m [7]. Computing $|w|_a$ modulo m , can clearly be done with a single Mod_m gates with n input wires and by a communication protocol of cost $2 \log |m|$. Thus, any K in $L(\mathbf{Ab})$ has linear-wire-size circuits and communication complexity $O(1)$. Our statement then follows from Theorem 5 and the decomposition result of Theorem 3.

We should note that the same idea can be used to show that for every language L recognized by $M \in \mathbf{DO} \cap \overline{\mathbf{G}_{nil}}$ there exists k such that the k -party communication complexity of L is $O(1)$ (see [14] for a discussion of the multi-party communication model).

Alternatively, one can view the linear-wire-size circuits for $\mathbf{DO} \cap \overline{\mathbf{Ab}}$ as evaluating a two-variable formula with no modular quantifier nested in another quantifier. First the circuit evaluates the most deeply nested subformulas with one free variable, say x . These are \mathbf{FF}_1 formulas and thus Boolean combinations of formulas such as $\phi(x) = \exists y(x < y \wedge Q_a y)$ and the Prefix-Suffix-OR construction allows us to simultaneously compute the value of $\phi(x)$ for each value of x using only $O(n)$ wires. These results are used in the next step to compute, for all positions y the value of formulas such as $\psi(y) = \exists x(x < y \wedge \phi(x))$. At the output level, we evaluate the value of a modular quantifier $\exists^{i \bmod m} x \chi(x)$. It suffices to feed the n values of $\chi(x)$ obtained in the previous step into a Mod_m gate.

In general, recognizing a language definable by an $\mathbf{FO} + \mathbf{MOD}_2$ sentence in which modular quantifiers are allowed in the scope of other quantifiers will require an ACC^0 circuit with a super-linear number of wires. However, these languages can still be recognized using only $O(n)$ gates. The strategy to build such a circuit is similar: we are given, at some stage in our circuit the values for each x of a formula $\phi(x)$ and want to compute for each y the value of a formula of the form $\psi(y) = \exists^{i \bmod m} x(x < y \wedge \phi(x))$. For each y , this can of course be computed by a single Mod_m gate in which we feed the results of $\phi(x)$ for each $x < y$. The sub-circuit computing all values $\psi(y)$ from the values $\phi(x)$ will use only n gates but $\Omega(n^2)$ wires. In fact, we conjecture that the

regular languages recognized by an ACC^0 circuit with a linear number of gates are exactly those definable in $\mathbf{FO} + \mathbf{MOD}_2$ and that, among these, the fine line between linear-gate-size and linear-wire-size is thus captured exactly by the ability to pull modular quantifiers out of the scope of any other quantifier.

It is also very natural to try and characterize regular languages which can be computed by linear-gate-size restricted ACC^0 circuits where we allow only Mod_m gates (i.e. CC^0 circuits), or only \wedge, \vee gates (i.e. AC^0 circuits). We believe that these regular languages are exactly those in \mathbf{MOD}_2 and \mathbf{FO}_2 respectively. In particular, we conjecture that every regular language recognized by an AC^0 circuit with a linear number of gates can also be recognized by an AC^0 circuit with a linear number of wires. Resolving this question for CC^0 circuits amounts to proving a lower bound of $\omega(n)$ for the number of gates in CC^0 circuits computing the AND of n bits or the word problem of a non-solvable group. To the best of our knowledge, the state-of-the-art lower bound state that CC^0 circuits for AND requires $\Omega(n)$ non-input gates, a world away from the suspected $\Omega(c^n)$. As a first step, it would an interesting start to establish an $\omega(n)$ lower bound for the number of wires in such circuits.

Abstract. Computing the order of the Jacobian group of a hyperelliptic curve over a finite field is very important to construct a hyperelliptic curve cryptosystem (HCC), because to construct secure HCC, we need Jacobian groups of order in the form $l \cdot c$ where l is a prime greater than about 2^{160} and c is a very small integer. But even in the case of genus two, known algorithms to compute the order of a Jacobian group for a general curve need a very long running time over a large prime field. In this article, we give explicit formulae of the order of Jacobian groups for hyperelliptic curves over a finite prime field of type $y^2 = x^{2k+1} + ax$, which allows us to search suitable curves for HCC. By using these formulae, we can find many suitable curves for genus-4 HCC and show some examples.

1 Introduction

Let C be a hyperelliptic curve of genus g over \mathbb{F}_q , J_C the Jacobian variety of C and $J_C(\mathbb{F}_q)$ the Jacobian group of C which is the set of \mathbb{F}_q -rational points of J_C . Then $J_C(\mathbb{F}_q)$ is a finite abelian group and we can construct a public-key-cryptosystem by using DLP on it. This cryptosystem is called “hyperelliptic curve cryptosystem (HCC)”. In particular, HCC obtained by using a hyperelliptic curve of genus g is called “genus- g HCC”. To construct secure HCC, the order of $J_C(\mathbb{F}_q)$ is required to be in the form $l \cdot c$ where l is a prime greater than about 2^{160} and c is a very small integer. We call a hyperelliptic curve “suitable for HCC” if its Jacobian group has such a suitable order. The advantage of HCC to an elliptic curve cryptosystem (ECC) is that we can construct a cryptosystem at the same security level as an elliptic one by using a smaller defining field. More precisely, we need a 160-bit field to construct a secure ECC, but for a genus- g HCC with $g \geq 2$, we only need about $(160/g)$ -bit field. This comes from the fact that the order of the Jacobian group of a hyperelliptic curve defined over an N -bit field is about (Ng) -bit. The merit of using higher genus HCC is its short

operand size; less than 64-bit for genus ≥ 3 ; its implementation on 64-bit CPUs does not need multi-precision arithmetic and it can encrypt very fast (cf. [12]).

Due to Gaudry [8], there is a variant of the index calculus attack which can solve the discrete logarithm problem in the Jacobian of hyperelliptic curves. As a result of it, it is recommended that the genus should be taken less than five to construct a secure HCC. In AsiaCrypt2003, Thériault [23] improved Gaudry's algorithm and recently Gaudry-Thomé [11] and Nagao [21] independently improved Thériault's result. The running time of their algorithms is asymptotically better than the original index calculus and the Rho method for curves of genus ≥ 3 . In particular Gaudry-Thomé showed by computer experiments on the genus 3 case that even for rather small sizes, their method is better than Pollard Rho algorithm and a genus-3 HCC should have a key size about 12 % larger than an elliptic curve cryptosystem for an equivalent security. This implies that a genus-3 HCC on a field of less than 64-bit may be insecure in comparison with 160-bit ECC in the near future. For genus-4 HCC, we also need a larger key size and hence a larger field, but it still has its advantage that it can be implemented on 64bit CPU because it has enough margins to enlarge a field size under 64bit. So the search for suitable curves for genus-4 HCC is still important.

As in the case of ECC, to get a fast algorithm for adding points on the Jacobian group and to give an efficient way to produce a suitable curve for HCC are very important to construct HCC. For the first problem, we have already got many good results. See [10][16][17] for genus two, [15] for genus three and [22] for genus four. For the second problem, we need to calculate the order of the Jacobian group. However, for HCC over prime fields, there are few results in this direction even for the genus two case (cf. [9]) and there is no efficient algorithm for the case of genus greater than two.

There is a known algorithm to construct a curve with complex multiplication (CM) whose Jacobian group has a 160-bit prime factor. But this algorithm is efficient only for genus two at this moment. For genus three, only a few examples of suitable curves are constructed by this method [24]. For a special curve of type $y^2 + y = x^n$ over a prime field \mathbb{F}_p , Buhler-Koblitz [2] obtained a point counting algorithm.

If the Jacobian of a curve is obtained as a reduction mod p of an abelian variety of CM type over \mathbb{Q} , the calculation of the order of the Jacobian group is much easier. For such curves, the problem is reduced to finding an element of norm p in a CM field. Note that such an element is defined up to a root of unity.

In this article, we study characteristic polynomials of curves defined by $y^2 = x^{2k+1} + ax$, $a \in \mathbb{F}_p$ and give explicit formulae giving the order of Jacobian groups of those curves. The Jacobian of such curve is obtained as a reduction mod p of an abelian variety of CM type over \mathbb{Q} . Our tactics for calculating the order of the Jacobian group of the curve $C : y^2 = x^{2k+1} + ax$ is to calculate $|C(\mathbb{F}_p)|$ for $r = 1, 2, \dots, g$ directly. Since the curve C is obtained as a quotient of a Fermat curve, $|C(\mathbb{F}_p)|$ is expressed by Jacobi sums over \mathbb{F}_p . But the explicit calculation of Jacobi sums over \mathbb{F}_p for $r \geq 2$ and large p is not easy. In this article, we prove Theorem 1; it reduces the calculation of $|C(\mathbb{F}_p)|$ to Jacobi sums

over \mathbb{F}_p . And as a result of it, we can determine the characteristic polynomial of the p -th power Frobenius endomorphism without ambiguity over unit elements. Moreover, we can give a necessary condition for such curves to be suitable for HCC. By using our formulae, we show that the case $k = 4$ produces suitable curves for genus-4 HCC when $p \equiv 1 \pmod{16}$ and give some examples of such curves. We can obtain explicit formulae for the case $k = 2$ and 3. But for the case $k = 3$, the genus three case, it is shown that the Jacobian splits over the base field and hence cannot produce suitable curves. So we omit the formulae for that case. For the case $k = 2$, we should note that it was already appeared in [7] and explicit formulae are given but under some condition on a . Combining our formula and the result in [7], we have a complete result for $k = 2$.

Our result gives a family of hyperelliptic curves with closed formula for the order of the Jacobian and a necessary condition on the parameter to be suitable for genus 4-HCC.

2 The Characteristic Polynomial and the Order of the Jacobian Group

Let p be an odd prime, \mathbb{F}_q a finite field of order $q = p^r$ and C a hyperelliptic curve of genus g defined over \mathbb{F}_q . Then the defining equation of C is given as $y^2 = f(x)$ where $f(x)$ is a polynomial in $\mathbb{F}_q[x]$ of degree $2g + 1$.

Let J_C be the Jacobian variety of a hyperelliptic curve C . We denote the group of \mathbb{F}_q -rational points on J_C by $J_C(\mathbb{F}_q)$ and call it the Jacobian group of C . Let $\chi_q(t)$ be the characteristic polynomial of the q -th power Frobenius endomorphism of C . We call $\chi_q(t)$ for C the characteristic polynomial of C and denote it by $\chi(t)$ for the convenience. Then, it is well-known that the order $|J_C(\mathbb{F}_q)|$ is given by

$$|J_C(\mathbb{F}_q)| = \chi(1). \tag{1}$$

Due to Mumford [19], every point on $J_C(\mathbb{F}_q)$ can be represented by a pair $\langle u(x), v(x) \rangle$ where $u(x)$ and $v(x)$ are polynomials in $\mathbb{F}_q[x]$ with $\deg v(x) < \deg u(x) \leq g$ such that $u(x)$ divides $f(x) - v(x)^2$. The identity element of the addition law is represented by $\langle 1, 0 \rangle$. By using this representation of points on $J_C(\mathbb{F}_q)$, we obtain an algorithm for adding two points on $J_C(\mathbb{F}_q)$. This algorithm was firstly given by Cantor [3] in general and has been improved for genus 2, 3 and 4 by many people [10][16][17][22].

In the following, for a generator g of \mathbb{F}_p^\times , we denote $\text{Ind}_g a = k$ when $a = g^k$, $k = 0, 1, \dots, p - 1$.

3 Jacobstahl Sum and the Key Theorem

For two characters ψ, ψ' of \mathbb{F}_p^\times , the Jacobi sum $J_r(\psi, \psi')$ is defined by

$$J_r(\psi, \psi') = \sum_{t \in \mathbb{F}} \psi(t)\psi'(1 - t).$$

For the convenience we use the notation $K_r(\psi) = \psi(4)J_r(\psi, \psi)$. When $r = 1$, we drop the subscript J_r and K_r . For properties of Jacobi sums, see [1].

Let ℓ be a positive integer and p a prime such that $p \equiv 1 \pmod{2\ell}$. Let ψ_2 be a character of order 2 on a finite field \mathbb{F}_p . For an element a in \mathbb{F}_p ,

$$\phi_{\ell,r}(a) := \sum_{x \in \mathbb{F}} \psi_2(x^{\ell+1} + ax)$$

is called a ‘‘Jacobstahl sum’’. It is easy to see that for a hyperelliptic curve defined by an equation $y^2 = x^{\ell+1} + ax$ over \mathbb{F}_p ,

$$|C(\mathbb{F}_p)| = p^r + 1 + \phi_{\ell,r}(a) \tag{2}$$

where $|C(\mathbb{F}_p)|$ denotes the number of rational points of C over \mathbb{F}_p .

The following properties of $\phi_{\ell,r}$ enables us to reduce the calculation of $\phi_{\ell,r}(a)$ to the case $p^r \equiv 1 \pmod{2\ell}$.

Lemma 1. (1) For $d = (\ell, p^r - 1)$, $\phi_{\ell,r}(a) = \phi_{d,r}(a)$.
 (2) If $p^r - 1 \equiv \ell \pmod{2\ell}$, then $\phi_{\ell,r}(a) = 0$.

Then we have the following theorem. This is the key theorem in our results.

Theorem 1. Let p be a prime such that $p \equiv 1 \pmod{2\ell}$ for some positive integer ℓ . For $a \in \mathbb{F}_p$,

$$\phi_{\ell,r}(a) = (-1)^{r-1} \hat{\psi}(-1) \hat{\psi}^{\ell+1}(a) \sum_{j=0}^{\ell-1} \hat{\psi}^{2j}(a) K(\psi^{2j+1})^r$$

where $\hat{\psi}$ is a character of \mathbb{F}_p^\times of order 2ℓ and $\psi = \hat{\psi} \circ N_{\mathbb{F}_p/\mathbb{F}}$.

Proof. Since $\hat{\psi}^\ell = \psi_2$,

$$\phi_{\ell,r}(a) = \sum_{x \in \mathbb{F}} \hat{\psi}^\ell(x) \hat{\psi}^\ell(x^\ell + a) = \sum_{x \in \mathbb{F}} \hat{\psi}(x^\ell) \hat{\psi}^\ell(x^\ell + a).$$

By the equality

$$\sum_{j=0}^{\ell-1} \hat{\psi}^{2j}(x) = \begin{cases} 0 & \hat{\psi}^2(x) \neq 1 \\ \ell & \hat{\psi}^2(x) = 1 \end{cases}$$

and the fact each fiber of the map $x \mapsto x^\ell$ has ℓ elements, we have

$$\phi_{\ell,r}(a) = \sum_{x \in \mathbb{F}} \hat{\psi}(x) \hat{\psi}^\ell(x + a) \sum_{j=0}^{\ell-1} \hat{\psi}^{2j}(x).$$

By the change of variable $x \rightarrow -x$ and $x \rightarrow -ax$,

$$\begin{aligned} \phi_{\ell,r}(a) &= \hat{\psi}(-1)\hat{\psi}^{1+\ell}(a) \sum_{x \in \mathbb{F}} \hat{\psi}(x)\hat{\psi}^\ell(1-x) \sum_{j=0}^{\ell-1} \hat{\psi}^{2j}(ax) \\ &= \hat{\psi}(-1)\hat{\psi}^{1+\ell}(a) \sum_{j=0}^{\ell-1} \hat{\psi}^{2j}(a) \sum_{x \in \mathbb{F}} \hat{\psi}^{2j+1}(x)\hat{\psi}^\ell(1-x) \\ &= \hat{\psi}(-1)\hat{\psi}^{1+\ell}(a) \sum_{j=0}^{\ell-1} \hat{\psi}^{2j}(a)J_r(\hat{\psi}^{2j+1}, \hat{\psi}^\ell). \end{aligned}$$

Since $J_r(\hat{\psi}^{2j+1}, \hat{\psi}^\ell) = \hat{\psi}^{2j+1}(4)J_r(\hat{\psi}^{2j+1}, \hat{\psi}^{2j+1}) = K_r(\hat{\psi}^{2j+1})$, we get the formula

$$\phi_{\ell,r}(a) = \hat{\psi}(-1)\hat{\psi}^{1+\ell}(a) \sum_{j=0}^{\ell-1} \hat{\psi}^{2j}(a)K_r(\hat{\psi}^{2j+1}).$$

It follows from the Hasse-Davenport relation (cf. [1–Theorem 11.5.2]) that for any integer m , $K_r(\hat{\psi}^m) = (-1)^{r-1}K_1(\psi^m)^r$. Hence our Theorem. □

Remark 1. Theorem 1 is a new result. Combining this theorem with the following well-known fact, we get the formula of $\chi(t)$ for the curve $C : y^2 = x^{2k+1} + ax$.

Theorem 2. *Let C be a hyperelliptic curve of genus g over \mathbb{F}_p . Assume $\chi(t)$ for C is decomposed as $\chi(t) = \prod_{i=1}^{2g} (t - \alpha_i)$. Then $|C(\mathbb{F}_p)| = p^r + 1 - \sum_{i=1}^{2g} \alpha_i^r$.*

4 Explicit Formula for $y^2 = x^5 + ax$

Let p be an odd prime and C a hyperelliptic curve defined by an equation $y^2 = x^5 + ax$ over \mathbb{F}_p . In [7], the explicit formulae of the order of $J_C(\mathbb{F}_p)$ are given for all cases except for the only one case $p \equiv 1 \pmod{8}$ with $\left(\frac{a}{p}\right) = -1$.

Here we show the explicit formula for the remaining case.

Theorem 3. *Let p be a prime such that $p \equiv 1 \pmod{8}$ and C a hyperelliptic curve defined by an equation $y^2 = x^5 + ax$ over \mathbb{F}_p . Put $f = (p - 1)/8$. Write p as $p = c^2 + 2d^2$ where $c \equiv 1 \pmod{4}$ and $2d \equiv -(a^f + a^{3f})c \pmod{p}$. Then the characteristic polynomial of p -th power Frobenius map for C is given by the following formula: $\chi(t) = t^4 + (-1)^f 4dt^3 + 8d^2t^2 + (-1)^f 4dpt + p^2$. In particular, $|J_C(\mathbb{F}_p)| = 1 + (-1)^f 4d + 8d^2 + (-1)^f 4dp + p^2$.*

Proof. This follows from Theorem 1, Theorem 2 and the formula for $K(\psi)$. (See [1]). □

This formula provides us a faster algorithm to compute the order of the Jacobian than in [7].

Remark 2. All formulae for $\chi(t)$ in this paper are obtained in the same way. Since we have not enough space, we describe the proof only for Theorem 4 which is the most important result of this article and omit the proofs for other formulae.

5 Remark on $y^2 = x^7 + ax$

Unfortunately the Jacobian of a hyperelliptic curve of type $y^2 = x^7 + ax$ splits over \mathbb{F}_p splits over \mathbb{F}_p , because for $k \equiv 0 \pmod{3}$, one has a degree 3 covering from $y^2 = x^{2k+1} + ax$ to $Y^2 = X^{2k/3+1} + aX$, given by $(x, y) \mapsto (x^3, xy)$. Therefore the characteristic polynomial is reducible over \mathbb{Z} and this curve is not suitable for HCC.

6 Explicit Formula for $y^2 = x^9 + ax$

Let p be an odd prime and C a hyperelliptic curve defined by an equation $y^2 = x^9 + ax$ over \mathbb{F}_p .

6.1 The Case of $p \equiv 1 \pmod{16}$

Let p be a prime such that $p \equiv 1 \pmod{16}$. We fix a generator g of \mathbb{F}_p^\times . Put $f = (p - 1)/16$ and $\alpha = g^{(p-1)/16}$. Then there exist integers x, u, v, w such that

$$\begin{aligned}
 p &= x^2 + 2(u^2 + v^2 + w^2), \quad 2xv = u^2 - 2uw - w^2, \quad x \equiv 1 \pmod{8}, \\
 x + u(\alpha + \alpha^7) + v(\alpha^2 - \alpha^6) + w(\alpha^3 + \alpha^5) &\equiv 0 \pmod{p}, \\
 2v^2 - x^2 &\equiv -(u^2 + 2uw - w^2)(\alpha^2 - \alpha^6) \pmod{p}.
 \end{aligned}
 \tag{3}$$

It is known that the above x, u, v, w are uniquely determined.

Let $\chi(t) = t^8 - s_1t^7 + s_2t^6 - s_3t^5 + s_4t^4 - s_3pt^3 + s_2p^2t^2 - s_1p^3t + p^4$ be the characteristic polynomial of C . Then by using the above notation, we have the following theorems.

Theorem 4. s_1, s_2, s_3 and s_4 are given by the following tables.

Ind _g a (mod 16)	s_1	Ind _g a (mod 16)	s_2
1, 7	$(-1)^f 8w$	1, 7, 9, 15	$32w^2 + 16xv$
9, 15	$(-1)^{f+1} 8w$	3, 5, 11, 13	$32u^2 - 16xv$
3, 5	$(-1)^{f+1} 8u$	2, 6, 10, 14	$32v^2$
11, 13	$(-1)^f 8u$	0, 8	$4p + 24x^2 - 16v^2$
2, 14	$(-1)^{f+1} 8v$	4, 12	$-4p + 8x^2 + 16v^2$
6, 10	$(-1)^f 8v$		
8	$(-1)^{f+1} 8x$		
0	$(-1)^f 8x$		
4, 12	0		

$\text{Ind}_g a \pmod{16}$	s_3
1, 7	$(-1)^{f+1}8(pu - 4(u^3 + w^3 + u^2w - 3uw^2))$
9, 15	$(-1)^f8(pu - 4(u^3 + w^3 + u^2w - 3uw^2))$
3, 5	$(-1)^{f+1}8(pw + 4(u^3 - w^3 + 3u^2w + uw^2))$
11, 13	$(-1)^f8(pw + 4(u^3 - w^3 + 3u^2w + uw^2))$
2, 14	$(-1)^{f+1}(8pv + 64v^3 - 32x^2v)$
6, 10	$(-1)^f(8pv + 64v^3 - 32x^2v)$
8	$(-1)^{f+1}(24px + 32x^3 - 64xv^2)$
0	$(-1)^f(24px + 32x^3 - 64xv^2)$
4, 12	0

$\text{Ind}_g a \pmod{16}$	s_4
1, 7, 9, 15	$32u^4 + 32w^4 + 64u^2w^2 - 64puw + 128u^3w - 128uw^3$
3, 5, 11, 13	$32u^4 + 32w^4 + 64u^2w^2 + 64puw + 128u^3w - 128uw^3$
2, 6, 10, 14	$2p^2 + 16x^4 + 64v^4 - 16px^2 - 64x^2v^2 + 32pv^2$
0, 8	$6p^2 + 16x^4 + 64v^4 + 48px^2 - 64x^2v^2 - 32pv^2$
4, 12	$6p^2 + 16x^4 + 64v^4 - 16px^2 - 64x^2v^2 - 32pv^2$

Proof. Here we show the outline of the proof. Let x, u, v, w be integers which satisfy the condition (3). Then for the character ψ which maps α to $e^{2\pi i/16}$,

$$K(\psi) = -x + v\sqrt{2} + iu\sqrt{2 - \sqrt{2}} - iw\sqrt{2 + \sqrt{2}}.$$

From this result, similar descriptions for $K(\psi^{2^{j+1}})$ can be easily obtained. Hence by using equations (1), (2) and Theorem 2, we have the theorem. \square

Corollary 1. *If $a^{1/8} \in \mathbb{F}_p$, the characteristic polynomial of C is given by*

$$\chi(t) = (t^4 - s_1t^3/2 + (s_2/2 - s_1^2/8)t^2 - s_1pt/2 + p^2)^2.$$

In particular, if $a^{1/8} \in \mathbb{F}_p$, it is not suitable for HCC.

We look at the case when $a^{1/8} \notin \mathbb{F}_p$. Since $\left(\frac{-1}{p}\right) = 1$, if a is square, then there is an element $b \in \mathbb{F}_p$ such that $b^2 = -a$. Then $x^9 + ax$ factors into $x(x^4 + b)(x^4 - b)$ and we have that $|J_C(\mathbb{F}_p)|$ is divided by at least 4. Moreover if $a^{1/4} \in \mathbb{F}_p$, $|J_C(\mathbb{F}_p)|$ is divided by at least 16.

If a is not a square, it is possible to obtain a Jacobian group whose order is in the form $2l$ where l is prime.

6.2 The Case of $p \equiv 7 \pmod{16}$

Let p be a prime such that $p \equiv 7 \pmod{16}$. Then there exist integers x, u, v, w such that

$$\begin{aligned} p &= x^2 + 2(u^2 + v^2 + w^2), \quad 2xv = u^2 - 2uw - w^2, \\ x &\equiv 1 \pmod{8}, \quad u \equiv v \equiv w \equiv 1 \pmod{2}. \end{aligned} \tag{4}$$

Let $\chi(t) = t^8 - s_1t^7 + s_2t^6 - s_3t^5 + s_4t^4 - s_3pt^3 + s_2p^2t^2 - s_1p^3t + p^4$ be the characteristic polynomial of C . Then, for a fixed generator g of \mathbb{F}_p^\times , we have the following theorem.

Theorem 5. *The characteristic polynomial of C is determined by the following formula. (1) $s_1 = s_3 = 0$, (2) $s_2 = (-1)^{\text{Ind}_g a}(4p - 8x^2 - 16v^2)$, (3) $s_4 = 6p^2 + 16x^4 + 64v^4 - 16px^2 - 64x^2v^2 - 32pv^2$.*

Remark 3. There is some ambiguity with respect to u, w and the sign of v . But it does not affect to determine the characteristic polynomial of C .

Corollary 2. *If a is square, the characteristic polynomial of C is given by*

$$\chi(t) = 5(t^4 + 4xt^3 + \delta t^2 + 4xpt + p^2)(t^4 - 4xt^3 + \delta t^2 - 4xpt + p^2), \quad \delta = 2p + 4x^2 - 8v^2.$$

In particular, if a is square, it is not suitable for HCC.

We look at the case when a is not a square. From Theorem 5, we have that $|J_C(\mathbb{F}_p)|$ is divided by at least 2^7 .

6.3 The Case of $p \not\equiv 1, 7 \pmod{16}$

Theorem 6. *If $p \equiv 3, 11 \pmod{16}$, then the characteristic polynomial of C is given by $\chi(t) = (t^4 + (-1)^{\text{Ind}_g a} p^2)^2$.*

Theorem 7. *Assume that $p \equiv 5, 13 \pmod{16}$. Then the characteristic polynomial of C is given by the following formula. (1) If $\text{Ind}_g a \not\equiv 0 \pmod{2}$, then $\chi(t) = t^8 + p^4$, (2) if $\text{Ind}_g a \equiv 0 \pmod{4}$, then $\chi(t) = (t^4 + p^2)^2$, (3) if $\text{Ind}_g a \equiv 2 \pmod{4}$, then $\chi(t) = (t^2 - p)^2(t^2 + p)^2$.*

Theorem 8. *Assume that $p \equiv 9 \pmod{16}$. Then the characteristic polynomial of C is given by the following formula. (1) If $\text{Ind}_g a \not\equiv 0 \pmod{2}$, then $\chi(t) = t^8 + p^4$, (2) if $\text{Ind}_g a \equiv 2 \pmod{4}$, then $\chi(t) = (t^4 + p^2)^2$, (3) if $\text{Ind}_g a \equiv 4 \pmod{8}$, then $\chi(t) = (t^2 - p)^4$, (4) if $\text{Ind}_g a \equiv 0 \pmod{8}$, then $\chi(t) = (t^2 + p)^4$.*

Theorem 9. *If $p \equiv 15 \pmod{16}$, then the characteristic polynomial of C is given by $\chi(t) = (t^2 + p)^4$.*

In particular, for $p \not\equiv 1, 7 \pmod{16}$, C is a supersingular curve which is not recommended to use for HCC.

6.4 Which Parameter Is Suitable for HCC?

From the above results, all the cases which can produce suitable curves for HCC are the followings: (1) $p \equiv 1 \pmod{16}$ with a not a square, (2) $p \equiv 1 \pmod{16}$ with a square but $a^{1/4} \notin \mathbb{F}_p$, (3) $p \equiv 1 \pmod{16}$ with $a^{1/4} \in \mathbb{F}_p$ but $a^{1/8} \notin \mathbb{F}_p$, (4) $p \equiv 7 \pmod{16}$ with a not a square. In each case, the best possible order is in the form (1) $2l$, (2) $4l$, (3) 2^4l and (4) 2^7l where l is a prime.

Now we consider splitting of the Jacobian over extension fields. Let $\chi(t)$ be the characteristic polynomial of a hyperelliptic curve C over \mathbb{F}_p . In the following,

we denote by $\chi_p(t)$ the characteristic polynomial of the p^r -th power Frobenius endomorphism of C as a curve over \mathbb{F}_p .

Proposition 1. *Let $\chi(t) = t^8 - s_1t^7 + s_2t^6 - s_3t^5 + s_4t^4 - s_3pt^3 + s_2p^2t^2 - s_1p^3t + p^4$ be the characteristic polynomial of a hyperelliptic curve C of genus four over \mathbb{F}_p . If $\chi(t)$ is irreducible over \mathbb{Q} , then the followings hold: (1) $\chi_{p^2}(t)$ is a product of two polynomials of degree four if and only if $s_1 = s_3 = 0$, (2) $\chi_{p^4}(t)$ is a product of four polynomials of degree two if and only if $\chi_{p^2}(t)$ is a product of two polynomials of degree four.*

Proof. Let γ be a root of $\chi(t)$. We have only to show that if $[\mathbb{Q}(\gamma^2) : \mathbb{Q}] = 4$, $s_1 = s_3 = 0$. Since $\gamma\bar{\gamma} = p$, we can show $(\gamma^2 + \bar{\gamma}^2)^2 \in \mathbb{Q}$ under the assumption $[\mathbb{Q}(\gamma^2) : \mathbb{Q}] = 4$. This implies $s_1 = s_3 = 0$. □

By Proposition 1 and Theorem 4, we have that in the case $p \equiv 1 \pmod{16}$ with a not a square, $\chi_{p^2}(t)$ is irreducible and therefore its DLP cannot be reduced to DLP of HCC of genus two over \mathbb{F}_{p^2} nor of ECC over \mathbb{F}_{p^4} .

7 Examples of Suitable Curves for Genus-4 HCC

In this section, we describe how to search suitable curves for genus-4 HCC of type $y^2 = x^9 + ax$ and show the result of search. Based on the argument in 6.4, we only treat the case of $p \equiv 1 \pmod{16}$.

7.1 LLL Algorithm

Let p be a prime such that $p \equiv 1 \pmod{16}$. We describe the algorithm to determine $|J_C(\mathbb{F}_p)|$. For a given p , if we obtain x, u, v and w in (3), we can determine the order of $J_C(\mathbb{F}_p)$ and check its suitability. So the main part of the algorithm is determining x, u, v, w in (3). To determine x, u, v, w , we use the LLL algorithm.

Let $\alpha_i, i = 1, 2, \dots, 7$ be positive integers such that $0 \leq \alpha_i < p$ and $\alpha_i \equiv g^{(p-1)i/16} \pmod{p}$. Let $\zeta \in \mathbb{C}$ be a primitive 16th root of unity and P a prime ideal over (p) in the integer ring \mathcal{O}_K of $K = \mathbb{Q}(\zeta + \zeta^7)$. A \mathbb{Z} -basis $\{b_0, b_1, b_2, b_3\}$ of P is given by

$$\begin{aligned} b_0 &= p, \quad b_1 = \zeta + \zeta^7 - \alpha_1 - \alpha_7, \\ b_2 &= \zeta^2 - \zeta^6 - \alpha_2 + \alpha_6, \quad b_3 = \zeta^3 + \zeta^5 - \alpha_3 - \alpha_5. \end{aligned} \tag{5}$$

For this basis, any entry of the Gram matrix with respect to an inner product $\langle u, v \rangle = \text{Tr}_{K/\mathbb{Q}}(u\bar{v})$ is an integer. Put $c_1 = -\alpha_1 - \alpha_7, c_2 = -\alpha_2 + \alpha_6, c_3 = -\alpha_3 - \alpha_5$. Then each entry of the Gram matrix is given as follows: $\langle b_0, b_0 \rangle = 4p^2, \langle b_0, b_i \rangle = 4pc_i \ (1 \leq i \leq 3), \langle b_i, b_j \rangle = 4c_i c_j \ (1 \leq i \neq j \leq 3), \langle b_i, b_i \rangle = 8 + 4c_i^2 \ (1 \leq i \leq 3)$. Then the LLL algorithm for the Gram matrix works and we can determine x, u, v and w in (3) by using the following algorithm. (For the details on the LLL algorithm, see [4] for example.)

Algorithm¹

Input p : a prime ($p \equiv 1 \pmod{16}$)

Output x, u, v, w satisfying (3)

(Step 1-5: Finding $\beta \in \mathcal{O}_K, N_{K/\mathbb{Q}}(\beta) = p.$)

Step 1 $g \leftarrow$ a generator of \mathbb{F}_p^\times .

Step 2 $\mathbf{b} = (b_0, b_1, b_2, b_3) \leftarrow$ a \mathbb{Z} -basis (5) of \mathcal{O}_K .

Step 3 $G \leftarrow$ the Gram matrix for \mathbf{b} .

Step 4 $H = (h_{ij}) \leftarrow$ a transformation matrix obtained by the LLL algorithm for G .

Step 5 $\beta \leftarrow \sum_{i=0}^3 b_i h_{0i}$

Step 6 Determine x, u, v, w by $\beta\tau(\beta) = x + u(\zeta + \zeta^7) + v(\zeta^2 - \zeta^6) + w(\zeta^3 + \zeta^5)$ and (3) where τ is an automorphism of $\mathbb{Q}(\zeta + \zeta^7)$ given by $\zeta \mapsto \zeta^3$.

Step 7 Return x, u, v, w .

This algorithm can be easily implemented and we can compute $|J_C(\mathbb{F}_p)|$ of C defined by $y^2 = x^9 + ax$ in a very short time, e.g. only 0.01 seconds over 41bit fields.

7.2 Examples of Suitable Curves

We can obtain many suitable curves for HCC by varying p and a .

Table 1. Search results

search range (r, s) for $r < p < s$	the number of primes ² s.t. $ J_C(\mathbb{F}_p) = 2 \cdot (\text{prime})$	time[sec]
$(2^{41}, 2^{41} + 10^6)$	714	267.054
$(2^{60}, 2^{60} + 10^6)$	349	293.421

Here we show some examples of suitable curves for HCC obtained by our algorithm.

Table 2. An Example of a suitable curve for genus-4 HCC over 41-bit fields

$y^2 = x^9 + 29x, p = 1759218504481(41\text{-bit})$	
s_1	4722688
s_2	14617568463136
s_3	29894897984637227312
s_4	46358542553945186095112704
$ J_C(\mathbb{F}_p) $	2.4789034620376653463540859489797855263219497047089(162-bit)

¹ This algorithm does not always give β with $N_{K/\mathbb{Q}}(\beta) = p$ theoretically. But the vector produced by this algorithm had norm p in all experiments we tried.

² Here we count the number of primes p such that $|J_C(\mathbb{F}_p)| = 2 \cdot (\text{prime})$ for at least one a .

Table 3. An Example of a suitable curve for genus-4 HCC over 60-bit fields

$y^2 = x^9 + 1953125x, p = 1152921504606851137(61\text{-bit})$	
s_1	564124384
s_2	1345970607051288832
s_3	-749185980839542708811633632

$ J_C(\mathbb{F}_p) $	2-8834235319569458676272278733923238248994105786494304997302 48324828139649(239-bit)

All computation were done on a system with Pentium 4 1.6GHz.

7.3 Notes on Security

All examples in Table 2 are not weak against Frey-Rück attack[6]. To see this, one can easily check that a large prime factor of $|J_C(\mathbb{F}_p)|$ does not divide $p^r - 1, r = 1, 2, \dots, 4^3 \lfloor \log^2 p \rfloor$.

From the result of Duursma, Gaudry and Morain [5], an automorphism of large order can be exploited to accelerate the Pollard’s rho algorithm. If there is an automorphism of order m , we can get a speed up of \sqrt{m} . The order of any automorphism of $y^2 = x^9 + ax$ is at most 16. So the Pollard’s rho algorithm for these curves can be improved only by a factor 4.

As we saw in 6.4, J_C in Table 2 and 3 cannot split over \mathbb{F}_{p^2} and \mathbb{F}_{p^4} . So examples in Table 2 cannot be reduced to genus-2 HCC of about 80-bit and ECC of about 160-bit. And an example in Table 3 cannot be reduced to genus-2 HCC of about 120-bit and ECC of about 240-bit.

8 Conclusions

We gave explicit formulae of the order of Jacobian groups for hyperelliptic curves of type $y^2 = x^{2k+1} + ax$ over a finite prime field and gave a necessary condition that the curves are suitable for genus-4 HCC. By using these formulae, we searched suitable curves for HCC among the above curves and found many suitable curves for genus-4 HCC.

Solvability of a System of Bivariate Polynomial Equations over a Finite Field

(Extended Abstract)

Neeraj Kayal

Indian Institute of Technology, Kanpur
and
National University of Singapore

Abstract. We investigate the complexity of the following polynomial solvability problem: Given a finite field \mathbb{F}_q and a set of polynomials

$$f_1(x, y), f_2(x, y), \dots, f_n(x, y), g(x, y) \in \mathbb{F}_q[x, y]$$

determine the \mathbb{F}_q -solvability of the system

$$f_1(x, y) = f_2(x, y) = \dots = f_n(x, y) = 0 \text{ and } g(x, y) \neq 0$$

We give a *deterministic* polynomial-time algorithm for this problem.

1 Motivation

The need to find solutions of polynomial congruences and to count their number over various fields has appeared in many important works in the history of number theory, algebra and geometry. For example, Fermat's Last Theorem asserts that for any integer $n \geq 3$ the following bivariate system has no solution over the field \mathbb{Q} of rational numbers.

$$x^n + y^n = 1 \quad \text{and} \quad xy \neq 0$$

The general algorithmic problem of the decidability of solvability of such systems over \mathbb{Q} remains a major open problem in algorithmic number theory. Here we examine the computational complexity of determining the existence of a solution to a system of bivariate polynomial equations over a given finite field \mathbb{F}_q . For a general polynomial system in n variables, the problem is known to be efficiently solvable when the system is linear and is **NP**-complete otherwise, even when the field is as small as 2 and the degree of each polynomial is bounded by 2.

Our focus is on *deterministic* algorithms for the problem of solvability of a system of bivariate polynomials over a given finite field \mathbb{F}_q . Huang and Wong, [HW99] give a *randomized* polynomial time algorithm for this problem when the field is a prime field. We give a *deterministic* polynomial-time algorithm for this problem over *any* given finite field \mathbb{F}_q . The techniques used herein also give an efficient *deterministic* approximation algorithm for the closely related problem of counting the number of solutions to a given bivariate system.

Problem - Existence of solution to a general bivariate system

Input. A finite field \mathbb{F}_q , polynomials $f_1(x, y), f_2(x, y), \dots, f_m(x, y) \in \mathbb{F}_q[x, y]$ and a polynomial $g(x, y) \in \mathbb{F}_q[x, y]$.

Question. Does there exist a point $(a, b) \in \mathbb{F}_q \times \mathbb{F}_q$ such that

$$f_i(a, b) = 0 \text{ for all } 1 \leq i \leq m$$

$$\text{and } g(a, b) \neq 0$$

We give an efficient deterministic algorithm for this problem. As an application of this result, we immediately get an efficient deterministic algorithm for recognizing permutation functions, wherein a rational function $f(x) = \frac{g(x)}{h(x)} \in \mathbb{F}_q(x)$ is said to be a permutation function if the corresponding map $f : \mathbb{F}_q \mapsto \mathbb{F}_q$ defined by $a \mapsto f(a)$ is total and bijective. Permutation functions have found numerous applications, including cryptography [LM83]. Indeed, the RSA cryptosystem [RSA78] is one such application. A survey of permutation functions and their applications can be found in the articles by Lidl and Mullen [LM88], [LM93]. Ma and Gathen showed that this problem is in **ZPP**, and had posed as an open problem the deterministic complexity of recognizing permutation functions :

“Besides the problem *PRIMES* of recognizing prime numbers, it seems to be the only natural decision problem in **ZPP** unknown to be in **P**.” - [MG94]

For polynomials, Lenstra [Len05] showed that this problem is in **P** by using a classification of permutation polynomials, this classification itself being based on the classification of finite simple groups. The problem of recognizing permutation functions can be easily seen to reduce to the bivariate system solvability problem above by noting that a rational function $f(x) = \frac{g(x)}{h(x)} \in \mathbb{F}_q(x)$ is a permutation function if and only if the system

$$h(x)(g(x)h(y) - h(x)g(y)) = 0, \quad x - y \neq 0$$

has no solution over \mathbb{F}_q . Thus our deterministic algorithm for bivariate systems immediately gives a deterministic test for permutation functions. Moreover, the proof of correctness of our algorithm is completely elementary.

Determining the existence of solutions to polynomial equations and finding these solutions is closely related to the problem of polynomial factorization. In spite of a lot of effort by several researchers, an efficient deterministic algorithm for the general polynomial factorization problem remains elusive. In the first part of this paper we examine the problem of deterministically factoring bivariate polynomials over a given finite field \mathbb{F}_q . We devise an algorithm that partially factors a given bivariate polynomial. We will later on describe precisely what the output of this partial factorization algorithm looks like. This algorithm is itself of independent interest. We then apply this factoring algorithm to solve the problem of existence of solution to systems of equations as mentioned above.

2 Some Definitions and Notation

2.1 Resultant and Discriminant

For two bivariate polynomials $f(x, y)$ and $g(x, y)$ in $\mathbb{F}_q[x, y]$ we will denote by $\text{Resultant}_x(f(x, y), g(x, y)) \in \mathbb{F}_q[y]$ the resultant of the two polynomials with respect to the variable x . We will denote by $\Delta_x(f(x, y)) \in \mathbb{F}_q[y]$ the discriminant of the polynomial $f(x, y)$ with respect to the variable x .

2.2 Nice Bivariate Polynomials

Definition 1. A bivariate polynomial $f(x, y) \in \mathbb{F}_q[x, y]$ of total degree n is nice if $f(x, 0)$ is squarefree and of degree n .

Note that the coefficient of x^i of a nice polynomial $f(x, y)$ as a polynomial in y has degree no more than $n - i$, in particular the leading coefficient of $f(x, y)$ with respect to x is in \mathbb{F}_q .

Also observe that a nice polynomial $f(x, y) \in \mathbb{F}_q[x, y]$ remains nice over any extension field \mathbb{K} of \mathbb{F}_q and that any factor of a nice polynomial is also a nice polynomial. We will see that the problem of general bivariate factoring can be reduced to factoring a nice bivariate polynomial.

2.3 Absolutely Irreducible Polynomial

Definition 2. A bivariate polynomial $h(x, y) \in \mathbb{F}[x, y]$ is said to be absolutely irreducible if it is irreducible over \mathbb{F} and remains irreducible over the algebraic closure $\overline{\mathbb{F}}$ of \mathbb{F} .

For example $(y^2 - x^3) \in \mathbb{F}_7[x, y]$ is absolutely irreducible whereas $(y^2 + x^2) \in \mathbb{F}_7[x, y]$ is irreducible over \mathbb{F}_7 but factors into $(y + \sqrt{-1}x)(y - \sqrt{-1}x)$ over the extension $\mathbb{F}_{7^2} = \mathbb{F}_7(\sqrt{-1})$ and hence is not absolutely irreducible over \mathbb{F}_7 . The importance of absolutely irreducible polynomials stems from a classic theorem of Weil which states that every non-singular absolutely irreducible curve of degree d over a finite field \mathbb{F}_q has a lot of (at least $q - d^2\sqrt{q}$) \mathbb{F}_q -rationals points. This has been generalized by Bach [Bac93] to all absolutely irreducible curves.

By the degree of a bivariate polynomial $h(x, y) \in \mathbb{F}[x, y]$ we will mean the total degree of $h(x, y)$. Moreover $h(x, y)$ has a unique factorization over the algebraic closure $\overline{\mathbb{F}}$ of \mathbb{F} . Now collect all the elements of $\overline{\mathbb{F}}$ that occur as the coefficient of some term $x^i y^j$ in some irreducible factor of $h(x, y)$ over $\overline{\mathbb{F}}$. Since this is a finite set, all these coefficients lie in some finite extension \mathbb{K} of \mathbb{F} . We will call the smallest such extension field \mathbb{K} the splitting field of $h(x, y)$. We will denote by $\dim_{\mathbb{F}}(h(x, y))$ the dimension of the splitting field of $h(x, y)$ over \mathbb{F} .

Definition 3. We will call a polynomial $h(x, y) \in \mathbb{F}_q[x, y]$ a (n, d) -uniform polynomial over \mathbb{F}_q if all its \mathbb{F}_q -irreducible factors have the same degree n and the same dimension d over \mathbb{F}_q .

Our first goal is to extend the distinct degree factorization algorithm of Gao, Kaltofen and Lauder [GKL04] to split a given polynomial $h(x, y) \in \mathbb{F}_q[x, y]$ into a product of uniform polynomials.

Theorem 1. [Uniform factoring] *There exists a deterministic algorithm that on input a polynomial $h(x, y) \in \mathbb{F}_q[x, y]$ outputs*

$$\langle (h_1(x, y), n_1, d_1), (h_2(x, y), n_2, d_2), \dots (h_k(x, y), n_k, d_k) \rangle$$

such that

$$h(x, y) = h_1(x, y)h_2(x, y) \cdots h_k(x, y)$$

where each $h_i(x, y)$ is a (n_i, d_i) -uniform polynomial over \mathbb{F}_q

Moreover the algorithm runs in time $\text{poly}(\text{deg}(h) \log q)$.

Note that the output of the algorithm of Theorem 1 is a refinement of the distinct degree factorization of $h(x, y)$ over \mathbb{F}_q . It also tells us about the irreducibility and the absolute irreducibility of $h(x, y)$ over \mathbb{F}_q . In the next section we prove some preliminary lemmas needed for the algorithm in Theorem 1.

3 Splitting of Nice \mathbb{F}_q -Irreducible Polynomials in Extensions of \mathbb{F}_q

Let \mathbb{K} be a field extension of the finite field \mathbb{F}_q . Let $\phi \in \text{Gal}_{\mathbb{K}/\mathbb{F}}$ be an automorphism of \mathbb{K} . We extend ϕ to $\mathbb{K}[x, y]$ as follows

Definition 4. Let $\phi \in \text{Gal}_{\mathbb{K}/\mathbb{F}}$ be an automorphism of \mathbb{K} . Define the map $\phi : \mathbb{K}[x, y] \mapsto \mathbb{K}[x, y]$ as

$$\phi(f(x, y)) = \sum_{1 \leq k, l \leq n} \phi(a_{kl})x^k y^l$$

$$\text{where } f(x, y) = \sum_{1 \leq k, l \leq n} a_{kl}x^k y^l$$

Observe that the map $\phi : \mathbb{K}[x, y] \mapsto \mathbb{K}[x, y]$ is an automorphism of the ring $\mathbb{K}[x, y]$ that fixes the subring $\mathbb{F}_q[x, y]$. In particular,

- $\phi(f(x, y) + g(x, y)) = \phi(f(x, y)) + \phi(g(x, y))$
- $\phi(f(x, y)g(x, y)) = \phi(f(x, y))\phi(g(x, y))$

We now define an equivalence relation on $\mathbb{K}[x, y]$ induced by such automorphisms of $\mathbb{K}[x, y]$.

Definition 5. Let $f(x, y) \in \mathbb{K}[x, y]$ be any bivariate polynomial. Then $\phi(f(x, y))$ for any $\phi \in \text{Gal}_{\mathbb{K}/\mathbb{F}}$ is said to be a conjugate of $f(x, y)$ over \mathbb{F}_q . When the underlying field \mathbb{F}_q is clear from context, we will simply say that $\phi(f(x, y))$ is a conjugate of $f(x, y)$.

Observe that conjugacy is an equivalence relation on $\mathbb{K}[x, y]$. Now consider a nice \mathbb{F}_q -irreducible polynomial $h(x, y) \in \mathbb{F}_q[x, y]$. Let $\mathbb{K} \supseteq \mathbb{F}_q$ be a finite field extension of $\mathbb{F}_q[x, y]$. How does $h(x, y)$ factor over \mathbb{K} ? We claim that all the \mathbb{K} -irreducible factors of $h(x, y)$ in \mathbb{K} are in fact conjugates of each other. In particular, all the \mathbb{K} -irreducible factors of $h(x, y)$ are of equal degree.

Claim 2. *Let $h(x, y) \in \mathbb{F}_q[x, y]$ be a nice irreducible polynomial of total degree n . Let \mathbb{K} be any finite field extension of \mathbb{F}_q . If $f_1(x, y) \in \mathbb{K}[x, y]$ and $f_2(x, y) \in \mathbb{K}[x, y]$ are any two factors of $h(x, y)$ that are irreducible over the extension field \mathbb{K} , then $f_1(x, y)$ and $f_2(x, y)$ are conjugates over the base field \mathbb{F}_q .*

Proof. For a polynomial $f(x, y) \in \mathbb{K}[x, y]$, define $H_f \leq Gal_{\mathbb{K}/\mathbb{F}}$ to be the subgroup of $Gal_{\mathbb{K}/\mathbb{F}}$ consisting of automorphisms in $Gal_{\mathbb{K}/\mathbb{F}}$ that fix $f(x, y)$. Since the galois groups of finite extensions of finite fields are cyclic groups, H_f must be a normal subgroup of $Gal_{\mathbb{K}/\mathbb{F}}$.

Let $f(x, y) \in \mathbb{K}[x, y]$ be a factor of $h(x, y)$ which is irreducible over \mathbb{K} . Let the set of distinct cosets of H_f in $Gal_{\mathbb{K}/\mathbb{F}}$ be

$$Gal_{\mathbb{K}/\mathbb{F}} / H_f = \{H_f\phi_1, H_f\phi_2, \dots H_f\phi_t\}$$

Then $\phi_1(f(x, y)), \phi_2(f(x, y)), \dots \phi_t(f(x, y))$ are all the distinct conjugates of $f(x, y)$. We claim that the unique factorization of $h(x, y)$ into irreducible polynomials over \mathbb{K} is simply the product of all these distinct conjugates of $f(x, y)$. That is,

$$h(x, y) = \prod_{H \in Gal_{\mathbb{K}/\mathbb{F}} / H} \phi(f(x, y)) \tag{1}$$

Let ϕ be any automorphism in $Gal_{\mathbb{K}/\mathbb{F}}$. Now

$$f(x, y) | h(x, y) \Rightarrow \exists g(x, y) \in \mathbb{K}[x, y] \text{ such that } h(x, y) = f(x, y)g(x, y)$$

$$\text{Applying } \phi \text{ to both sides, } \phi(h(x, y)) = \phi(f(x, y))\phi(g(x, y))$$

$$\text{or, } h(x, y) = \phi(f(x, y))\phi(g(x, y))$$

$$\Rightarrow \phi(f(x, y)) | h(x, y)$$

By the same reasoning $\phi(f(x, y)) \in \mathbb{K}[x, y]$ is irreducible over \mathbb{K} for if any $g(x, y) \in \mathbb{K}[x, y]$, $deg(g(x, y)) < deg(\phi(f(x, y))) = deg(f(x, y))$ divides $\phi(f(x, y))$ then $\phi^{-1}(g(x, y))$ divides $f(x, y)$, contradicting the irreducibility of $f(x, y)$ over \mathbb{K} . Thus any conjugate of $f(x, y)$ is also an irreducible factor of $h(x, y)$. Moreover, $f(x, y)$ being irreducible over \mathbb{K} , is coprime to all conjugates distinct from itself. Thus the rhs of equation (1) divides $h(x, y)$. Moreover the rhs of equation (1) is fixed by all the automorphisms in $Gal_{\mathbb{K}/\mathbb{F}}$. Since finite extensions of finite fields are normal extensions, so any polynomial in $\mathbb{K}[x, y]$ that is fixed by all the automorphisms in $Gal_{\mathbb{K}/\mathbb{F}}$ is in fact a polynomial in $\mathbb{F}_q[x, y]$. Hence the rhs of equation (1) is in fact a polynomial in $\mathbb{F}_q[x, y]$ that divides $h(x, y)$. By the irreducibility of $h(x, y)$ over \mathbb{F}_q , we deduce that equation (1) is indeed the unique factorization of $h(x, y)$. Thus all the irreducible factors of $h(x, y)$ over \mathbb{K} are precisely all the distinct conjugates of $f(x, y)$.

Now consider an irreducible polynomial $h(x, y) \in \mathbb{F}_q[x, y]$ that factors in the algebraic closure of \mathbb{F}_q . What is the splitting field of $h(x, y)$? Can we put a bound on the dimension of the splitting field over \mathbb{F}_q ? Assuming that $h(x, y)$ is a nice polynomial, the following proposition shows that if $t(x)$ is an irreducible factor of $h(x, 0)$, then the splitting field of $h(x, y)$ is a subfield of the finite field $\mathbb{F}_q[z]/\langle t(z) \rangle$. In particular, if $h(x, 0)$ has a root $\alpha \in \mathbb{F}_q$, then $h(x, y)$ must be absolutely irreducible.

Proposition 3. *Let $h(x, y) \in \mathbb{F}_q[x, y]$ be a nice irreducible polynomial of total degree n . Let $\dim_{\mathbb{F}}(h(x, y)) = d$. Also let $t(z) \in \mathbb{F}_q[z]$ be an irreducible factor of $h(z, 0)$. Then $d \deg(t(z))$ and $h(x, y)$ breaks into absolutely irreducible factors over $\mathbb{K} := \mathbb{F}_q[z]/\langle t(z) \rangle$, each irreducible factor over \mathbb{K} being of degree $m = \frac{n}{d}$.*

Proof. Let $f(x, y) \in \mathbb{K}[x, y]$ be an irreducible factor of $h(x, y)$ in $\mathbb{K}[x, y]$. Suppose if possible that $f(x, y)$ is not absolutely irreducible but breaks further over some finite extension $\mathbb{L} \supset \mathbb{K}$.

Let H_f be as in claim 2. By claim 2

$$h(x, y) = \prod_{H \phi \in G/H} \phi(f(x, y)) \tag{2}$$

Let $\alpha \in \mathbb{K}$ be a root of the polynomial $t(z)$. Now

$$\begin{aligned} (x - \alpha) \mid (h(x, 0) &= \prod_{H \phi \in G/H} \phi(f(x, 0))) \\ \Rightarrow \exists \phi \in Gal_{\mathbb{K}/\mathbb{F}} \text{ such that } (x - \alpha) \mid &\phi(f(x, 0)) \\ \Rightarrow (x - \beta) \mid f(x, 0) \text{ where } \beta = \phi^{-1}(\alpha) \end{aligned}$$

Note that $\beta = \phi^{-1}(\alpha) \in \mathbb{K}$ is also a root of the polynomial $t(z)$.

By claim 2 the irreducible factors of $f(x, y)$ over \mathbb{L} are all conjugates. Let $f_1(x, y)$ be an irreducible factor of $f(x, y)$ over \mathbb{L} such that $(x - \beta)$ divides $f_1(x, 0)$. Let $\psi \in Gal_{\mathbb{L}/\mathbb{K}}$ be such that $\psi(f_1(x, y))$ is another irreducible (over \mathbb{L}) factor of $f(x, y)$ distinct from $f_1(x, y)$. Now since $(x - \beta) \mid f_1(x, 0)$, we must also have $(x - \psi(\beta)) = (x - \beta) \mid \psi(f_1(x, 0))$. This implies that $(x - \beta)^2$ divides $f(x, 0)$ which is a contradiction since $h(x, 0)$ and hence $f(x, 0)$ are squarefree.

Thus the irreducible factors of $h(x, y)$ over \mathbb{K} are absolutely irreducible. Hence there exists a subfield $\mathbb{F} \subseteq \mathbb{K}$ which is the splitting field of $h(x, y)$. Therefore $d = [\mathbb{F} : \mathbb{F}_q]$ divides $\deg(t(z)) = [\mathbb{K} : \mathbb{F}_q] = [\mathbb{K} : \mathbb{F}][\mathbb{F} : \mathbb{F}_q]$.

By the definition of the splitting field of $h(x, y)$, the coefficients occurring in $f(x, y)$ lie in the field \mathbb{F} and do not all lie in some proper subfield of \mathbb{F} . Hence \mathbb{F} is precisely the subfield of \mathbb{K} which is fixed by every automorphism in H_f . So

$$d = [\mathbb{F} : \mathbb{F}_q] = ord(Gal_{\mathbb{K}/\mathbb{F}} / H_f)$$

Further $ord(Gal_{\mathbb{K}/\mathbb{F}} / H_f)$ is the number of distinct absolutely irreducible factors of $h(x, y)$. Since all the irreducible factors of $h(x, y)$ are of the same degree, say m , we have

$$m \cdot ord(Gal_{\mathbb{K}/\mathbb{F}} / H_f) = deg(h(x, y))$$

$$\begin{aligned} \Rightarrow m \cdot d &= n \\ \Rightarrow m &= \frac{n}{d} \end{aligned}$$

In summary, if $h(x, y) \in \mathbb{F}_q[x, y]$ is a nice polynomial that is \mathbb{F}_q -irreducible and $t_1(z), t_2(z) \in \mathbb{F}_q[z]$ are any two \mathbb{F}_q -irreducible factors of $h(z, 0)$, then the degree of an irreducible factor of $h(x, y)$ over $\mathbb{K}_1 := \mathbb{F}_q[z]/\langle t_1(z) \rangle$ is the same as the degree of an irreducible factor of $h(x, y)$ over $\mathbb{K}_2 := \mathbb{F}_q[z]/\langle t_2(z) \rangle$. Moreover, this degree is $m = \frac{n}{d}$, where the dimension d of $h(x, y)$ was defined independently of the choice of any factor of $h(z, 0)$. This observation will be the key to our uniform-factoring algorithm.

4 Algorithm for Uniform Factoring

Given a polynomial $f(x, y) \in \mathbb{F}_q[x, y]$, the first step of our algorithm is to invoke the algorithm in [GKL04] on $f(x, y)$ thereby obtaining a distinct-degree factorization of $f(x, y)$. So now we can assume that the input to our algorithm is a nice bivariate polynomial $h(x, y) \in \mathbb{F}_q[x, y]$ and an integer n , such that each \mathbb{F}_q irreducible factor of $h(x, y)$ has the same degree n .

If we could construct an irreducible polynomial $t(z) \in \mathbb{F}_q[z]$ of degree n in deterministic polynomial time, we could simply invoke the distinct-degree factorization algorithm on $h(x, y)$ over the field $\mathbb{F}_q[z]/\langle t(z) \rangle$ and obtain all the distinct dimension factors as well. No deterministic algorithm is currently known for constructing irreducible polynomials. Fortunately we can get around this problem by working over the ring $R \stackrel{\text{def}}{=} \mathbb{F}_q[z]/\langle h(z, 0) \rangle$.

Our algorithm from this point onwards is the similar to that in [GKL04] but with one key difference - we work over the ring R whereas [GKL04] work over the Berlekamp subalgebra of R . The proof of correctness is also similar and we omit the details due to lack of space.

5 Solvability of a Bivariate Polynomial System

Recall the problem we started with - given a set of polynomials $f_1, f_2, \dots, f_m, g \in \mathbb{F}_q[x, y]$ does there exist a point $(a, b) \in \mathbb{F}_q \times \mathbb{F}_q$ such that

$$f_1(a, b) = f_2(a, b) = \dots = f_m(a, b) = 0 \quad , \quad g(a, b) \neq 0 \quad ?$$

5.1 Overview of the Algorithm

In this section we apply the uniform factoring algorithm devised above to the problem of determining the solvability of a bivariate polynomial system. We now give an overview of the algorithm. If the size of the field q is very small ($< d^5 m$), we can determine the solvability in $O(d^{10}m)$ time by simply trying all possible values of x and y . Henceforth we shall assume that $q > d^5$.

There is an initial preprocessing stage, the effect of which is to make *all* the given polynomials nice and separable with respect to x . For now assume that all the input polynomials are *nice*. Our algorithm is recursive and we now consider two special base cases of this recursion.

Special case: $m \geq 2$ and $\text{Resultant}_x(f_1, f_2) \neq 0$. Suppose that $m \geq 2$ and consider $f_1(x, y), f_2(x, y) \in \mathbb{F}_q[x, y]$. Further suppose that

$$\rho(y) \stackrel{\text{def}}{=} \text{Resultant}_x(f_1, f_2) \neq 0$$

In this case for any point $(a, b) \in \mathbb{F}_q \times \mathbb{F}_q$ satisfying $f_1(a, b) = f_2(a, b) = 0$, it must be the case that b is a root of $\rho(y)$. We will say that y is algebraic over \mathbb{F}_q and in this case we can devise a deterministic polynomial-time algorithm that not only determines the existence of a solution to the given system but also determines the exact number of distinct solutions to the system.

Special case: $m = 1$. Here we are looking for \mathbb{F}_q solutions to the system

$$f_1(x, y) = 0 \text{ and } g(x, y) \neq 0$$

By removing those factors from $f_1(x, y)$ that are common to both $f_1(x, y)$ and $g(x, y)$, we can assume that $\text{Resultant}_x(f_1, g) \neq 0$.

We use the uniform bivariate factoring algorithm devised above to determine whether $f_1(x, y)$ has an absolutely irreducible factor or not. Suppose that $f_1(x, y)$ does indeed have an absolutely factor $l(x, y) \in \mathbb{F}_q[x, y]$. Then Weil’s theorem [Bac93] assures us of the existence of a large (about q) number of \mathbb{F}_q -solutions to the equation $l(x, y) = 0$ and hence to the equation $f_1(x, y) = 0$. Moreover, Bezout’s theorem assures us that only a few ($\leq d^2$) of these solutions to $f_1(x, y) = 0$ are common to $g(x, y) = 0$. So if $f_1(x, y)$ does have an absolutely irreducible factor and if the size of the field q is large enough ($\geq d^5$) then the existence of a solution to the above system is guaranteed.

Otherwise none of the \mathbb{F}_q -irreducible factors of $f_1(x, y)$ are absolutely irreducible and hence by lemma 3 it follows that every \mathbb{F}_q -point (a, b) on the curve $f_1(x, y) = 0$ is a repeated point. In particular (a, b) is also a zero of $f_2(x, y) \stackrel{\text{def}}{=} \frac{\partial f_1}{\partial x}$. The preprocessing stage assures us that $\Delta_x(f_1) = \text{Resultant}_x(f_1, f_2) \neq 0$. This boils our problem down to the first special case.

General case. We now return to the general problem where $m \geq 2$ and $\text{Resultant}_x(f_1, f_2) = 0$. Compute $l(x, y) = \text{gcd}_x(f_1, f_2)$ which must be non-trivial since the resultant is zero. Then we can express the given polynomials f_1 and f_2 as

$$f_1(x, y) = l(x, y)f_{11}(x, y) \text{ , } f_2(x, y) = l(x, y)f_{21}(x, y)$$

where $\text{Resultant}_x(f_{11}, f_{21}) \neq 0$. Thus the given system has a \mathbb{F}_q -solution if and only if either the system

$$f_{11} = f_{21} = f_3 = f_4 = \dots = f_m = 0 \text{ , } g \neq 0$$

or the system

$$l = f_3 = f_4 = \dots = f_m = 0, g \neq 0$$

has a \mathbb{F}_q -solution. The first system is the first special case considered above. The \mathbb{F}_q -solvability of the second system is determined recursively. Thus if the time taken by the algorithm is denoted by $T(m, d, q)$ then

$$T(m, d, q) = T(m - 1, d, q) + \text{poly}(md \log q)$$

Or, $T(m, d, q) = T(1, d, q) + \text{poly}(md \log q)$

Or, $T(m, d, q) = \text{poly}(md \log q)$

5.2 Handling the Case $m \geq 2$ and Resultant $_x(f_1, f_2) \neq 0$

In this section, we present the details of how to deterministically determine the solvability of a bivariate system of this form. Compute

$$\rho(y) \stackrel{\text{def}}{=} \gcd(y^q - y, \text{Resultant}_x(f_1, f_2)) \neq 0$$

which has degree at most d^2 . Suppose that $(a, b) \in \mathbb{F}_q \times \mathbb{F}_q$ is a solution to the system $f_1(x, y) = f_2(x, y) = 0$. This implies that

$$\text{Resultant}_x(f_1(x, b), f_2(x, b)) = 0$$

(Note that the converse is not true since $f_1(x, b)$ and $f_2(x, b)$ may share a common root which does not lie in \mathbb{F}_q but in some finite extension of \mathbb{F}_q). Thus b is an \mathbb{F}_q -root of $\text{Resultant}_x(f_1, f_2)$ and hence must be a root of $\rho(y)$. Let the roots of $\rho(y)$ be $b_1, b_2, \dots, b_l \in \mathbb{F}_q$. Then the given system has a solution if and only if there exists a $b \in \{b_1, b_2, \dots, b_l\}$ such that

$$g(x, b) \neq 0 \pmod{h(x)}$$

where

$$h(x) \stackrel{\text{def}}{=} \gcd(f_1(x, b), f_2(x, b), \dots, f_m(x, y), x^q - x)$$

We can check for the existence of such a b without needing to actually factor $\rho(y)$ by working over the ring $R \stackrel{\text{def}}{=} \mathbb{F}_q[y]/\langle \rho(y) \rangle$. We simply view f_1, f_2, \dots, f_m, g as univariate polynomials in the variable x over the ring R and compute $h(x) \in R[x], h(x) \stackrel{\text{def}}{=} \gcd_x(f_1(x), f_2(x), \dots, f_m(x), x^q - x)$. (This gcd can be computed by the standard Euclidean algorithm applied over the ring R with just one minor modification - if the leading coefficient $\alpha \in R$ of a divisor polynomial $b(x) \in R[x]$ is not a unit of R , then the zero-divisoriness of α allows us to factor the ring R into a direct sum of rings R_1 and R_2 . Having obtained this factorization, we can carry out the division in each of these rings R_1 and R_2 and combine the result using chinese remaindering to get the result in the original ring R). Then the given system has an \mathbb{F}_q -solution if and only if

$$g(x) \neq 0 \pmod{h(x)} \text{ (over } R)$$

5.3 Preprocessing

The job of the preprocessing stage is to make the given polynomials nice with respect to x .

Preprocessing: Input and Output specifications

Input. A finite field \mathbb{F}_q of characteristic p , a set of bivariate polynomials

$$f_1(x, y), f_2(x, y), \dots, f_m(x, y), f_{m+1}(x, y) \in \mathbb{F}_q[x, y]$$

of total degree at most d . Further $q \geq 2d^2m$.

Output. Polynomials $\hat{f}_1(x, y), \hat{f}_2(x, y), \dots, \hat{f}_m(x, y), \hat{h}(x, y) \in \mathbb{F}_q[x, y]$ of total degree at most d^2 such that each $\hat{f}_i(x, y)$ is a nice and separable polynomial with respect to x . Moreover the number of solutions to the system

$$f_1(x, y) = f_2(x, y) = \dots = f_m(x, y) = 0 \text{ , } f_{m+1}(x, y) \neq 0$$

is the same as the number of solutions to the system

$$\hat{f}_1(x, y) = \hat{f}_2(x, y) = \dots = \hat{f}_m(x, y) = 0 \text{ , } \hat{f}_{m+1}(x, y) \neq 0$$

In the first part of the preprocessing stage we make each of the given polynomials square-free by replacing each polynomial by its radical and then doing a substitution of the following form:

$$\hat{f}_i(x, y) = f_i(x, y + ax)$$

Suppose that $f_i(x, y)$ has total degree d_i then note that the coefficient of x^d in \hat{f}_i is a polynomial t_i in a of degree at most d_i . Thus we need to choose an $a \in \mathbb{F}_q$ such that

$$t(a) \stackrel{\text{def}}{:=} \prod_{1 \leq i \leq m+1} t_i(a) \neq 0$$

$t(a)$ is a polynomial of degree at most dm and thus we can certainly find such an a in deterministic polynomial time. Thus in what follows we will assume that each $f_i(x, y)$ is squarefree and monic in x .

Making the polynomials separable with respect to x requires a little more work. Let $l \stackrel{\text{def}}{:=} \lceil \log_p d \rceil$. The main idea is that if $f_i(x, y)$ is not separable with respect to x (i.e. $\Delta_x(f(x, y)) = 0$) then we can deterministically compute a factorization of $f_i(x, y)$ of the form

$$f_i(x, y) = \prod_{0 \leq k \leq l} f_{ik}(x^p, y)$$

where each $f_{ik}(x, y)$ is a polynomial in x^p but not a polynomial x^{p+1} .

For a polynomial $f(x, y) = \sum_{i,j} a_{ij}x^i y^j \in \mathbb{F}_q[x, y]$ let us define $f^{(p)}(x, y)$ to be the polynomial $f^{(p)}(x, y) \stackrel{\text{def}}{:=} \sum_{i,j} a_{ij}x^i y^j$. Note that for any point $(a, b) \in \mathbb{F}_q \times \mathbb{F}_q$,

$$f(a, b) = 0 \iff f^{(p)}(a^p, b^p) = 0$$

That is, the set of zeroes of $f(x, y)$ is exactly the same as the set of zeroes of the polynomial $f^{(p)}(x^p, y^p)$.

Corresponding to every input polynomial

$$f_i(x, y) = \prod_{0 \leq k \leq l} f_{ik}(x^p, y)$$

we output the polynomial

$$\hat{f}_i(x, y) \stackrel{\text{def}}{=} \prod_{0 \leq k \leq l} f_{ik}^{(p^{-1})}(x, y^{p^{-1}})$$

It can be shown that the number of \mathbb{F}_q -solutions to this new system is the same as the number of \mathbb{F}_q -solutions to the original system. We omit the proof due to lack of space.

6 Conclusion

A very general problem in algorithmic number theory is the following: let

$$f_1, f_2, \dots, f_m \in \mathbb{F}_q[x_1, x_2, \dots, x_n]$$

be a collection of m dense polynomials in n variables over the finite field \mathbb{F}_q . Let Q_1, Q_2, \dots, Q_n be some sequence of quantifiers, i.e. each quantifier is either " \exists " or " \forall ". What is the computational complexity of determining the truth value of the following statement:

$$Q_1 x_1 \in \mathbb{F}_q \cdots Q_n x_n \in \mathbb{F}_q \quad f_1 = f_2 = \dots = f_m = 0$$

when the number n of variables is bounded? (For unbounded number of variables, the problem is **PSPACE**-complete and bounding the number of alternations between " \exists " and " \forall ", we get the different levels of the polynomial hierarchy).

Generalizing the techniques of this paper quite a bit further, it has recently been shown by the author that the existential version of this problem in which all the quantifiers are existential can be solved deterministically in time polynomial in the size of the input. Beyond this, we do not know an efficient solution for even the Π_2 -version of this problem with 2 variables -

Open Question. Is there a random polynomial time algorithm for determining the truth of the statement

$$\forall x \in \mathbb{F}_q \exists y \in \mathbb{F}_q \quad f(x, y) = 0 \quad ?$$

Acknowledgements

The author is grateful to Alan Lauder, Manindra Agrawal and Nitin Saxena for giving many helpful comments on an earlier version of this paper that improved the presentation. The author also wishes to thank Igor Shparlinski and

Hendrik Lenstra for pointing out the existence of a classification of permutation polynomials and the derived algorithm for recognizing permutation functions in deterministic polynomial time.

Abstract. We present an efficient cache-oblivious implementation of the shortest-path algorithm for planar graphs by Klein et al., and prove that it incurs no more than $\mathcal{O}\left(\frac{N}{B^{1/2}} + \frac{N}{B} \log N\right)$ block transfers on a graph with N vertices. This is the first cache-oblivious algorithm for this problem that incurs $o(N)$ block transfers.

1 Introduction

The *single-source shortest-path* (SSSP) problem is a fundamental combinatorial optimization problem with numerous applications. Let $G = (V, E)$ be a directed graph with vertex set V and edge set E ; let $s \in V$ be a distinguished vertex, called the *source vertex*; and let $\omega : E \rightarrow \mathbb{R}^+$ be an assignment of non-negative real weights to the edges of G . The SSSP-problem is to find, for every vertex $v \in V$, the distance $d(v)$ from s to v , that is, the weight of a minimum-weight (shortest) path from s to v . This problem is well-studied in the RAM-model. The classical algorithm for this problem is Dijkstra's algorithm [15], which has seen many improvements (e.g., [19, 21, 22, 23]). In particular, on planar graphs, much progress has been made: Frederickson [17] proposes an algorithm that takes $\mathcal{O}(N\sqrt{\log N})$ time, pioneering the idea to use separator decompositions to speed up shortest-path computations. Klein et al. [19] present a non-trivial refinement of Frederickson's approach that uses a hierarchy of nested separator decompositions to solve SSSP in planar directed graphs in linear time.

More recently, the SSSP-problem has been studied in memory hierarchy models, which take the varying access times of different levels of cache, main memory, and disk into account. Such algorithms can be *cache-aware* or *cache-oblivious*. The former require knowledge of the parameters of the different levels of memory and often explicitly transfer data between the different levels; the latter are oblivious of these parameters, but help the default paging algorithm by laying out the data appropriately and accessing it in a local fashion.

The most widely used model for the design of *cache-aware* algorithms is the I/O-model of Aggarwal and Vitter [1]. This model assumes a memory hierarchy consisting of two levels: the lower level has size M ; data is transferred

* Research supported by the Natural Sciences and Engineering Research Council of Canada and by the Canadian Foundation for Innovation.

between the two levels in blocks of B consecutive data items. The complexity of an algorithm is the number of blocks transferred (*I/Os*). Algorithms that perform a small number of *I/Os* are usually referred to as *I/O-efficient* algorithms. The strength of the *I/O-model* is its simplicity, while it still adequately models the situation when the *I/Os* between two levels of the memory hierarchy dominate the running time of the algorithm, which is often the case in large-scale applications. Complexities that arise often in *I/O-efficient* algorithms are the sorting bound, $\text{sort}(N) = \Theta\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right)$ *I/Os* [1, 18], the permutation bound, $\text{perm}(N) = \Theta(\min(N, \text{sort}(N)))$ *I/Os* [1], and the scanning bound, $\text{scan}(N) = \Theta(N/B)$ *I/Os*.

Solving interesting problems using cache-aware algorithms for *multi-level* hierarchies is cumbersome, because it is necessary to tune the algorithms to the sizes and block sizes of all levels of memory. *Cache-oblivious* algorithms provide an elegant solution to this problem. They are designed to be *I/O-efficient* without knowing M or B ; that is, they are formulated in the RAM-model and analyzed in the *I/O-model*, assuming that the memory transfers are performed by an optimal offline paging algorithm. Since the analysis holds for any block and memory sizes, it holds for *all* levels of a multi-level memory hierarchy (see [18] for details). Thus, the cache-oblivious model elegantly combines the simplicity of the *I/O-model* with a coverage of the entire memory hierarchy. The bounds for sorting and scanning are the same as in the *I/O-model* [9, 18], whereas $\text{perm}(N) = \text{sort}(N)$ in the cache-oblivious model [11]. Since any internal-memory algorithm is by definition cache-oblivious, but usually incurs a substantial number of block transfers, we refer to an algorithm as *cache-oblivious* in this paper if it is cache-oblivious in the sense of the definition and incurs $o(T(N))$ block transfers, where $T(N)$ is the computation time of the best internal-memory algorithm.

Previous work on graph algorithms for memory hierarchies has focused mainly on *I/O-efficient* algorithms, motivated by a number of large-scale applications that have to deal with massive graphs, such as geographic information systems, web modelling, and data mining of phone call databases. The obtained results include a large number of algorithms for planar graphs, such as $\mathcal{O}(\text{sort}(N))$ -*I/O* algorithms for computing connected components [13], minimum spanning trees [13], and strongly connected components [8]; breadth-first search (BFS) [3] and undirected depth-first search (DFS) [5]; single-source shortest paths [3]; and topological sorting [6, 7]. Directed planar DFS is studied in [8], and an optimal $\mathcal{O}(N^2/B)$ -*I/O* all-pairs shortest path algorithm is presented in [4].

Recently, a number of cache-oblivious graph algorithms have been obtained for general graphs, including algorithms for computing connected components and minimum spanning trees [2], directed breadth-first search and depth-first search [2], undirected breadth-first search [12], and undirected shortest paths [12, 14]. All these algorithms are obtained from *I/O-efficient* algorithms for these problems by designing cache-oblivious data structures that can replace the cache-aware ones in these algorithms. This strategy does not seem to work for most of the specialized algorithms for planar graphs, mentioned above: Their dependence on B is not hidden in data structures; and many of them exploit that

computation in internal memory is free in the I/O-model, by performing $\Omega(BN)$ computation in main memory. In a multi-level hierarchy, this extra computation may incur block transfers at lower cache levels, thereby leading to an excessive number of block transfers. The internal-memory computation can often be reduced. For example, for shortest paths, it can be reduced to $\mathcal{O}(n \cdot \text{polylog}(B))$, using results from [16]; but these algorithms are not easily made cache-oblivious. Nevertheless, a number of cache-oblivious algorithms for planar graphs exist. Using cache-oblivious data structures from [2, 10], the I/O-efficient algorithms for connectivity, biconnectivity, and minimum spanning trees [13], and for topologically sorting planar directed acyclic graphs [7] can be made cache-oblivious, without asymptotically increasing their complexities.

2 New Result

We make the first progress towards solving the SSSP-problem cache-obliviously in planar graphs, by analyzing the number of block transfers incurred by a cache-efficient implementation of the algorithm of [19]. We assume that a suitable multi-level separator decomposition of the graph is given. We consider finding such a decomposition the central open problem in the design of cache-oblivious algorithms for planar graphs, because separators also have played a central role in the design of I/O-efficient algorithms for planar graphs. In Sec. 7, we suggest one approach that may lead to a cache-oblivious algorithm for this problem. Our result is summarized in the following theorem.

Theorem 1. *The SSSP-problem in a planar directed graph G with N vertices and non-negative edge weights can be solved using a cache-oblivious algorithm that incurs $\mathcal{O}\left(\frac{N}{B^{1/2-\epsilon}} + \frac{N}{B} \log N\right)$ block transfers, for any constant $\epsilon > 0$, provided that a suitable multi-level separator decomposition of G is given.*

In this paper, we assume that every vertex in G has in-degree at most 2 and out-degree at most 2. A simple transformation described, for instance, in [20] achieves this. The discussion of the algorithm is divided into several sections. In Sec. 3, we discuss the necessary terminology regarding graph separators. We outline the linear-time SSSP-algorithm of [19] in Sec. 4. We show in Sec. 5 how to implement this algorithm in a cache-efficient manner. The analysis of the algorithm is provided in Sec. 6. Open problems are discussed in Sec. 7.

3 Separator Decompositions

The algorithm of [19], as many other SSSP-algorithms for planar graphs, uses a separator decomposition to organize its computation. Next we define the required partition and discuss its representation.

Definition. For a planar graph $G = (V, E)$ and an integer parameter $r > 0$, an r -partition of G is a pair $(S, \{G_1, G_2, \dots, G_h\})$ with the following properties:

(i) S is a subset of V of size $\mathcal{O}(N/\sqrt{r})$. (ii) The graphs G_1, G_2, \dots, G_h are edge-disjoint subgraphs of G whose union is G and such that any two such graphs G_i and G_j share only vertices in S . (iii) Every graph G_i , $1 \leq i \leq h$, contains at most r edges and at most \sqrt{r} vertices from S . We call the vertices in S *separator vertices*. The set of vertices in S that are contained in a graph G_i are the *boundary* of G_i .

Given a vector $\mathbf{r} = (r_0, r_2, \dots, r_k)$, a *recursive \mathbf{r} -partition* \mathcal{P} of G consists of a sequence of partitions of G , $(\mathcal{P}_0, \mathcal{P}_1, \dots, \mathcal{P}_k)$, with the following properties: (i) Each \mathcal{P}_i is an r_i -partition of G . (ii) For two consecutive partitions $\mathcal{P}_i = (S_i, \{G_1, G_2, \dots, G_s\})$ and $\mathcal{P}_{i+1} = (S_{i+1}, \{G'_1, G'_2, \dots, G'_t\})$, $S_i \supset S_{i+1}$ and, for every graph G_j in \mathcal{P}_i , there exists a graph G'_ℓ in \mathcal{P}_{i+1} such that $G_j \subseteq G'_\ell$.

In this paper, a recursive \mathbf{r} -partition will always satisfy $r_0 = 1$ and $r_k = |E|$; that is, the lowest level of the partition splits G into its edges, and the highest level consists of the entire graph.

Representation. A recursive \mathbf{r} -partition \mathcal{P} can be represented quite naturally by a rooted tree. The root of the tree is the single subgraph in \mathcal{P}_k , which is G . For a node corresponding to a graph R in \mathcal{P}_i , $i > 0$, its children represent the graphs in \mathcal{P}_{i-1} that are subgraphs of R . The leaves represent the edges of G . We call this tree the *partition tree* of \mathcal{P} . The subgraphs of G corresponding to the nodes in this tree are referred to as *regions*. The edges of G , which correspond to the leaves of the tree, are *atomic regions*, as they cannot be split any further. The *level* of a region R is the index i such that R is a graph in \mathcal{P}_i . We define ancestry of regions to be the ancestry of the corresponding nodes in the partition tree.

4 Outline of the Algorithm

The algorithm of [19] is a variant of Dijkstra’s algorithm, implemented using a hierarchy of priority queues associated with the regions of a recursive \mathbf{r} -partition of G (see Alg. 1). The entries in the priority queue $Q(R)$ of region R are the children of R ; the priority of such a child R' is the minimum tentative distance of the source vertices of all unrelaxed edges in R' . Initially, the priorities of the regions containing out-edges of s are 0 and those of the rest are $+\infty$. The algorithm chooses the child with minimal priority from $Q(G)$ and recurses on this child. If the child is non-atomic, it repeats this process; otherwise it relaxes the edge (u, v) in this region and updates the priorities of all regions containing the out-edges of v . Procedure Shortest-Paths is called on G until all edges are relaxed, that is, the priority of G itself is $+\infty$.

If every invocation of this procedure on a non-atomic region were to return after the first recursive call it makes on one of its children, this algorithm would be Dijkstra’s algorithm. However, the procedure returns from a recursive call on a level- i region R only after all edges in the region have been relaxed or α_i recursive calls have been made on children of R , for a suitable parameter α_i .

By keeping the algorithm focused on a region for some time, once a recursive call has been made on this region, Klein et al. limit the number of priority queue

Shortest-Paths(R)

```

1  $\triangleright R$  is the region on which the current invocation operates.
2  $j \leftarrow \text{level}(R)$ 
3 if  $j = 0$ 
4   then Relax the edge  $(u, v)$  in  $R$ , that is, set  $d(v) = \min(d(v), d(u) + \omega(u, v))$ .
5     if this changes the distance of  $v$  from  $s$ 
6       then Change the priority of every out-edge  $(v, w)$  of  $v$  to  $d(v)$ .
7         Change the priority of every ancestor of  $(v, w)$  whose priority is
           greater than  $d(v)$  to  $d(v)$ .
8     Change the priority of  $(u, v)$  to  $\infty$ .
9   else  $i \leftarrow 0$ 
10     while the minimum entry in  $Q(R)$  is not  $\infty$  and  $i < \alpha_j$ 
11       do  $R' \leftarrow \text{Delete-Min}(Q(R))$ 
12         Shortest-Paths( $R'$ )
13         Let the priority of  $R'$  in  $Q(R)$  be the minimum priority in  $Q(R')$ .
14          $i \leftarrow i + 1$ 

```

Algorithm 1. Outline of the shortest-path algorithm. This procedure is called repeatedly with the whole graph G as the argument until all edges are relaxed

operations on large priority queues (that is, priority queues attached to regions at higher levels) and obtain a linear time bound for their algorithm. The other advantage this approach has is that it avoids “jumping around randomly”; that is, once the algorithm focuses on a subgraph that fits into cache, it stays focused on this subgraph for a while. The computation inside the subgraph does not incur any block transfers after the whole subgraph has been loaded into the cache. To take full advantage of this, however, the algorithm has to be implemented using cache-oblivious data structures, and the parameters in the algorithm have to be chosen differently, which increases the amount of computation to $\mathcal{O}(N \log N)$. In Sec. 7, we argue that, while a reduction of the log-factor may be possible, it cannot be eliminated entirely.

5 Cache-Oblivious Implementation

In [19], Algorithm 1 is used more or less verbatim to obtain a linear running time. The updates of the priorities of all relevant regions in Lines 6 and 7 are performed using a so-called GlobalUpdate operation. This operation traverses the path from region (v, w) to the lowest common ancestor of regions (u, v) and (v, w) in the partition tree and performs the updates described in Lines 6 and 7.

A cache-efficient algorithm cannot use this strategy because the updates of atomic regions alone would require $\Theta(N)$ block transfers in the worst case. But we can exploit that the recursive calls in the algorithm correspond to a traversal of the partition tree: The correct priority of a region R has to be known only

by the time the traversal visits its parent R' because only then this information is required to extract the correct child to be visited from $Q(R')$. In order to reach R' , we have to traverse the path from the current region (u, v) to R' . Thus, if the relaxation of edge (u, v) affects the priority of R , we can carry this update along the path from (u, v) to R' and apply it to $Q(R')$ immediately before the next Delete-Min operation is to be performed on $Q(R')$. The details are as follows:

Every invocation I on a region R collects all updates on atomic regions outside of R that are triggered by descendants of I and passes them to its parent invocation I' when it returns. Let R' be the region of I' . Then I' inspects the updates received from I . Every update on an atomic region outside of R' is scheduled to be passed to the parent of I' . Updates on atomic regions inside R' are scheduled to be sent to the appropriate children of R' when the next invocations on these children are made. When an invocation on R' makes a recursive call on one of these children, R'' , the updates scheduled to be sent to R'' are applied to $Q(R'')$ and then scheduled to be sent to the appropriate children of R'' , based on which child contains the edge affected by each update.

Line 5 presents a similar problem, with a similar solution: We cannot afford to access vertex v to test whether the relaxation of edge (u, v) decreases $d(v)$. To avoid this, we store $d(v)$ with both in-edges (u_1, v) and (u_2, v) of v . When one in-edge, say (u_1, v) , decreases the distance, it informs the other in-edge, (u_2, v) , by sending an Update-Target message to (u_2, v) . Again, the correct distance of v has to be known to region (u_2, v) only when the next invocation on this region is made; that is, Update-Target messages can be delivered in the same fashion as Update messages for the out-edges of v .

We implement this strategy using the following data structures: We use a stack S to collect and pass updates to ancestors of the current region. We associate a cache-oblivious buffered repository tree (BRT) $B(R)$ [2] with every region, which we use to collect all updates to be sent from R to its children. The tree $B(R)$ serves yet another purpose: Since the updates to be performed on $Q(R)$ are in fact updates on atomic regions, and it is too costly to identify the child of R affected by every update, we store atomic regions in $Q(R)$. When retrieving the minimum entry (u, v) from $Q(R)$, we have to (1) determine the child R' of R that contains edge (u, v) , in order to make a recursive call on R' , and (2) remove all edges in R' from $Q(R)$, in order to effectively set the priority of R' to $+\infty$. Using the BRT, we can achieve both: Assume that the leaves of the partition tree are numbered left to right and that every internal node has been labelled with the interval of numbers of its descendant leaves. (This can be achieved in a preprocessing step.) We associate with every leaf of a BRT $B(R)$, which corresponds to a region R' , the interval associated with R' and with every internal node the union of the intervals of its children. This is sufficient to decide, for every update on an atomic region, to which leaf in the BRT it should be sent and to use any atomic region contained in a child R' as the key for an Extract operation that identifies R' and retrieves all up-

CO-Shortest-Paths(R, U)

```

1  ▷  $R$  is the region on which the current invocation operates;  $U$  is an array of Update
    operations provided by the parent invocation.
2   $j \leftarrow \text{level}(R)$ 
3  if  $j = 0$ 
4    then Update  $d(u)$  and  $d(v)$  using the minimum priorities of the Update and
        Update-Target operations in  $U$ , respectively.
5        Relax the edge  $(u, v)$  in  $R$ , that is, set  $d(v) = \min(d(v), d(u) + \omega(u, v))$ .
6        if Line 5 changes the distance of  $v$  from  $s$ 
7            then Insert an Update( $(v, w), d(v)$ ) operation into  $S$ , for every out-
                edge  $(v, w)$  of  $v$ ; mark this operation as inserted by region  $R$ .
8                Insert an Update-Target( $(u', v), d(v)$ ) operation into  $S$ , where
                 $(u', v)$  is the other in-edge of  $v$ ; mark this operation as inserted
                by region  $R$ .
9                Change the priority of  $(u, v)$  to  $\infty$  and return region  $(u, v)$  with
                priority  $\infty$ , for insertion into the parent's priority queue.
10   else Perform the updates in  $U$  on  $Q(R)$  and insert them into  $B(R)$ .
11        $i \leftarrow 0$ 
12       while the minimum entry in  $Q(R)$  is not  $\infty$  and  $i < \alpha_j$ 
13           do  $(u, v) \leftarrow \text{Delete-Min}(Q(R))$ 
14               Identify the child  $R'$  of  $R$  that contains edge  $(u, v)$  and extract all
                   updates on descendants of  $R'$  from  $B(R)$ .
15               Store these updates in an array  $U'$  and delete all regions affected
                   by these updates from  $Q(R)$ .
16               CO-Shortest-Paths( $R', U'$ ); let  $(x, y)$  be the edge returned by this
                   recursive call, and let  $p$  be its priority.
17               Insert edge  $(x, y)$  into  $Q(R)$ , with priority  $p$ , and into  $B(R)$ .
18               Extract all updates from  $S$  that have been inserted by  $R'$ . Re-insert
                   the updates on edges outside of  $R$  and mark them as inserted by
                    $R$ . Apply all other updates to  $Q(R)$  and insert them into  $B(R)$ .
19                $i \leftarrow i + 1$ 
20       Return the minimum-priority entry in  $Q(R)$  for insertion into the parent's
           priority queue.

```

Algorithm 2. Cache-oblivious implementation of the shortest-path algorithm

dates on descendants of R' . Once the updates on R' are retrieved, they can be deleted from $Q(R)$. The details of the cache-oblivious implementation are shown in Alg. 2.

From our discussion, it follows that the modifications do not change the sequence of edge relaxations performed by the algorithm. Hence, the algorithm remains correct. We summarize this in the following lemma:

Lemma 1. *Procedure CO-Shortest-Paths terminates with the label $d(v)$ of every vertex v set to its distance from s in G .*

6 Analysis

In this section, we analyze the number of block transfers incurred by the algorithm. One of the keys to minimizing the number of block transfers is an appropriate layout of the data structures in memory. We describe this layout in Sec. 6.1. We also describe the paging strategy we use in our analysis; the optimal paging strategy cannot do worse than ours. In Sec. 6.2, we show that our paging strategy incurs at most the number of block transfers stated in Thm. 1.

6.1 Memory Layout and Space Bound

The partition, including the associated data structures, is laid out in memory as follows: We number the nodes of the partition tree in a depth-first manner. For every node representing a region R of size r , we allocate space for $Q(R)$, $B(R)$, and a buffer space $H(R)$ of size $3a^{1/2a}r^{1-1/2a}$, for some constant $1 < a \leq 2$ defined in Sec. 6.2, which holds the buffers associated with the nodes in $B(R)$. If we refer to every region by its number, we arrange these structures in the order $Q(1), B(1), H(1), Q(2), B(2), H(2), \dots$. The space for stack S succeeds these data structures and buffer spaces for the regions in the partition.

The space allocated for every data structure is fixed, that is, the memory layout is static. Preallocating space for the BRT's and priority queues is easy because we can bound their sizes by $\mathcal{O}(r^{1/a})$ and $\mathcal{O}(r^{1-1/2a})$, respectively. For the BRT, excluding buffers, this follows because we will show in Sec. 6.2 that the number of children of R is $\mathcal{O}(r^{1-1/a})$, and $B(R)$ contains one leaf per child. For the priority queue, we observe that an edge (atomic region) stored in $Q(R)$ is either incident to a boundary vertex of a child of R or it is the value returned by the last recursive call to a child of R . The number of entries of the first type is bounded by the number of edges incident to boundary vertices of children of R , which is $\mathcal{O}(r^{1-1/2a})$. For entries of the second type, we observe that each such entry is removed before the next recursive call to the child that inserted the entry. Hence, there can be at most one such entry per child of R in $Q(R)$, that is, at most $\mathcal{O}(r^{1-1/a}) = \mathcal{O}(r^{1-1/2a})$ entries. In order to bound the buffer space required by the BRT, we exploit that, similar to $Q(R)$, $B(R)$ cannot store updates on more than $\mathcal{O}(r^{1-1/2a})$ atomic regions, which allows us to use a variant of the BRT with limited buffer space. This variant is discussed in the next paragraph.

Another way to look at the above space bound is that every level uses space proportional to the number of boundary vertices at the next lower level. Since the number of boundary vertices at level 0 is $\mathcal{O}(N)$, and the number of boundary vertices per level decreases by at least a constant factor as we proceed towards the root (see Sec. 6.2), we obtain the following lemma:

Lemma 2. *The layout of the partition tree, including priority queues, BRT's, and buffer spaces associated with its nodes, uses linear space.*

A BRT with Limited Buffer Space. In order to limit the buffer space for every BRT, we exploit that, if there is more than one update pending on an atomic

region, it suffices to perform the update with minimum priority. We partition the buffer space for the BRT of R into three regions of size $t = a^{1/2a}r^{1-1/2a}$, called the *sorted*, *unsorted*, and *root* buffer space. The root buffer space holds the root buffer. The unsorted buffer space holds buffers for all non-root nodes as in [2]. The sorted buffer space stores additional buffers, one per leaf, whose entries are sorted by the atomic regions they affect. As will become clear from the following discussion, the sorted buffer space can never overflow. As long as neither the root buffer nor the unsorted buffer space overflows, we operate on the BRT as described in [2], except that an Extract operation needs to read out an additional leaf buffer in the sorted buffer space.

When either the root buffer or the unsorted buffer space overflows, we sort the contents of these buffer spaces and then merge them with the contents of the sorted buffer space. If there are duplicate entries in the resulting list, we keep only the one with minimum priority. Hence, the resulting list has size at most t and completely fits into the sorted buffer space.

The cost of all BRT operations, excluding the cost of compacting the buffers when the root buffer or unsorted buffer space overflows, remains $\mathcal{O}(\frac{\log N}{B})$ for Insert operations and $\mathcal{O}(\log N + K/B)$ for Extract operations. Next we argue that the cost of buffer compaction is $\mathcal{O}(\frac{\log t}{B})$ amortized per element, if $t \geq B$: The cost of sorting the contents of the unsorted and root buffer space is $\mathcal{O}(\text{sort}(t'))$, where t' is the number of elements in these two buffer spaces. The rest of the compaction takes two scans of $\mathcal{O}(t)$ data, which requires $\mathcal{O}(t/B)$ block transfers. This is $\mathcal{O}(\frac{\log t}{B})$ amortized per element if we can prove that $t' \geq t/\log t$. To do so, observe that every element, as it is propagated down the tree, requires us to allocate one memory cell at each level in the BRT, $\log t$ in total. Hence, it takes $t' \geq t/\log t$ elements to make the unsorted or root buffer space overflow.

A Paging Strategy. We permanently keep the top two blocks of S in cache. For every invocation on a region of size at most B , we load the part of the data structure into memory that corresponds to the region and its descendants. We call such an invocation *small*. The same argument that establishes the linear space bound in Lem. 2 implies that the size of this portion of the data structure is $\mathcal{O}(B)$; and it is stored consecutively in memory. Hence, such an invocation costs $\mathcal{O}(1)$ block transfers, and the descendant invocations do not incur any further block transfers, except for stack operations. For any invocation on a region of size greater than B , we load the first block of $Q(R)$ and the last block of the root buffer of $B(R)$ into cache. Thus, excluding the cost of priority queue, BRT, and stack operations, each such invocation costs $\mathcal{O}(1)$ I/Os. We call such an invocation *large*.

6.2 Counting Block Transfers

It remains to analyze the number of block transfers performed by our paging algorithm. We start by choosing suitable region sizes r_1, r_2, \dots, r_k and parameters $\alpha_1, \alpha_2, \dots, \alpha_k$. In order to obtain the complexity stated in Thm. 1, we choose

$$r_j = a^j \cdot 2^{a/(a-1)} \quad \text{and} \quad \alpha_j = 2^{a^{-1/2}},$$

where $a = 1/(1 - \epsilon) > 1$. The height of the recursive partition is the minimum k such that $r_k \geq 3N$; thus, the height of the partition is no more than $\log_a((a - 1) \log 3N) = \mathcal{O}(\log \log N)$. We can divide the block transfers incurred by the algorithm into 4 groups, depending on which part of the algorithm triggers them:

- $T_1(N)$: The cost of loading buffer blocks for large invocations and complete data structures for small invocations. We call these block transfers *invocation swaps*.
- $T_2(N)$: The cost of priority queue operations and Insert operations on BRT's.
- $T_3(N)$: The cost of Extract operations on BRT's.
- $T_4(N)$: The cost of stack operations.

We prove that $T_1(N) = \mathcal{O}(\frac{N}{B^{1/2-}})$, $T_2(N) = \mathcal{O}(\frac{N}{B} \log N)$, $T_3(N) = \mathcal{O}(\frac{N}{B^{1/2-}} + \frac{N}{B} \log \log N)$, and $T_4(N) = \mathcal{O}(\frac{N}{B} \log \log N)$. Summing these four terms, we obtain the following lemma:

Lemma 3. *Algorithm 2 incurs $\mathcal{O}(\frac{N}{B^{1/2-}} + \frac{N}{B} \log N)$ block transfers.*

Next we sketch how to derive the above bounds for $T_1(N)$ through $T_4(N)$. Details will be provided in the full paper.

Invocation Swaps. It suffices to count the number of invocations whose parent regions have size at least B because each such invocation incurs $\mathcal{O}(1)$ block transfers, and these are the only invocations that incur block transfers. Klein et al. [19] classify invocations as *truncated* or *non-truncated*. The former is an invocation that returns because all edges in the region have been relaxed. The latter returns because α_j recursive calls on children of the current region have been made. We denote the number of truncated level- j invocations by S'_j and the total number of level- j invocations by S_j . Using a non-trivial charging scheme, Klein et al. prove that the number of truncated level- j invocations is

$$S'_j \leq \sum_{i \geq j} \mathcal{O}(\beta_{ij} \cdot N/\sqrt{r_i}),^1$$

where $\beta_{ij} = \prod_{k=j+1}^i \alpha_k$. Each non-truncated invocation at level j gives rise to α_j invocations at level $j - 1$. Hence, the total number of invocations at level j is

$$S_j \leq \frac{S_{j-1}}{\alpha_j} + S'_j.$$

Note that all level-0 invocations are truncated, that is, $S_0 = S'_0$. Using our choice of parameters α_i , we have $\beta_{ij} = \frac{2^{-(j-i)}}{2^{-(j-i)}}$. Substituting this in the expressions for S'_j and S_j , we obtain that $S'_j = \mathcal{O}(N/\sqrt{r_j})$ and $S_j = \mathcal{O}((j + 1)a^{j/2}N/\sqrt{r_j})$. Since the r_j increase doubly exponentially, we have $\sum_{i \geq j} S_i = \mathcal{O}(S_j)$. Hence,

¹ They prove $S'_j \leq \sum_{i \geq j} \mathcal{O}(\beta_{ij} \cdot Nf(r_i)/r_i)$, where $f(r_i)$ is a bound on the boundary size of every level- i region. We use optimal planar separators; hence, $f(r_i) = \mathcal{O}(\sqrt{r_i})$.

it suffices to argue that, for the maximum j_0 such that $r_{j_0} \leq B$, we obtain $S_{j_0} = \mathcal{O}(\frac{N}{B^{1/2-}})$. For this j_0 , we have $r_{j_0+1} = a^{j_0+1} \cdot 2^{a^{j_0+1}/(a-1)} > B$, that is, $r_{j_0} \geq (r_{j_0+1}/a)^{1/a} = \Omega(B^{1/a})$. On the other hand, we have $j_0 \leq \log_a((a-1) \log B) = \mathcal{O}(\log \log B)$ because $r_{j_0} \leq B$. Hence, $T_1(N) = \mathcal{O}(\sum_{i \geq j_0} S_i) = \mathcal{O}(\frac{N \sqrt{\log B \log \log B}}{B^{1/2}}) = \mathcal{O}(\frac{N}{B^{1/2-}})$.

Priority Queue Operations and Insertions into BRT's. The cost of a priority queue operation or an Insert operation on a BRT of a level- j region is $\mathcal{O}(\frac{\log r}{B})$. The number of priority queue operations is bounded by the number of insertions into the BRT. Hence, it suffices to bound the cost of the latter.

Every insertion into a BRT is the result of the relaxation of an edge (u, v) . Such a relaxation triggers updates of the priorities of both out-edges of v and their ancestors and an Update-Target operation on the other in-edge of v . We argue about the cost of updates on the out-edges; the cost of the Update-Target operations can be bounded in a similar manner. In the worst case, the lowest common ancestor of edge (u, v) and an out-edge (v, w) of v is the root. Then the update of (v, w) traverses all levels in the partition and triggers one insertion at every level. Hence, the cost per level-0 invocation is at most $\sum_{j \geq 0} \mathcal{O}(\frac{\log r}{B})$, which is $\mathcal{O}(\frac{\log r}{B}) = \mathcal{O}(\frac{\log N}{B})$ because the graph sizes r_j increase doubly exponentially. Hence, the total cost of priority queue operations and BRT insertions is $T_2(N) = \mathcal{O}(\frac{S_0}{B} \log N) = \mathcal{O}(\frac{N}{B} \log N)$.

Extractions from BRT's. Every Extract operation on the BRT of a level- j region costs $\mathcal{O}(\log r_i + K/B)$ block transfers, where K is the number of extracted elements. Every extracted element must have been inserted before, and we have argued that every level-0 invocation triggers at most three insertions per level. The number of extract operations at level j equals the number of invocations at level $j-1$. Hence, $T_3(N) = \mathcal{O}(\sum_{i > j_0} S_{i-1} \log r_i) + \mathcal{O}(\frac{S_0}{B} \log \log N)$. Using similar arguments as the ones we used to bound the cost of invocation swaps, this simplifies to $T_3(N) = \mathcal{O}(S_{j_0} \log B^a) + \mathcal{O}(\frac{N}{B} \log \log N) = \mathcal{O}(\frac{N}{B^{1/2-}} + \frac{N}{B} \log \log N)$.

Stack Operations. Every update incurs at most a constant number of stack operations at every level. Hence, the cost of all stack operations is $T_4(N) = \mathcal{O}(\frac{S_0}{B} \log \log N) = \mathcal{O}(\frac{N}{B} \log \log N)$.

7 Open Problems

The most interesting open questions are the following: (1) Can the required separator decomposition be computed cache-obliviously? (2) Can the $\mathcal{O}(\frac{N}{B^{1/2-}})$ -term in the complexity of the algorithm be reduced to $o(N/B^{1/2})$? (3) Can the $\mathcal{O}(\frac{N}{B} \log N)$ -term be reduced to $\mathcal{O}(N/B)$ (the equivalent of the linear time bound obtained in [19]).

To answer question (1), we believe that the contraction-based separator algorithm of [20] can be extended to compute the desired partition: At every

contraction level, use the (by a constant factor suboptimal) separator produced at the previous level to compute a BFS-tree of the current level. Then use this BFS-tree to obtain an optimal separator for the current level (which is constant-factor suboptimal for the next level), and iterate.

The answer to question (2) may be yes, but not using purely separator-based ideas because these algorithms trade-off the number of times a region is loaded into cache against a certain amount of wasteful computation in each region. While the I/O-model can ignore the latter, a cache-oblivious algorithm cannot and must therefore balance this trade-off, which is what our choice of parameters in the algorithm of [19] achieves. The answer to question (3) is most definitely no because this would violate the $\Omega(\text{perm}(N))$ lower bound for shortest paths [13], which is $\Omega(\text{sort}(N))$ in the cache-oblivious model.

Abstract. Two new adaptive sorting algorithms are introduced which perform an optimal number of comparisons with respect to the number of inversions in the input. The first algorithm is based on a new linear time reduction to (non-adaptive) sorting. The second algorithm is based on a new division protocol for the GenericSort algorithm by Estivill-Castro and Wood. From both algorithms we derive I/O-optimal cache-aware and cache-oblivious adaptive sorting algorithms. These are the first I/O-optimal adaptive sorting algorithms.

1 Introduction

1.1 Adaptive Sorting

A well known fact concerning sorting is that optimal sorting algorithms perform $\Theta(n \log n)$ comparisons [9–Section 9.1]. However, in practice there are many cases where the input sequences are already nearly sorted, i.e. have low disorder according to some measure [16, 19]. In such cases one can hope for a sorting algorithm to be faster.

In order to quantify the disorder of input sequences, several *measures of pre-sortedness* have been proposed, e.g. see [11, 16, 18]. One of the most commonly considered measures is *Inv*, the number of inversions in the input, defined by $Inv(X) = |\{(i, j) \mid i < j \wedge x_i > x_j\}|$ for a sequence $X = (x_1, \dots, x_N)$. Other examples of measures include: *Runs*, the number of boundaries between ascending subsequences; *Max*, the largest difference between the ranks of an element

in the input and the sorted sequence; Dis , the largest distance determined by an inversion. A sorting algorithm is denoted *adaptive* if the time complexity is a function dependent on the size as well as the presortedness of the input sequence [19]. For an overview concerning adaptive sorting, see e.g. the survey by Estivill-Castro and Wood [13].

Manilla [18] introduced the concept of optimality of an adaptive sorting algorithm in the comparison model. An adaptive sorting algorithm S is optimal with respect to some measure of presortedness \mathcal{D} , if for some constant $c > 0$ and for all inputs X , the time complexity $T_A(X)$ satisfies

$$T_A(X) \leq c \cdot \max(N, \log |\text{below}(X, \mathcal{D})|),$$

where $\text{below}(X, \mathcal{D})$ is the number of permutations of the input sequence Y for which $\mathcal{D}(Y) \leq \mathcal{D}(X)$ and $\log x$ denotes $\log_2 x$. By the usual information theoretic lower bound, this is asymptotically the best possible. In particular, an adaptive sorting algorithm that is optimal with respect to the measure Inv performs $\Theta(N(1 + \log(1 + Inv/N)))$ comparisons [15].

1.2 The I/O Model and the Cache-Oblivious Model

Traditionally, the RAM model has been used in the design and analysis of algorithms. It consists of a CPU and an infinite memory, where all memory accesses are assumed to take equal time. However, this model is not always adequate in practice, due to the memory hierarchy found on modern computers. Modern computers have several memory levels, each level having smaller size and access time than the next one. Typically, a desktop computer contains CPU registers, L1, L2, and L3 caches, main memory and hard-disk. The access time increases from one cycle for registers and level 1 cache to around 10, 100 and 10,000,000 cycles for level 2 cache, main memory and disk, respectively. Therefore, the I/Os of the disk often become a bottleneck with respect to the running time of a given algorithm, and the number of I/Os, not CPU cycles, should be minimized.

Several models have been proposed to capture the effect of memory hierarchies. The most successful of these is the *I/O model*, introduced by Aggarwal and Vitter [1]. It models a simple two-level memory hierarchy consisting of a fast memory of size M and a slow infinite memory. The data transfers between the slow and fast memory are performed in *blocks* of size B of consecutive data. The I/O complexity of an algorithm is the number of transfers it performs between the slow and the fast memories. A comprehensive list of I/O efficient algorithms for different problems have been proposed, e.g. see the surveys by Vitter [21] and Arge [2]. Among the fundamental results concerning the I/O model is that sorting a sequence of size N requires $\Theta(\frac{N}{B} \log \frac{N}{B})$ I/Os [1].

The I/O model assumes that the size M of the fast memory and the block size B are known, which does not always hold in practice. Moreover, as the modern computers have multiple memory levels with different sizes and block sizes, different parameters are required at the different memory levels. Frigo et

al. [14] proposed the *cache-oblivious model*, which is similar to the I/O model, but assumes no knowledge about M and B . In short, a cache-oblivious algorithm is an algorithm described in the RAM model, but analyzed in the I/O model with an analysis valid for any values of M and B . The power of this model is that if a cache-oblivious algorithm performs well on a two-level memory hierarchy with arbitrary parameters, it performs well between all the consecutive levels of a multi-level memory hierarchy.

Many problems have been addressed in the cache-oblivious model (see the surveys by Arge et al. [3], Brodal [6], and Demaine [10]). Among these there are several optimal cache-oblivious sorting algorithms. Frigo et al. [14] gave two optimal cache-oblivious algorithms for sorting: *Funnelsort* and a variant of *Distributionsort*. Brodal and Fagerberg [7] introduced a simplified version of Funnelsort, *Lazy Funnelsort*. The I/O complexity of all these sorting algorithms is $O(\frac{N}{B} \log_{\frac{B}{M}} \frac{N}{B})$. All these algorithms require a *tall cache* assumption, i.e. $M = \Omega(B^{1+\varepsilon})$ for a constant $\varepsilon > 0$. In [8] it is shown that a tall cache-assumption is required for all optimal cache-oblivious sorting algorithms.

1.3 Results and Outline of Paper

In Section 2 we apply the lower bound technique from [4] to obtain lower bounds on the number of I/Os for comparison based sorting algorithms that are adaptive with respect to different measures of presortedness.

In Section 3 we present a linear time reduction from adaptive sorting to general (non-adaptive) sorting, directly implying comparison optimal and I/O-optimal cache-aware and cache-oblivious algorithms with respect to measure *Inv*.

In Section 4 we describe a cache-aware generic sorting algorithm, *cache-aware GenericSort* based on *GenericSort*, introduced in [12], and characterize its I/O adaptiveness. Section 5 introduces a cache-oblivious version of *GenericSort*.

In Section 6 we introduce a new greedy division protocol for *GenericSort*, interesting in its own right due to its simplicity. We prove that the resulting algorithm, *GreedySort*, is comparison optimal with respect to measure *Inv*. We show that using our division protocol we obtain both cache-aware and cache-oblivious algorithms that are optimal with respect to *Inv*.

In the remainder of this paper, sorted means sorted in increasing order.

2 I/O Lower Bounds

In this section we show lower bounds on the number of I/Os performed by comparison based sorting algorithms that are adaptive with respect to several measures of presortedness.

Theorem 1. *A comparison based sorting algorithm performs $\Omega(\frac{N}{B}(1 + \log_{\frac{B}{M}}(1 + \frac{Inv}{N})))$ I/Os for sorting input sequences of size N and Inv inversions, assuming $M = \Omega(B^2)$.*

Measure of presortedness	I/Os	Comparisons [13]
<i>Dis</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + Dis\right)\right)\right)$	$\Omega(N(1 + \log(1 + Dis)))$
<i>Exc</i>	$\Omega\left(\frac{N}{B}\left(1 + Exc \log_{-}\left(1 + Exc\right)\right)\right)$	$\Omega(N + Exc \log(1 + Exc))$
<i>Enc</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + Enc\right)\right)\right)$	$\Omega(N(1 + \log(1 + Enc)))$
<i>Inv</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + \frac{Inv}{N}\right)\right)\right)$	$\Omega\left(N\left(1 + \log\left(1 + \frac{Inv}{N}\right)\right)\right)$
<i>Max</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + Max\right)\right)\right)$	$\Omega(N(1 + \log(1 + Max)))$
<i>Osc</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + \frac{Osc}{N}\right)\right)\right)$	$\Omega\left(N\left(1 + \log\left(1 + \frac{Osc}{N}\right)\right)\right)$
<i>Reg</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + Reg\right)\right)\right)$	$\Omega(N(1 + \log(1 + Reg)))$
<i>Rem</i>	$\Omega\left(\frac{N}{B}\left(1 + Rem \log_{-}\left(1 + Rem\right)\right)\right)$	$\Omega(N + Rem \log(1 + Rem))$
<i>Runs</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + Runs\right)\right)\right)$	$\Omega(N(1 + \log(1 + Runs)))$
<i>SMS</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + SMS\right)\right)\right)$	$\Omega(N(1 + \log(1 + SMS)))$
<i>SUS</i>	$\Omega\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + SUS\right)\right)\right)$	$\Omega(N(1 + \log(1 + SUS)))$

Fig. 1. Lower bounds on the number of I/Os and the number of comparisons

Proof. Consider an adaptive sorting algorithm A and some input sequence X of size N . Let $T_A(X)$ and $I/O_A(X)$ denote the number of comparisons and the number of I/Os performed by a comparison based sorting algorithm A for sorting an input sequence X respectively.

Recall that $\text{below}(X, Inv)$ denotes the set of all permutations Y for the input sequence with $Inv(Y) \leq Inv(X)$. Consider the decision tree of A (see e.g. [9–Section 9.1]) restricted to the inputs in $\text{below}(X, Inv)$. The tree has at least $|\text{below}(X, Inv)|$ leaves and therefore A performs at least $\log |\text{below}(X, \mathcal{D})|$ comparisons in the worst case. Therefore, for any sequence X , there is a sequence $Y \in \text{below}(X, Inv)$, such that $\log |\text{below}(X, Inv)| \leq T_A(Y)$.

Using the decision tree translation by Arge et al. [4–Theorem 1] we get:

$$\log(|\text{below}(X, Inv)|) \leq N \log B + \max_{Y \in \text{below}(X, Inv)} I/O_A(Y) \left(B \log \left(\frac{M}{B} \right) + 3B \right).$$

Since $\log(|\text{below}(X, Inv)|) = \Omega(N(1 + \log(1 + \frac{Inv}{N})))$ [15], we obtain that $\max_{Y \in \text{below}(X, Inv)} I/O_A(Y) = \Omega(\frac{N}{B}(1 + \log_{-}(1 + \frac{Inv}{N})))$, given $M = \Omega(B^2)$. \square

Using a similar technique we obtain lower bounds on the number of I/Os for other measures of presortedness, assuming that $M = \Omega(B^2)$. Figure 1 lists these lower bounds. For definitions of the different measures, refer to [13].

3 GroupSort

In this section we describe a reduction to derive *Inv* adaptive sorting algorithms from non-adaptive sorting algorithms. The reduction is cache-oblivious and requires $O(N)$ comparisons and $O(N/B)$ I/Os.

The basic idea is to distribute the input sequence into a sequence of buckets S_1, \dots, S_k each of size at most $32(\text{Inv}/N)^2$, where the elements in bucket S_i are all smaller than or equal to the elements in S_{i+1} . Each S_i is then sorted independently by a non-adaptive cache-oblivious sorting algorithm [7, 14]. During the construction of the buckets S_1, \dots, S_k some elements might fail to get inserted into an S_i and are instead inserted into a *fail set* F . It will be guaranteed that at most half of the elements are inserted into F . The fail set F is sorted recursively and merged with the sequence of sorted buckets.

The S_i buckets are constructed by scanning the input left-to-right by inserting an element x into the rightmost bucket S_k if $k = 1$ or $x \geq \min(S_k)$ and otherwise inserting x in F . During the construction we generate increasing bucket capacities $\beta_j = 2 \cdot 4^j$, which will be used for $\alpha_j = N/(2 \cdot 2^j)$ insertions into F . If during construction $|S_k| > \beta_j$, the bucket S_k is split into two buckets S_k and S_{k+1} by computing its median using the cache-oblivious selection algorithm from [5] and distributing its elements relatively to the median. This ensures $|S_i| \leq \beta_j$ for $1 \leq i \leq k$. We maintain the invariant $|S_k| \geq \beta_j/2$ if there are at least two buckets by repeatedly concatenating the two last buckets after an increment of i . Since $\beta_{j-1} = \beta_j/4$, this ensures $\beta_j/2 \leq |S_k| \leq \frac{3}{4}\beta_j$ after this concatenation process. If only one bucket remains, then $|S_k| \leq \frac{3}{4}\beta_j$.

The pseudo-code of the reduction is given in Figure 2. We assume that S_1, \dots, S_k are stored consecutively in an array by storing the start index and the minimum element from each bucket on a separate stack, i.e. the concatenation of S_{k-1} and S_k can be done implicitly in $O(1)$ time. The fail set F is stored as a list of subsets F_1, \dots, F_j , where F_i stores the elements inserted into F while the bucket size is β_i . Similarly F_1, \dots, F_j are stored consecutively in an array.

Theorem 2. *GroupSort is cache-oblivious and is comparison optimal and I/O-optimal with respect to *Inv*, assuming $M = \Omega(B^2)$.*

Proof. Consider the last bucket capacity β_j and fail set size α_j . Each element x inserted into the fail set F_j induces in the input sequence at least $\beta_j/2$ inversions, since $|S_k| \geq \beta_j/2$ when x is inserted into F_j and all elements in S_k appeared before x in the input and are larger than x .

For $i = \lceil \log \frac{\text{Inv}}{N} \rceil + 1$, we have $\alpha_i \cdot \frac{\beta}{2} = \frac{N}{2 \cdot 2} \cdot \frac{2 \cdot 4}{2} \geq \text{Inv}$, i.e. F_i is guaranteed to be able to store all failed elements. This immediately leads to $j \leq \lceil \log \frac{\text{Inv}}{N} \rceil + 1$, and $\beta_j = 2 \cdot 4^j \leq 32 \left(\frac{\text{Inv}}{N}\right)^2$. The fail set F has size at most $\sum_{i=1}^j \alpha_i = \sum_{i=1}^j N/(2 \cdot 2^i) \leq N/2$.

Taking into account that the total size of the fail sets is at most $N/2$, the number of comparisons performed by GroupSort is given by the following recurrence:

```

procedure GroupSort( $X$ )
Input: Sequence  $X = (x_1, \dots, x_N)$ 
Output: Sequence  $X$  sorted
begin
   $S_1 = (x_1); F_1 = (); \beta_1 = 8; \alpha_1 = N/4; j = 1; k = 1;$ 
  for  $i = 2$  to  $N$ 
    if  $k = 1$  or  $x_i \geq \min(S_k)$ 
       $\text{append}(S_k, x_i);$ 
      if  $|S_k| > \beta_j$ 
         $(S_k, S_{k+1}) = \text{split}(S_k); k = k + 1;$ 
      else
         $\text{append}(F_j, x_i);$ 
        if  $|F_j| > \alpha_j$ 
           $\beta_{j+1} = \beta_j \cdot 4; \alpha_{j+1} = \alpha_j/2; j = j + 1;$ 
          while  $k > 1$  and  $|S_k| < \beta_j/2$ 
             $S_{k-1} = \text{concat}(S_{k-1}, S_k); k = k - 1;$ 
           $S = \text{concat}(\text{sort}(S_1), \text{sort}(S_2), \dots, \text{sort}(S_k));$ 
           $F = \text{concat}(F_1, F_2, \dots, F_j);$ 
          GroupSort( $F$ );
           $X = \text{merge}(S, F);$ 
  end

```

Fig. 2. Linear time reduction to non-adaptive sorting

$$T(N) = T\left(\frac{N}{2}\right) + \sum_{i=1}^k T_{\text{Sort}}(|S_i|) + O(N),$$

where the $O(N)$ term accounts for the bucket splittings and the final merge of S and F . The $O(N)$ term for splitting buckets follows from that when a bucket with β_j elements is split then at least $\beta_j/4$ elements in a bucket have been inserted since the most recent bucket splitting or increase in bucket capacity, and we can charge the splitting of the bucket to these recent $\beta_j/4$ elements.

Since $T_{\text{Sort}}(N) = O(N \log N)$ and each $|S_i| \leq \beta_j = O((\frac{Inv}{N})^2)$ the number of comparisons performed by GroupSort is:

$$T(N) = T\left(\frac{N}{2}\right) + O\left(N \left(1 + \log\left(1 + \left(\frac{Inv}{N}\right)^2\right)\right)\right).$$

Since F is a subsequence of the input, Inv for the recursive call is at most Inv for the input. As $\sum_{i=0}^{\infty} \frac{N}{2} \log \frac{Inv}{N/2} = N \log \frac{Inv}{N} \sum_{i=0}^{\infty} \frac{1}{2} + N \sum_{i=0}^{\infty} \frac{i}{2}$, it follows that GroupSort performs $T(N) = O(N(1 + \log(1 + \frac{Inv}{N})))$ comparisons, which is optimal.

The cache-oblivious selection algorithm from [5] performs $O(N/B)$ I/Os and the cache-oblivious sorting algorithms [7, 14] perform $O(\frac{N}{B} \log \frac{N}{B})$ I/Os for $M = \Omega(B^2)$. Since GroupSort otherwise does sequential access to the input and data structures, we get that GroupSort is cache-oblivious and the number of I/Os performed is given by the recurrence:

$$I/O(N) = I/O\left(\frac{N}{2}\right) + O\left(\frac{N}{B}\left(1 + \log_{-}\left(1 + \left(\frac{Inv}{N}\right)^2 \cdot \frac{1}{B}\right)\right)\right).$$

It follows that GroupSort performs $O\left(\frac{N}{B}(1 + \log_{-}(1 + \frac{Inv}{N}))\right)$ I/Os provided $M = \Omega(B^2)$, which by Theorem 1 is I/O-optimal. \square

Pagh et al. [20] gave a related reduction for adaptive sorting on the RAM model. Their reduction assumes that a parameter q is provided such that the number of inversions is at most qN . A valid q is found by selecting increasing values for q such that the running time doubles for each iteration. In the cache oblivious setting the doubling approach fails, since the first q value should depend on the unknown parameter M . We circumvent this limitation of the doubling technique by selecting the increasing β_j values internally in the reduction.

4 Cache-Aware GenericSort

Estivill-Castro and Wood [12] introduced a generic sorting algorithm, *GenericSort*, as a framework for adaptive sorting algorithms. It is a generalization of Mergesort, and is described using a generic division protocol, i.e. an algorithm for splitting an input sequence into two or more subsequences. The algorithm works as follows: consider an input sequence X ; if X is sorted then the algorithm returns; if X is “small”, then X is sorted using some alternate non-adaptive sorting algorithm; otherwise, X is divided according to the division protocol and the resulting subsequences are recursively sorted and merged.

In this section we modify GenericSort to achieve a generic I/O-adaptive sorting algorithm. Consider an input sequence $X = (x_1, \dots, x_N)$ and some division protocol DP such that DP splits the input in $s \geq 2$ subsequences of roughly equal sizes in a single scan, visiting each element of the input exactly once. To avoid testing whether X is sorted before applying the division protocol, we derive a new division protocol DP' by modifying DP to identify the longest sorted prefix of X : we scan the input sequence until we find some i such that $x_i < x_{i-1}$. Denote $S = (x_1, \dots, x_{i-1})$ and $X' = (x_i, \dots, x_N)$. We apply DP to X' , recursively sort the resulting s subsequences, and finally merge them with S . The adaptive bounds for GenericSort proved in [12–Theorem 3.1] are not affected by these modifications, and we have the following theorem.

Theorem 3. *Let \mathcal{D} be a measure of presortedness, d and s constants, $0 < d < 2$, and DP a division protocol that splits some input sequence of size N into s subsequences of size at most $\lceil \frac{N}{s} \rceil$ each using $O(N)$ comparisons.*

- *the modified GenericSort performs $O(N \log N)$ comparisons in the worst case;*

- if for all sequences X , the division of a suffix of X into X_1, \dots, X_s by DP satisfies that $\sum_{j=1}^s \mathcal{D}(X_j) \leq d \lfloor \frac{s}{2} \rfloor \cdot \mathcal{D}(X)$, then the modified *GenericSort* performs $O(N(1 + \log(1 + \mathcal{D}(X))))$ comparisons.

We now describe a cache-aware version of the modified *GenericSort* provided that the division protocol DP works in a single scan of the input. Let T be the recursion tree of *GenericSort* using the new division protocol DP' . We obtain a new tree T' by contracting T top-down such that every node in T' corresponds to a subtree of height $O(\log_s(M/B))$ in T and each node in T' has a fanout of at most m , where $m = \Theta(M/B)$. There are $O(m)$ sorted prefixes for every node in T' . In cache-aware *GenericSort*, for each node of T' we scan its input sequence and distribute the elements accordingly to one of the $O(m)$ output sequences. Each output sequence is a linked list of blocks of size $\Theta(B)$. If the size of the input sequence is at most M , then we sort it in internal memory, hence performing $O(N/B)$ I/Os. Theorem 4 gives a characterization of the adaptiveness of cache-aware *GenericSort* in the I/O model. It is an I/O version of Theorem 3.

Theorem 4. *Let \mathcal{D} be a measure of presortedness, d and s constants, $0 < d < 2$ and $s \leq \frac{M}{2B}$, and DP a division protocol that splits some input sequence of size N into s subsequences of size at most $\lceil \frac{N}{s} \rceil$ each using $O(\frac{N}{B})$ I/Os. If DP performs the splitting in one scan visiting each element of the input exactly once, then:*

- cache-aware *GenericSort* performs $O(\frac{N}{B} \log_- \frac{N}{B})$ I/Os in the worst case;
- if for all sequences X , the division of a suffix of X into X_1, \dots, X_s by DP satisfies that $\sum_{j=1}^s \mathcal{D}(X_j) \leq d \lfloor \frac{s}{2} \rfloor \cdot \mathcal{D}(X)$, then cache-aware *GenericSort* performs $O\left(\frac{N}{B} \left(1 + \log_-(1 + \mathcal{D}(X))\right)\right)$ I/Os.

Proof. We analyze the I/Os performed at the nodes of T' separately for the nodes having input sizes less than or equal to M and greater than M .

At a node with input X and $|X| > M$, $O(m + |X|/B) = O(|X|/B)$ I/Os are performed to read the input and to write to the at most $m - 1$ sorted output prefixes and m sequences to be recursively sorted. If we charge $O(1/B)$ I/Os per element in the input this will pay for the I/Os required at the node.

At a node with input X and $|X| \leq M$, $O(1 + |X|/B)$ I/Os are performed. These I/Os can be charged to the parent node, since at the parent we will already charge $O(1 + |X|/B)$ I/Os to write the output X .

By Theorem 3 we have that the sum of the depths in T reached by the elements in the input X is bounded by $O(N(1 + \log(1 + \mathcal{D}(X))))$. Since each node in T' spans $\Theta(\log \frac{M}{B})$ levels from T , we get that cache-aware *GenericSort* performs $O(\frac{N}{B} + N(1 + \log(1 + \mathcal{D}(X)))/(B \log \frac{M}{B})) = O(\frac{N}{B}(1 + \log_-(1 + \mathcal{D}(X))))$ I/Os, where the N/B term counts for the I/Os at the root of T' . \square

The power of cache-aware *GenericSort* lies in its generality, meaning that using different division protocols we obtain sorting algorithms that are I/O adaptive with respect to different measures of presortedness. For example, using the

straight division protocol, we achieve I/O optimality with respect to *Runs*. Using the odd-even division protocol, we obtain an algorithm that is I/O optimal with respect to *Dis* and *Max*. Furthermore, the different division protocols can be combined as shown in [13] in order to achieve I/O optimality with respect to more measures of presortedness.

5 Cache-Oblivious GenericSort

We give a cache-oblivious algorithm that achieves the same adaptive bounds as the cache-aware GenericSort introduced in Section 4. It works only for division protocols that split the input into two unsorted subsequences. It is based on a modification of the k -merger used in FunnelSort [7, 14].

A k -merger is a binary tree stored using the recursive van Emde Boas layout. The edges contain buffers of variable sizes and the nodes are binary mergers. The tree and the buffer sizes are recursively defined: consider an output sequence of size k^3 and h the height of the tree. We split the tree at level $\frac{h}{2}$ yielding $k^{\frac{1}{2}} + 1$ subtrees, each of size $O(k^{\frac{1}{2}})$. The buffers at this level have sizes $k^{\frac{2}{3}}$. See [7] for further details.

Consider DP division protocol that scans the input a single time and DP' the modified DP as introduced in Section 4. Each node of the k -merger corresponds to a node in the recursion tree of GenericSort using DP' as the division protocol. Therefore, each node has a fanout of three and becomes a ternary merger. The resulting unsorted sequences are pushed in the buffers to the children, while the sorted prefix is stored as a list of memory chunks of size $O(N^{\frac{2}{3}})$ for an input buffer of size N .

Our algorithm uses a single $N^{\frac{1}{3}}$ -merger. It fills the buffers in a top-down fashion and then merges the resulted sorted subsequences in a bottom-up manner. The $N^{\frac{1}{3}}$ output buffers at the leaves of the k -merger are sorted using a non-adaptive I/O-optimal cache oblivious sorting algorithm [7, 14].

Lemma 1. *The $N^{\frac{1}{3}}$ -merger and the sorted subsequences use $O(N)$ space.*

Proof. Consider the $N^{\frac{1}{3}}$ -merger and an input sequence of size N . The total size of the inner buffers is $O(N^{\frac{2}{3}})$ [14]. The memory chunks storing the sorted subsequences use $O(N)$ space because there are $N^{\frac{1}{3}}$ nodes in the merger and the size of a single memory chunk is $O(N^{\frac{2}{3}})$. Adding the input sequence, we conclude that the $N^{\frac{1}{3}}$ -merger and the sorted subsequences take $O(N)$ space together. \square

Lemma 2. *Cache-oblivious GenericSort and cache-aware GenericSort have the same comparison and I/O complexity, for division protocols that split the input into two subsequences.*

Proof. Consider $\ell = \frac{1}{3} \log N$ the height of the $N^{\frac{1}{3}}$ -merger of the cache-oblivious GenericSort.

We first prove that cache-aware and cache-oblivious GenericSort have the same comparison complexity. For some element x_i let d_i be its depth in the recursion tree of the GenericSort using DP' as a division protocol. If $d_i \leq \ell$ then x_i reaches the same level in the recursion tree of cache-oblivious GenericSort, because the two algorithms have the same recursion trees at the top ℓ levels. If $d_i > \ell$ then the number of comparisons performed by cache-oblivious GenericSort for x_i is $O(\log N) = O(d_i)$ because $d_i > \ell = \Omega(\log N)$.

We analyze the number of I/Os used by cache-aware and cache-oblivious GenericSort. Consider an element x_i that reaches level d_i in the recursion tree of cache-aware GenericSort.

If $d_i < \ell$ then x_i is placed in a sorted prefix at a node in the $N^{\frac{1}{3}}$ -merger. In this case, cache-oblivious GenericSort spends linear I/Os when the size of the input reaches $O(M)$ because the $N^{\frac{1}{3}}$ -merger together with the sorted subsequences take linear space by Lemma 1. Taking into account that the height of the $N^{\frac{1}{3}}$ -merger is $O(\log(M/B))$ due to the tall cache assumption, it follows that $O(1 + d_i/(\log(M/B)))$ I/Os are performed by cache-oblivious GenericSort for getting x_i to its sorted subsequence.

If $d_i > \ell$ then x_i reaches an output buffer of the $N^{\frac{1}{3}}$ -merger, where it is sorted using an optimal cache-oblivious sorting algorithm. In this case the number of I/Os performed for the sorting involving x_i is still $O(1/B + d_i/(B \log(M/B)))$, because both the $N^{\frac{1}{3}}$ -merger and the optimal sorting algorithms require $O(1/B + d_i/(B \log(M/B)))$ I/Os for the sorting involving x_i , since $d_i = \Theta(\log N)$.

We obtain that the number of I/Os performed by cache-oblivious GenericSort is $O\left(\frac{N}{B} + \frac{\sum_{d=1}^d}{B \log(M/B)}\right)$. Cache-aware GenericSort performs $O\left(\frac{N}{B} + \frac{\sum_{d=1}^d}{B \log -}\right)$ I/Os too because the fanout of the nodes in the recursion tree is $O(\log \frac{M}{B})$. We conclude that cache-aware GenericSort and cache-oblivious GenericSort have the same I/O complexity. \square

6 GreedySort

We introduce *GreedySort*, a sorting algorithm based on GenericSort using a new division protocol, *GreedySplit*. The protocol is inspired by a variant of the Kim-Cook division protocol, which was introduced and analyzed in [17]. Our division protocol achieves the same adaptive performance with respect to *Inv*, but is simpler and moreover facilitates cache-aware and cache-oblivious versions. It may be viewed as being of a greedy type, hence the name. We first describe GreedySort and its division protocol and then prove that it is optimal with respect to *Inv*. GreedySplit partitions the input sequence X into three subsequences S , Y , and Z , where S is sorted and Y and Z have balanced sizes, i.e. $|Z| \leq |Y| \leq |Z| + 1$. In one scan it builds an ascending subsequence S of the input in a greedy fashion and at the same time distributes the remaining elements in two subsequences, Y and Z , using an odd-even approach.

Lemma 3. *GreedySplit splits an input sequence X in the three subsequences S , Y and Z , where S is sorted and $\text{Inv}(X) \geq \frac{5}{4} \cdot (\text{Inv}(Y) + \text{Inv}(Z))$.*

Proof. Let $X = (x_1, \dots, x_N)$. By construction S is sorted. Consider an inversion in Y , $y_i > y_j$, $i < j$ and i_1 and j_1 the indices in X of y_i and y_j respectively. Due to the odd-even construction of Y and Z , there exists an $x_k \in Z$ such that in the original sequence X we have $i_1 < k < j_1$.

We prove that there is one inversion between x_k and at least one of x_{i_1} and x_{j_1} , for any $i_1 < k < j_1$. Indeed, if $x_{i_1} > x_k$, we get an inversion between x_{i_1} and x_k . If $x_{i_1} \leq x_k$, we get an inversion between x_{j_1} and x_k , because we assume that $y_i > y_j$ which yields $x_{i_1} > x_{j_1}$. Let z_i, \dots, z_{j-1} be all the elements from Z which appear between y_i and y_j in the original sequence. We know that there exists at least an inversion between $z_{\lfloor (i+j)/2 \rfloor}$ and y_i or y_j . The inversion $(y_i, z_{\lfloor (i+j)/2 \rfloor})$ can be counted for two different pairs in Y , $(y_i, y_{i+2\lfloor (j-i)/2 \rfloor})$ and $(y_i, y_{i+1+2\lfloor (j-i)/2 \rfloor})$. Similarly, the inversion $(z_{\lfloor (i+j)/2 \rfloor}, y_j)$ can be counted for two different pairs in Y . Taking into account that the inversions involving elements of Y and elements of Z appear in X , but neither in Y nor Z , we have that $\text{Inv}(X) \geq \text{Inv}(Y) + \text{Inv}(Z) + \text{Inv}(Y)/2$. In a similar manner we obtain $\text{Inv}(X) \geq \text{Inv}(Y) + \text{Inv}(Z) + \text{Inv}(Z)/2$. Summing the two equations we obtain $\text{Inv}(X) \geq \frac{5}{4}(\text{Inv}(Y) + \text{Inv}(Z))$. \square

Theorem 5. *GreedySort performs $O(N(1 + \log(1 + \text{Inv}(X)/N)))$ comparisons to sort a sequence X of size N , i.e. it is comparison optimal with respect to Inv .*

Proof. Similar to [17], we first prove the claimed bound for the upper levels of recursion where the total number of inversions is greater than $N/4$ and then prove that the total number of comparisons for the remaining levels is linear. Let $\text{Inv}_i(X)$ denote the total number of inversions in the subsequences at the i^{th} level of recursion. By Lemma 3, $\text{Inv}_i(X) \leq (\frac{4}{5})^i \text{Inv}(X)$.

We want to find the first level ℓ of the recursion for which $(\frac{4}{5})^\ell \text{Inv}(X) \leq \frac{N}{4}$, which yields $\ell = \left\lceil \frac{\log(4\text{Inv}(X)/N)}{\log(5/4)} \right\rceil$.

At each level of recursion GreedySort performs $O(N)$ comparisons. Therefore at the first ℓ levels of recursion the total number of comparisons performed is $O(\ell \cdot N) = O(N(1 + \log(1 + \text{Inv}(X)/N)))$. We now prove that the remaining levels perform a linear number of comparisons.

Let $|(X, i)|$ denote the total size of Y s and Z s at the i^{th} level of recursion. As each element in Y and Z is obtained as a result of an inversion in the sequence X , we have $|(X, i)| \leq \text{Inv}_{i-1}(X)$. Using Lemma 3 we obtain: $|(X, \ell + i)| \leq \text{Inv}_{\ell+i-1}(X) \leq (\frac{4}{5})^{i-1} \cdot (\frac{4}{5})^\ell \cdot \text{Inv}(X) \leq (\frac{4}{5})^{i-1} \frac{N}{4}$. Taking into account that the sum of the $|(X, \ell + i)|$ s is $O(N)$ and that at each level $\ell + i$ we perform a linear number of comparisons with respect to $|(X, \ell + i)|$, it follows that the total number of comparisons performed at the lower levels of the recursion tree is $O(N)$. We conclude that GreedySort performs $O(N(1 + \log(1 + \frac{\text{Inv}}{N})))$ comparisons. \square

We derive both cache-aware and cache-oblivious algorithms by using our greedy division protocol in both the cache-aware and the cache-oblivious

GenericSort frameworks described in Sections 4 and 5. In both cases the division protocol considered does not identify the longest prefix of the input, but simply apply the greedy division protocol. We prove that these new algorithms, *cache-aware GreedySort* and *cache-oblivious GreedySort* achieve the I/O-optimality with respect to *Inv* under the tall cache assumption $M = \Omega(B^2)$.

Theorem 6. *Cache-aware GreedySort and cache-oblivious GreedySort are I/O-optimal with respect to Inv, provided that $M = \Omega(B^2)$.*

Proof. From Theorem 5 the average number of levels of recursion for an element is $O(1 + \log(1 + \text{Inv}/N))$. In Theorem 4 each element is charged $O(\frac{1}{B})$ I/Os for every $\Theta(\log \frac{M}{B})$ levels. This implies that cache-aware GreedySort performs $\Theta(\frac{N}{B}(1 + \log_-(1 + \frac{\text{Inv}}{N})))$ I/Os, which is optimal by Theorem 1. Similar observations apply to cache-oblivious GreedySort based on the proof of Lemma 2. \square

Simulated Annealing Beats Metropolis in Combinatorial Optimization

Ingo Wegener*

FB Informatik, LS2, Univ. Dortmund, Germany
ingo.wegener@uni-dortmund.de

Abstract. The Metropolis algorithm is simulated annealing with a fixed temperature. Surprisingly enough, many problems cannot be solved more efficiently by simulated annealing than by the Metropolis algorithm with the best temperature. The problem of finding a natural example (artificial examples are known) where simulated annealing outperforms the Metropolis algorithm for all temperatures has been discussed by Jerrum and Sinclair (1996) as “an outstanding open problem.” This problem is solved here. The examples are instances of the well-known minimum spanning tree problem. Moreover, it is investigated which instances of the minimum spanning tree problem can be solved efficiently by simulated annealing. This is motivated by the aim to develop further methods to analyze the simulated annealing process.

1 Introduction

Simple randomized search heuristics like randomized local search (RLS), the Metropolis algorithm (MA), simulated annealing (SA), evolutionary algorithms (EA), and genetic algorithms (GA) find many applications. One cannot hope that they outperform sophisticated problem-specific algorithms for well-studied problems. They are easy to implement and good alternatives if one does not know efficient problem-specific algorithms and if one shies away from developing a clever algorithm. They are the tool of choice in black-box optimization where the problem instance is hidden from the algorithm. And they are useful as parts of hybrid algorithms combining general search principles with problem-specific modules.

Hence, it is interesting to understand the working principles behind these heuristics. The aim is to analyze the expected optimization time and the success probability within a given time bound of heuristics applied to specific problems. Up to now there are not many of such results. One reason is that the heuristics are not designed to support their analysis (in contrast to many problem-specific

* Supported in part by the Deutsche Forschungsgemeinschaft (DFG) as part of the Collaborative Research Center “Computational Intelligence” (SFB 531) and by the German-Israeli Foundation (GIF) in the project “Robustness Aspects of Algorithms”.

algorithms). To simplify the problem many authors have first investigated quite artificial problems hoping to develop methods which can be used in many other situations.

Here, we are interested in simulated annealing and the Metropolis algorithm (which can be defined as SA with a fixed temperature). Both algorithms are defined in Section 2. It is an obvious question how to use the freedom to choose a cooling schedule for SA and whether this option is essential. Little is known about this leading Jerrum and Sinclair (1996, page 516) to the following statement: “It remains an outstanding open problem to exhibit a natural example in which simulated annealing with any non-trivial cooling schedule provably outperforms the Metropolis algorithm at a carefully chosen fixed value of α .” In their paper, α is the temperature. The notion of a “natural example” is vague, but the known examples are obviously artificial. Sorkin (1991) has proven the considered effect for a so-called fractal energy landscape. The chaotic behavior of this function asks for different temperatures in different phases of the search. The artificial example due to Droste, Jansen, and Wegener (2001) allows a simpler analysis.

Jerrum and Sorkin (1998) have analyzed the Metropolis algorithm for the graph bisection problem. They focus the interest on problems from combinatorial optimization: “Unfortunately no combinatorial optimization problem that has been subjected to rigorous theoretical analysis has been exhibited this phenomenon: those problems that can be solved efficiently by simulated annealing can be solved just as effectively by ‘annealing’ at a single carefully selected temperature. A rigorous demonstration that annealing is provably beneficial for some natural optimization problems would rate as a significant theoretical advance.”

Our problem of choice is the minimum spanning tree problem (MSTP) which is contained in all textbooks on combinatorial optimization and should be accepted as “natural optimization problem.” It should be obvious that SA cannot beat MA for each problem instance. E. g., for graphs where all edge weights equal 1 the frozen MA (at temperature 0) cannot be beaten by SA. In Section 3, we describe the notion of efficiency for randomized search heuristics and, in Section 4, we describe simple instances of the MSTP where SA outperforms MA. The underlying graphs will be so-called connected triangles (CT), see Figure 1.

Fig. 1. Graphs called connected triangles.

The idea is to produce examples as simple as possible. This allows proofs which can be taught in introductory courses on randomized search heuristics. Afterwards, we try to understand which instances of the MSTP can be solved efficiently by SA and MA, only by SA, or by none of them. Weights w_1, \dots, w_m are called $(1 + \varepsilon)$ -separated if $w_i > w_j$ implies $w_i \geq (1 + \varepsilon) \cdot w_j$. For each $\varepsilon(m) = o(1)$ there are graphs with $(1 + \varepsilon(m))$ -separated weights such that SA

cannot attack them efficiently (Section 5). For each constant $\varepsilon > 0$, SA can attack all graphs with $(1 + \varepsilon)$ -separated weights efficiently (Section 6). These results imply that SA outperforms MA on a much larger class of graphs than the connected triangles discussed in Section 4. We finish with some conclusions.

It should be obvious that we do not hope that SA or MA beats the well-known algorithms due to Kruskal and to Prim. Again we like to transfer a statement of Jerrum and Sorkin (1998) from minimum bisections to minimum spanning trees (MSTs): “Our main contribution is not, then, to provide a particularly effective algorithm for the minimum bisection problem . . . , but to analyze the performance of a popular heuristic applied to a reasonably realistic problem in combinatorial optimization.”

2 Metropolis Algorithm, Simulated Annealing, and Minimum Spanning Trees

An instance of the MSTP consists of an undirected graph $G = (V, E)$ with n vertices and m edges and a weight $w(e)$ for each edge e . Weights are positive integers. The problem is to find an edge set E' connecting all vertices with minimal total weight. The edges are numbered and edge sets are described as characteristic vectors, i. e., $x \in \{0, 1\}^m$ describes the set of edges e_i where $x_i = 1$. This formalization is well-suited for MA and SA.

We describe the Metropolis algorithm with temperature T for minimization problems on $\{0, 1\}^m$. The first search point x is chosen in some way discussed later. Each round of an infinite loop consists of local change and selection.

Local change: Let x be the current search point. Choose $i \in \{1, \dots, m\}$ uniformly at random and flip x_i , i. e., let $x' = (x'_1, \dots, x'_m)$ where $x'_j = x_j$, if $j \neq i$, and $x'_i = 1 - x_i$.

Selection of the new current search point with respect to a fitness function f :
 if $f(x') \leq f(x)$: select x' ,
 if $f(x') > f(x)$: select x' with probability $\exp\{-(f(x') - f(x))/T\}$, otherwise select x .

We have to discuss some details in order to ensure that our results are not based on too special choices. Randomized search heuristics do not produce a certificate that a search point is optimal. Therefore, the algorithm contains an infinite loop, but the run time is defined as the number of rounds until an optimal search point is produced. A round cannot be performed in time $O(1)$ but quite efficiently and people have agreed to count the number of rounds.

We choose 1^m as starting point. This is similar to the choice 0^m for the maximum matching problem (Sasaki and Hajek (1988)) and the maximum clique problem (Jerrum (1992)). The starting points are the worst legal solutions. This choice of the starting point implies that we cannot apply the lower bound technique for MA due to Sasaki (1991) which ensures only the existence of some bad starting point. It would be an alternative to start with a search point chosen uniformly at random. For many graphs, we then choose a non-legal solution (an

unconnected graph) and the fitness function has to contain hints directing the search to legal search points. It is not difficult to obtain similar results in this situation. However, most papers on MA and SA only work on legal search points.

We have chosen the fitness function f where $f(x) = \infty$ for search points x describing unconnected graphs and where $f(x)$ is the total weight of all chosen edges if x describes a connected graph. Unconnected graphs are never accepted as current search points. This again is in accordance with Sasaki and Hajek (1988) and Jerrum (1992). All search points are legal solutions in the graph bisection problem and therefore Jerrum and Sorkin (1993, 1998) start with randomly chosen search points.

We follow Sasaki and Hajek (1988) and Jerrum (1992) in allowing only 1-bit neighborhoods. Neumann and Wegener (2004) have analyzed RLS with 1-bit and 2-bit flips (RLS equals the frozen MA at temperature $T = 0$) and a simple EA for the MSTP. These algorithms do not select new search points which are worse than the old one. Hence, their search strategy is completely different from the strategy applied by MA and SA that have to accept sometimes worsenings to find the optimum. Flips of two bits allow to include an edge into a tree and to exclude simultaneously an edge of the newly created cycle. RLS and the simple EA find an MST in an expected number of $O(m^2(\log m + \log w_{\max}))$ steps, where w_{\max} denotes the maximal weight. Note that we are not looking for a “best” algorithm for the MSTP. The main idea of an elitist EA is to reject worsenings and to escape from local optima by non-local steps. The main idea of MA and SA is to work with very local steps and to escape from local optima by accepting worsenings. The situation here is similar to the case of maximum matchings where also flips of 2 bits are helpful to shorten augmenting paths, compare Sasaki and Hajek (1988) who analyze SA with 1-bit flips only and Giel and Wegener (2003) who analyze RLS with 1-bit and 2-bit flips and a simple EA.

Finally, we introduce SA based on a cooling schedule $T(t)$. The initial temperature $T(1)$ may depend on m and the largest possible weight w_{\max} . The temperature $T(t)$ applied by the selection operator in step t equals $\alpha^{t-1} \cdot T(1)$, where $\alpha < 1$ is a constant which may depend on m and an upper bound on w_{\max} . This cooling schedule does not include any knowledge about the problem instance. We use a kind of “continuous cooling”, other possibilities are longer phases with a constant temperature or dynamic cooling schedules that depend on the success rate (where a step is called successful if x' is selected) or the rate of f -improving steps.

3 Efficiency Measures

There are many well-known convergence results on MA and SA. We want to distinguish “efficient behavior” from non-efficient one. The first idea is to define efficiency as expected polynomial time. We think that this is not a good choice. There may be a small probability of missing a good event for temperatures in some interval $[T_1, T_2]$. For temperatures smaller than T_1 it may be very unlikely

that the good event happens. This may cause a superpolynomial or even exponential expected run time although the run time is polynomially bounded with overwhelming probability.

Definition 1. *Let A be a randomized search heuristic (RSH) running for a polynomial number of $p(m)$ rounds and let $s(m)$ be the success probability, i. e., the probability that A finds an optimal search point within this phase. A is called*

- *successful, if $s(m) \geq 1/q(m)$ for some polynomial $q(m)$,*
- *highly successful, if $s(m) \geq 1 - 1/q(m)$ for some polynomial $q(m)$, and*
- *successful with overwhelming probability, if $s(m) = 1 - e^{-\Omega(m^\epsilon)}$ for some $\epsilon > 0$.*

One can be satisfied with successful RSHs, since then multistart variants not depending on p and q are successful with overwhelming probability and have an expected polynomial run time. An RSH is called unsuccessful if, for each polynomial p , the success probability within $p(m)$ steps is $o(m^{-k})$ for each constant k . This implies a superpolynomial expected optimization time. Moreover, multistart variants do not help.

4 Simulated Annealing Beats Metropolis on Some Simple Graphs

Our plan is to present simple graphs where SA beats MA for each temperature. The graphs should allow proofs as simple as possible. The idea behind the chosen graphs is the following. The problem to compute an MST on graphs with many two-connected components is separable, i. e., an MST consists of MSTs on the two-connected components. We investigate graphs where each two-connected component can be handled easily by MA with a well-chosen temperature, but different components need different temperatures. To keep the analysis easy the components have constant size. This implies that, for high temperatures, each component can be optimized, but the solutions are not stable. They are destroyed from time to time and then reconstructed. Therefore, it is unlikely that all the components are optimized simultaneously. SA can handle these graphs efficiently.

As announced, we investigate connected triangles (CT), see Figure 1, with $m = 6n$ edges. The number of triangles equals $2n$ and the number of vertices equals $4n + 1$. The weight profile (w_1, w_2, w_3) of a triangle is simply the ordered vector of the three edge weights. We investigate CTs with n triangles with weight profile $(1, 1, m)$ and n triangles with weight profile (m^2, m^2, m^3) . The unique MST consists of all edges of weight 1 or m^2 .

Theorem 1. *The probability that the Metropolis algorithm applied to CTs with n triangles with weight profile $(1, 1, m)$ and n triangles with weight profile (m^2, m^2, m^3) computes the MST within e^{cm} steps (c a positive constant which is small enough) is bounded above by $e^{-\Omega(m)}$, i. e., MA is unsuccessful on these instances.*

Proof. We distinguish the cases of high temperature ($T \geq m$) and low temperature ($T < m$).

The low temperature case is easy. We do not care about the triangles with weight profile $(1, 1, m)$. For each other triangle, MA accepts the exclusion of the first flipping edge. By Chernoff bounds, with probability $1 - 2^{-\Omega(m)}$, we obtain $\Omega(m)$ triangles where the first spanning tree contains the heavy edge. In order to obtain the MST it is necessary to include the missing edge of weight m^2 . If this edge is chosen to flip, the probability of selecting the new search point equals $e^{-m^2/T} \leq e^{-m}$. Hence, the success probability within $e^{m/2}$ steps is $e^{-\Omega(m)}$.

In the high temperature case, we do not care about the heavy triangles. For the light triangles, we distinguish between complete triangles (the search point chooses all three edges), optimal triangles (the two weight-1 edges are chosen), and bad triangles. The status of each triangle starts with “complete” and follows a Markov chain with the following transition probabilities:

	complete	optimal	bad
complete	$1 - 3/m$	$1/m$	$2/m$
optimal	$\frac{1}{m} \cdot e^{-m/T}$	$1 - \frac{1}{m} \cdot e^{-m/T}$	0
bad	$\frac{1}{m} \cdot e^{-1/T}$	0	$1 - \frac{1}{m} \cdot e^{-1/T}$

Let X_t be the number of optimal triangles after time step t , i. e., $X_0 = 0$. We are waiting for the first point of time t when $X_t = n$. Obviously, $|X_{t+1} - X_t| \leq 1$. Moreover,

$$\text{Prob}(X_{t+1} = a + 1 \mid X_t = a) \leq \frac{n - a}{m}$$

since it is necessary to flip the heaviest edge in one of the at most $n - a$ complete triangles, and

$$\text{Prob}(X_{t+1} = a - 1 \mid X_t = a) = \frac{a}{m} \cdot e^{-m/T} \geq \frac{a}{3m}$$

since $T \geq m$ and since it is necessary to flip the heaviest edge in one of the optimal triangles and to accept the new search point. Since we are interested in lower bounds, we use the upper bound for the probability of increasing a and the lower bound for the probability of decreasing a . Ignoring steps not changing a , we obtain the following transition probabilities for the new Markov chain Y_t :

$$\text{Prob}(Y_{t+1} = a - 1 \mid Y_t = a) = \frac{a/(3m)}{a/(3m) + (n - a)/m} = \frac{a}{3n - 2a}.$$

There has to be a phase where the Y -value increases from $(10/11)n$ to n without reaching $(9/11)n$. In such a phase the probability of decreasing steps is bounded below by $\frac{(9/11)n}{3n - (18/11)n} = \frac{3}{5}$. Applying results on the gambler’s ruin problem, the

probability that one phase starting at $a = (10/11)n$ and finishing at $a = (9/11)n$ or $a = n$ stops at $a = n$ is bounded above by

$$\left(\frac{3}{2}\right)^{n/11} - 1 / \left(\frac{3}{2}\right)^{2n/11} - 1 = e^{-\Omega(m)}$$

since the probability of decreasing steps is at least by a factor of $3/2$ larger than the probability of increasing steps. Hence, the probability of finding the MST within e^{cm} steps, $c > 0$ small enough, is bounded by $e^{-\Omega(m)}$. \square

Theorem 2. *Let p be a polynomial and let the cooling schedule be described by $T(1) = m^3$ and $\alpha = 1 - 1/(cm)$ for some constant $c > 0$. If c is large enough, the probability that simulated annealing applied to CTs with n $(1, 1, m)$ -triangles and n (m^2, m^2, m^3) -triangles computes the MST within $3cm \ln m$ steps is bounded below by $1 - 1/p(m)$.*

Proof. We only investigate the search until the temperature drops below 1. This phase has a length of at most $3cm \ln m$ steps and contains two subphases where the temperature is in the interval $[m^2, m^{5/2}]$ or in the interval $[1, m^{1/2}]$. The length of each subphase is at least $(c/4)m \ln m$.

If $T \leq m^{5/2}$, the probability of including an edge of weight m^3 is bounded above by $e^{-m^{1/2}}$. Each run where such an event happens is considered as unsuccessful. If $T \in [m^2, m^{5/2}]$ and an (m^2, m^2, m^3) -triangle is optimal, this triangle remains optimal unless the event considered above happens. Applying Chernoff bounds to each edge and choosing c large enough, the probability of not flipping edges of each triangle at least $c' \log m$ times is bounded by m^{-k} , $c' > 0$ and k arbitrary constants. This is a second source of bad behavior. Now, we investigate one (m^2, m^2, m^3) -triangle and the steps flipping one of its edges. For each complete or bad triangle, there is a chance that it turns into optimal within the next two steps concerning this triangle. This happens if the right two edges flip in the right order (probability $1/9$) and the inclusion of the edge with weight m^2 is accepted (probability $e^{-m^2/T} \geq e^{-1}$). The probability of not having a good pair among the at least $(c'/2) \log m$ step pairs, can be made much smaller than m^{-k} by choosing c' large enough. Altogether, the probability that the first subphase does not finish with MSTs on all (m^2, m^2, m^3) -triangles can be made smaller than $1/(3p(m))$.

The same calculations for $T \in [1, m^{1/2}]$ and the $(1, 1, m)$ -triangles show that the probability that the second subphase does not finish with MSTs on all $(1, 1, m)$ -triangles can be made smaller than $1/(3p(m))$. Finally, the probability that an (m^2, m^2, m^3) -triangle has turned from optimal into non-optimal after the first subphase is smaller than $1/(3p(m))$. This proves the theorem. \square

We have proved that SA is highly successful for the considered graph instances. It is easy to choose a cooling schedule such that SA is even successful with overwhelming probability, e. g., $T(1) = m^3$ and $\alpha = 1 - 1/m^2$. See Neumann and Wegener (2004) to compare SA with simple evolutionary algorithms.

This section contains the result announced in the title of the paper. In the remaining sections, we investigate which graphs can be handled efficiently by MA and SA, only by SA, or by none of them.

5 Connected Triangles with the Same Weight Profile

It is interesting to understand how much different weights have to differ such that MA or SA are able to construct efficiently an MST. For this reason, we investigate graphs consisting of connected triangles in more detail. In this section, we consider the case of n CTs with the same weight profile $(w, w, (1 + \varepsilon(m)) \cdot w)$ where $\varepsilon(m) > 0$. We distinguish the cases where $\varepsilon(m)$ is bounded below by a positive constant ε and the case where $\varepsilon(m) = o(1)$.

Theorem 3. *If $\varepsilon(m) \geq \varepsilon > 0$, MA with an appropriate temperature finds the MST on CTs with n $(w, w, (1 + \varepsilon(m)) \cdot w)$ -triangles in expected polynomial time and is successful with overwhelming probability.*

Proof. A good temperature has to fulfil two properties:

- It has to be low enough to distinguish w -edges effectively from $(1 + \varepsilon) \cdot w$ -edges.
- It has to be high enough to allow the inclusion of a w -edge in expected polynomial time.

We choose $\gamma := 3/\varepsilon$ and $T := w/(\gamma \cdot \ln m)$. The probability to accept the inclusion of a w -edge equals $e^{-w/T} = m^{-\gamma}$ while the corresponding probability for a $((1 + \varepsilon(m)) \cdot w)$ -edge equals $m^{-\gamma \cdot (1 + \varepsilon(m))} \leq m^{-\gamma - 3}$. We analyze the success probability of a phase of length $m^{\gamma+2}$ starting with an arbitrary connected graph. The event to accept the inclusion of a heavy edge is considered as an unsuccessful phase. The probability of this event is bounded above by $1/m$. Following the lines of the proof of Theorem 2 we have for each triangle with overwhelming probability $\Omega(m^{\gamma+1})$ steps flipping an edge of this triangle which we partition into $\Omega(m^{\gamma+1})$ pairs of consecutive steps. The probability that a complete or bad triangle is turned within such two steps into an optimal one is $\Omega(m^{-\gamma})$. Hence, with overwhelming probability, all triangles turn into optimal during this phase and with probability at least $1 - 1/m$ none of them is turned into non-optimal. Hence, the expected number of phases is $O(1)$ and the probability that a sequence of m phases is unsuccessful is exponentially small. □

It is obvious how to tune the parameters in order to get improved run times. We omit such calculations which do not need new ideas. SA finds the MST in polynomial time with a probability exponentially close to 1 if it starts with $T(1) := w/(\gamma \cdot \ln m)$ and has a cooling schedule that cools down the temperature sufficiently slow. This follows in the same way as Theorem 3.

Theorem 4. *If $\varepsilon(m) = o(1)$, MA and SA are unsuccessful on CTs with n $(w, w, (1 + \varepsilon(m)) \cdot w)$ -triangles.*

Proof. First, we investigate MA. The search starts with n complete triangles and each one has a probability of $2/3$ to be turned into a bad one before it is turned into an optimal one. With overwhelming probability, at least $n/2$ bad triangles are created where the missing w -edge has to be included in order to be able to turn it into an optimal triangle. The probability of including a w -edge within a polynomial number of $p(m)$ steps is bounded above by $p(m) \cdot e^{-w/T}$. This is bounded below by $\Omega(m^{-k})$ only if $e^{-w/T} = \Omega(m^{-\gamma})$ for some constant $\gamma > 0$. Hence, we can assume that $T \geq w/(\gamma \cdot \ln m)$ for some constant $\gamma > 0$.

Let $p^*(T)$ be the probability of accepting the inclusion of a w -edge and $p^{**}(T)$ the corresponding probability for a $((1 + \varepsilon(m)) \cdot w)$ -edge. Since $T \geq w/(\gamma \cdot \ln m)$ and $\varepsilon(m) = o(1)$,

$$\begin{aligned} p^*(T)/p^{**}(T) &= e^{-w/T} \cdot e^{(1+\varepsilon(m)) \cdot w/T} \\ &= e^{\varepsilon(m) \cdot w/T} \\ &\leq e^{\varepsilon(m) \cdot \gamma \cdot \ln m} \\ &= m^{\varepsilon(m) \cdot \gamma}. \end{aligned}$$

Choosing m large enough, this gets smaller than any m^δ , $\delta > 0$. It will turn out that this advantage of w -edges against $((1 + \varepsilon(m)) \cdot w)$ -edges is too small. The stochastic process behind MA can be described by the parameters b (number of bad triangles) and c (number of complete triangles). We use the potential function $2b + c$ which starts with the value n and has the value 0 for the MST. The value of the potential function changes in the following way:

- It increases by 1 if a complete triangle turns into a bad one or an optimal one turns into a complete one. The probability of the first event equals $2c/m$, since we have to flip one of the two light edges of one of the complete triangles. The probability of the second event equals $p^{**}(T) \cdot (n - b - c)/m$ since we have to flip the heavy edge in one of the $n - b - c$ optimal triangles and to accept this flip.
- It decreases by 1 if a complete triangle turns into an optimal one (probability c/m) or a bad triangle turns into a complete one (probability $p^*(T) \cdot b/m$).
- It remains unchanged, otherwise.

Since we are interested in lower bounds on the optimization time, we can ignore all non-accepted steps, i. e., all steps not changing the potential. If $b \leq n^{1/2}$ and m is large enough, the probability that an accepted step increases the potential is at least $3/5$. This claim is equivalent to

$$\frac{2c/m + p^{**}(T) \cdot (n - b - c)/m}{2c/m + p^{**}(T) \cdot (n - b - c)/m + c/m + p^*(T) \cdot b/m} \geq \frac{3}{5}$$

which is equivalent to

$$2c + p^{**}(T) \cdot (n - b - c) \geq \frac{9}{5}c + \frac{3}{5} \cdot p^{**}(T) \cdot (n - b - c) + \frac{3}{5}p^*(T) \cdot b$$

and

$$\frac{1}{5}c + \frac{2}{5}p^{**}(T) \cdot (n - b - c) \geq \frac{3}{5} \cdot p^*(T) \cdot b.$$

This is obviously true if $c \geq 3 \cdot b$. Otherwise, $n - b - c \geq n - 4b \geq n - 4n^{1/2}$ and it is sufficient to show that

$$2 \cdot p^{**}(T) \cdot (n - 4n^{1/2}) \geq 3 \cdot p^*(T) \cdot n^{1/2}$$

or

$$p^*(T)/p^{**}(T) \leq \frac{2}{3}(n^{1/2} - 4).$$

We have shown that this holds for large enough m , since $n = \Omega(m)$. The claim for MA follows now from results on the gambler’s ruin problem. The probability to start with a potential of $n^{1/2}/2$ and to reach the value 0 before the value $n^{1/2}$ is exponentially small. Finally, we investigate a polynomial number of $p(m)$ steps of SA. Let d be chosen such that $p(m) \leq m^d$. We claim that it is unlikely that the potential drops below $n^{1/2}/4$ within m^d steps. With overwhelming probability, we produce a bad triangle. Therefore, it is necessary to accept the inclusion of a w -edge. Hence, as seen above, only steps where the temperature is at least $w/(\gamma \cdot \ln m)$ for some appropriate constant $\gamma > 0$ have to be considered. However, the analysis of MA treats all these temperatures in the same way. The probability to start with a potential of $n^{1/2}/2$ and to reach the value $n^{1/2}/4$ before $(3/4)n^{1/2}$ is still exponentially small. \square

The proof also shows that SA with an arbitrary cooling schedule is unsuccessful in the considered situation.

6 Simulated Annealing Is Successful for $(1 + \varepsilon)$ -Separated Weights

We have seen in Theorem 4 that MA and even SA are unsuccessful on certain graphs if we allow that different weights may differ by a factor of $1 + \varepsilon(m)$ where $\varepsilon(m)$ is an arbitrary function such that $\varepsilon(m) = o(1)$. Here, we prove that SA is highly successful on all graphs if the different weights differ at least by a factor of $1 + \varepsilon$ for some constant $\varepsilon > 0$.

Before proving this result, we repeat some well-known facts about MSTs. Let E_1, \dots, E_r be the partition of the edge set E such that all edges in E_i have the same weight W_i and $W_1 > \dots > W_r$. Let $c_i, 1 \leq i \leq r + 1$, be the number of connected components of $G_i := (V, E_i \cup \dots \cup E_r)$. Each MST contains exactly $a_i := c_{i+1} - c_i$ E_i -edges such that the chosen edges from $E_i \cup \dots \cup E_r$ span the connected components of G_i . A set E_i^* of a_i E_i -edges is called optimal if $G_i^* := (V, E_i^* \cup E_{i+1} \cup \dots \cup E_r)$ has the same connected components as G_i . An MST contains exactly the edges of optimal sets E_1^*, \dots, E_r^* . The set E_i^* is not necessarily uniquely defined. The idea of the proof is the following. There is some point of time $t_i, 1 \leq i \leq r + 1$, such that, with large probability, the following holds. After step t_i , no inclusion of an edge from $E_1 \cup \dots \cup E_i$ is accepted and at step t_i the current search point has chosen among all E_j -edges, $1 \leq j \leq i - 1$, an optimal subset E_j^* . This implies that after step t_i no edges from $E_1 \cup \dots \cup E_{i-1}$ are included (the first property) or excluded (this would destroy the connectedness

of the graph described by the search point). Moreover, no edges from E_i are included and we hope to exclude enough E_i -edges until step t_{i+1} such that then the search point chooses an optimal set E_i^* of E_i -edges. Note that after time step t_i the set of chosen E_i -edges is always a superset of an optimal set E_i^* since, otherwise, the considered graph would be unconnected. Finally, the properties imply that at step t_{r+1} the search point describes an MST.

Theorem 5. *Let the weights of the edges be bounded by 2^m and $(1+\varepsilon)$ -separated for some constant $\varepsilon > 0$, i. e., $w_i > w_j$ implies $w_i \geq (1 + \varepsilon) \cdot w_j$. SA with an appropriate cooling schedule is highly successful when searching for an MST on such graphs.*

Proof. Let $T(1) := 2^m$, $\gamma := 8/\varepsilon$, α be the cooling factor such that it takes $m^{\gamma+7}$ steps to decrease the temperature from T to $T/(1 + \varepsilon/2)$, and β be defined by $(1 + \varepsilon/2)^\beta = 2$. Then we set $t_{r+1} := 2\beta m^{\gamma+8}$. Until step t_{r+1} , the temperature has dropped (far) below $1/m$. Our claim is that, with a probability of $1 - O(1/m)$, the search point at step t_{r+1} describes an MST.

To follow the proof strategy discussed above let $t_i, 1 \leq i \leq r$, be the earliest point of time when $T(t_i) \leq W_i / ((1 + \varepsilon) \cdot \gamma \cdot \ln m)$. The probability of accepting the inclusion of an edge of weight W_i after step t_i is bounded above by $m^{-\gamma-8}$. During the next $m^{\gamma+7}$ steps, with overwhelming probability, there are $O(m^{\gamma+6})$ steps flipping a specified edge and the probability to accept this edge at least once is $O(1/m^2)$. Afterwards, the temperature has dropped by a factor of $1/(1 + \varepsilon/2)$. The probability to accept this edge is then bounded by $m^{-\gamma-12}$ and the probability to accept the edge during the next $m^{\gamma+7}$ steps is $O(1/m^5)$. This argumentation can be continued implying that the probability to accept the inclusion of the considered edge after step t_i is $O(1/m^2)$. Hence, with probability $1 - O(1/m)$, it holds that, for all i , edges of weight W_i are not included after step t_i . In the following, we assume that this event holds.

We assume that at step t_i the search point chooses optimal sets E_1^*, \dots, E_{i-1}^* and a superset E_i' of an optimal set E_i^* . This is obviously true for $i = 1$. We analyze the steps $t_i, \dots, t_i + m^{\gamma+7} - 1$. The probability to accept an edge with weight $w \leq W_{i+1}$ in one step is bounded below by $m^{-\gamma-4}$ during this phase. By our assumption, we do not include edges of weight $w \geq W_i$. Let $b_i := |E_i'| - |E_i^*|$ at step t_i . As long as $|E_i'| > |E_i^*|$ there are at least $|E_i'| - |E_i^*|$ candidate E_i -edges whose exclusion is possible. The exclusion of such an edge is only accepted if this edge lies on a cycle. Either the edge lies on a cycle or there is a missing edge of weight $w \leq W_{i+1}$ whose inclusion creates a cycle containing the considered E_i -edge. If no cycle with an E_i -edge exists, the probability of creating such a cycle in the next step is at least $m^{-\gamma-5}$. If a cycle with an E_i -edge exists, the probability to destroy the cycle by excluding an E_i -edge is at least $1/m$ (there may be more than one E_i -edge on the cycle). Let us assume that we do not exclude b_i E_i -edges within the considered $m^{\gamma+7}$ steps. Let s be the number of steps in this phase where a cycle with an E_i -edge exists.

If $s \geq m^{3/2}$, then the probability of less than $b_i \leq m$ steps excluding an E_i -edge on the cycle is exponentially small. If $s < m^{3/2}$, then the probability that among the at least $m^{\gamma+7} - m^{3/2}$ steps without a cycle with E_i -edges there are less than $m^{3/2}$ steps creating such a cycle is exponentially small. Hence, with overwhelming probability, enough E_i -edges are excluded and the claim holds for step t_{i+1} .

Altogether, with a probability of $1 - O(1/m)$, SA has found an MST after $O(m^{\gamma+8})$ steps. \square

It is easy to see that we can generalize the result to weights up to $2^{p(m)}$ for a polynomial p . The run time increases by a factor of $O(p(m)/m)$. It is possible to tune the parameters to obtain better run times. However, the purpose of Theorem 4 and Theorem 5 was to identify the border (with respect to quotients of different weights) between cases where SA is highly successful and cases where SA can be unsuccessful. With respect to these aims we have obtained optimal results. It is easy to generalize our results to prove that SA is always highly successful if one is interested in $(1 + \varepsilon)$ -optimal spanning trees. It remains an open problem to find other sufficient conditions implying that MA or SA is successful or unsuccessful on the MSTP.

7 Conclusions

The paper contributes to the theory of randomized search heuristics, in particular, the Metropolis algorithm and simulated annealing. The problem to present a natural example from combinatorial optimization where simulated annealing beats the Metropolis algorithm is solved by investigating the problem of computing minimum spanning trees. Moreover, the minimal factor between different weights to guarantee that simulated annealing finds minimum spanning trees efficiently is determined.

Abstract. We study interval coloring problems and present new upper and lower bounds for several variants. We are interested in four problems, online coloring of intervals with and without bandwidth and a new problem called lazy online coloring again with and without bandwidth. We consider both general interval graphs and unit interval graphs. Specifically, we establish the difference between the two main problems which are interval coloring with and without bandwidth. We present the first non-trivial lower bound of **3.2609** for the problem with bandwidth. This improves the lower bound of 3 that follows from the tight results for interval coloring without bandwidth presented in [9].

1 Introduction

We study online interval coloring problems. In the basic problem intervals are presented one by one and the online algorithm must assign each interval a color before the next interval arrives where two intersecting intervals can not be colored by the same color. We are also interested in the case where every interval has an associated bandwidth in $[0,1]$, this problem was first introduced by Adamy and Erlebach [1]. A set of intervals can be assigned the same color c , if for any point p , on the real line, the sum of the bandwidths of intervals colored c and containing p , does not exceed 1. We refer to a coloring satisfying the above condition as a *proper coloring*.

As mentioned in [1], the interval coloring problem with bandwidth arises in many applications. Most of the applications come from networks field.

Consider a network with a line topology that consists of links, where each link has channels of constant capacity. This can be either an all-optical WDM (wavelength-division multiplexing) network or an optical network supporting SDM (space-division multiplexing). A connection request is from one network node a to another node b has a bandwidth associated with it. The set of requests assigned to a channel must not exceed the capacity of the channel on any of the links on the path $[a, b]$. The goal is to minimize the number of channels (colors) used. A connection request from a to b corresponds to an interval $[a, b]$ with the respective bandwidth requirement and the goal is to minimize the number of required channels to serve all requests.

Another network related application is that if the requests have constant duration c , and we have to serve all requests as fast as possible. With respect to our online interval

coloring problem with bandwidth, the colors correspond to time slots, and the total number of colors corresponds to the schedule length.

The last example comes from scheduling, a requested job has a duration and resource requirement during its execution. Jobs (intervals) arrive online and must be assigned to a machine (color) immediately. All the machines have the same capabilities and the objective is to minimize the number of machines used.

The unweighted problem is equivalent to coloring an interval graph, where each interval corresponds to a node and an edge between two nodes appears if the corresponding intervals intersect. Interval graphs are perfect, therefore the chromatic number of the graph is the maximum clique size [6], which represents a point where the most intervals intersect. It can be elaborated for the bandwidth case, if we refer to the maximum clique size as the maximum weighted clique. Each node has the weight of the related interval, i.e., its bandwidth, and the clique size is the sum of weights of the clique.

We study online coloring problems in terms of competitive analysis. Thus we compare an online algorithm to an optimal offline algorithm OPT that knows the complete sequence of intervals in advance. In this paper, we make use of two types of competitive ratios. The *absolute competitive ratio* and the *asymptotic competitive ratio*.

Let $B(\sigma)$ (or B , if the sequence σ is clear from the context), be the cost of algorithm B on the request sequence σ . An algorithm A is \mathcal{R} -competitive (with respect to the absolute competitive ratio) if for every sequence σ , $A(\sigma) \leq \mathcal{R} \cdot OPT(\sigma)$. The absolute competitive ratio of an algorithm is the infimum value of \mathcal{R} such that the algorithm is \mathcal{R} -competitive.

The asymptotic competitive ratio for an online algorithm A is defined to be

$$\mathcal{R}_A^\infty = \limsup_{n \rightarrow \infty} \sup_{\sigma} \left\{ \frac{A(\sigma)}{OPT(\sigma)} \mid OPT(\sigma) = n \right\}.$$

Most results in this paper hold for both definitions of competitive ratio. We mention the cases where a result holds for only one definition.

Coloring interval graphs has been intensively studied, Kierstead and Trotter [9] constructed an online algorithm which uses at most $3\omega - 2$ colors where ω is the maximum clique size of the interval graph. They also presented a matching lower bound of $3\omega - 2$ on the number of colors in a coloring of an arbitrary online algorithm. As mentioned above, the chromatic number of interval graphs equals to the size of a maximum clique. This means that the optimal offline algorithm can color every interval graph with ω colors.

Much research has been done analyzing the performance of the simple First Fit algorithm. An upper bound of 40 on the competitive ratio was proven in [7], and later on an upper bound of 25.72 was presented by Kierstead and Qin [8]. In a recent study [11], a competitive ratio of 10 was proved. Chrobak and Slusarek [3] show a lower bound close to 4.5 on the competitive ratio of First Fit.

Coloring intervals with bandwidth was first posed in 2003 in [1], they presented an online algorithm with a competitive ratio of 195. In [10] Narayanaswamy presented a new algorithm with a competitive ratio of 10.

Motivated by The Maximum Resource Bin Packing Problem [2], we introduce a new problem called Lazy Interval Coloring. As opposed to the regular interval coloring

problem, we seek to use as many colors as possible. If all bandwidths are 1, a new color may be used for an interval, only if it intersects intervals with all the previously used colors. We also consider the bandwidth case, where intervals have bandwidth in $[0,1]$. For both problems, a newly presented interval must be colored by a used color if a proper coloring can be achieved. An application for this problem can be any of the applications mentioned before, where using additional colors (channels/time slots/machines) can improve the quality of service. The scheduler (who assigns colors) has the purpose of using as many colors as possible. However, to avoid the usage of too many colors, the instructions of a scheduler (given by the boss, who pays for the equipment) are not to use a new color unless it is absolutely necessary.

Our Results: We show that introducing bandwidth to interval coloring makes the problem harder. We present the first non-trivial lower bound of **3.2609**, which improves the lower bound of 3 for interval coloring without bandwidth. Recall that for the problem without bandwidth, the bound 3 is tight. We also show that bandwidth makes lazy interval coloring a much harder problem.

In this work we consider resource augmentation for the problem of interval coloring with and without bandwidth. We show that there exists an online algorithm that when uses twice as much resource for each color, can perform as good as the optimal offline algorithm. We also present a matching lower bound.

For the bandwidth case we study two interesting cases. In the first case, the online algorithm may use twice as much capacity for each color as the offline algorithm, for which we present an online algorithm that uses at most 3 times the number of colors that the optimal offline algorithm uses. In the second case, we present an online algorithm that uses at most as many colors as OPT in the worst case, where each color has a capacity of 4.

Another interesting variant is to restrict the class of intervals, so all intervals are of the same length. This type of graph is called “Unit Interval Graph”. For the interval coloring problem we show that First Fit uses at most $2\omega - 1$ colors and that the analysis is tight. We also show a lower bound of $\frac{3}{2}$ on the competitive ratio of any online algorithm.

For interval coloring with bandwidth for unit interval graphs, we present several algorithms, the best algorithm has $3\frac{1}{2}$ competitive ratio. We also present a lower bound of 2. For the asymptotic competitive ratio, the bounds become 3.17778 and 1.831.

For lazy interval coloring, we prove that for general instances any online algorithm performs arbitrarily bad. However if all intervals have the same length we present upper and lower bounds of 2. When introducing bandwidth to the lazy interval coloring problem, we show that any online algorithm is arbitrarily bad compared to the maximum weighted clique (even for unit interval graphs). We summarize our results and previous results in the following table.

Remark: All omitted proofs can be found in the full version of the paper.

2 Preliminaries

A weighted interval graph G , is a graph where each node corresponds to an interval. The weight of the node is the bandwidth of the interval related to it. If two intervals

Table 1. Results obtained in this paper and previous work. For each case, a single entry means that the results hold for both asymptotic and absolute competitive ratios. If two entries exist, the first one is the asymptotic competitive ratio and the second one stands for the absolute competitive ratio

intersect, there is an edge between their related nodes in G . Recall that we denote the optimal coloring of the offline algorithm by OPT .

Let $\omega(G)$ denote the size of the maximum cardinality clique in G (ω for short), i.e., ignoring the weights. Let $\omega^*(G)$ (ω^* for short) denote the largest weighted clique in G . A weighted clique is the sum of the weights of the vertices in a clique. Note that for the interval coloring problem with bandwidth we have $OPT \geq \lceil \omega^* \rceil$

Below we give a generalized presentation of the algorithm of Kierstead and Trotter [9]. We use specific cases of the generalized algorithm for the variant of resource augmentation in the next sections. We present the algorithm using notations similar to these of [10].

Let $\sigma = v_1, \dots, v_n$ be the list of vertices of G , in the order of arrival. Algorithm $KT_{l,b}$ is defined for inputs σ such that, $b(v_i) \in (0, b]$. The algorithm partitions the intervals (i.e. the vertices of G) into sets A_m (for integer values of m , such that $m \geq 1$). We use C_m to denote the set of colors dedicated to A_m . Every set A_m is colored using First Fit, independently of other sets. Therefore the colors have the property $C_x \cap C_y = \emptyset$ for $x \neq y$. A *critical point*, q , in interval $v_i \in A_{m(v)}$, is a point where $\omega^*(G_{m(v)-1}(v_i) \cup \{v_i\}) > (m(v_i) - 1) \cdot l$. Since $v_i \in A_{m(v)}$, there is at least one such point for every interval in $A_{m(v)}$.

Algorithm 1. $KT_{l,b}$

On a new interval v_i :

- 1: For every integer $m \geq 1$, let $V_m(v_i)$ and $E_m(v_i)$ be the following subsets of $V(G)$ and $E(G)$ respectively.
 $V_m(v_i) = \{v_j \in V(G) : j < i, m(v_j) \leq m\};$
 $E_m(v_i) = \{(u, v) \in E(G) : u, v \in V_m(v_i)\};$
 $G_m(v_i) \cup \{v_i\} = G(V_m(v_i) \cup v_i, E_m(v_i) \cup \{(u, v_i) \in E(G) : u \in V_m(v_i)\})$
 $\omega_i^*(H) =$ The maximum weighted clique in graph H containing interval v_i
 - 2: Let $G_m(v_i) = G(V_m(v_i), E_m(v_i))$
 - 3: $m(v_i) =$ the smallest m such that $\omega_i^*(G_m(v_i) \cup \{v_i\}) \leq m \cdot l$.
 - 4: $A_{m(v)} \leftarrow A_{m(v)} \cup \{v_i\}$
 - 5: Color v_i considering only the intervals of $A_{m(v)}$ using First Fit on colors of $C_{m(v)}$.
-

Lemma 1. *Given an interval v_i , let $m = m(v_i)$. For the set A_m and every critical point $q \in v_i$, the total bandwidth at q of intervals in A_m does not exceed $b + l$.*

Lemma 2. *For every m , $\omega^*(A_m) \leq 2(b + l)$.*

Proof. Proof by contradiction, assume that there is a weighted clique of more than $2(b + l)$ in A_m obtained at point p_j . By the previous lemma, this point is not a critical point of any interval in A_m . For every interval $v_i \in A_m$, where $p_j \in v_i$, there is a critical point either to the right of p_j or the left of p_j or both. Denote the closest critical point (of any interval of A_m which contains p_j) to the left of p_j , q_l and the closest critical point to the right of p_j , q_r . Since there is at least one critical point for every v_i , either $q_l \in v_i$ or $q_r \in v_i$ or both for every $v_i \in A_m$ (since the critical point of v_i cannot be in the interval (q_l, q_r)). But this means that either q_l or q_r have a total bandwidth of more than $b + l$. By Lemma 1, this is not possible. Note that either q_l or q_r or both must exist. If one of q_r or q_l does not exist, we get the contradiction at the point that exists.

Lemma 3. *If all intervals have the same bandwidth, b , and l is divisible by b , for every m , $\omega^*(A_m) \leq 2l$.*

Lemma 4. (i) *The largest value of m ever used in $KT_{l,b}$ is $\lceil \frac{\omega^*}{l} \rceil$*

(ii) *The coloring of $KT_{l,b}$ is at most $\lceil \frac{\omega^*}{l} \rceil (\max_m FF(C_m))$, where $FF(C_m)$ denotes the coloring of the First Fit algorithm on the set C_m of intervals that were presented online.*

Proof. (i): For a maximum weighted clique of ω^* and for every interval $v_i \in \sigma$, $\omega^*(G_{\lceil \frac{\omega^*}{l} \rceil}(v_i) \cup \{v_i\}) \leq \omega^* \leq \lceil \frac{\omega^*}{l} \rceil \cdot l$ (ii): By (i) the largest value of m is at most $\lceil \frac{\omega^*}{l} \rceil$. For each m , A_m is colored by First Fit using the related colors of C_m (last step of the algorithm).

2.1 Variants of Interval Coloring

Resource Augmentation in Interval Coloring: In the resource augmentation approach, the online algorithm is given more resources than the offline algorithm. Interval coloring is a natural problem to consider with resource augmentation. In this case, in the online coloring, the total bandwidth of intersecting intervals with the same color can exceed 1. The allowed maximum bandwidth of the intersecting intervals in the online coloring will be denoted by B . For the analysis we use the concept of competitive ratio.

Equal length intervals in Interval Coloring: If the intervals must be of equal length, the associated graph is called a unit interval graph. Recognition of unit interval graphs has been studied in [13, 4, 12]. It was also studied in the context of interval selection in [5]. For simplicity, we use intervals of length 1 in some of the proofs of this paper.

3 Interval Coloring

3.1 Resource Augmentation

In [9] Kierstead and Trotter give a lower and upper bound of 3. The main goal when resource augmentation is allowed, is to find a value of B for which there exists an

algorithm with a competitive ratio 1. We argue that for $B = 2$, the online algorithm presented in [9] uses $\max\{1, OPT - 1\}$ colors. We also present a matching lower bound of $\max\{1, OPT - 1\}$ on the number of colors used by any online algorithm.

Theorem 1. *An adaptation of the algorithm of Kierstead and Trotter [9] can be used for interval coloring with $B = 2$, and uses at most $\max\{1, OPT - 1\}$ colors.*

Proof. Algorithm: $KT_{1,1}$ without bandwidth is exactly the the algorithm of Kierstead and Trotter.

According to Lemma 3 every set A_m has a maximum bandwidth of at most 2. Since $B = 2$, First Fit can color each A_m by a unique color. Moreover, by the definition of sets A_1 and A_2 , the total bandwidth of intervals in $A_1 \cup A_2$ does not exceed 2. We use the same color for $m = 1, 2$, and one color for each other value of m . By Lemma 4, we get a coloring which uses $\lceil \omega^* \rceil - 1 \leq OPT - 1$ colors, if $OPT \geq 1$ and otherwise it uses a single color.

We prove that the above bound cannot be improved. Clearly if $OPT = 1$ the algorithm also uses at least one color, therefore we need to show a lower bound of $OPT - 1$. The lower bound construction holds only for the absolute competitive ratio.

Theorem 2. *There exists an infinite sequence of values of α , such that there exists an input for which $OPT = \alpha$ and any online algorithm for interval coloring with $B = 2$, uses at least $OPT - 1$ colors.*

3.2 Unit Interval Graphs

In the following 2 theorems, we show that First Fit uses at most $2\omega - 1$ colors for unit interval graphs and that the analysis is tight.

Theorem 3. *First Fit uses at most $2\omega - 1$ colors for coloring unit interval graphs.*

Proof. In this version, since all the intervals are of equal length, if the maximum clique equals to ω , then there is no interval that intersects with more than $2\omega - 2$ different intervals. Assume by contradiction that there exists an interval $I = [x, x + 1]$ that does intersect with more than $2\omega - 2$ different intervals. Since all intervals are of unit length, every interval that intersects I , must contain either the point x or $x + 1$ (or both). Therefore either the point x or the point $x + 1$ is contained in more than $\omega - 1$ intervals not including interval I . This contradicts the fact that the maximum clique size does not exceeds ω . Therefore First Fit uses at most $2\omega - 1$ colors.

Theorem 4. *There exist unit interval graphs on which First Fit uses exactly $2\omega - 1$ colors.*

Proof. We show a family of instances, where k is the size of largest clique on which First Fit uses exactly $2k - 1$ colors to color it. We define the sequence of intervals in phases.

Phase i ($1 \leq i \leq 2k - 1$) contains $2k - i$ intervals that receive the same color by First Fit. The largest clique size after phase i is $\lfloor \frac{i}{2} \rfloor + 1$. The intervals of phase i are

$[i - 1 + 2^{-i+1} + 2j, i - 1 + 2^{-i+1} + 2j + 1]$, for $0 \leq j < 2k - i$. All intervals have length 1, and all consecutive intervals of one phase have fixed distances of 1 between them.

We prove the following claims.

1. The largest clique after phase $2\ell + 1$ is of size $\ell + 1$, and in ranges of the form $(2j, 2j + 2^{-2\ell})$, the total requested bandwidth is at most ℓ .
2. All intervals of phase i receive the color i .

Proof of 1: We prove the claim by induction. After phase 1 ($\ell = 0$), the largest clique is clearly of size 1 (the intervals are non-intersecting). The ranges $(2j, 2j + 1)$ are empty since the intervals of phase 1 start at odd points. Assume now that the claim holds for $\ell = s - 1$ and prove for $\ell = s$. Phases $2s$ and $2s + 1$ introduce two sets of intervals. To show the first part of the claim we need to show that the overlap between the intervals does not overlap with areas where the largest clique is s . Non overlapping parts of new intervals may increase the size of the largest clique by 1. By definition, the overlap interval between intervals of these two phases are intervals of the form $[2j + 2^{-2s}, 2j + 2^{1-2s}]$. Using the inductive hypothesis, intervals of the form $(2j, 2j + 2^{2-2s})$ have bandwidth request of size $s - 1$ only, and therefore the largest clique in these intervals after phase $2s + 1$ does not exceed $s + 1$. To prove the second part of the claim, the interval $(2j, 2j + 2^{-2s})$ is not a part of the overlap between phases $2s$ and $2s + 1$, therefore its bandwidth request increases by at most 1, and becomes at most s .

Proof of 2: We prove that an interval of phase i intersects with intervals of all smaller colors. If i is odd, then its left endpoint intersects with all intervals of even colors, and its right endpoint with all intervals of odd colors. If i is even, its left endpoint intersects with intervals of all odd colors, and its right endpoint with even colors. This can be easily verified by the intervals definitions.

Theorem 5. *Any online algorithm for unit interval graphs has a competitive ratio of at least $\frac{3}{2}$*

4 Online Coloring of Intervals with Bandwidth

Interval coloring with bandwidth was recently studied by [1] and [10]. Adamy and Erlebach [1] gave a 195-competitive ratio algorithm and Narayanaswamy [10] gave a 10-competitive ratio. However, is this case really harder? In the theorem below we answer that question affirmatively. We give a lower bound which is strictly higher than the upper bound for the problem of interval coloring without bandwidth presented in [9]. To prove the lower bound we adapt the lower bound on classical interval coloring given in [9]. In that paper a lower bound of $3\omega - 2$ colors is shown, for inputs where $OPT = \omega$. Since interval graphs are perfect, these are exactly inputs where the largest clique has size ω . Note that two intervals whose width is strictly larger than $\frac{1}{2}$ cannot have the same color. Therefore the same lower bound can be applied not only for intervals of width 1, but for intervals of arbitrary widths in $(\frac{1}{2}, 1]$. In this case, let q be the largest number of intersecting intervals of width in $(\frac{1}{2}, 1]$, then we immediately

get a lower bound of $3q - 2$. Finally, we make another adaptation to the lower bound, namely, we make use of the following lemma.

Lemma 5. *The lower bound $3q - 2$ on the number of colors holds even if q is given in advance.*

With this, we are ready to prove our main theorem of this section.

Theorem 6. *Any deterministic online algorithm for interval coloring with bandwidth has competitive ratio of at least 3.2609*

Proof. Let α be a constant rational number fixed later and let t be an integer such that αt is integer (there are infinitely many such values of t). Let $\varepsilon = \frac{1}{2\alpha t + 1}$. The first phase of requests is a large number $T = N!(2\alpha t + 1)$ of identical requests (for a large enough integer N), all of bandwidth ε . The requests are for a long enough interval. All future requests will be given within this interval, and therefore they all intersect the initial requests. The sequence either stops here (and has $OPT = N!$) or continues with a second phase which contains requests which are all of bandwidth $1 - \frac{k}{2\alpha t + 1} = 1 - k\varepsilon$, for some $t \leq k \leq \alpha t$.

Furthermore, these requests all have bandwidth larger than $\frac{1}{2}$, therefore if they are packed independently from the first phase, they are treated as requests of width 1. Adding the first phase means that colors that were used for at least $k + 1$ intervals, cannot be used again in the second phase, and other colors can be used again. Intervals of the second phase are introduced as in Lemma 5 so that the optimal number to color them is ω , and the number of colors used in this phase is 3ω . If the bandwidth of these intervals is $1 - k\varepsilon$, then we use $\omega = \frac{T}{k}$, so that an optimal coloring uses ω colors, and each color is used for k intervals of the first phase. We denote by X_i ($1 \leq i \leq \alpha t$) the number of colors used in the first phase for exactly i intervals. The algorithm has no reason to color less than t intervals with one color, since a color used for t intervals can always be used again, therefore $X_i = 0$ for $i < t$. If a color is used for more than αt intervals, it will not be used again, so we can assume that in such a case, the color is used for $\frac{1}{\varepsilon}$ intervals. We denote by Y the number of colors that are used for this maximum number of intervals. We have $T = Y(2\alpha t + 1) + \sum_{i=t}^{\alpha t} i \cdot X_i$. If there is

no second phase, $OPT = T\varepsilon$ and $ALG = Y + \sum_{i=1}^{2\alpha t} X_i$. Otherwise, we compute the number of colors used by the algorithm for a specific choice of $t \leq k \leq \alpha t$. We get $ALG = Y + \sum_{i=k+1}^{\alpha t} X_i + 3\frac{T}{k} = Y + \sum_{i=k+1}^{\alpha t} X_i + 3 \cdot OPT$.

Let C be the competitive ratio of ALG . We have $Y + \sum_{i=1}^{\alpha t} X_i \leq C \cdot T\varepsilon$ and for every

$t \leq k \leq \alpha t$, $Y + \sum_{i=k+1}^j X_i \leq (C - 3)\frac{T}{k}$. We multiply the first inequality by t , the last inequality (i.e., the second inequality for $k = \alpha t$) by $\alpha t + 1$, and all other inequalities by 1 (i.e., the second inequality for all other values of k). We sum them and get $T = \sum_{i=t}^{\alpha t} iX_i + (2\alpha t + 1)Y \leq C \cdot T \frac{t}{2\alpha t + 1} + (C - 3) \sum_{i=t}^{\alpha t} \frac{T}{2\alpha t + 1} + (C - 3)T$. Letting t tend to infinity, we have $\sum_{i=t}^{\alpha t} \frac{T}{2\alpha t + 1} \rightarrow \ln \alpha$. We get $C \geq \frac{3 \ln \alpha + 4}{\frac{1}{2} + \ln \alpha + 1}$.

Solving in Maple, we see that for an appropriate choice of α this gives a lower bound of 3.2609.

4.1 Resource Augmentation

In this section we consider two interesting possible values of B . For $B = 4$ we provide an online algorithm that can color with $OPT - 3$ colors. For $B = 2$ we provide an online algorithm that uses $3OPT - 2$ colors. The lower bound on the competitive ratio for $B = 2$ is at least 1 as was shown for the case of interval coloring without bandwidth.

Proposition 1. *An adaptation of the algorithm of Kierstead and Trotter [9] can be used for interval coloring with $B = 4$, and uses at most $\max\{1, OPT - 3\}$ colors.*

Proof. We use **Algorithm:** $KT_{1,1}$ with bandwidth. According to Lemma 2 every A_m has a maximum bandwidth of at most 4. By Lemma 4 the coloring of $KT_{1,1}$ with bandwidth, is $\omega^* \cdot 1 = \omega^*$. Since $B = 4$, First Fit can color each A_m by a unique color. Moreover, by the definition of sets A_1, \dots, A_4 bandwidth of intervals in $A_1 \cup A_2 \cup A_3 \cup A_4$ does not exceed 4. We use the same color for $m = 1, 2, 3, 4$, and one color for each other value of m . By Lemma 4, we get a coloring which uses $\lceil \omega^* \rceil - 3 \leq OPT - 3$ colors. If $m \leq 4$ we get a coloring using a single color.

Proposition 2. *There exists an online algorithm for interval coloring with bandwidth with $B = 2$, that uses at most $3OPT - 1$ colors.*

4.2 Unit Interval Graphs

For this version we present three algorithms.

1. First Fit.

2. 2-First Fit. Perform an online partition of the intervals into two subsequences according to the bandwidth of the intervals. One subsequence for intervals with bandwidth b such that $b \leq \frac{1}{2}$ and the other for intervals with bandwidth b such that $b > \frac{1}{2}$. Apply First Fit on each subsequence separately with disjoint sets of colors.

3. Odd-Even bin packing. Scale the real line into integers and assume all intervals are of unit length.

Perform an online partition of the intervals into two subsequences called *evens* and *odds*. Each interval intersects an integer point. If an interval is exactly between two integers, assign it to the left integer point, and otherwise there is a unique integer point. If the integer point is an even number assign the interval into the evens subsequence, otherwise assign it to the odds subsequence. Apply the best online bin packing algorithm known separately for the odds subsequence and for the evens subsequence using two disjoint sets of colors. Each class of intervals that was assigned to an integer point is handled as an instance of a bin packing problem.

In the following we show that algorithms First Fit, 2-First Fit and Odd-Even bin packing have an absolute competitive ratios of at most the values 8, 6, 3.5 respectively.

Intensive research has been done analyzing the performance of the simple First Fit algorithm for the problem of interval coloring. Adamy and Erlebach [1] argue that First Fit is arbitrarily bad when introducing bandwidth. In the following theorem we show that on unit interval graph the competitive ratio of first fit is constant.

Theorem 7. (i) *Algorithm First Fit has a competitive ratio of 8 for unit interval graphs with bandwidth.* (ii) *Algorithm First Fit has a competitive ratio of 4 for unit interval graphs with bandwidth if each interval has a bandwidth of at most $\frac{1}{2}$.*

Proposition 3. *Algorithm 2-First Fit uses at most 6ω colors.*

Proof. 2-First Fit uses different sets of colors for intervals of bandwidth in $(0, \frac{1}{2}]$ and in $(\frac{1}{2}, 1]$. By Theorem 7 part (ii) First Fit on intervals with bandwidth of at most $\frac{1}{2}$ has a competitive ratio of 4. By Theorem 3 First Fit for intervals with bandwidth that exceeds $\frac{1}{2}$, the competitive ratio is 2. Combining these competitive ratios we get a competitive ratio of at most 6.

Proposition 4. (i) *Algorithm Odd Even bin packing has an absolute competitive ratio of 3.5 for coloring unit interval graphs with bandwidth, using First Fit as the online bin packing algorithm.* (ii) *The asymptotic competitive ratio of the algorithm Odd Even bin packing is at most 3.17778 using the algorithm Harmonic++ of Seiden [14].*

Proof. We claim that the odds subsequence can be split into different classes, such that an interval intersects all intervals within its class, but no other intervals. Each class is represented by an odd number and it contains all the intervals that were assigned to that odd integer by the algorithm. Same argument holds for the evens subsequence. Note that, since all intervals of the same class intersect, each class can be viewed as an instance to the online bin packing problem. For the first part we use the fact that First Fit for bin packing has competitive ratio of at most 1.75 with respect to the absolute measure [15]. Since we use it with two sets of colors, we get a competitive ratio of at most 3.5. For the second part we use the Harmonic++ algorithm of Seiden [14] and therefore get 3.17778.

Theorem 8. *Any online algorithm for unit interval graph with bandwidth has an absolute competitive ratio of at least 2. Any online algorithm for unit interval graph with bandwidth has an asymptotic competitive ratio of at least 1.831.*

Proof. We prove the lower bound of 2, the proof of the lower bound 1.831 is omitted. We introduce two identical intervals $I_1 = I_2 = [1, 2]$ and have bandwidth $\frac{1}{3}$. If they are assigned distinct colors then already $ALG = 2$ and $OPT = 1$, and we are done. Otherwise all future intervals have bandwidth $\frac{2}{3}$ and intersect with the previous intervals. This means that no future interval has the same color as the first two. Two further intervals are first given, $I_3 = [\frac{1}{5}, \frac{6}{5}]$ and $I_4 = [\frac{9}{5}, \frac{14}{5}]$. If they receive distinct colors, we introduce the interval $I_5 = [1, 2]$ which gets a fourth color. It is possible to color using two colors only, coloring I_1, I_3, I_4 with one color and I_2, I_5 with a second color. If they receive the same color, we introduce two intervals $I_6 = [\frac{3}{5}, \frac{8}{5}]$, $I_7 = [\frac{7}{5}, \frac{12}{5}]$, which must receive two new colors. The total number of colors used is again 4, while it is possible to color using only two colors, one color for I_1, I_3, I_7 , and a second color for I_2, I_4, I_6 .

5 Lazy Online Interval Coloring

Motivated by The Maximum Resource Bin Packing Problem, we introduce a new problem called Lazy Online Interval Coloring. In this problem the objective is to use as many colors as possible. A newly presented interval can be colored by a new color only if it intersects intervals with all the previously used colors.

Theorem 9. *Any online algorithm for the problem Lazy Online Interval Coloring is arbitrarily bad.*

5.1 Unit Interval Graphs

Proposition 5. *Any online algorithm for the Lazy Online Interval Coloring with equal length intervals uses at least $\frac{OPT+1}{2}$ colors.*

Proof. In this version, since all the intervals are of equal length, if the maximum size clique equals to ω , then there is no interval that intersects with more than $2\omega - 2$ different intervals (see proof of Theorem 3). Therefore OPT can only use as much as $2\omega - 1$ colors. Since any online coloring uses at least ω we get a coloring of at least $\frac{OPT+1}{2}$ colors.

Theorem 10. *There is an upper bound of $\frac{OPT+1}{2}$ on the coloring of any online algorithm for the Lazy Online Interval Coloring problem on unit interval graphs.*

5.2 Lazy Online Coloring of Intervals with Bandwidth

In this case we show that no algorithm is competitive even on unit interval graphs.

Theorem 11. *Any online algorithm for lazy online coloring of intervals with bandwidth and equal length intervals is arbitrarily bad.*

Proof. For an integer $D > 0$, we show that the competitive ratio is at least D . We break up the construction of the sequence of intervals into $2D - 1$ phases. In the initial phase (phase 0) we provide two identical intervals of bandwidth 1 which are requests for $[0, 1]$. These are colored by two colors by any online algorithm. We denote these colors by 1 and 2. For the next phases, it suffices to show that for every phase i , we increase the number of colors used by OPT from $i + 1$ to $i + 2$ while the number of colors used by the online algorithm remains two.

Phase i: In the first step we present intersecting intervals of bandwidth $\delta = \frac{1}{2D}$. The amount of intervals never exceeds $2D$ so the total requested bandwidth is at most 2. The online algorithm can only color these intervals with colors 1 and 2. These intervals are presented such that all intervals colored by 1 by the online algorithm are slightly shifted to the left with respect to all intervals that are colored 2. Moreover all the intervals presented here intersect. We present exactly $2i + 1$ intervals in the following way.

Let $I_1 = [a, a + 1]$ be the rightmost interval colored by 1 and let $I_2 = [d, d + 1]$ be the leftmost interval colored by 2. If there is no interval colored 1 we say that I_1 is empty and If there is no interval colored 2 we say that I_2 is empty. For $0 < \varepsilon \ll \frac{1}{12D}$ a new interval, I , is presented as follows.

1. If both I_1 and I_2 are empty (presentation of the first interval) then $I = [5i - 1, 5i]$.
2. If only I_1 is empty, $I = [d - \varepsilon, d + 1 - \varepsilon]$
3. If only I_2 is empty, $I = [a - 1 + \varepsilon, a + \varepsilon]$
4. If I_1 and I_2 are not empty then, $I = [\frac{d+a}{2}, \frac{d+a}{2} + 1]$, this is an interval of length 1, located halfway between I_1 and I_2 and intersecting all previously presented intervals of this step.

After $2i + 1$ intervals there are at least $i + 1$ intervals with the same color. In the next step, an interval of bandwidth 1 that intersects these $i + 1$ intervals of the same color and does not intersect any other interval is presented. The online algorithm has to color this interval by the second color and therefore does not increase the number of colors. An offline algorithm can color the $i + 1$ intervals with $i + 1$ colors it used before. The next interval can be colored by a new color $i + 2$ since it intersects intervals that are colored with $i + 1$ distinct colors.

Acknowledgment. We would like to thank an anonymous referee for pointing out an error in an earlier version of this paper.

Abstract. This paper studies the dynamic bin packing problem, in which items arrive and depart at arbitrary time. We want to pack a sequence of unit fractions items (i.e., items with sizes $1/w$ for some integer $w \geq 1$) into unit-size bins such that the maximum number of bins used over all time is minimized. Tight and almost-tight performance bounds are found for the family of any-fit algorithms, including first-fit, best-fit, and worst-fit. We show that the competitive ratio of best-fit and worst-fit is 3, which is tight, and the competitive ratio of first-fit lies between 2.45 and 2.4985. We also show that no on-line algorithm is better than 2.428-competitive. This result improves the lower bound of dynamic bin packing problem even for general items.

1 Introduction

Bin packing problem has been studied since the early 70's and different variants of the problem continue to attract researchers attentions (see the survey [6, 9, 10]). In the classical bin packing problem, we want to pack a sequence of items each with size in the range $(0, 1]$ into unit-size bins using the minimum number of bins. One of the generalizations of the problem is known as the *dynamic bin packing problem* [8], in which items arrive and depart at arbitrary time. The objective is to minimize the maximum number of bins used over all time. In this paper, we study dynamic bin packing of *unit fractions items*. A unit fraction item has size of the form $1/w$ for some integer $w \geq 1$. We analyze the performance of the family of any-fit algorithms, which includes first-fit, best-fit and worst-fit, and provide tight and almost-tight performance bounds. Our lower bound on dynamic bin packing of unit fractions items even improves the lower bound of Coffman et al. [8] on dynamic bin packing of general items.

There is a long history of results for the classical bin packing problem and its variants [6, 9, 10]. Most of the previous works considered the “static” bin packing

* This research was supported in part by Hong Kong RGC Grant HKU-5172/03E.

** This research was supported in part by Nuffield Foundation Grant NAL/01004/G.

where items will not depart. In this model, the off-line bin packing problem is NP-hard [11]. In the on-line setting, each item must be assigned to a bin, without knowledge of the subsequent items. Moreover, no migration of items are allowed, i.e., items are not allowed to move from one bin to another. The performance is measured in terms of competitive ratio (see [3] for a survey). The current best upper bound is due to Seiden [14], who proved that the algorithm HARMONIC++ has a competitive ratio at most 1.58889¹. The current best lower bound is due to van Vliet [15] who showed that no on-line algorithm can achieve a competitive ratio less than 1.54014.

In many real applications, item sizes are often not arbitrary real numbers in $(0, 1]$. Bar-Noy et al. [2] initiated the study of the *unit fractions bin packing problem* (UFBP), a restricted version of the classical bin packing problem in which all sizes are of the form $1/w$ for some integer $w \geq 2$. In the on-line setting, they gave an on-line algorithm with a competitive ratio $1 + O(1/\sqrt{H})$, where H denotes the sum of sizes of all items. Note that this algorithm is asymptotically optimal. Bin packing with other restricted form of item sizes includes divisible item sizes [7] (where each possible item size can be divided by the next smaller item size) and discrete item sizes [5] (where possible item sizes are $\{1/k, 2/k, \dots, j/k\}$ for some $1 \leq j \leq k$).

Dynamic bin packing is a generalization of the classical bin packing problem introduced by Coffman et al. [8]. The problem assumes that items may depart at arbitrary time, and the objective is to minimize the maximum number of bins used over all time. It was shown in their paper that the on-line algorithm first-fit has a competitive ratio lies between 2.75 and 2.897, and no on-line algorithm can achieve a competitive ratio better than 2.5. Note that these results assume a very general optimal off-line algorithm, which can re-pack the items. Coffman et al. also gave an improved lower bound of 2.388 when the off-line algorithm is not allowed to re-pack the items. Ivkovic and Lloyd [12] studied an even more general problem called the *fully dynamic bin packing problem*, where migration of items are allowed, and gave a 1.25-competitive on-line algorithm for this problem.

This paper studies the problem of dynamic bin packing of unit fractions items, the main contribution are several very close upper and lower bounds (see Table 1). We show that any-fit algorithms, which include first-fit, best-fit and worst-fit are 3-competitive. We further show that the performance of best-fit and worst-fit are indeed tight, i.e., they cannot be better than 3-competitive. On the other hand, we show that first-fit has a better performance, its competitive ratio lies between 2.45 and 2.4985. In addition, we prove that no on-line algorithm can be better than 2.428-competitive. This result improves the lower bound of 2.388 of Coffman et al. [8] on dynamic bin packing for general items.

There is a problem related to UFBP, called the *windows scheduling problem* (WS) [1, 2, 4], as pointed out by Bar-Noy et al. [2]. Similar to UFBP, the input of WS is a sequence of items, each with a *window* represented by an inte-

¹ Seiden [14] pointed out that the previous best algorithm HARMONIC+1 by Richey [13] has competitive ratio at least 1.59217 rather than the claimed 1.58872.

Table 1. Summary of results

Algorithms	Upper bounds	Lower bounds
First-fit	2.4985	2.45
Best-fit	3	3
Worst-fit	3	3
Any-fit	3	2.428
Any on-line algorithms	–	2.428

ger. Each item represents a piece of information to be broadcast to all clients. It is assumed that all items are of the same length, which takes the same amount of time to broadcast. The objective of WS is to use the minimum number of broadcast channels to broadcast each item periodically such that the duration between two consecutive broadcasts of the same item must not exceed the window of that item. By letting the bins as broadcast channels and the reciprocal of item sizes as windows, UFBP can be considered as a special case of WS, and hence the lower bound result on UFBP applies to WS. (Note that the upper bound on UFBP does not carry over to WS.) Chan and Wong [4] considered the dynamic version of WS, in which items may also depart. They gave a 5-competitive algorithm and showed that no on-line algorithm can be better than 2-competitive. The lower bound of dynamic bin packing of unit fractions item in this paper improves the lower bound for the dynamic version of WS to 2.428.

The rest of the paper is organized as follows. Section 2 gives some definitions. Section 3 analyzes the performance of the family of any-fit algorithms. This includes upper and lower bounds for first-fit (Sections 3.1 and 3.2, respectively), and upper and lower bounds for best-fit and worst-fit (Section 3.3). Finally, Section 4 gives a lower bound for any on-line algorithm.

2 Preliminaries

In this section, we give a precise definition of the dynamic unit fractions bin packing problem and the necessary notations for further discussion. We are to pack a sequence of items into bins of unit-capacity. Items arrive and depart at arbitrary time. We denote the i -th item by m_i and its arrival time by a_i . Each item m_i comes with a size s_i which is a reciprocal of an integer, i.e., $s_i = 1/w_i$ for some integer $w_i \geq 1$. When item m_i arrives at a_i , it must be assigned to a bin immediately. At any time, the *load* of a bin is the total size of items that are currently assigned to that bin and have not yet departed, and this load must be at most 1 because of unit-capacity. Migration is not allowed in the sense that once an item is assigned to a bin, it cannot be moved to another bin. The objective is to minimize the maximum number of bins used over all time.

As with previous work, we measure the performance of an on-line algorithm in terms of a competitive ratio. Given a sequence σ of items and an on-line bin packing algorithm \mathcal{A} , let $\mathcal{A}(\sigma, t)$ denote the number of bins used by \mathcal{A} at time t .

We say that \mathcal{A} is c -competitive if there exists a constant k such that for any input sequence σ , we have $\max_t \mathcal{A}(\sigma, t) \leq c \cdot \max_t \mathcal{O}(\sigma, t) + k$, where \mathcal{O} is the optimal off-line algorithm.

In this paper, we consider several on-line algorithms: any-fit, first-fit, best-fit, and worst-fit. When an item arrives, all these algorithms pack the item into an occupied bin as long as there exists such a bin that can accommodate the item; a new bin is only used when no occupied bins can accommodate the item. The algorithms differ in the rule used to choose the occupied bin for the newly arrived item. To describe the rules of these algorithms, we first define a way to label the occupied bins at a specific time.

At any time t , suppose that there are n occupied bins. For any bin X among these n bins, let $f(x) \leq t$ be the latest time X turns from empty to non-empty. At time t , we label these n non-empty bins using integers $1, 2, \dots, n$ such that the label of bin X is less than that of bin Y if $f(X) \leq f(Y)$. Notice that the labels of bins change over time.

When a new item m_i arrives, if there is any occupied bin with load no more than $1 - 1/w_i$, the algorithms assign m_i to one of these bins as follows:

- Any-fit (AF)** assigns m_i to any of these bins arbitrarily.
- First-fit (FF)** assigns m_i to the one with the smallest label at a_i .
- Best-fit (BF)** assigns m_i to the heaviest load one; ties are broken arbitrarily.
- Worst-fit (WF)** assigns m_i to the lightest load one; ties are broken arbitrarily.

3 Performance of the Family of Any-Fit Algorithms

In this section we analyze the performance of any-fit algorithms. In Sections 3.1 and 3.2, we give an upper bound of 2.4985 and a lower bound of 2.45 for the competitive ratio of FF. Then in Section 3.3, we show that both BF and WF cannot be better than 3-competitive and then give the matching upper bounds.

3.1 Upper Bound for First-Fit

Before we analyze the upper bound of FF, let us have some definitions. Consider any positive integers x and y . Suppose that we pack a bin using items of sizes $1, 1/2, \dots, 1/x$ only. We want to define the notion of the minimum load that such a bin must have in order that an additional item of size $1/y$ cannot be packed into the bin. We define a function $\alpha(x, y)$ to capture this notion. Formally,

$$\alpha(x, y) = \min_{1 \leq j \leq x \ \& \ n \geq 0} \{n_1 + n_2/2 + \dots n_x/x \mid n_1 + n_2/2 + \dots n_x/x > 1 - 1/y\}.$$

For example, when $x = 4$ and $y = 3$, we have $\alpha(4, 3) = 3/4$ and correspondingly $n_1 = 0, n_2 = 1, n_3 = 0$ and $n_4 = 1$.

With respect to a particular input σ , we define a sequence of integer pairs (b_i, r_i) as follows. Let b_1 denote the maximum number of bins used by FF over all time.

Suppose the smallest item that FF ever packs into a bin with label b_1 is of size $1/r_1$. We define b_i and r_i for $i \geq 2$ as follows. Let $b_i < b_{i-1}$ be the largest integer such that FF ever packs an item of size smaller than $1/r_{i-1}$ into a bin with label b_i . The size of the smallest item that FF ever packs into a bin with label b_i is denoted $1/r_i$. Let k be the largest value of i that b_i and r_i can be defined. Notice that $b_1 > b_2 > \dots > b_k$ and $r_1 < r_2 < \dots < r_k$.

Now we are ready for the analysis. Consider the time instance t_k when FF packs an item X of size $1/r_k$ into a bin B with label b_k . Since k is the largest index of b_i that can be defined, no item with size smaller than $1/r_k$ has ever been packed into any bin, in particular the bins with label from 1 to $b_k - 1$. Together with the fact that FF packs X into B but not bins with labels 1 to $b_k - 1$, we can conclude that at time t_k , each of the bins with labels from 1 to $b_k - 1$ must have a load at least $\alpha(r_k, r_k)$. Including item X , the total load of all bins at t_k is at least $1/r_k + (b_k - 1) \cdot \alpha(r_k, r_k)$. Let

$$\ell_k = 1/r_k + (b_k - 1) \cdot \alpha(r_k, r_k).$$

Next, for any integer $1 \leq i \leq k - 1$, consider the time instance t_i when FF packs an item X_i of size $1/r_i$ into a bin with label b_i . By the definition of b_i and r_i , we can use a similar argument as before to show that: (1) each of the bins with labels from 1 to b_k must have load at least $\alpha(r_k, r_i)$; (2) for any integer p with $k > p \geq i + 1$, each of the bins with labels from $b_{p+1} + 1$ to b_p must have load at least $\alpha(r_p, r_i)$; and (3) each of the bins with labels from $b_{i+1} + 1$ to $b_i - 1$ must have load at least $\alpha(r_i, r_i)$. Including item X_i , the total load of all bins at time t_i is at least $1/r_i + (b_i - b_{i+1} - 1) \cdot \alpha(r_i, r_i) + \sum_{p=i+1}^{k-1} (b_p - b_{p+1}) \cdot \alpha(r_p, r_i) + b_k \cdot \alpha(r_k, r_i)$. For $1 \leq i \leq k - 1$, let

$$\ell_i = 1/r_i + (b_i - b_{i+1} - 1) \cdot \alpha(r_i, r_i) + \sum_{p=i+1}^{k-1} (b_p - b_{p+1}) \cdot \alpha(r_p, r_i) + b_k \cdot \alpha(r_k, r_i).$$

Let $\ell = \max_{1 \leq i \leq k} \ell_i$. The number of bins used by the optimal off-line algorithm is at least ℓ . On the other hand, the maximum number of bins used by FF is b_1 . Below we show that $b_1 < 2.4985\ell + 1.337$, which implies the following theorem.

Theorem 1. *First-fit is 2.4985-competitive.*

To prove Theorem 1, we assume $k \geq 5$. The case for $k < 5$ can be proved similarly and will be given in the full paper. Depending on the values of r_i 's, we consider the following six sub-cases: **Case 1:** $r_1 \geq 2$; **Case i ,** for $2 \leq i \leq 5$: $r_1 = 1, r_2 = 2, \dots, r_{i-1} = i - 1$, and $r_i \geq i + 1$; and **Case 6:** $r_1 = 1, r_2 = 2, \dots, r_5 = 5$. We analyze the relationship between b_1 and ℓ case by case in each of the following lemmas.

Lemma 1. *If $r_1 \geq 2$, then $b_1 < 2\ell + 1$.*

Proof. Since $\alpha(x, y) > 1 - 1/y$ for any integers x and y , we have $\ell_1 > 1/r_1 + (b_1 - b_2 - 1)(1 - 1/r_1) + \sum_{p=2}^{k-1} (b_j - b_{j+1})(1 - 1/r_1) + b_k(1 - 1/r_1) = 1/r_1 + (b_1 - 1)(1 - 1/r_1)$. By simple arithmetic, we have $b_1 < \ell_1 r_1 / (r_1 - 1) + (r_1 - 2) / (r_1 - 1) < 2\ell + 1$; the latter inequality holds because $r_1 \geq 2$ and $\ell_1 \leq \ell$.

Lemma 2. *If $r_1 = 1$ and $r_2 \geq 3$, then $b_1 < 2.4445\ell + 1$.*

Proof. Notice that for any integer x , $\alpha(x, 1)$ is the minimum value in the form of $n_1 + n_2/2 + n_3/3 + \dots + n_x/x$ that is greater than 0; therefore, $\alpha(x, 1)$ must be equal to $1/x$. Then, we have $\ell_1 = 1/1 + (b_1 - b_2 - 1) \cdot \alpha(1, 1) + \sum_{p=2}^{k-1} (b_p - b_{p+1}) \cdot \alpha(r_p, 1) + b_k \cdot \alpha(r_k, 1) > (b_1 - b_2) + (b_2 - b_3)/r_2$.

Next, by the definition that $\alpha(x, y) \geq 1 - 1/y$ for any integers x and y , we have $\ell_2 = 1/r_2 + (b_2 - b_3 - 1) \cdot \alpha(r_2, r_2) + \sum_{p=3}^{k-1} (b_p - b_{p+1}) \cdot \alpha(r_p, r_2) + b_k \cdot \alpha(r_k, r_2) > (b_2 - 1)(1 - 1/r_2)$. Similarly, we have $\ell_3 > (b_3 - 1)(1 - 1/r_3)$. By solving the three inequalities, we have $b_1 < 22\ell/9 + 1 < 2.4445\ell + 1$.

Lemma 3. *If $r_1 = 1$, $r_2 = 2$, and $r_3 \geq 4$, then $b_1 < 2.4792\ell + 1.25$.*

Proof. Recall that $\alpha(x, 1) > 1/x$ for any integer x . We have $\ell_1 > (b_1 - b_2) + (b_2 - b_3)/2 + (b_3 - b_4)/r_3$. By the fact that $\alpha(2, 2) = 1$ and $\alpha(x, 2) > 1/2$ for any integer x , we have $\ell_2 = 1/2 + (b_2 - b_3 - 1) \cdot \alpha(2, 2) + \sum_{p=3}^{k-1} (b_p - b_{p+1}) \cdot \alpha(r_p, 2) + b_k \cdot \alpha(r_k, 2) > (b_2 - b_3 - 1) + b_3/2$. We can also prove that $\ell_3 > (b_3 - 1)(1 - 1/r_3)$ and $\ell_4 > (b_4 - 1)(1 - 1/r_4)$. By solving the four inequalities, we have $b_1 < 119\ell/48 + 5/4 < 2.4792\ell + 1.25$, and the lemma follows.

Lemma 4. *If $r_1 = 1$, $r_2 = 2$, $r_3 = 3$, and $r_4 \geq 5$, then $b_1 < 2.4942\ell + 1.3167$.*

Proof. Using the same approach, we have

$$\begin{aligned} \ell_1 &> (b_1 - b_2) + (b_2 - b_3)/2 + (b_3 - b_4)/3 + (b_4 - b_5)/r_4, \\ \ell_2 &> (b_2 - b_3 - 1) + (b_3 - b_4)(2/3) + b_4/2, & \{ \cdot \alpha(3, 2) = 2/3 \} \\ \ell_3 &> ((b_3 - b_4 - 1)(5/6) + 2b_4/3, & \{ \cdot \alpha(3, 3) = 5/6 \} \\ \ell_4 &> (b_4 - 1)(1 - 1/r_4), \text{ and} \\ \ell_5 &> (b_5 - 1)(1 - 1/r_5). \end{aligned}$$

By solving the five inequalities, we have $b_1 < 2993\ell/1200 + 79/60 < 2.4942\ell + 1.3167$, and the lemma follows.

Lemma 5. *If $r_i = i$ for all $1 \leq i \leq 4$, and $r_5 \geq 6$, then $b_1 < 2.49345\ell + 1.3325$.*

Proof. Using the same approach, we have

$$\begin{aligned} \ell_1 &> (b_1 - b_2) + (b_2 - b_3)/2 + (b_3 - b_4)/3 + (b_4 - b_5)/4 + (b_5 - b_6)/r_5, \\ \ell_2 &> (b_2 - b_3 - 1) + (b_3 - b_4)(2/3) + (b_4 - b_5)(7/12) + b_5/2, & \{ \cdot \alpha(4, 2) = 7/12 \} \\ \ell_3 &> (b_3 - b_4 - 1)(5/6) + (b_4 - b_5)(3/4) + 2b_5/3, & \{ \cdot \alpha(4, 3) = 3/4 \} \\ \ell_4 &> ((b_4 - b_5 - 1)(5/6) + b_5(3/4), & \{ \cdot \alpha(4, 4) = 5/6 \} \\ \ell_5 &> (b_5 - 1)(1 - 1/r_5), \text{ and} \\ \ell_6 &> (b_6 - 1)(1 - 1/r_6). \end{aligned}$$

Solving these inequalities, we have $b_1 < 2.4935\ell + 1.3325$, and the lemma follows.

Lemma 6. *If $r_i = i$ for all $1 \leq i \leq 5$, then $b_1 < 2.4985\ell + 1.337$.*

The proof of Lemma 6 uses a similar approach as in Lemmas 1 to 5, and the details will be given in the full paper. By Lemmas 1 to 6, Theorem 1 follows.

In fact, we conjecture that the worst case happens when $r_i = i$ for all $1 \leq i \leq k$. In that case, the computed competitive ratio is approaching 2.48.

3.2 Lower Bound for First-Fit

In this section we give a lower bound for FF by constructing an adversary sequence of items such that the maximum number of bins used by FF is at least 2.45 times that used by the optimal off-line algorithm. For any positive integers x and y , define $\beta(x, y)$ to be the minimum number of items of size $1/x$ in a bin such that an additional item of size $1/y$ cannot be packed into the bin. Formally,

$$\beta(x, y) = \min_{z \in \mathbb{Z}^+} \{z \mid z/x > 1 - 1/y\},$$

i.e., $\beta(x, y) = 1 + x - \lceil x/y \rceil$. For example, if $x = 4$ and $y = 3$, then $\beta(x, y) = 3$.

Let n be an integer and let $D = n!$. The adversary sequence consists of n stages. In each stage, some items released in the previous stage depart and a number of new items of the same size are released. The choices of which items to depart depend on how FF packs the items in previous stages. In Stage 1, Dn items of size $1/n$ are released. FF packs all Dn items into D bins, and each bin is fully packed.

For subsequent stages, i.e., Stage i , for $2 \leq i \leq n$, the adversary targets to maintain an invariant on how FF packs the items: At the beginning of Stage i ,

- each occupied bin contains only items of the same size; and
- a bin that contains items of size $1/x$ contains $\beta(x, n - i + 2)$ items.

The invariant holds at the beginning of Stage 2 because each occupied bin contains $\beta(n, n) = n$ items of size $1/n$. Stage i consists of two steps.

1. For each occupied bin, if it contains items of size $1/x$, we arbitrarily choose $\beta(x, n - i + 2) - \beta(x, n - i + 1)$ items and let them depart, in other words, there are $\beta(x, n - i + 1)$ items remained. Let D_i be the sum of item size for all the departed items. We will prove later that D_i is an integer (see Lemma 7).
2. Next, $D_i(n - i + 1)$ items of size $1/(n - i + 1)$ are released. Since each bin with item of size $1/x$ contains $\beta(x, n - i + 1)$ items, none of the newly released items can be packed into any occupied bin. Therefore, FF will use D_i empty bins to pack all these items, each bin contains $n - i + 1 = \beta(n - i + 1, n - i + 1)$ items. Thus, the invariant also holds at the beginning of Stage $i + 1$.

Define $D_1 = D$, which is the number of empty bins used in Stage 1. From the above discussion, we can see that the number of empty bins required for items of size $1/(n - i + 1)$ in Stage i is D_i . Then, at the beginning of Stage i , there will be D_j bins each with items of size $1/(n - j + 1)$ for all $1 \leq j \leq i - 1$. Therefore, the sum of the size of all departed items in Stage i satisfies:

$$D_i = \sum_{j=1}^{i-1} \left\{ \frac{D_j(\beta(n - j + 1, n - i + 2) - \beta(n - j + 1, n - i + 1))}{n - j + 1} \right\}.$$

Lemma 7. D_i is an integer multiple of $(n - i + 1)$ for $1 \leq i \leq n$.

Proof. We prove by induction a stronger claim that D_i is an integer multiple of $(n - i + 1)!$ for $1 \leq i \leq n$. It is clear that $D_1 = D$ is an integer multiple of $n!$. Suppose D_i is an integer multiple of $(n - i + 1)!$ for $1 \leq i \leq k$. We have $D_{k+1} = \sum_{j=1}^k (D_j / (n - j + 1)) (\beta(n - j + 1, n - k + 1) - \beta(n - j + 1, n - k))$. Since the function β gives an integer output and $D_j / (n - j + 1)$ is an integer multiple of $(n - j)!$, the summation gives an integer multiple of $(n - k)!$, which completes the induction.

The following lemmas give the performance of FF on the adversary sequence.

Lemma 8. *There exists some integer n such that the maximum number of bins used by FF is at least $2.45D$.*

Proof. After Stage n , FF uses $\sum_{i=1}^n D_i$ bins. We carry out the analysis on the value of $\sum_{i=1}^n D_i$ by actually computing the value of $\sum_{i=1}^n D_i$ with different values of n . We find that the increase in n generally leads to an increase in $\sum_{i=1}^n D_i$, though not monotonically. By letting $n = 21421$, and computing the values of D_i , we have $\sum_{i=1}^n D_i > 2.45D$.

Lemma 9. *The optimal off-line algorithm uses at most D bins at any time.*

Proof. We give an algorithm \mathcal{O} to pack the items in the adversary such that \mathcal{O} uses at most D bins over all time. In this proof permanent items refer to the items remain after Stage n and temporary items refer to the items depart in Stage n or before.

The algorithm \mathcal{O} runs as follows. In each stage, when there are new items released, \mathcal{O} packs the new items using the minimum number of empty bins such that a bin contains only permanent items, or temporary items that will depart in the same stage. We claim that \mathcal{O} uses exactly D bins after each stage. In the initial stage, \mathcal{O} packs the $D = n!$ permanent items into $(n - 1)!$ bins and the $(n - 1)n!$ temporary items to another $(n - 1)(n - 1)!$ bins. Totally, there are $n! = D$ occupied bins.

We prove that in each subsequent Stage i , for $2 \leq i \leq n$, the departed items produce D_i empty bin and \mathcal{O} uses the D_i empty bins to pack the $D_i(n - i + 1)$ items of size $1/(n - i + 1)$ released. First, the number of empty bins produced in Stage i equals $\sum_{j=1}^{i-1} \lfloor D_j (\beta(n - j + 1, n - i + 2) - \beta(n - j + 1, n - i + 1)) / (n - j + 1) \rfloor$, which is equal to D_i because by Lemma 7, the term $D_j / (n - j + 1)$ is an integer. Second, among the $D_i(n - i + 1)$ items of size $1/(n - i + 1)$ released in Stage i , the total size of those items that will depart in Stage p , for $i + 1 \leq p \leq n$, is $D_i (\beta(n - j + 1, n - p + 2) - \beta(n - j + 1, n - p + 1)) / (n - i + 1)$, which is an integer because by Lemma 7, $D_i / (n - i + 1)$ is an integer. Thus, we show that \mathcal{O} can use D_i empty bins to pack all $D_i(n - i + 1)$ items of size $1/(n - i + 1)$. In other words, \mathcal{O} , and thus the optimal off-line algorithm, uses at most D bins at any time, and the lemma follows.

By Lemmas 8 and 9, the following theorem holds.

Theorem 2. *FF is at least 2.45-competitive.*

3.3 Performance of Other Any-Fit Algorithms

We show that BF and WF have a worse performance than FF, precisely, we show that BF and WF cannot be better than 3-competitive. On the other hand, we give the matching upper bounds. We prove in the Appendix that AF, including BF and WF, is 3-competitive.

Theorem 3. *Any-fit is 3-competitive.*

We give an adversary for WF as follows. Let k be an arbitrarily large integer constant and let $w = 2k$. The sequence contains $5k$ items, m_1, m_2, \dots, m_{5k} , with m_i arriving at time i . There are three different sizes of the items: (1) $s_i = 1/2$ for $i = 1, 3, \dots, 4k - 1$; (2) $s_i = 1/w$ for $i = 2, 4, \dots, 4k$; and (3) $s_i = 1$ for $i = 4k + 1, 4k + 2, \dots, 5k$. All items of size $1/2$ depart at time $4k$ while items of size $1/w$ and 1 never depart. In the Appendix we show that the maximum number of bins used by WF is at least $3k$ and by the optimal off-line algorithm is at most $k + 1$. For any $0 < \epsilon \leq 3/2$, setting $k = 3/\epsilon - 1$ results in the competitive ratio $3k/(k + 1) > (3 - \epsilon)$. Hence, we have the following theorem.

Theorem 4. *Worst-fit is no better than 3-competitive.*

Next, we give an adversary for BF. Let k be an arbitrarily large integer constant and let $w = 2k$. The adversary sequence consists of $2k$ stages, each lasts for 4 time units. Precisely, Stage i spans from time $4i + 1$ to $4i + 4$. There are three different sizes of items: $1/w$, $1/2$ and 1 , all items of size $1/2$ will depart at some time while items of size $1/w$ and 1 never depart. Before Stage 0, two items are released, one with size $1/2$, and the other with size $1/w$. The stages proceed as follows. **Stage i** , for $0 \leq i \leq 2k - 2$: At time $4i + 1$, i items of size $1/2$ are released. At time $4i + 2$, one more item of size $1/2$ is released. At time $4i + 3$, all items of size $1/2$ released before time $4i + 2$ depart, including those released at time $4i + 1$ and the one released in Stage $i - 1$. At time $4i + 4$, a single item with size $1/w$ is released. **Stage $2k - 1$** : At time $4(2k - 1) + 3$, the item with size $1/2$ released in Stage $(2k - 2)$ departs. At time $4(2k - 1) + 4$, k items of size 1 are released. In the Appendix, we show that the maximum number of bins used by BF is at least $3k$ and that by the optimal off-line algorithm is at most $k + 1$. For any $0 < \epsilon \leq 3/2$, setting $k = 3/\epsilon - 1$ results in the competitive ratio $3k/(k + 1) > (3 - \epsilon)$. Hence, we have the following theorem.

Theorem 5. *Best-fit is no better than 3-competitive.*

4 General Lower Bound

We give an adversary sequence of items such that the maximum number of bins used by any on-line algorithm is at least 2.428 times that used by the optimal off-line algorithm. First, we need the following notion. For any positive integers x and y , define $\lambda(x, y)$ to be the maximum number of items of size $1/x$ that can be packed into a bin containing an item of size $1/y$. Formally,

$$\lambda(x, y) = \max_{z \in \mathcal{Z}^+} \{z \mid z/x \leq 1 - 1/y\},$$

i.e., $\lambda(x, y) = x - \lceil x/y \rceil$. For example, if $x = 4$ and $y = 3$, then $\lambda(x, y) = 2$.

Consider any on-line algorithm \mathcal{A} . Let n be an integer and let $F = n!(n-1)!$. The adversary sequence consists of n stages and has the following properties: In each stage, some items released in the previous stage depart and a number of items of the same size are released. The arrival of items in the adversary sequence ensures that at the end of each stage, \mathcal{A} has to use some additional bins to pack the items released in that stage. We are going to define a sequence of numbers F_i for $1 \leq i \leq n$, which is related the number of additional bins required in Stage i .

In Stage 1, Fn items of size $1/n$ are released. The algorithm \mathcal{A} uses at least F bins to pack the Fn items. If \mathcal{A} uses more than F bins, all items in bins other than the first F bins depart. We define F_1 to be F .

In each of the subsequent stages, i.e., Stage i , for $2 \leq i \leq n$, there are three steps. (1) For each occupied bin, all its items except the smallest one depart. (2) Let R_i be the total size of the items remained. (We will prove later, in the proof of Lemma 11, that R_i is indeed an integer.) The adversary then releases $(F - R_i)(n - i + 1)$ items of size $1/(n - i + 1)$. At this point, the total size of all items not yet departed, including those released in previous stages, is F . (3) Define

$$F_i = F - \sum_{j=1}^{i-1} F_j \left(\frac{1}{n-j+1} + \frac{\lambda(n-j+1, n-i+1)}{n-i+1} \right).$$

If \mathcal{A} uses more than F_i additional bins in Stage i , all items packed into the additional bins other than the first F_i additional bins depart. Roughly speaking, F_i is the minimum number of additional bins required in Stage i ; the term $\lambda(n-j+1, n-i+1)$ reflects the maximum number of items released in Stage i that can be packed into an occupied bin which was an additional bin in Stage j . We will prove this formally in Lemma 11. We first prove a property of F_i .

Lemma 10. *F_i is an integer multiple of $(n-i+1)!(n-i)!$ for $1 \leq i \leq n$.*

Proof. We prove the lemma by induction. It is clear that $F_1 = F$ is an integer multiple of $n!(n-1)!$. Suppose F_i is an integer multiple of $(n-i+1)!(n-i)!$ for $1 \leq i \leq k$. We have $F_{k+1} = F - \sum_{j=1}^k F_j(1/(n-j+1) + \lambda(n-j+1, n-i+1)/(n-k))$. Since the function λ gives an integer output and $F_j/((n-j+1)(n-k))$ is an integer multiple of $(n-k)!(n-k-1)!$ as $k \geq j$, the summation gives an integer multiple of $(n-k)!(n-k-1)!$, which completes the induction.

Lemma 11. *For $1 \leq i \leq n$, \mathcal{A} uses no less than F_i additional bins in Stage i .*

Proof. In Stage 1, it is clear that \mathcal{A} uses at least $F_1 = F$ additional bins. We show by induction that in Step (2) of Stage i for $2 \leq i \leq n$, \mathcal{A} also uses at least F_i additional bins. Assume that it is true for $i = k$. Before Step (2) of Stage $k+1$, \mathcal{A} already has F_j bins containing a single item of size $1/(n-j+1)$ for $1 \leq j \leq k$. Therefore, $R_{k+1} = \sum_{j=1}^k F_j/(n-j+1)$. We can see that R_{k+1} is an integer as

F_j is an integer multiple of $(n - j + 1)!(n - j)!$. The number of items of size $1/(n - k)$ released is $(F - R_{k+1})(n - k) = (F - \sum_{j=1}^k F_j/(n - j + 1))(n - k)$. The number of items that can be packed into the occupied bins is equal to $\sum_{j=1}^k F_j \cdot \lambda(n - j + 1, n - k)$. Therefore, the number of additional bins needed in Stage $k + 1$ is at least

$$\begin{aligned} & F - \sum_{j=1}^k \frac{F_j}{n - j + 1} - \sum_{j=1}^k \frac{F_j \cdot \lambda(n - j + 1, n - k)}{n - k} \\ &= F - \sum_{j=1}^k F_j \left(\frac{1}{n - j + 1} + \frac{\lambda(n - j + 1, n - k)}{n - k} \right) = F_{k+1}. \end{aligned}$$

This induction is completed.

Lemma 12. *There exists some integer n such that the maximum number of bins used by \mathcal{A} is at least $2.428F$.*

Proof. After Stage n , \mathcal{A} uses $\sum_{i=1}^n F_i$ bins. We carry out the analysis on the value of $\sum_{i=1}^n F_i$ by actually computing the value of $\sum_{i=1}^n F_i$ with different values of n . We find that the increase in n results an increase in $\sum_{i=1}^n F_i$ monotonically. In particular, by letting $n = 12794$, and computing the values of F_i , we have $\sum_{i=1}^n F_i > 2.428F$.

Theorem 6. *Any on-line algorithm is at least 2.428-competitive.*

Proof. Similar to Lemma 9, we can show that the optimal off-line algorithm uses at most F bins. Together with Lemma 12, the theorem follows.

Appendix

Proof of Theorem 3: Consider any input sequence σ . Suppose AF uses at most n bins. The proof is based on two notions. (1) Let t_1 be a time instance such that AF uses n occupied bins, and n_1 be the number of occupied bins with item of size 1 at time t_1 . Notice that the optimal off-line algorithm uses at least n_1 occupied bins at time t_1 . (2) Let n_2 be the largest integer such that AF packs an item m of size $1/2$ or less into an empty bin with label n_2 and suppose this happens at t_2 . At time t_2 , all bins with labels smaller than n_2 have load greater than $1/2$; otherwise, AF can pack m to one of these bins. In that case, the optimal off-line algorithm uses at least $\lceil n_2/2 \rceil$ bins at time t_2 . By the definition of n_2 , at time t_1 , every bin with label greater than n_2 contains an item of size greater than $1/2$, i.e., 1. Hence, we have $n \leq n_1 + n_2$. On the other hand, the optimal off-line algorithm uses at least $\max\{n_1, \lceil n_2/2 \rceil\}$ bins. By simple arithmetic, we have $n \leq 3 \max\{n_1, \lceil n_2/2 \rceil\}$ (the worst case happens when $n_1 = \lceil n_2/2 \rceil$).

Proof of Theorem 4: We first describe how WF packs the $5k$ items in the adversary. WF packs the item m_{2j-1} of size $1/2$ and m_{2j} of size $1/w$ to the same bin with label j , for $1 \leq j \leq 2k$. After all items of size $1/2$ depart, there are $2k$ occupied bins; k more bins are needed for the items of size 1. Therefore, WF uses $3k$ bins.

On the other hand, the optimal off-line algorithm can use a single bin to pack all the items of size $1/w$ and k bins to pack the items of size $1/2$. This packing uses $k + 1$ bins. After all the items of size $1/2$ depart, the k bins can be used to pack the items of size 1. Thus, the optimal off-line algorithm uses at most $k + 1$ bins, and the competitive ratio of WF is at least $3k/(k + 1)$. For any $0 < \epsilon \leq 3/2$, picking k to be $3/\epsilon - 1$ implies that WF is no better than $(3 - \epsilon)$ -competitive.

Proof of Theorem 5: We first describe how BF packs the items in the adversary. We claim that for $1 \leq i \leq 2k - 1$, at the beginning of Stage i , BF uses $i + 1$

bins, one of them has load $1/2 + 1/w$, and the other i bins each has load $1/w$. The base case for Stage 1 can be verified easily. Suppose the claim is true for some $i \geq 1$. Consider what happens in Stage i . At time $4i + 1$, BF packs each of the i new items into the i bins with load $1/w$. All the $i + 1$ occupied bins now have load $1/2 + 1/w$. The item of size $1/2$ released at time $4i + 2$ must then be packed into a new bin. After the departure of items of size $1/2$ at time $4i + 3$, we are left with a bin with load $1/2$ and $i + 1$ bins each with load $1/w$. When the item of size $1/w$ is released at time $4i + 4$, BF packs it into the bin with load $1/2$. Then, at the beginning of Stage $i + 1$, BF uses $i + 2$ bins where $i + 1$ of them have load $1/w$ and one has load $1/2 + 1/w$, and the claim follows. Finally, in Stage $2k - 1$, BF needs k more bins, and thus uses at least $2k + k = 3k$ bins.

On the other hand, the optimal off-line algorithm can reserve a single bin for the $2k$ items of size $1/w$. At any time, there are at most $2k$ items of size $1/2$ which can be packed into k bins. In the final stage, all these items depart and the k bins can be used for the items of size 1. Hence, the optimal off-line algorithm uses at most $k + 1$ bins, and the competitive ratio of BF is at least $3k/(k + 1)$. For any $0 < \epsilon \leq 3/2$, picking k to be $3/\epsilon - 1$ implies that BF is no better than $(3 - \epsilon)$ -competitive.

Reordering Buffer Management for Non-uniform Cost Models*

Department of Computer Science,
RWTH Aachen, D-52056 Aachen, Germany
{englert, marsu}@cs.rwth-aachen.de

Abstract. A sequence of objects which are characterized by their color has to be processed. Their processing order influences how efficiently they can be processed: Each color change between two consecutive objects produces non-uniform cost. A reordering buffer which is a random access buffer with storage capacity for k objects can be used to rearrange this sequence in such a way that the total cost are minimized. This concept is useful for many applications in computer science and economics.

We show that a reordering buffer reduces the cost of each sequence by a factor of at most $2k - 1$. This result even holds for cost functions modeled by arbitrary metric spaces. In addition, a matching lower bound is presented. From this bound follows that each strategy that does not increase the cost of a sequence is at least $(2k - 1)$ -competitive.

As main result, we present the deterministic Maximum Adjusted Penalty (MAP) strategy which is $O(\log k)$ -competitive. Previous strategies only achieve a competitive ratio of k in the non-uniform model. For the upper bound on MAP, we introduce a basic proof technique. We believe that this technique can be interesting for other problems.

1 Introduction

Frequently, a number of tasks has to be processed and their processing order influences how efficiently they can be processed. Hence, a reordering buffer can be expedient to influence the processing order. This concept is useful for many applications in computer science and economics. In the following and in Sect. 1.2 we give some examples.

In computer graphics, a rendering system displays a 3D scene which is composed of primitives. In current rendering systems a significant factor for the performance are the state changes performed by the graphics hardware. A state change occurs when two consecutively rendered primitives differ in their attribute values, e.g., in their texture or shader program. These state changes slow down a rendering system. Note that the duration of a state change is non-uniform and heavily depends on the attribute values of the primitive causing this state change, e.g., textures and shader programs vary significantly in size which has

* Supported by the DFG grant WE 2842/1.

a great impact on the state change. To reduce the cost of the state changes, a reordering buffer can be included between application and graphics hardware. This reordering buffer, which is a random access buffer with limited memory capacity, can be used to rearrange the incoming sequence of primitives online in such a way that the cost of the state changes are minimized.

Hard disks consist of one or more rotating platters. A read/write head is positioned above the rotating surface of each platter. The position of a head determines which cylinder can be accessed. The latency of an access is mainly induced by the movement of the head to the respective cylinder. The latencies are the dominating factor for the performance of a hard disk. This can be modeled by a non-uniform metric, e.g., the line metric: Accesses are categorized according to their destination cylinder, and the cost are defined as the distance between start and destination cylinder. A reordering buffer can be used to rearrange the incoming sequence of accesses online in such a way that latencies are minimized. This problem is known as disk scheduling (see, e.g., [1]).

File servers are high-capacity storage devices which each computer in a network can access to retrieve files. A file on a server is denoted as open, if it is ready to be accessed. Otherwise, it is denoted as closed. By technical reasons, the number of open files on a server is limited. The overhead induced by the opening and closing processes is a significant factor for the performance of a file server. Note that the cost of an opening or closing process is non-uniform and depends on the characteristics of the involved file. This overhead can be minimized by preceding a file server with a reordering buffer. If several open files are allowed, this scenario is a generalization of the rendering scenario. In addition to the possibility to choose a file that has to be opened next, there is the possibility to choose a file that has to be closed in the case that the maximum number of files is open. This scenario is equivalent to the classical paging problem (see, e.g., [2]) if the reordering buffer has storage capacity for only one file.

1.1 The Model

An *input sequence* $\sigma = \sigma_1\sigma_2\cdots$ of objects which are only characterized by a specific attribute has to be processed. To simplify matters, we suppose that the objects are characterized by their color, and, for each object σ_i , let $c(\sigma_i)$ denote the color of σ_i . A *reordering buffer* which is a random access buffer with storage capacity for k objects can be used to rearrange the input sequence in the following way.

The *current input object* σ_i , i.e., the first object of σ that is not handled yet, can be stored in the reordering buffer, or objects currently stored in the reordering buffer can be removed. These removed objects result in an *output sequence* $\sigma_{\pi^{-1}} = \sigma_{\pi^{-1}(1)}\sigma_{\pi^{-1}(2)}\cdots$ which is a partial permutation of σ . Let the *current output object* denote the object that was last assigned to the output sequence. We suppose that the reordering buffer is initially empty and, after processing the whole input sequence, the buffer is empty again.

For each color c , we are given *weight* b_c . Cost b_c are produced for each color change to color c , i.e., for two consecutive objects $\sigma_{\pi^{-1}(i)}$ and $\sigma_{\pi^{-1}(i+1)}$ of the

output sequence, we define the cost function $d(\sigma_{\pi^{-1}(i)}, \sigma_{\pi^{-1}(i+1)}) = b_c(\sigma_{\pi^{-1}(i)}, \sigma_{\pi^{-1}(i+1)})$, if $c(\sigma_{\pi^{-1}(i)}) \neq c(\sigma_{\pi^{-1}(i+1)})$, and $d(\sigma_{\pi^{-1}(i)}, \sigma_{\pi^{-1}(i+1)}) = 0$, otherwise. Then, the goal is to minimize the cost $C^A(\sigma) = \sum_i d(\sigma_{\pi^{-1}(i)}, \sigma_{\pi^{-1}(i+1)})$ of a management strategy A . Note that this models the presented application examples well except disk scheduling (see also Sect. 1.3).

The notion of an online strategy is intended to formalize the realistic scenario, where the strategy does not have knowledge about the whole input sequence in advance. The online strategy has to serve the input sequence σ one after the other, i.e., a new object is not issued before there is a free slot in the reordering buffer. Online strategies are typically evaluated in a competitive analysis. In this kind of analysis the cost of the online strategy are compared with the cost of an optimal offline strategy. For a given sequence σ , let $C^{\text{op}}(\sigma)$ denote the minimum cost produced by an optimal offline strategy. An online strategy is denoted as α -competitive if it produces cost at most $\alpha \cdot C^{\text{op}}(\sigma) + \kappa$, for each sequence σ , where κ is a term that does not depend on σ . The value α is also called the competitive ratio of the online strategy.

W.l.o.g., we only consider *lazy* strategies, i.e., strategies that fulfill the following two properties:

- If an object with the same color as the current output object is stored in the reordering buffer, a lazy strategy does not make a color change.
- If the current input object can be stored in the reordering buffer, a lazy strategy does not remove an object from the reordering buffer.

Note that every (in particular every optimal offline) strategy can be transformed into a lazy strategy without increasing the cost.

1.2 Previous Work

Web caching with request reordering extends the classic paging model by allowing reordering of requests under the constraint that a request is delayed by no longer than a predetermined number of time steps (see, e.g., [3, 4]). Albers [3] presents a deterministic strategy that achieves an optimal competitive ratio of $k+1$, where k denotes the storage capacity of the cache. Feder et al. [4] introduce a randomized strategy that achieves an asymptotically optimal competitive ratio of $\Theta(\log k)$.

The uniform case of our problem is studied in, e.g., [5, 6]. In the uniform model, for each color c , weight $b_c = 1$, i.e., just the number of color changes is considered. Racke, Sohler and Westermann [5] show that several standard strategies are unsuitable for a reordering buffer, i.e., the competitive ratio of the First In First Out and Least Recently Used strategy is $\Omega(\sqrt{k})$ and the competitive ratio of the Most Common First strategy is $\Omega(k)$, where k denotes the buffer size. Further, the deterministic Bounded Waste strategy is presented and it is proven that this strategy achieves a competitive ratio of $O(\log^2 k)$ in the uniform model. Kohrt and Pruhs [6] present a polynomial-time offline algorithm that achieves a constant approximation ratio. However, their goal is to maximize the number of saved color changes. Note that a constant approximation of the

minimal number of color changes in the output sequence is preferable, if it is possible to save a large number of color changes.

Krokowski et al. [7] examine the previously mentioned rendering application in an uniform version, i.e., just the number of state changes is considered. They use a small reordering buffer to rearrange the incoming sequence of primitives online in such a way that the number of state changes is minimized. Due to its simple structure and its low memory requirements this method can easily be implemented in software or even hardware. In their experimental evaluation this method typically reduces the number of state changes by an order of magnitude and the rendering time by roughly 30%. Note that the studied strategies do not consider the individual cost of a state change. A conclusion is that there is a lack of efficient strategies that consider these individual cost.

In the painting shop of a car plant, a sequence of cars bodies traverses the final layer painting where each car body is painted with its own top coat. If two consecutive cars have to be painted in different colors then a color change is required which causes set-up cost. In addition to the color change cost, further important non-uniform cost arise, e.g., the individual accessing times of the parking slots for the car bodies. These costs can be minimized by preceding the final layer painting with a reordering buffer. In several practical work, heuristic strategies for reordering buffers are evaluated by simulation (see, e.g., [8]). Efficient strategies for reordering buffer are considered to be a major problem of operating a paint shop.

1.3 Results and Further Work

In Sect. 2, the possible gain of a reordering buffer is investigated. We show that a reordering buffer of size k reduces the cost of each sequence by a factor of at most $2k - 1$. This result holds for online and offline strategies and even for cost functions modeled by arbitrary metric spaces, i.e., the cost function $d(\sigma_{\pi^{-1}(i)}, \sigma_{\pi^{-1}(i+1)})$ can be any positive and symmetric function obeying the triangle inequality. In addition, a matching lower bound is presented. From this basic upper bound follows immediately that each strategy that does not increase the cost of an input sequence is at least $(2k - 1)$ -competitive. In particular, the simple online strategy that does no reordering at all is already $(2k - 1)$ -competitive. This shows the poor performance of some strategies. For example, Yeh et al. [9] give a lower bound of $2k - 1$ on the competitive ratio of the disk scheduling strategies Shortest Seek Time First and Look in the line metric model.

In Sect. 3, we show a lower bound of k on the competitive ratio of the Bounded Waste (BW) strategy in our model, where k denotes the size of the reordering buffer. The BW strategy is introduced by Racke, Sohler and Westermann [5] for the uniform case of our problem: For each color c , weight $b_c = 1$, i.e., just the number of color changes is considered. Note that this lower bound even holds for the case that BW takes the non-uniform cost into account, i.e., BW is aware of the individual cost b_c , for each color c . In Sect. 4, the deterministic Maximum Adjusted Penalty (MAP) strategy is presented. We show that the MAP strategy is $O(\log k)$ -competitive, where k denotes the size of the reordering buffer. Note

that, although MAP is equivalent to BW in the uniform case of our model, our analysis provides a better result. Currently, we only know a trivial lower bound of $5/3$ on the competitive ratio of any deterministic strategy.

For the upper bound on MAP we introduce the following basic proof technique: First, it is shown that MAP with buffer size k is 4-competitive against an optimal offline strategy with buffer size $k/4$. Finally, it is proven that an optimal offline strategy with buffer size $k/4$ is $O(\log k)$ -competitive against an optimal offline strategy with buffer size k . We believe that this technique can be interesting for other problems.

Our non-uniform scenario can be modeled by the following star-like metric space: $d(x, y) = (b_x + b_y)/2$, if $x \neq y$, and $d(x, y) = 0$, otherwise. Above, we conclude that there is a lack of efficient strategies for the disk scheduling problem, i.e., the line metric space. We consider to transfer this technique from star-like to line metric spaces.

2 Basic Upper Bound

In this section, we show that a reordering buffer of size k reduces the cost of each sequence by a factor of at most $2k - 1$. This result holds for online and offline strategies and even for cost functions modeled by arbitrary metric spaces. Note that this result is tight. Fix the two colors c_1 and c_2 with weights $b_{c_1} = b_{c_2} = 1$. The input sequence $\sigma = (c_1 c_2)^k$ of length $2k$ can obviously be reordered to $\sigma_{\pi^{-1}} = c_1^k c_2^k$ with a reordering buffer of size k . The cost of σ is $C(\sigma) = 2k - 1$, and the cost of $\sigma_{\pi^{-1}}$ is $C(\sigma_{\pi^{-1}}) = 1$. Hence, $C(\sigma) = (2k - 1) \cdot C(\sigma_{\pi^{-1}}) \geq (2k - 1) \cdot C^{op}(\sigma)$, where $C^{op}(\sigma)$ denotes the cost of an optimal offline strategy using a reordering buffer of size k .

Theorem 1. *For every metric space (M, d) , and every input sequence $\sigma = \sigma_1 \cdots \sigma_l$, with $\sigma_i \in M$,*

$$C(\sigma) \leq (2k - 1) \cdot C^{op}(\sigma) ,$$

where $C(\sigma)$ denotes the cost of σ , and $C^{op}(\sigma)$ denotes the cost of an optimal offline strategy using a reordering buffer of size k .

Proof. Fix an input sequence $\sigma = \sigma_1 \cdots \sigma_l$. Let $\sigma_{\pi^{-1}} = \sigma_{\pi^{-1}(1)} \cdots \sigma_{\pi^{-1}(l)}$ denote the output sequence of an optimal offline strategy using a reordering buffer of size k . We define a *subsequence* $I_r^s = \sigma_{\pi^{-1}(r)} \cdots \sigma_{\pi^{-1}(s)}$, if $r \leq s$, and $I_r^s = \sigma_{\pi^{-1}(s)} \cdots \sigma_{\pi^{-1}(r)}$, otherwise. Let $C(I_r^s)$ denote the cost of this subsequence, i.e., $C(I_r^s) = \sum_{j=\min\{r,s\}}^{\max\{r,s\}-1} d(\sigma_{\pi^{-1}(j)}, \sigma_{\pi^{-1}(j+1)})$.

Due to the triangle inequality, $d(\sigma_i, \sigma_{i+1}) \leq C(I_{\pi(i)}^{\pi(i+1)})$. Thus,

$$C(\sigma) = \sum_{i=1}^{l-1} d(\sigma_i, \sigma_{i+1}) \leq \sum_{i=1}^{l-1} C(I_{\pi(i)}^{\pi(i+1)}) .$$

Fix two consecutive objects $\sigma_{\pi^{-1}(j)}$ and $\sigma_{\pi^{-1}(j+1)}$ of $\sigma_{\pi^{-1}}$. We show that these objects do only occur in at most $2k - 1$ of the subsequences above. If

$\sigma_{\pi^{-1}(j)}$ and $\sigma_{\pi^{-1}(j+1)}$ are part of a subsequence $I_{\pi(i)}^{\pi(i+1)}$, one of the following two cases is true:

1. $\pi(i) \leq j$ and $\pi(i + 1) \geq j + 1$
2. $\pi(i + 1) \leq j$ and $\pi(i) \geq j + 1$

In case (1), σ_i is one of the first j objects and σ_{i+1} is not under the first j objects of $\sigma_{\pi^{-1}}$. In case (2), it is the other way around.

Obviously, the following observation can be made.

Observation 2. *For each input sequence $\sigma = \sigma_1 \cdots \sigma_l$, the output sequence of a reordering buffer of size k is a permutation $\sigma_{\pi^{-1}} = \sigma_{\pi^{-1}(1)} \cdots \sigma_{\pi^{-1}(l)}$ of σ , with $\pi^{-1}(i) < i + k$, for each i . In addition, each such permutation can be generated using a reordering buffer of size k .*

The observation shows that only one of the first $i + k - 1$ objects of σ can be placed at the i -th position of $\sigma_{\pi^{-1}}$. Thus, we conclude for case (1) that $i \leq j + k - 1$. In the same way, we conclude for case (2) the even stronger inequality $i + 1 \leq j + k - 1$.

In the following, we consider case (1). The above conclusions provide that σ_{i+1} must be one of the first $j + k$ objects of σ . But, σ_{i+1} is not one of the first j objects of $\sigma_{\pi^{-1}}$. Recall that the observation shows that the first j objects of $\sigma_{\pi^{-1}}$ have to be under the first $j + k - 1$ objects of σ . Hence, at most k objects of the first $j + k$ objects of σ cannot be under the first j objects of $\sigma_{\pi^{-1}}$. It follows that case (1) is true for at most k different subsequences. Obviously, case (2) can be addressed analogously. It follows that case (2) is true for at most $k - 1$ different subsequences.

Hence,

$$C(\sigma) \leq \sum_{i=1}^{l-1} C(I_{\pi(i)}^{\pi(i+1)}) \leq (2k - 1) \sum_{i=1}^{l-1} d(\sigma_{\pi^{-1}(i)}, \sigma_{\pi^{-1}(i+1)}) = (2k - 1) \cdot C^{op}(\sigma) ,$$

since at most $2k - 1$ subsequences are containing the two objects $\sigma_{\pi^{-1}(i)}$ and $\sigma_{\pi^{-1}(i+1)}$. □

3 Lower Bound for the BW Strategy

The Bounded Waste (BW) strategy is introduced in [5] for the uniform case of our model: For each color c , weight $b_c = 1$, i.e., just the number of color changes is considered. BW chooses one color as the active color, and continues to remove objects of this active color from the reordering buffer until all objects in the buffer have a color different from the active color. Then a new active color has to be chosen. For this purpose, a counter P_c , which is initially set to zero, is assigned to each color c . At each color change, the counter of each color c is increased by the number of objects of color c currently stored in the buffer. Then a color c' with maximal counter $P_{c'}$ is chosen as the new active color and $P_{c'}$ is reset to zero.

The following theorem shows a lower bound of k , where k denotes the size of the reordering buffer, on the competitive ratio of BW in our non-uniform model. Note that this lower bound even holds for the case that BW takes the non-uniform weights of the colors into account.

Theorem 3. *The competitive ratio of BW is at least k , where k denotes the size of the reordering buffer.*

Proof. Fix one expensive color x with weight $b_x = 1$, and several inexpensive colors c_1, \dots, c_l with weights $b_{c_1} = \dots = b_{c_l} = \varepsilon$. The input sequence $\sigma = \sigma_1 \dots \sigma_l$ with $l = k \cdot (k + 1)$ is defined as follows: σ_i is of color x , if i is divisible by $(k + 1)$, and of color c_i , otherwise. Obviously, it is possible to produce an output sequence $\sigma_{\pi^{-1}}^{\text{op}}$ with cost $C(\sigma_{\pi^{-1}}^{\text{op}}) = 1 + (k^2 - 1) \cdot \varepsilon$ by aggregating objects of the expensive color.

Each pair of objects in σ has different colors, except the pairs where both objects have the color x . However, BW will never hold two objects of color x in the reordering buffer at the same time. Assume this statement holds until some step i in which an object of color x arrives. If each pair of objects in the buffer of BW has different colors, the values of the counters are exclusively based on the number of steps the corresponding objects are stored in the buffer. The object of color x is after $k - 1$ steps the oldest object in the buffer. Hence, this object is removed from the buffer in the next step, i.e., one step before the next object of color x arrives.

The cost of the produced output sequence $\sigma_{\pi^{-1}}^{\text{op}}$ is $C(\sigma_{\pi^{-1}}^{\text{op}}) = C(\sigma) = k + k^2 \cdot \varepsilon$. Since the input sequence σ can be iterated and ε can be chosen arbitrarily small, this yields a lower bound of k on the competitive ratio. Of course, BW could take the non-uniform weights of the colors into account, i.e., the counter P_c is increased by the number of objects of color c currently stored in the buffer times the weight of color c . However, this proof does not depend on this decision. □

4 The MAP Strategy

In this section, we present the Maximal Adjusted Penalty (MAP) strategy. We show that the MAP strategy is $O(\log k)$ -competitive, where k denotes the size of the reordering buffer.

MAP chooses one color as the active color, and removes at each time step one object of this active color from the reordering buffer until all objects in the buffer have a color different from the active color. Then a new active color has to be chosen. For this purpose, a penalty counter P_c , which is initially set to zero, is assigned to each color c . MAP chooses a color c as the new active color with $P_c - k \cdot b_c \geq P_{c'} - k \cdot b_{c'}$, for each color c' . The counters are updated after a new active color is chosen. Suppose a step in which a color change from color x to color y occurs. Let n_c denote the number of objects of color c stored in the buffer at the beginning of this step. Then each counter P_c is increased by $n_c \cdot b_y$ and counter P_x is reset to zero.

The MAP strategy does not need to know the weights of all colors in advance. It is sufficient to provide the weight b_c when the first object of color c arrives. In addition, a counter P_c can be deleted if no objects of color c are stored in the buffer. Hence, each step can be performed in time $O(k)$, since at most k counters are active at the same time.

Theorem 4. *The MAP strategy is $O(\log k)$ -competitive, where k denotes the size of the reordering buffer.*

Proof. The proof consists of two parts.

1. First, we prove that MAP with buffer size k is 4-competitive against an optimal offline strategy with buffer size $h = k/4$.
2. Finally, we show that an optimal offline strategy with buffer size h is $O(\log k)$ -competitive against an optimal offline strategy with buffer size k .

Together, this yields the theorem.

Part 1. Fix an input sequence σ and a lazy optimal offline strategy OPT. MAP has a reordering buffer of size k and OPT has a reordering buffer of size h . We exclude the last k color changes of MAP. Hence, it can be assumed that there are k objects in the buffer of MAP at any time. Under this assumption we show that MAP is 4-competitive against OPT. This yields part 1, since the last k color changes of MAP produce at most cost $k \cdot \max_{\text{color } c} \{b_c\}$.

Color changes of MAP and OPT are denoted as online and offline color changes, respectively. An *online (offline) c -interval* starts with an online (offline) color change from color c to a different color and ends right before the next online (offline) color change from c to a different color (the first online (offline) c -interval starts with the first step). Each object of color c falls into exactly one online and one offline c -interval, and it enters and leaves the buffer of the respective strategy in the same c -interval. Also each step i falls into exactly one online and one offline c -interval, and these intervals are denoted as *active* at step i .

Now, we introduce counters to which k -times the cost of each online color change is assigned. For each color c , and each online c -interval I , the two counters $w_c^{\text{on},I}$ and $\hat{w}_c^{\text{on},I}$ are introduced. $w_c^{\text{on},I}(i)$ and $\hat{w}_c^{\text{on},I}(i)$ denote the value of $w_c^{\text{on},I}$ and $\hat{w}_c^{\text{on},I}$ at the beginning of step i , respectively. The counters are initially set to zero, and they are monotonously increasing. A counter is denoted as active at step i , if the according online c -interval I is active at step i . Otherwise, the counter is denoted as inactive. For simplicity, we just write $w_c^{\text{on}}(i)$ and $\hat{w}_c^{\text{on}}(i)$ to denote the active counters for color c at the beginning of step i . Inactive counters do not change their value.

Fix a step i . In the following, we describe how k -times the cost of an online color change is distributed among the counters. Let $n_c^{\text{on}}(i)$ denote the number of objects with color c in the buffer of MAP at the beginning of step i . For simplicity, we just write n_c^{on} , if the step is fixed. Note that $\sum_{\text{color } c} n_c^{\text{on}} = k$. Suppose there is an online color change to color c' in step i . Then $k \cdot b_{c'}$ has to be assigned to the counters. For each color c , w_c^{on} is increased by $n_c^{\text{on}} \cdot b_{c'}$. In total, we assign $\sum_{\text{color } c} n_c^{\text{on}} \cdot b_{c'} = k \cdot b_{c'}$ to active counters.

But we prevent a counter w_c^{on} from becoming larger than $k \cdot b_c$. This restriction might cause that nothing or only a part of the value $n_c^{\text{on}} \cdot b_{c'}$ is really assigned to w_c^{on} . The remaining part, i.e., the part that would lead to a counter w_c^{on} larger than $k \cdot b_c$, is assigned to $\hat{w}_{c'}^{\text{on}}$ instead. Note that w_c^{on} equals the P_c counter in MAP, as long as $P_c \leq k \cdot b_c$. Otherwise, w_c^{on} remains on the value $k \cdot b_c$, but P_c is further increased. Note in addition that, for each color c' and each online c' -interval I , the counter $\hat{w}_{c'}^{\text{on},I}$ is increased in at most one step.

Since we have assigned k -times the produced cost to counters, we can express the cost of MAP $C^{\text{on}} = (1/k) \cdot \sum_{\text{color } c} \sum_{\text{on. } c\text{-int. } I} (W_c^{\text{on},I} + \hat{W}_c^{\text{on},I})$, where $W_c^{\text{on},I}$ and $\hat{W}_c^{\text{on},I}$ denote the final, i.e., maximum, value of the counters $w_c^{\text{on},I}$ and $\hat{w}_c^{\text{on},I}$, respectively.

In addition, for each color c and each online c -interval I , the counter $w_c^{\text{op},I}$ is introduced. $w_c^{\text{op},I}(i)$ denotes the value of $w_c^{\text{op},I}$ at the beginning of step i . The counters are initially set to zero, and they are monotonously increasing. A counter is denoted as active at step i , if the according online c -interval I is active at step i . Otherwise, the counter is denoted as inactive. For simplicity, we just write $w_c^{\text{op}}(i)$ to denote the active counter for color c at the beginning of step i . Inactive counters do not change their value.

Fix a step i . Let $n_c^{\text{op}}(i)$ denote the number of objects with color c in the buffer of OPT at the beginning of step i . For simplicity, we just write n_c^{op} , if the step is fixed. Note that $\sum_{\text{color } c} n_c^{\text{op}} = h$. Suppose there is an online color change to color c' in step i . For each color c , w_c^{op} is increased by $n_c^{\text{op}} \cdot b_{c'}$. In total, we assign $\sum_{\text{color } c} n_c^{\text{op}} \cdot b_{c'} = h \cdot b_{c'}$ to active counters.

Hence, we yield a new possibility to express the cost of MAP $C^{\text{on}} = (1/h) \cdot \sum_{\text{color } c} \sum_{\text{on. } c\text{-int. } I} W_c^{\text{op},I}$, where $W_c^{\text{op},I}$ denotes the final, i.e., maximum, value of the counter $w_c^{\text{op},I}$.

For each color c , we show the following *main inequality*

$$4k \cdot C_c^{\text{op}} + \sum_{\text{on. } c\text{-int. } I} (4W_c^{\text{op},I} - (W_c^{\text{on},I} + \hat{W}_c^{\text{on},I})) \geq \sum_{\text{on. } c\text{-int. } I} (W_c^{\text{on},I} + \hat{W}_c^{\text{on},I}) ,$$

where C_c^{op} denotes the total cost produced by offline color changes to color c . Summing up over all colors, we yield $4k \cdot C^{\text{op}} + 4h \cdot C^{\text{on}} - k \cdot C^{\text{on}} \geq k \cdot C^{\text{on}}$. Hence, $4C^{\text{op}} \geq C^{\text{on}}$. This yields part 1.

We distinguish between two kinds of online c -intervals. An online c -interval I is denoted as *problematic*, if $4W_c^{\text{op},I} < 2(W_c^{\text{on},I} + \hat{W}_c^{\text{on},I})$. Otherwise, I is denoted as *non-problematic*. Now, we show the following inequality

$$4k \cdot C_c^{\text{op}} \geq 2 \sum_{\text{prob. } c\text{-int. } I} (W_c^{\text{on},I} + \hat{W}_c^{\text{on},I}) .$$

Obviously, the main inequality can be concluded with the help of the above inequality.

The following lemma provides an upper bound on $W_c^{\text{on},I}$ and $\hat{W}_c^{\text{on},I}$. Then, an upper bound on the number of problematic c -intervals is shown. These two results together complete part 1 of the proof.

Lemma 5. *For each color c and each online c -interval I ,*

$$\hat{W}_c^{\text{on},I} \leq W_c^{\text{on},I} \leq k \cdot b_c .$$

Proof. Due to the cost assignment for $w_c^{\text{on},I}$, $W_c^{\text{on},I} \leq k \cdot b_c$. Suppose that $\hat{W}_c^{\text{on},I} > 0$. Recall that $\hat{w}_c^{\text{on},I}$ is increased in at most one step. We consider the step i in which $\hat{w}_c^{\text{on},I}$ is increased due to the online color change to color c in the online c -interval I . In this step, for each color c' , $P_c - k \cdot b_c \geq P_{c'} - k \cdot b_{c'}$.

Now, we distinguish the following two cases.

- Suppose that $W_c^{\text{on},I} = k \cdot b_c$.

The color change in step i produces cost b_c . Hence, $k \cdot b_c$ is assigned to the counters in this step. Even if the whole value $k \cdot b_c$ is assigned to $\hat{w}_c^{\text{on},I}$, $\hat{W}_c^{\text{on},I} \leq k \cdot b_c = W_c^{\text{on},I}$, since $\hat{w}_c^{\text{on},I}$ is increased in at most one step.

- Suppose that $W_c^{\text{on},I} < k \cdot b_c$.

In this case, $P_c = w_c^{\text{on}}(i)$ in step i . In fact, for each color c' , $P_{c'} = w_{c'}^{\text{on}}(i)$ at the beginning of step i , since $w_{c'}^{\text{on}}(i) < k \cdot b_{c'}$. If, for some color $c' \neq c$, $w_{c'}^{\text{on}}(i) = k \cdot b_{c'}$, MAP would have chosen color c' as new active color in step i . Of course, for a color $c' \neq c$, the active counter $w_{c'}^{\text{on}}$ can reach its limit $k \cdot b_{c'}$ in this step. $w_{c'}^{\text{on}}$ exceeds its limit by $x_{c'} = \max\{0, w_{c'}^{\text{on}}(i) + n_{c'}^{\text{on}}(i) \cdot b_{c'} - k \cdot b_{c'}\}$. Due to MAP, $w_{c'}^{\text{on}}(i) - k \cdot b_{c'} \leq w_c^{\text{on}}(i) - k \cdot b_c$. Hence, $x_{c'} \leq \max\{0, w_c^{\text{on}}(i) + n_{c'}^{\text{on}}(i) \cdot b_{c'} - k \cdot b_{c'}\}$.

Let V denote the set of all colors c' with $x_{c'} > 0$. If $V = \emptyset$, $\hat{W}_c^{\text{on},I} = 0$. Otherwise,

$$\begin{aligned} \hat{W}_c^{\text{on},I} &= \sum_{c' \in V} x_{c'} \leq |V| \cdot (w_c^{\text{on}}(i) - k \cdot b_c) + \sum_{c' \in V} n_{c'}^{\text{on}}(i) \cdot b_{c'} \\ &\leq w_c^{\text{on}}(i) - k \cdot b_c + \sum_{c' \in V} n_{c'}^{\text{on}}(i) \cdot b_{c'} \leq w_c^{\text{on}}(i) \leq W_c^{\text{on},I} , \end{aligned}$$

since $w_c^{\text{on}}(i) - k \cdot b_c < 0$.

This finishes the proof of the lemma. \square

The beginning of an offline c -interval I , before the offline color change to color c occurs, is denoted as increasing phase, since the number of objects of color c in the offline buffer is monotonously increasing. The remaining part of I , after the offline color change to color c , is denoted as decreasing phase, since the number of objects of color c in the offline buffer is monotonously decreasing.

Lemma 6. *At most one problematic online c -interval starts in an offline c -interval.*

Proof. Fix a problematic online c -interval I . From Lem. 5 follows $4W_c^{\text{op},I} < 4W_c^{\text{on},I}$. Hence, there exists at least one step i in I with $n_c^{\text{op}}(i) < n_c^{\text{on}}(i)$. Let I' denote the offline c -interval in which I starts.

Suppose I starts in the increasing phase of I' . Let $\text{start}(I)$ denote the first step of interval I . Then $n_c^{\text{op}}(\text{start}(I)) \geq 0 = n_c^{\text{on}}(\text{start}(I))$. Hence, no step i with

$n_c^{op}(i) < n_c^{on}(i)$ can exist in this increasing phase, since every arriving object of color c is stored in the offline buffer and no objects of color c are removed from the offline buffer.

Consider the decreasing phase of I' . If n_c^{on} is decreased, then n_c^{op} is decreased by the same amount. Hence, if there exists a step i with $n_c^{op}(i) < n_c^{on}(i)$ in the decreasing phase of I' , the offline c -interval I' ends before the end of the problematic online c -interval I . \square

The total number of offline c -intervals is C_c^{op}/b_c . We can exclude the first offline c -interval, if c is the color of the first object in the output sequence of OPT, since the total produced cost by MAP in the only problematic interval starting in this offline c -interval can be bounded by a term independent of σ . Note that we exclude, for only one color c , an offline c -interval. From the lemma above it follows that the total number of problematic online c -intervals is at most C_c^{op}/b_c . Then

$$\begin{aligned} 2 \sum_{\text{prob. } c\text{-int. } I} (W_c^{on,I} + \hat{W}_c^{on,I}) &\leq 2 \sum_{\text{prob. } c\text{-int. } I} k \cdot b_c + k \cdot b_c \\ &\leq 4k \cdot b_c \cdot C_c^{op}/b_c = 4k \cdot C_c^{op} . \end{aligned}$$

This completes part 1 of the proof.

Part 2. It remains to show, that an optimal offline strategy with buffer size $h = k/4$ is $O(\log k)$ -competitive against an optimal offline strategy with buffer size k . Fix an input sequence σ . For each step i , let $n_c^h(i)$ denote the number of objects of color c in the buffer of size h and let $n_c^k(i)$ denote the number of objects of color c in the buffer of size k .

Fix a lazy optimal offline strategy LARGE for the reordering buffer of size k . The offline strategy SMALL for the reordering buffer of size h chooses a new active color c , with $n_c^h(i) \geq n_c^k(i)/4$. Note that there exists always such a color, since $\sum_{\text{color } c} n_c^h(i) = \sum_{\text{color } c} n_c^k(i)/4$.

Large (small) c -intervals are defined for LARGE (SMALL) according to the definition of online and offline c -intervals. The definitions of increasing and decreasing phases apply to large c -intervals, too. Note that the total number of large (small) c -intervals is order of the total number of color changes to color c of LARGE (SMALL).

For every color c , we show that there are at most $O(\log k)$ small c -intervals in one large c -interval. Then, $C_c^h \leq O(\log k) \cdot C_c^k$, where C_c^h (C_c^k) denotes the cost of LARGE (SMALL) for color c . This yields part 2 of the proof.

Fix a color c . In the following, we only consider small c -intervals that are completely contained in a large c -interval. In addition, we exclude a small c -interval, if LARGE performs a color change to color c during this interval. Hence, in total at most two small c -intervals are excluded for every large c -interval. The remaining small c -intervals are completely contained either in an increasing or in a decreasing phase of a large c -interval.

The following lemma shows that there are at most $O(\log k)$ small c -intervals in a large c -interval, since the buffer size of LARGE is k .

Lemma 7. *Let $\text{start}(I)$ and $\text{end}(I)$ denote the first and last step of a small c -interval I , respectively.*

- *In an increasing phase: $n_c^k(\text{end}(I)) \geq (5/4)n_c^k(\text{start}(I))$.*
- *In a decreasing phase: $n_c^k(\text{start}(I)) \geq (5/4)n_c^k(\text{end}(I))$.*

Proof. We only prove the inequality for the increasing phase. The inequality for the decreasing phase can be addressed analogously. Fix a small c -interval I . Let i be the step in I at which SMALL performs a color change to color c . Due to SMALL, $n_c^h(i) \geq n_c^k(i)/4$.

At least $n_c^h(i)$ objects of color c arrive in I . Since I lies in an increasing phase, these objects are not removed from the buffer of LARGE during I . At the end of I , the $n_c^k(\text{start}(I))$ objects of color c stored in the buffer of LARGE before I , are still there, and at least $n_c^h(i) \geq n_c^k(i)/4 \geq n_c^k(\text{start}(I))/4$ new objects of color c are added. Hence, at least $(5/4)n_c^k(\text{start}(I))$ objects of color c are stored in the buffer of LARGE at the end of I . \square

This completes part 2 of the proof. \square

Abstract. Most of the decision procedures for symbolic analysis of protocols are limited to a fixed set of algebraic operators associated with a fixed intruder theory. Examples of such sets of operators comprise XOR, multiplication/exponentiation, abstract encryption/decryption. In this paper we give an algorithm for combining decision procedures for arbitrary intruder theories with disjoint sets of operators, provided that solvability of ordered intruder constraints, a slight generalization of intruder constraints, can be decided in each theory. This is the case for most of the intruder theories for which a decision procedure has been given. In particular our result allows us to decide trace-based security properties of protocols that employ any combination of the above mentioned operators with a bounded number of sessions.

1 Introduction

Recently many procedures have been proposed to decide insecurity of cryptographic protocols in the Dolev-Yao model w.r.t. a finite number of protocol sessions [2, 5, 18]. Among the different approaches the symbolic ones [16, 10, 4] are based on reducing the problem to constraint solving in a term algebra. This reduction has proved to be quite effective on standard benchmarks and also was able to discover new flaws on several protocols [4].

However while most formal analysis of security protocols abstracts from low-level properties, i.e., certain algebraic properties of encryption, such as the multiplicative properties of RSA or the properties induced by chaining methods for block ciphers, many real attacks and protocol weaknesses rely on these properties. For attacks exploiting the XOR properties in the context of mobile communications see [7]. Also the specification of *Just Fast Keying* protocol (an alternative to IKE) in [1] employs a set constructor that is idempotent and commutative and a Diffie-Hellman exponentiation operator with the property $(g^y)^z = (g^z)^y$.

In this paper we present a general procedure for deciding security of protocols in presence of algebraic properties. This procedure relies on the combination of constraint solving algorithm for disjoint intruder theories, provided that solvability of ordered intruder constraints, a slight generalization of intruder constraints,

^{*} Supported by IST-2001-39252 AVISPA, ACI SATIN, ACI-Jeune Chercheur JC9005.

can be decided in each theory. Such combination algorithm already exists for solving E -unification problems [19, 3]. We have extended it in order to solve intruder constraints on disjoint signatures. This extension is non trivial since intruder deduction rules allow one to build *contexts* above terms and therefore add some second-order features to the *standard* first-order E -unification problem.

Our approach is more modular than the previous ones and it allows us to decide interesting intruder theories that could not be considered before by reducing them to simpler and independent theories. For instance it allows one to combine the exponentiation with abelian group theory of [17] with the Xor theory of [8].

Related works. Recently several protocol decision procedures have been designed for handling algebraic properties in the Dolev-Yao model [15, 6, 11, 8]. These works have been concerned by fixed equational theories corresponding to a fixed intruder power. A couple of works only have tried to derive generic decidability results for *class* of intruder theories. For instance, in [12] Delaune and Jacquemard consider the class of *public collapsing* theories. These theories have to be presented by rewrite systems where the right-hand side of every rule is a ground term or a variable, which is a strong restriction.

2 Motivation

Combination of algebraic operators. We consider in this section the Needham-Schroeder Public-Key protocol. This well-known protocol is described in the Alice and Bob notation by the following sequence of messages, where the comma denotes a pairing of messages and $\{M\}K_a$ denotes the encryption by the public key K_a of A .

$$\begin{aligned} A &\rightarrow B : \{N_a, A\}K_b \\ B &\rightarrow A : \{N_a, N_b\}K_a \\ A &\rightarrow B : \{N_b\}K_b \end{aligned}$$

Assume now that the encryption algorithm follows El-Gamal encryption scheme. The public key of A is defined by three publicly-available parameters: a modulus p_a , a base g_a and the proper public key $(g_a)^a \bmod p_a$. The private key of A is a . Denoting \exp_p the exponentiation modulo p , and with new nonces k_1, k_2 and k_3 we can rewrite the protocol as:

$$\begin{aligned} A &\rightarrow B : \exp_p(g_b, k_1), (N_a, A) \oplus \exp_p(\exp_p(g_b, b), k_1) \\ B &\rightarrow A : \exp_p(g_a, k_2), (N_a, N_b) \oplus \exp_p(\exp_p(g_a, a), k_2) \\ A &\rightarrow B : \exp_p(g_b, k_3), (N_b) \oplus \exp_p(\exp_p(g_b, b), k_3) \end{aligned}$$

In this simple example we would like to model the group properties of the Exclusive-or (\oplus), the associativity of exponential ($((x^y)^z = x^{y \times z})$), the group properties of the exponents. Several works have already been achieved toward taking into account these algebraic properties for detecting attacks on a bounded number of sessions. However none of these works handles the analysis of protocols combining several algebraic operators like the example above. The algorithm

given in this paper will permit to decide the trace-based security properties of such protocols.

Examples of intruder theories. A convenient way to specify intruder theories in the context of cryptographic protocols is by giving a set L of *deduction rules* describing how the intruder can construct new messages from the ones she already knows and a set of *equational laws* \mathcal{E} verified by the functions employed in messages. We give here two examples of intruder theories. Some other theories are given in [9].

Abelian group theory. This intruder may treat messages as elements of an abelian group. We assume here there is only one such group and that the composition law is $\cdot \times \cdot$, the inverse law is $i(\cdot)$ and the neutral element is denoted 1.

$$L_{\times} \left\{ \begin{array}{l} \rightarrow 1 \\ x \rightarrow i(x) \\ x, y \rightarrow x \times y \end{array} \right. \quad \mathcal{E}_{\times} \left\{ \begin{array}{l} (x \times y) \times z = x \times (y \times z) \\ x \times y = y \times x \\ 1 \times x = x \\ x \times i(x) = 1 \end{array} \right.$$

Dolev Yao with explicit destructors. The intruder is given with a pairing operator and projections to retrieve the components of a pair. There are symmetric encryption ($se(\cdot, \cdot)$) and decryption ($sd(\cdot, \cdot)$) operators. For conciseness we omit the public-key encryption specification.

$$L_{DY} \left\{ \begin{array}{l} x, y \rightarrow \langle x, y \rangle \\ x \rightarrow \pi_1(x) \\ x \rightarrow \pi_2(x) \\ x, y \rightarrow se(x, y) \\ x, y \rightarrow sd(x, y) \end{array} \right. \quad \mathcal{E}_{DY} \left\{ \begin{array}{l} \pi_1(\langle x, y \rangle) = x \\ \pi_2(\langle x, y \rangle) = y \\ sd(se(x, y), y) = x \end{array} \right.$$

3 Terms and Subterms

We consider an infinite set of free constants \mathcal{C} and an infinite set of variables \mathcal{X} . For all signatures \mathcal{G} (i.e. a set of function symbols with arities), we denote by $T(\mathcal{G})$ (resp. $T(\mathcal{G}, \mathcal{X})$) the set of terms over $\mathcal{G} \cup \mathcal{C}$ (resp. $\mathcal{G} \cup \mathcal{C} \cup \mathcal{X}$). The former is called the set of ground terms over \mathcal{G} , while the latter is simply called the set of terms over \mathcal{G} . Variables are denoted by x, y, v , terms are denoted by s, t, u , and finite sets of terms are written E, F, \dots , and decorations thereof, respectively.

A *constant* is either a free constant or a function symbol of arity 0. Given a term t we denote by $\text{Var}(t)$ the set of variables occurring in t and by $\text{Cons}(t)$ the set of constants occurring in t . We denote by $\text{Atoms}(t)$ the set $\text{Var}(t) \cup \text{Cons}(t)$. We denote by \mathcal{A} the set of all constants and variables. A substitution σ is an involutive mapping from \mathcal{X} to $T(\mathcal{G}, \mathcal{X})$ such that $\text{Supp}(\sigma) = \{x \mid \sigma(x) \neq x\}$, the *support* of σ , is a finite set. The application of a substitution σ to a term t (resp. a set of terms E) is denoted $t\sigma$ (resp. $E\sigma$) and is equal to the term t (resp. E) where all variables x have been replaced by the term $x\sigma$. A substitution σ is *ground* w.r.t. \mathcal{G} if the image of $\text{Supp}(\sigma)$ is included in $T(\mathcal{G})$.

In this paper, we consider 2 disjoint signatures \mathcal{F}_1 and \mathcal{F}_2 , and 2 consistent equational theories \mathcal{E}_1 and \mathcal{E}_2 on \mathcal{F}_1 and \mathcal{F}_2 , resp. We denote by \mathcal{F} the union of the signatures \mathcal{F}_1 and \mathcal{F}_2 , \mathcal{E} the union of the theories \mathcal{E}_1 and \mathcal{E}_2 . A term t in $\mathsf{T}(\mathcal{F}_1, \mathcal{X})$ (resp. in $\mathsf{T}(\mathcal{F}_2, \mathcal{X})$) is called a *pure 1-term* (resp. a *pure 2-term*).

The *syntactic subterms* of a term t are defined recursively as follows and denoted $\text{Sub}_{\text{syn}}(t)$. If t is a variable or a constant then $\text{Sub}_{\text{syn}}(t) = \{t\}$. If $t = f(t_1, \dots, t_n)$ then $\text{Sub}_{\text{syn}}(t) = \{t\} \cup \bigcup_{i=1}^n \text{Sub}_{\text{syn}}(t_i)$. The *positions* in a term t are defined recursively as usual (*i.e.* as sequences of integers), ϵ being the empty sequence. We denote by $t|_p$ the syntactic subterm of t at position p . We denote by $t[p \leftarrow s]$ the term obtained by replacing in t the syntactic subterm $t|_p$ by s . We denote by $\text{Sign}(\cdot)$ the function that associates to each term $t \notin C \cup \mathcal{X}$ the signature (\mathcal{F}_1 , or \mathcal{F}_2) of its symbol at position ϵ . For $t \in C \cup \mathcal{X}$ we define $\text{Sign}(t) = \perp$, with \perp a new symbol. The term s is *alien* to u if $\text{Sign}(s) \neq \text{Sign}(u)$. *Factors*. We define the set of *factors* of a term t , and denote $\text{Factors}(t)$, the set of maximal syntactic subterms of t that are either alien to t or atoms and different from t . In particular $\text{Factors}(t) = \emptyset$ for $t \in \mathcal{A}$.

Subterms. We now define the notion of *subterm values*. Given a term t , the set of its subterm values is denoted by $\text{Sub}(t)$ and is defined recursively by: $\text{Sub}(t) = \{t\} \cup \bigcup_{u \in \text{Factors}(t)} \text{Sub}(u)$. For a set of terms E , $\text{Sub}(E)$ is defined as the union of the subterms values of the elements of E .

As an example consider $\mathcal{F}_1 = \{\oplus, 0\}$ and $\mathcal{F}_2 = \{f\}$ where f has arity 1. Then $\text{Sub}(a \oplus (b \oplus 0)) = \{a \oplus (b \oplus 0), a, b, 0\}$. On the other hand $\text{Sub}(f(b \oplus c)) = \{f(b \oplus c), b \oplus c, b, c\}$. This shows the difference with the notion of *syntactic subterms*. In the rest of this paper and unless otherwise indicated, *the notion of subterm will refer to subterm values*.

Congruences and ordered rewriting. We shall introduce the notion of *ordered rewriting* [13], which is a useful technique that has been utilized (e.g. [3]) for proving the correctness of combination of unification algorithms.

Let $<$ be a simplification ordering on $\mathsf{T}(\mathcal{G})^1$ assumed to be total on $\mathsf{T}(\mathcal{G})$ and such that the minimum for $<$ is a constant $c_{\min} \in C$. Given a possibly infinite set of equations \mathcal{O} on the signature $\mathsf{T}(\mathcal{G})$ we define the ordered rewriting relation $\rightarrow_{\mathcal{O}}$ by $s \rightarrow_{\mathcal{O}} s'$ iff there exists a position p in s , an equation $l = r$ in \mathcal{O} and a substitution τ such that $s = s[p \leftarrow l\tau]$, $s' = s[p \leftarrow r\tau]$, and $l\tau > r\tau$.

It has been shown (see [13]) that by applying the *unfailing completion procedure* [14] to a set of equations \mathcal{H} we can derive a (possibly infinite) set of equations \mathcal{O} such that:

1. the congruence relations $=_{\mathcal{O}}$ and $=_{\mathcal{H}}$ are equal on $\mathsf{T}(\mathcal{F})$.
2. $\rightarrow_{\mathcal{O}}$ is convergent (*i.e.* terminating and confluent) on $\mathsf{T}(\mathcal{F})$.

We shall say that \mathcal{O} is an *o-completion* of \mathcal{H} . The relation $\rightarrow_{\mathcal{O}}$ being convergent on ground terms we can define $(t) \downarrow_{\mathcal{O}}$ as the unique normal form of the ground term t for $\rightarrow_{\mathcal{O}}$. Given a ground substitution σ we denote by $(\sigma) \downarrow_{\mathcal{O}}$ the substitution with the same support such that for all variables $x \in \text{Supp}(\sigma)$ we have

¹ By definition $<$ satisfies for all $s, t, u \in \mathsf{T}(\mathcal{G})$ $s < t[s]$ and $s < u$ implies $t[s] < t[u]$.

$x(\sigma)\downarrow_{\mathcal{O}} = (x\sigma)\downarrow_{\mathcal{O}}$. A substitution σ is *normal* if $\sigma = (\sigma)\downarrow_{\mathcal{O}}$. We will denote by R an o-completion of $\mathcal{E} = \mathcal{E}_1 \cup \mathcal{E}_2$. We denote by C_{spe} the set containing the constants in \mathcal{F} and c_{min} .

4 Protocols, Intruders and Constraint Systems

Security of a given protocol is assessed with respect to a class of environments in which the protocol is executed. Dolev and Yao have described the environment not in terms of possible attacks on the protocol but by the deduction an intruder attacking a protocol execution is able to perform.

In Subsection 4.1 we define an extension of Dolev-Yao model to arbitrary operators for modeling the possible deductions of the intruder. In Subsection 4.2 we define the protocol semantics for an execution within an hostile environment controlled by the intruder and in Subsection 4.3 we describe how we represent this execution by a constraint system.

4.1 Intruder Systems

We shall model messages as ground terms and intruders deduction rules as rewrite rules on sets of messages representing the knowledge of an intruder. An intruder derives new messages from a given (finite) set of messages by applying intruder rules. Since we assume some equational axioms \mathcal{H} are verified by functions symbols in the signature, all these derivations have to be considered *modulo* the equational congruence $=_{\mathcal{H}}$ generated by these axioms.

An intruder deduction rule in our setting is specified by a term t in some signature \mathcal{G} . Given values for the variables of t the intruder is able to generate the corresponding instance of t .

Definition 1. An intruder system \mathcal{I} is given by a triple $\langle \mathcal{G}, T, \mathcal{H} \rangle$ where \mathcal{G} is a signature, $T \subseteq \mathsf{T}(\mathcal{G}, \mathcal{X})$ and \mathcal{H} is a set of axioms between terms in $\mathsf{T}(\mathcal{G}, \mathcal{X})$. To each $t \in T$ we associate a deduction rule $L^t : \text{Var}(t) \rightarrow t$ and $L^{t:\mathcal{G}}$ denotes the set of ground instances of the rule L^t :

$$L^{t:\mathcal{G}} = \{l \rightarrow r \mid \exists \sigma, \text{ground substitution on } \mathcal{G} \text{ s.t. } l = \text{Var}(t)\sigma \text{ and } r =_{\mathcal{H}} t\sigma\}$$

The set of rules $L_{\mathcal{I}}$ is defined as the union of the sets $L^{t:\mathcal{G}}$ for all $t \in T$.

Each rule $l \rightarrow r$ in $L_{\mathcal{I}}$ defines an intruder deduction relation $\rightarrow_{l \rightarrow r}$ between finite sets of terms. Given two finite sets of terms E and F we define $E \rightarrow_{l \rightarrow r} F$ if and only if $l \subseteq E$ and $F = E \cup \{r\}$. We denote $\rightarrow_{\mathcal{I}}$ the union of the relations $\rightarrow_{l \rightarrow r}$ for all $l \rightarrow r$ in $L_{\mathcal{I}}$ and by $\rightarrow_{\mathcal{I}}^*$ the transitive closure of $\rightarrow_{\mathcal{I}}$. We simply denote by \rightarrow the relation $\rightarrow_{\mathcal{I}}$ when there is no ambiguity about \mathcal{I} .

For instance we can define $\mathcal{I}_{\times} = \langle \{\times, \text{i}, 1\}, \{x \times y, \text{i}(x), 1\}, \mathcal{E}_{\times} \rangle$ and we have $a, b, c \rightarrow_{\mathcal{I}_{\times}} a, b, c, c \times a$ by applying the rule $c, a \rightarrow c \times a \in L^{x \times y, \mathcal{G}}$.

A *derivation* D of length n , $n \geq 0$, is a sequence of steps of the form $E_0 \rightarrow_{\mathcal{I}} E_0 \cup \{t_1\} \rightarrow_{\mathcal{I}} \dots \rightarrow_{\mathcal{I}} E_n$ with finite sets of ground terms E_0, \dots, E_n , and ground

terms t_1, \dots, t_n , such that $E_i = E_{i-1} \cup \{t_i\}$ for every $i \in \{1, \dots, n\}$. The term t_n is called the *goal* of the derivation. We define $\overline{E}^{\mathcal{I}}$ to be equal to the set $\{t \mid \exists F \text{ s.t. } E \rightarrow_{\mathcal{I}}^* F \text{ and } t \in F\}$ i.e. the set of terms that can be derived from E . If there is no ambiguity on the deduction system \mathcal{I} we write \overline{E} instead of $\overline{E}^{\mathcal{I}}$.

Let \mathcal{O} be an o-completion of \mathcal{H} . We will assume from now that all the deduction rules generate terms that are normalized by $\rightarrow_{\mathcal{O}}$ and the goal and the initial set are in normal form for $\rightarrow_{\mathcal{O}}$. It can be shown [9] that this is not restrictive for our main decidability result.

Given a set of terms $T \subseteq T(\mathcal{G}, \mathcal{X})$ we define the set of terms $\langle T \rangle$ to be the minimal set such that $T \subseteq \langle T \rangle$ and for all $t \in \langle T \rangle$ and for all substitutions σ with image included in $\langle T \rangle$, we have $t\sigma \in \langle T \rangle$. Hence terms in $\langle T \rangle$ are built by composing terms in T iteratively. We can prove easily that the intruder systems $\mathcal{I} = \langle \mathcal{G}, T, \mathcal{H} \rangle$ and $\mathcal{J} = \langle \mathcal{G}, \langle T \rangle, \mathcal{H} \rangle$ define the same sets of derivable terms, i.e. for all E we have $\overline{E}^{\mathcal{I}} = \overline{E}^{\mathcal{J}}$.

We want to consider the union of the 2 intruder systems $\mathcal{I}_1 = \langle \mathcal{F}_1, T_1, \mathcal{E}_1 \rangle$ and $\mathcal{I}_2 = \langle \mathcal{F}_2, T_2, \mathcal{E}_2 \rangle$. In particular we are interested in the derivations obtained by using $\rightarrow_{\mathcal{I}_1} \cup \rightarrow_{\mathcal{I}_2}$. It can be noticed that $\langle T_1 \cup T_2 \rangle = \langle \langle T_1 \rangle \cup \langle T_2 \rangle \rangle$. Hence by the remarks above the derivable terms using $\langle T_1 \cup T_2 \rangle$ or $\langle T_1 \rangle \cup \langle T_2 \rangle$ are the same. For technical reason it will be more convenient to use $\langle T_1 \rangle \cup \langle T_2 \rangle$ for defining the union of 2 intruder systems:

Definition 2. *The union of the two intruder systems $\langle \mathcal{F}_1, T_1, \mathcal{E}_1 \rangle, \langle \mathcal{F}_2, T_2, \mathcal{E}_2 \rangle$ is the intruder system $\mathcal{U} = \langle \mathcal{F}, \langle T_1 \rangle \cup \langle T_2 \rangle, \mathcal{E} \rangle$.*

A derivation $E_0 \rightarrow_{\mathcal{U}} E_0 \cup \{t_1\} \rightarrow_{\mathcal{U}} \dots \rightarrow_{\mathcal{U}} E_n$ of intruder system \mathcal{U} is *well-formed* if for all $i \in \{1, \dots, n\}$ we have $t_i \in \text{Sub}(E_0 \cup \{t_n\})$; in other words every message generated by an intermediate step either occurs in the goal or in the initial set of messages. In the following lemma the derivations refer to the intruder system $\mathcal{U} = \langle \mathcal{F}, \langle T_1 \rangle \cup \langle T_2 \rangle, \mathcal{E} \rangle$. For the proof see [9]:

Lemma 1. *A derivation of minimal length starting from E of goal t is well-formed.*

4.2 Protocol Analysis

In this subsection we describe how protocols are modelled. In the following we only model a single session of the protocol since it is well-known how to reduce several sessions to this case. Our semantics follows the one by [12].

In Dolev-Yao model the intruder has complete control over the communication medium. We model this by considering the intruder *is* the network. Messages sent by honest agents are sent directly to the intruder and messages received by the honest agents are always sent by the intruder. From the intruder side a finite execution of a protocol is the interleaving of a finite sequence of messages she has to send and a finite sequence of messages she receives (and add to her knowledge).

We also assume that the interaction of the intruder with one agent is an atomic step. The intruder sends a message m to an honest agent, this agent

tests the validity of this message and responds to it. Alternatively an agent may initiate an execution and in this case we assume it reacts to a dummy message c_{\min} sent by the intruder.

A *step* is a triplet $(\text{RECV}(x); \text{SEND}(s); \text{COND}(e))$ where $x \in \mathcal{X}$, $s \in \text{T}(\mathcal{G}, \mathcal{X})$ and e is a set of equations between terms of $\text{T}(\mathcal{G}, \mathcal{X})$. The meaning of a step is that upon receiving message x , the honest agent checks the equations in e and sends the message s . An execution of a protocol is a finite sequence of steps.

Example 1. Consider the following toy protocol where K is a symmetric key initially known by A only:

$$\begin{aligned} A \rightarrow B &: \{M \oplus B\}_K \\ B \rightarrow A &: B \\ A \rightarrow B &: K \\ B \rightarrow A &: M \end{aligned}$$

Assuming the algebraic properties of \oplus , symmetric encryption $\text{se}(\cdot)$ and symmetric decryption $\text{sd}(\cdot)$ we model this protocol as:

$$\begin{aligned} &\text{RECV}(v_1); \text{SEND}(\text{se}(M \oplus B, K)); \text{COND}(v_1 = c_{\min}) \\ &\text{RECV}(v_2); \text{SEND}(B); \text{COND}(\emptyset) \\ &\text{RECV}(v_3); \text{SEND}(K); \text{COND}(v_3 = B) \\ &\text{RECV}(v_4); \text{SEND}(\text{sd}(v_2, v_4) \oplus B); \text{COND}(v_2 = \text{se}(x, v_4,)) \\ &\text{RECV}(v_5); \text{SEND}(c_{\min}); \text{COND}(v_5 = M) \end{aligned}$$

Note that in our setting we can model that at some step i the message must match the pattern t_i by adding an equation $v_i \stackrel{?}{=} t_i$ as a condition for this step.

In order to define whether an execution of a protocol is feasible we must first define when a substitution σ satisfies a set of equations \mathcal{S} .

Definition 3. (*Unification systems*) Let \mathcal{H} be a set of axioms on $\text{T}(\mathcal{G}, \mathcal{X})$. An \mathcal{H} -Unification system \mathcal{S} is a finite set of equations in $\text{T}(\mathcal{G}, \mathcal{X})$ denoted by $(t_i \stackrel{?}{=} u_i)_{i \in \{1, \dots, n\}}$. It is satisfied by a ground substitution σ , and we note $\sigma \models \mathcal{S}$, if for all $i \in \{1, \dots, n\}$ $t_i \sigma =_{\mathcal{H}} u_i \sigma$.

Let $\mathcal{I} = \langle \mathcal{G}, T, \mathcal{H} \rangle$ be an intruder system. A *configuration* is a couple $\langle P, N \rangle$ where P is a finite sequence of steps and N is a set of ground terms (the knowledge of the intruder). From the configuration $\langle (\text{RECV}(x); \text{SEND}(s); \text{COND}(e)) \cdot P, N \rangle$ a transition to $\langle P', N' \rangle$ is possible iff there exists a ground substitution σ such that $x\sigma \in \bar{N}$, $\sigma \models e$, $N' = N \cup \{s\sigma\}$ and $P' = P\sigma$. Trace based-security properties like secrecy can be reduced to the *Execution feasibility* problem:

Execution feasibility

- Input:** an initial configuration $\langle P, N_0 \rangle$
- Output:** SAT iff there exists a reachable configuration $\langle \emptyset, M \rangle$

4.3 Constraints Systems

We express the execution feasibility of a protocol by a constraint problem \mathcal{C} .

Definition 4. (*Constraint systems*) Let $\mathcal{I} = \langle \mathcal{G}, \mathcal{T}, \mathcal{H} \rangle$ be an intruder system. An \mathcal{I} -Constraint system \mathcal{C} is denoted: $((E_i \triangleright v_i)_{i \in \{1, \dots, n\}}, \mathcal{S})$ and it is defined by a sequence of couples $(E_i, v_i)_{i \in \{1, \dots, n\}}$ with $v_i \in \mathcal{X}$ and $E_i \subseteq \mathbb{T}(\mathcal{G}, \mathcal{X})$ for $i \in \{1, \dots, n\}$ and $E_{i-1} \subseteq E_i$ for $i \in \{2, \dots, n\}$ and by an \mathcal{H} -unification system \mathcal{S} . It is deterministic iff for all $i \in \{1, \dots, n\}$, $\text{Var}(E_i) \subseteq \{v_1, \dots, v_{i-1}\}$

An \mathcal{I} -Constraint system \mathcal{C} is satisfied by a ground substitution σ if for all $i \in \{1, \dots, n\}$ we have $v_i \sigma \in \overline{E_i \sigma}$ and if $\sigma \models \mathcal{S}$. We denote that a ground substitution σ satisfies a constraint system \mathcal{C} by $\sigma \models_{\mathcal{I}} \mathcal{C}$.

Constraint systems are denoted by \mathcal{C} and decorations thereof. Note that if a substitution σ is a solution of a constraint system \mathcal{C} , by definition of constraints and of unification systems the substitution $(\sigma) \downarrow_{\mathcal{O}}$ is also a solution of \mathcal{C} (where \mathcal{O} is an o-completion of H). In the context of cryptographic protocols the inclusion $E_{i-1} \subseteq E_i$ means that the knowledge of an intruder does not decrease as the protocol progresses: after receiving a message an honest agent will respond to it. This response can be added to the knowledge of an intruder who listens all communications.

The condition defining the *deterministic* constraint systems expresses that a message to be sent at some step i should be built from previously received messages recorded in the variables v_j for $j < i$ and from the initial knowledge.

Example 2. We model the protocol of Example 1 by the following constraint system. First we gather all conditions in a unification system \mathcal{S}

$$\mathcal{S} = \left\{ v_1 \stackrel{?}{=} c_{\min}, v_3 \stackrel{?}{=} B, v_2 \stackrel{?}{=} \text{se}(x, v_4), v_5 \stackrel{?}{=} M \right\}$$

The protocol execution for intruder \mathcal{I} with initial knowledge $\{c_{\min}\}$ is then expressed by the constraint system:

$$\begin{aligned} \mathcal{C} = (& (c_{\min} \triangleright v_1, \\ & c_{\min}, \text{se}(M \oplus B, K) \triangleright v_2, \\ & c_{\min}, \text{se}(M \oplus B, K), B \triangleright v_3, \\ & c_{\min}, \text{se}(M \oplus B, K), B, K \triangleright v_4), \\ & c_{\min}, \text{se}(M \oplus B, K), B, K, \text{sd}(v_2, v_4) \oplus B \triangleright v_5, \mathcal{S}) \end{aligned}$$

The *deterministic* condition imposes to write the last message $\text{sd}(v_2, v_4)$ instead of x though both are equivalent with respect to satisfiability.

The decision problems we are interested in are the *satisfiability* and the *ordered satisfiability* of intruder constraint systems.

Satisfiability

- Input:** an \mathcal{I} -constraint system \mathcal{C}
- Output:** SAT iff there exists a substitution σ such that: $\sigma \models_{\mathcal{I}} \mathcal{C}$.

In order to be able to combine solutions of constraints in component theories to get a solution for the full theory these solutions have to satisfy some ordering constraints too. Intuitively, this is to avoid introducing cycle when building a global solution. With respect to this use we can always assume c_{\min} is the minimum of \prec in the following definition:

Ordered Satisfiability

- Input:** an \mathcal{I} -constraint system \mathcal{C} , X the set of all variables and C the set of all free constants occurring in \mathcal{C} and a linear ordering \prec on $X \cup C$.
- Output:** SAT iff there exists a substitution σ such that:

$$\begin{cases} \sigma \models_{\mathcal{I}} \mathcal{C} \\ \forall x \in X \text{ and } \forall c \in C, x \prec c \text{ implies } c \notin \text{Sub}_{\text{syn}}(x\sigma) \end{cases}$$

The main result of this paper is the following modularity result:

Theorem 1. *If the ordered satisfiability problem is decidable for two intruders $\langle \mathcal{F}_1, T_1, \mathcal{E}_1 \rangle$ and $\langle \mathcal{F}_2, T_2, \mathcal{E}_2 \rangle$ for disjoint signatures \mathcal{F}_1 and \mathcal{F}_2 then the satisfiability problem is decidable for deterministic constraint systems for the intruder $\mathcal{U} = \langle \mathcal{F}, \langle T_1 \rangle \cup \langle T_2 \rangle, \mathcal{E} \rangle$.*

This result is obtained as a direct consequence of the next section where we give an algorithm for solving \mathcal{U} -constraints using algorithms for solving *ordered satisfiability* for intruders $\langle \mathcal{F}_1, T_1, \mathcal{E}_1 \rangle$ and $\langle \mathcal{F}_2, T_2, \mathcal{E}_2 \rangle$.

5 Combination of Decision Procedures

We introduce Algorithm 1 for solving satisfiability of constraint systems for the union \mathcal{U} of two intruders systems $\mathcal{I}_1 = \langle \mathcal{F}_1, T_1, \mathcal{E}_1 \rangle$ and $\mathcal{I}_2 = \langle \mathcal{F}_2, T_2, \mathcal{E}_2 \rangle$ with disjoint signatures \mathcal{F}_1 and \mathcal{F}_2 . The completeness of Algorithm 1 is sketched below, and the proofs (for completeness and soundness) are fully detailed in [9]. Let us explain this algorithm:

Step 2 The algorithm input is a \mathcal{U} -Constraint system $(\mathcal{D}, \mathcal{S})$. An equational system \mathcal{S} is *homogeneous* if for all $u \stackrel{?}{=} v \in \mathcal{S}$, u and v are both pure 1-terms or both pure 2-terms. It is well-known that equational systems can be transformed into equivalent (w.r.t. satisfiability) homogeneous systems. Thus we can assume that \mathcal{S} is homogeneous without loss of generality.

Step 3 abstracts every subterm t of \mathcal{C} by a new variable $\psi(t)$. A choice of ψ such that $\psi(t) = \psi(t')$ will lead to solutions that identify t and t' .

Step 4 assign non-deterministically a signature to the root symbol of the subterms of \mathcal{C} instantiated by a solution. The choice $th(\psi(t)) = 0$ corresponds to the situation where t gets equal to a free constant.

Steps 5–8 choose and order non-deterministically the intermediate subterms in derivations that witness that the solution satisfies the constraints in \mathcal{D} .

Step 9 defines a constraint problem \mathcal{C}' collecting the previous choices on subterms identification, subterms signatures and derivation structures.

Step 10 splits the problem \mathcal{S}' in two pure subproblems.

Step 11 splits non-deterministically the problem \mathcal{D}' , that is we select for each $E \triangleright v$ in \mathcal{D}' an intruder system to solve it.

Step 12 guesses an ordering on variables: this ordering will preclude the value of a variable from being a subterm of the value of a smaller variable. This is used to avoid cycles in the construction of the solution.

Step 13 solves independently the 2 pure subproblems obtained at steps 10–11. In \mathcal{C}_i the variables q with $th(q) \neq i$ will be considered as constants.

Algorithm 1. Combination Algorithm

- 1: **Solve** $_{\mathcal{U}}(\mathcal{C})$
- 2: **Let** $\mathcal{C} = ((E_i \triangleright v_i)_{i \in \{1, \dots, n\}}, \mathcal{S})$ with \mathcal{S} homogeneous.
- 3: **Choose** ψ an application from $\text{Sub}(\mathcal{C})$ to $\mathcal{X} \setminus \text{Var}(\mathcal{C})$ and let $Q = \psi(\text{Sub}(\mathcal{C}))$
- 4: **Choose** a theory $th(q) \in \{0, 1, 2\}$ **for all** $q \in Q$
- 5: **for** $i = 1$ to n **do**
- 6: Choose $Q_i \subseteq Q$
- 7: Choose a linear ordering over the elements of Q_i say $(q_{i,1}, \dots, q_{i,k})$
- 8: **end for**
- 9: **Let** $\mathcal{C}' = (\mathcal{D}', \mathcal{S}')$ where

$$\begin{cases} \mathcal{S}' = \mathcal{S} \cup \{z \stackrel{?}{=} \psi(z) \mid z \in \text{Sub}(\mathcal{C})\} \\ \mathcal{D}' = \Delta_1, \dots, \Delta_i, \dots, \Delta_n \end{cases}$$

and $\Delta_i = (K_i, Q_i^{<j} \triangleright q_{i,j})_{j \in \{1, \dots, k\}}$, $(K_i, Q_i \triangleright \psi(v_i))$ with

$$\begin{cases} K_i = \psi(E_i) \cup \bigcup_{j=1}^{i-1} Q_j \\ Q_i^{<j} = q_{i,1}, q_{i,2}, \dots, q_{i,j-1} \end{cases}$$

- 10: **Split** \mathcal{S}' into $\mathcal{S}_1, \mathcal{S}_2$ such that $\mathcal{S}' = \mathcal{S}_1 \cup \mathcal{S}_2$ and:

$$\begin{cases} \mathcal{S}_1 = \{z \stackrel{?}{=} z' \in \mathcal{S}' \mid z, z' \text{ are pure 1-terms}\} \\ \mathcal{S}_2 = \{z \stackrel{?}{=} z' \in \mathcal{S}' \mid z, z' \text{ are pure 2-terms}\} \end{cases}$$

- 11: **Split** non-deterministically \mathcal{D}' into $\mathcal{D}_1, \mathcal{D}_2$
- 12: **Choose** a linear ordering \prec over Q .
- 13: **Solve** $\mathcal{C}_i = (\mathcal{D}_i, \mathcal{S}_i)$ for intruder \mathcal{I}_i with linear ordering \prec for $i \in \{1, 2\}$
- 14: **if** both are satisfied **then**
- 15: **Output:** SATISFIED
- 16: **end if**

We assume $\mathcal{C}_{\text{spe}} \subseteq \text{Sub}(\mathcal{C})$. Recall that R is the rewrite system associated to $\mathcal{E} = \mathcal{E}_1 \cup \mathcal{E}_2$. We say a normal substitution σ is *bound* if for all variables x with $x\sigma \neq x$ and for all $t \in \text{Sub}(x\sigma)$ there exists $u \in \text{Sub}(\mathcal{C})$ such that $(u\sigma) \downarrow_R = t$. A key proposition is:

Proposition 1. *If \mathcal{C} is a satisfiable constraint system there exists a bound substitution σ such that $\sigma \models \mathcal{C}$. Moreover $\text{Sub}((\text{Sub}(\mathcal{C})\sigma) \downarrow_R) = (\text{Sub}(\mathcal{C})\sigma) \downarrow_R$.*

5.1 Completeness of the Algorithm

Proposition 2. *If \mathcal{C} is satisfiable then there exists \mathcal{C}_1 and \mathcal{C}_2 satisfiable at Step 13 of the algorithm.*

Proof. First let us prove that the 11 first steps of the algorithm preserve satisfiability. Assume \mathcal{C} is satisfiable. By Proposition 1 there exists a normal bound substitution σ which satisfies \mathcal{C} . Define ψ to be a function from $\text{Sub}(\mathcal{C})$ to a set of variables Q such that $\psi(t) = \psi(t')$ if and only if $(t\sigma)\downarrow_R = (t'\sigma)\downarrow_R$. Thus by Proposition 1 there exists a bijection ϕ from Q to $\text{Sub}((\text{Sub}(\mathcal{C})\sigma)\downarrow_R)$. We let $th(q) = i$ if $\text{Sign}(\phi(q)) = \mathcal{F}_i$ and $th(q) = 0$ if $\text{Sign}(\phi(q)) = \perp$. By the construction of \mathcal{S}' and the choice of ψ we can extend σ on Q by $q\sigma = (\psi^{-1}(q)\sigma)\downarrow_R$ for all $q \in Q$.

For each $i \in \{1, \dots, n\}$ by Lemma 1 we can consider a well-formed derivation D_i starting from $F_i = (E_i\sigma)\downarrow_R$ and of goal $g_i = v_i\sigma$:

$$D_i : F_i \rightarrow_{\mathcal{U}} F_i \cup \{r_{i,1}\} \rightarrow_{\mathcal{U}} \dots \rightarrow_{\mathcal{U}} F_i \cup \{r_{i,1}, \dots, r_{i,k}\} \rightarrow_{\mathcal{U}} F_i \cup \{r_{i,1}, \dots, r_{i,k}, g_i\}$$

We have $\text{Sub}(F_i, g_i) \subseteq \text{Sub}((\text{Sub}(\mathcal{C}\sigma)\downarrow_R)$. Since the derivation is well-formed we have $\{r_{i,1}, \dots, r_{i,k}\} \subseteq \text{Sub}(F_i, g_i)$. By Proposition 1, $\text{Sub}((\text{Sub}(\mathcal{C}\sigma)\downarrow_R) = (\text{Sub}(\mathcal{C})\sigma)\downarrow_R$. Thus the function ϕ^{-1} is defined for each $r_{i,j}$. Let $q_{i,j} = \phi^{-1}(r_{i,j})$ and Q_i be the sequence of the $q_{i,j}$.

The algorithm will non-deterministically produce a \mathcal{C}' corresponding to these choices and satisfied by σ (extended over Q by $\psi(t)\sigma = (t\sigma)\downarrow_R$) by construction. Since \mathcal{S} is satisfiable, following the lines of F. Baader and K. Schulz [3] permits to prove that \mathcal{S}_1 and \mathcal{S}_2 are satisfiable with a linear constant restriction \prec chosen such that $q \prec q'$ implies $q'\sigma$ is not a subterm of $q\sigma$.

We choose the sequence of constraints in \mathcal{D}_1 (resp. \mathcal{D}_2) to be the subsequence of constraints $F \triangleright q$ from \mathcal{D}' such that the corresponding transition in the solution was performed by a rule in $L^{u,g}$ with $\text{Sign}(u) = \mathcal{F}_1$ (resp. \mathcal{F}_2). By construction these two systems are satisfiable.

From the soundness and completeness of Algorithm 1 we can derive our main result on the combination of two intruders. It can be easily generalized to n intruders over disjoint signatures $\mathcal{F}_1, \dots, \mathcal{F}_n$.

The main drawback of the combination algorithm that we have presented here is that it requires the solvability of general constraints from sub-theories. However the decision procedures which already exist for fixed intruder theories are limited to *deterministic* constraint systems. Fortunately we have been able to show ([9]) that our combination algorithm can be adapted so that it suffices to decide the solvability of *deterministic* constraints systems in sub-theories.

6 Conclusion

We have proposed an algorithm for combining decision procedures for intruder constraints on disjoint signatures. This algorithm allows for a modular treat-

ment of algebraic operators in protocol analysis and we believe that it will contribute to a better understanding of complexity issues in the domain. Since constraint satisfiability is required only from the intruder sub-theories the approach should permit one to handle more complex protocols than with alternative techniques.

Abstract. In this paper we study the link between formal and cryptographic models for security protocols in the presence of a passive adversary. In contrast to other works, we do not consider a fixed set of primitives but aim at results for an arbitrary equational theory. We define a framework for comparing a cryptographic implementation and its idealization *w.r.t.* various security notions. In particular, we concentrate on the computational soundness of static equivalence, a standard tool in cryptographic pi calculi. We present a soundness criterion, which for many theories is not only sufficient but also necessary. Finally, we establish new soundness results for the exclusive OR and a theory of ciphers and lists.

1 Introduction

Today's ubiquity of computer networks increases the need for theoretic foundations for cryptographic protocols. For more than twenty years now, two communities separately developed two families of models. Both views have been very useful in increasing the understanding and quality of security protocol design. On the one hand *formal* or *logical* models have been developed, based on the seminal work of Dolev and Yao [9]. These models view cryptographic operations in a rather abstract and idealized way. On the other hand *cryptographic* or *computational* models [10] are closer to implementations: cryptographic operations are modeled as algorithms manipulating bit-strings. Those models cover a large class of attacks, namely all those implementable by a probabilistic polynomial-time Turing machine.

The advantage of formal models is that security proofs are generally simpler and suitable for automatic procedures, even for complex protocols. Unfortunately, the high degree of abstraction and the limited adversary power raise serious questions regarding the security offered by such proofs. Potentially, justifying symbolic proofs with respect to standard computational models has tremendous benefits: protocols can be analyzed using automated tools and still benefit from the security guarantees of the computational model.

Recently, a significant research effort has been directed at linking these two approaches. In their seminal work [3], Abadi and Rogaway prove the computational soundness of formal (symmetric) encryption in the case a passive attacker. Since then, many results [5, 11, 12] have been obtained. Notably, Backes *et al.* [5] prove the soundness of

a rich language including digital signatures, public-key and symmetric key encryption in the presence of an active attacker. Laud [11] presents an automated procedure for computationally sound proofs of confidentiality in the case of an active attacker and symmetric encryption when the number of sessions is bounded.

Each of these results considers a fixed set of primitives, *e.g.* symmetric or public-key encryption. In this paper, we aim at presenting general results for arbitrary equational theories, such as encryption, but also less studied ones, *e.g.* groups or exclusive OR. We concentrate on *static equivalence*, a now standard notion originating from the applied pi calculus [2]. Intuitively, static equivalence asks whether an attacker can distinguish between two tuples of terms, by exhibiting an equation which holds on one tuple but not on the other. This provides an elegant means to express security properties against passive attackers. Moreover there exist exact [1] and approximate [8] algorithms to decide static equivalence for a large family of equational theories.

Our first contribution is a general framework for comparing formal and computational models in the presence of a passive attacker. We define the notions of *soundness* and *faithfulness* of a cryptographic implementation *w.r.t.* equality, static equivalence and deducibility. Soundness holds when each formal proof has a computational interpretation. Faithfulness is the converse, *i.e.* the formal model does not provide false attacks.

Our second contribution is a sufficient criterion for soundness *w.r.t.* static equivalence: intuitively the usual computational semantics of terms has to be indistinguishable to an idealized one. We also provide a general definition of patterns for arbitrary equational theories that encompasses the notion usually defined for symmetric and public encryption. Those patterns allow us to characterize a large class of theories for which our soundness criterion is necessary.

Our third contribution consists in applying our framework to obtain two novel soundness results. The first theory deals with the exclusive OR. Interestingly, our proof reflects the unconditional security (in the information-theoretic sense) of the One-Time Pad encryption scheme. Second we consider a theory of symmetric encryption and lists. In some sense, the result is similar to the one of Abadi and Rogaway [3]. However, we consider deterministic, length-preserving, symmetric encryption schemes *a.k.a.* ciphers. To the best of our knowledge, this is the first result on such schemes, whose specificity is that decryption always succeeds.

Outline of the paper. In the next section, we introduce our abstract and concrete models together with the notions of indistinguishability. We then define the notions of soundness and faithfulness and illustrate some consequences of soundness *w.r.t.* static equivalence on groups. In Section 4, we define the ideal semantics of abstract terms, present our soundness criterion and also show that for a large family of interesting equational theories, the soundness criterion is a necessary condition. As an illustration (Section 5), we prove the soundness for the theories modeling exclusive OR, as well as ciphers and lists. We then conclude and give directions for future work. Note that, due to lack of space most proofs have been omitted; those can be found in the extended version [7].

2 Modeling Cryptographic Primitives with Abstract Algebras

In this section we introduce some notations and set our abstract and concrete models.

2.1 Abstract Algebras

Our abstract models—which we call *abstract algebras*—consist of term algebras defined on a first-order signature with sorts and equipped with equational theories.

Specifically a *signature* $(\mathcal{S}, \mathcal{F})$ is made of a set of *sorts* $\mathcal{S} = \{s, s_1 \dots\}$ and a set of *symbols* $\mathcal{F} = \{f, f_1 \dots\}$ together with arities of the form $\text{ar}(f) = s_1 \times \dots \times s_k \rightarrow s$, $k \geq 0$. Symbols that take $k = 0$ arguments are called *constants*; their arity is simply written s . We fix an infinite set of *names* $\mathcal{N} = \{a, b \dots\}$ and an infinite set of *variables* $\mathcal{X} = \{x, y \dots\}$. We assume that names and variables are given with sorts. The set of *terms of sort* s is defined inductively by

$$\begin{array}{l}
 T ::= \text{term of sort } s \\
 \quad | \ x \quad \text{variable } x \text{ of sort } s \\
 \quad | \ a \quad \text{name } a \text{ of sort } s \\
 \quad | \ f(T_1, \dots, T_k) \text{ application of symbol } f \in \mathcal{F}
 \end{array}$$

where for the last case, we further require that T_i is a term of some sort s_i and $\text{ar}(f) = s_1 \times \dots \times s_k \rightarrow s$. As usual, we write $\text{var}(T)$ and $\text{names}(T)$ for the set of variables and names occurring in T respectively. A term is *ground* or *closed* iff it has no variables.

Substitutions are written $\sigma = \{x_1 = T_1, \dots, x_n = T_n\}$ with domain $\text{dom}(\sigma) = \{x_1, \dots, x_n\}$. We only consider *well-sorted* substitutions, that is, substitutions $\sigma = \{x_1 = T_1, \dots, x_n = T_n\}$ for which x_i and T_i have the same sort. σ is *closed* iff all of the T_i are closed. We extend the notation $\text{names}(\cdot)$ from terms to substitutions in the obvious way. The application of a substitution σ to a term T is written $\sigma(T) = T\sigma$.

Symbols in \mathcal{F} are intended to model cryptographic primitives, whereas names in \mathcal{N} are used to model nonces *i.e.* concretely random numbers. The abstract semantics of symbols is described by an equational theory E , that is an equivalence relation (also written $=_E$) which is stable by application of contexts and well-sorted substitutions of variables. We further require that E is stable under substitution of names. All the equational theories that we consider in this paper satisfy these properties. For instance, symmetric and deterministic encryption is modeled by the theory E_{enc} generated by the classical equation $E_{\text{enc}} = \{\text{dec}(\text{enc}(x, y), y) = x\}$.

2.2 Frames, Deducibility and Static Equivalence

Following [2, 1], a *frame* is an expression $\varphi = \nu \tilde{a}.\sigma$ where \tilde{a} is a set of *bound (or restricted) names* and σ is a well-sorted substitution. Intuitively, frames represent sequences of messages learned by an attacker during the execution of a protocol.

For simplicity we only consider frames $\nu \tilde{a}.\sigma$ which restrict *every* name occurring in σ , that is $\tilde{a} = \text{names}(\sigma)$. In other words, names a must be disclosed *explicitly* by adding a mapping $x_a = a$ to the substitution. Thus we tend to assimilate frames and their underlying substitutions.

A term T is *deducible* from a closed frame φ , written $\varphi \vdash_E T$ iff there exists a term M with $\text{var}(M) \subseteq \text{dom}(\varphi)$ and $\text{names}(M) \cap \text{names}(\varphi) = \emptyset$ such that $M\varphi =_E T$. Consider for instance the theory E_{enc} and the frame $\varphi_1 = \nu k_1, k_2, k_3, k_4. \{x_1 = \text{enc}(k_1, k_2), x_2 = \text{enc}(k_4, k_3), x_3 = k_3\}$: the name k_4 is deducible from φ_1 since $\text{dec}(x_2, x_3)\varphi_1 =_{E_{\text{enc}}} k_4$ but neither k_1 nor k_2 are deducible.

Deducibility is not always sufficient to account for the knowledge of an attacker. *E.g.* it lacks partial information on secrets. This is why the notion of static equivalence is used. Two closed frames φ_1 and φ_2 are *statically equivalent*, written $\varphi_1 \approx_E \varphi_2$, iff (i) $\text{dom}(\varphi_1) = \text{dom}(\varphi_2)$, (ii) for all terms M, N with variables included in $\text{dom}(\varphi_i)$ and using no names occurring in φ_1 or φ_2 , $M\varphi_1 =_E N\varphi_1$ is equivalent to $M\varphi_2 =_E N\varphi_2$.

For instance, the two frames $\nu k. \{x = \text{enc}(0, k)\}$ and $\nu k. \{x = \text{enc}(1, k)\}$ are statically equivalent with respect to E_{enc} , whereas the two frames $\nu k. \{x = \text{enc}(0, k), y = k\}$ and $\nu k, k'. \{x = \text{enc}(0, k'), y = k\}$ are not.

2.3 Concrete Semantics

We now give terms and frames a concrete semantics, parameterized by an implementation of the primitives. Provided a set of sorts \mathcal{S} and a set of symbols \mathcal{F} as above, a $(\mathcal{S}, \mathcal{F})$ -computational algebra A consists of

- a non-empty set of bit-strings $\llbracket s \rrbracket_A \subseteq \{0, 1\}^*$ for each sort $s \in \mathcal{S}$;
- a computable function $f_A : \llbracket s_1 \rrbracket_A \times \dots \times \llbracket s_k \rrbracket_A \rightarrow \llbracket s \rrbracket_A$ for each $f \in \mathcal{F}$ with $\text{ar}(f) = s_1 \times \dots \times s_k \rightarrow s$;
